Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

The textbook *Principles of Regenerative Medicine* was created as a primary resource for scientists, clinicians, teachers, and students from academia, industry, and government, as well as the public at large. The initial edition was the first comprehensive body of work dedicated entirely to the field and quickly became the most relevant textbook in the arena of regenerative medicine. The first and second editions of the textbook have had broad appeal and are currently ranked as the most distributed textbooks in the field. I am honored to have had the opportunity to continue to edit the textbook, now in its third edition, with our coeditors, Robert Lanza, Tony Mikos, and Robert Nerem. We welcome Tony Mikos as a new editor and would like to thank Jamie Thomson for his contributions to the first two editions. The contributions of the editors cannot be overestimated. We are indebted to their vision and the strong foundation they have created, upon which the current text was built.

The specialty of regenerative medicine continues to grow and change rapidly. There have been major areas of advances in just the past few years. The field encompasses multiple areas of scientific inquiry, each of which is complex, but together they are a powerful combination of technologies, such as stem cells, gene editing, nuclear transfer, proteomics, pharmacology, nanotechnology, tissue engineering, three-dimensional printing, and biomanufacturing. We are now in an era of translation of bench site discoveries to clinical therapies. We hope that this book will enlighten all of these areas and supply guidance where it is most needed.

The textbook was organized in a manner that builds upon the basic science of the field and goes forward into clinical applications and possible clinical utility. The textbook is organized into seven major areas, starting with chapters that encompass some of the fundamentals of the field. The biologic and molecular bases of regenerative medicine are covered with the molecular, mechanistic, and phenotypic aspects of cells and the extracellular matrix. The second section encompasses cells and tissue development, dealing with the various types of cells and determinants of tissue formation. The third section explores the mechanical, physical, and morphogenetic aspects of regenerative medicine, including nanotechnology applications. The fourth section is dedicated to the area of biomaterials for regenerative medicine. The fifth section covers enabling technologies for regenerative medicine, including infection control, gene editing, preclinical models, bioreactors, bioprinters, and body-on-a-chip applications. The sixth section discusses the topics of therapeutic applications and deals mostly with specific tissue and organ types. The last section of the book is dedicated to the regulatory, manufacturing, policy, and ethical aspects of the field. This area is becoming increasingly more important because the nexus between science, safety, and ethics is constantly changing. The third edition of the *Principles of Regenerative Medicine* builds on the knowledge base of the prior editions; most relevant chapters have been updated and other relevant topics are added with the inclusion of new chapters.

Once again, the leading scientists and physicians in the field have contributed their expertise to this comprehensive collection. We would like to thank all of the authors for their contributions; the publisher, Elsevier, and its staff, including Timothy Bennett, who worked diligently to complete the book; and our commissioning editors, Micah Lewis and Elizabeth Brown, who nurtured this project from its concept to completion.

Anthony Atala

CHAPTER

1

Molecular Organization of Cells

Jon D. Ahlstrom

PolarityTE, Salt Lake City, UT, United States

INTRODUCTION

Multicellular tissues exist in one of two types of cellular arrangements, epithelial or mesenchymal. Epithelial cells adhere tightly to each other at their lateral surfaces and to an organized extracellular matrix (ECM) at their basal domain, thereby producing a sheet of cells resting on a basal lamina with an apical surface. Mesenchymal cells, in contrast, are individual cells with a bipolar morphology that are held together as a tissue within a three-dimensional (3D) ECM (Fig. 1.1). The conversion of epithelial cells into mesenchymal cells, an "epithelial–mesenchymal transition" (EMT), is central to many aspects of embryonic morphogenesis and adult tissue repair, as well as a number of disease states [1–3]. The reverse process whereby mesenchymal cells coalesce into an epithelium is a "mesenchymal–epithelial transition" (MET). Understanding the molecules that regulate this transition between epithelial and mesenchymal states offers important insights into how cells and tissues are organized.

The early embryo is structured as one or more epithelia. An EMT allows the rearrangements of cells to create additional morphological features. Well-studied examples of EMTs during embryonic development include gastrulation in *Drosophila* [3], the emigration of primary mesenchyme cells (PMCs) in sea urchin embryos [4], and gastrulation in amniotes (reptiles, birds, and mammals) at the primitive streak [2]. EMTs also occur later in vertebrate development, such as during the emigration of neural crest cells from the neural tube [5], the formation of the sclerotome from epithelial somites, and palate fusion [2]. The reverse process of MET is likewise crucial to development; examples include the condensation of mesenchymal cells to form the notochord and somites [6], kidney tubule formation from nephrogenic mesenchyme [7], and the creation of heart valves from cardiac mesenchyme [8]. In the adult organism, EMTs and METs occur during wound healing and tissue remodeling [9]. The conversion of neoplastic epithelial cells into invasive cancer cells has long been considered an EMT process [1,10]. However, there are also examples of tumor cells that have functional cell–cell adhesion junctions yet are still migratory and invasive as a group [11]. This "collective migration" also occurs during development [11]. Hence, there is debate whether an EMT model accurately describes all epithelial metastatic cancers. Similarly, the fibrosis of cardiac, kidney, lens, and liver epithelial tissue has also long been categorized as an EMT event [6,12]. However, research in the kidney in vivo shows that the myofibroblasts induced after kidney injury are derived from mesenchymal pericytes rather than the proximal epithelial cells [13]. Therefore, defining the origin of the cells that contribute to fibrotic tissue scarring (epithelial or otherwise) will require further investigation.

The focus of this chapter is on the molecules that regulate the organization of cells into epithelium or mesenchyme. We will first discuss the cellular changes that occur during an EMT, including changes in cell–cell and cell–ECM adhesions, changes in cell polarity, and the stimulation of invasive cell motility. Then we will consider the molecules and mechanisms that control the EMT or MET, including the structural molecules, transcription factors, and signaling pathways that regulate EMTs.

MOLECULES THAT ORGANIZE CELLS

The conversion of an epithelial sheet into individual migratory cells and back again requires the coordinated changes of many distinct families of molecules.

Principles of Regenerative Medicine, Third Edition

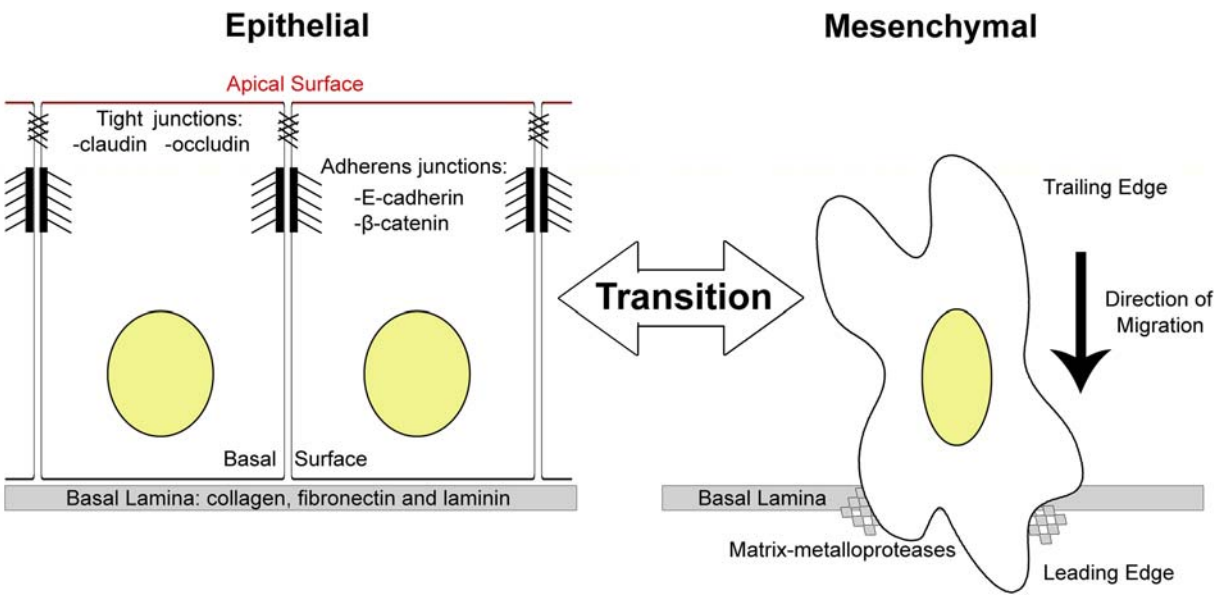

FIGURE 1.1 **Epithelial versus Mesenchymal.** Epithelial cells adhere tightly together by tight junctions and adherens junctions localized near the apical surface. Epithelial cells also have a basal surface that rests on a basal lamina. In contrast, mesenchymal cells do not have well-defined cell–cell adhesion complexes; they have front-end/back-end polarity instead of apicobasal polarity, and mesenchymal cells are characterized by their ability to invade the basal lamina.

Changes in Cell–Cell Adhesion

Epithelial cells are held together by specialized cell–cell junctions, including adherens junctions, desmosomes, and tight junctions [14]. These junctions are localized in the lateral domain near the apical surface and establish the apical polarity of the epithelium. For an epithelial sheet to produce individual mesenchymal cells, cell–cell adhesions must be disrupted. The principal transmembrane proteins that mediate cell–cell adhesions are members of the cadherin superfamily [15]. E-cadherin and N-cadherin are classical cadherins that interact homotypically through their extracellular immunoglobulin G domains with like-cadherins on adjacent cells. Cadherins are important mediators of cell–cell adhesion. For example, misexpression of E-cadherin is sufficient to promote cell–cell adhesion and assembly of adherens junctions in fibroblasts [16]. In epithelial cancers (carcinomas), E-cadherin acts as a tumor suppressor [10]. In a mouse model for β-cell pancreatic cancer, the loss of E-cadherin is the rate-limiting step for transformed epithelial cells to become invasive [17]. Although the loss of cadherin-mediated cell–cell adhesion is necessary for an EMT, the loss of cadherins is not always sufficient to generate a complete EMT in vivo. For example, the neural tube epithelium in mice expresses N-cadherin, but in the N-cadherin knockout mouse an EMT is not induced in the neural tube [18]. Hence, cadherins are essential for maintaining epithelial integrity, and the loss of cell–cell adhesion caused by the reduction of cadherin function is an important step for an EMT.

One characteristic of an EMT is "cadherin switching." Often, epithelia that express E-cadherin will downregulate E-cadherin expression at the time of the EMT and express different cadherins such as N-cadherin [19]. Cadherin switching may promote motility. For instance, in mammary epithelial cell lines, the misexpression of N-cadherin is sufficient for increased cell motility. However, blocking N-cadherin expression does not result in motility even though the adherens junctions are reduced. Hence, cadherin switching may be necessary for cell motility, but cadherin switching alone is not sufficient to bring about a complete EMT [20].

There are several ways in which cadherin expression and function are regulated. Transcription factors that are central to most EMTs, such as Snail-1, Snail-2, Zinc finger E-box-binding (Zeb)1, Zeb2, Twist, and E2A, all bind to E-boxes on the *E-cadherin* promoter and repress the transcription of *E-cadherin* [21]. Posttranscriptionally, the E-cadherin protein is ubiquitinated by the E3-ligase, Hakai, which targets E-cadherin to the proteasome [22]. E-cadherin turnover at the membrane is regulated by either caveolae-dependent endocytosis or clathrin-dependent endocytosis [23], and p120-catenin prevents endocytosis of E-cadherin at the membrane [24]. E-cadherin function can also be disrupted by matrix metalloproteases, which degrade the extracellular domain of E-cadherin [25]. Some or all of these mechanisms may occur during an EMT to disrupt cell–cell adhesion.

Cell–cell adhesion is maintained principally by cadherins, and changes in cadherin expression are typical of an EMT.

Changes in Cell–Extracellular Matrix Adhesion

Altering the way in which a cell interacts with the ECM is also important in EMTs. For example, at the time that sea urchin PMCs ingress, the cells have increased adhesiveness for ECM [4]. Cell–ECM adhesion is mediated principally by integrins. Integrins are transmembrane proteins composed of two noncovalently linked subunits, α and β, that bind to ECM components such as fibronectin, laminin, and collagen. The cytoplasmic domain of integrins links to the cytoskeleton and interacts with signaling molecules. Changes in integrin function are required for many EMTs, including neural crest emigration [26], mouse primitive streak formation [2], and cancer metastasis [27]. However, the misexpression of integrin subunits is not sufficient to bring about a full EMT in vitro [28] or in vivo [29].

The presence and function of integrins are modulated in several ways. For example, the promoter of the *integrin β6* gene is activated by the transcription factor Ets-1 during colon carcinoma metastasis [30]. Most integrins can also cycle between "on" (high-affinity) or "off" (low-affinity) states. This "inside-out" regulation of integrin adhesion occurs at the integrin cytoplasmic tail [31]. In addition to integrin activation, the "clustering" of integrins on the cell surface affects the overall strength of integrin–ECM interactions. The increased adhesiveness of integrins caused by clustering, known as avidity, can be activated by chemokines and depends on RhoA and phosphatidylinositol 3′ kinase (PI3K) activity [31].

Changes in ECM adhesion are required for an EMT. Cell–ECM adhesions are maintained by integrins, which have varying degrees of adhesiveness depending on the presence, activity, or avidity of the integrin subunits.

Changes in Cell Polarity and Stimulation of Cell Motility

Cellular polarity is defined by the distinct arrangement of cytoskeletal elements and organelles in epithelial versus mesenchymal cells. Epithelial polarity is characterized by cell–cell junctions found near the apicolateral domain (nonadhesive surface), and a basal lamina opposite of the apical surface (adhesive surface). Mesenchymal cells, in contrast, do not have apicobasal polarity, but rather front-end/back-end polarity, with actin-rich lamellipodia and Golgi localized at the leading edge [2]. Molecules that establish cell polarity include Cdc42, PAK1, PI3K, PTEN, Rac, Rho, and the PAR proteins [32,33]. Changes in cell polarity help to promote an EMT. In mammary epithelial cells, the activated transforming growth factor-β (TGF-β) receptor II causes Par6 to activate the E3 ubiquitin ligase Smurf1, which then targets RhoA to the proteasome. The loss of RhoA activity results in the loss of cell–cell adhesion and epithelial cell polarity [34].

For mesenchymal cells to leave the epithelium, they must become motile. Many of the same polarity (Crumbs, PAR, and Scribble complexes), structural (actin and microtubules), and regulatory molecules (Cdc42, Rac1, and RhoA) that govern epithelial polarity are also central to cell motility [35]. Cell motility mechanisms also vary depending on whether the environment is two-dimensional or 3D [36]. Many mesenchymal cells express the intermediate filament vimentin, which may be responsible for several aspects of the EMT phenotype [37].

In short, a wide variety of structural, polarity, and regulatory molecules must be reassigned as cells transition between epithelial polarity and mesenchymal migration.

Invasion of the Basal Lamina

In most EMTs, the emerging mesenchymal cells must penetrate a basal lamina, which consists of ECM components such as collagen type IV, fibronectin, and laminin. The basal lamina functions to stabilize the epithelium and is a barrier to migratory cells [38]. One mechanism that mesenchymal cells use to breach the basal lamina is to produce enzymes that degrade it. Plasminogen activator is one protease associated with a number of EMTs, including neural crest emigration [38] and the formation of cardiac cushion cells during heart morphogenesis [39]. The type II serine protease TMPRSS4 also promotes an EMT and metastasis when overexpressed in vitro and in vivo [40]. Matrix-metalloprotease (MMPs) are also important for many EMTs. When MMP-2 activity is blocked in the neural crest EMT, neural crest emigration is inhibited, but not neural crest motility [41]. In mouse mammary cells, MMP-3 overexpression is sufficient to induce an EMT in vitro and in vivo [42]. Misexpressing MMP-3 in cultured cells induces an alternatively spliced form of Rac1 (Rac1b), which then causes an increase in reactive oxygen species (ROS) intracellularly, and Snail-1 expression. Either Rac1b activity or ROS is necessary and sufficient for an MMP-3–induced EMT [43]. Hence, a number of extracellular proteases are important to bring about an EMT.

Although epithelial cells undergoing an EMT eventually lose cell−cell adhesion and apicobasal polarity and gain invasive motility, the EMT program is not necessarily ordered or linear. For example, in a study in which neural crest cells were labeled with cell adhesion or polarity markers and individual live cells were observed to undergo the EMT in slice culture, neural crest cells changed epithelial polarity either before or after the complete loss of cell−cell adhesion, or lost cell−cell adhesion either before or after cell migration commenced [44]. Therefore, whereas an EMT consists of several distinct phases, these steps may occur in different orders or combinations, some of which (e.g., the complete loss of cell-cell adhesion) may not always be necessary.

Changes in a wide range of molecules are needed for an EMT because epithelial cells lose cell−cell adhesion, change cellular polarity, and gain invasive cell motility.

THE EPITHELIAL−MESENCHYMAL TRANSITION TRANSCRIPTIONAL PROGRAM

At the foundation of every EMT or MET program are the transcription factors that regulate the gene expression required for these cellular transitions. Whereas many of the transcription factors that regulate EMTs have been identified, the complex regulatory networks are still incomplete. Here we review the transcription factors that are known to promote the various phases of an EMT. Then we examine how these EMT transcription factors themselves are regulated at the promoter and posttranscriptional levels.

Transcription Factors That Regulate Epithelial−Mesenchymal Transition

The Snail family of zinc-finger transcription factors, including Snail-1 and Snail-2 (formerly Snail and Slug), are direct regulators of cell−cell adhesion and motility during EMTs [21,45]. The knockout of *Snail-1* in mice is lethal early in gestation, and the presumptive primitive streak cells that normally undergo an EMT retain apicobasal polarity and adherens junctions, and express *E-cadherin* messenger RNA [46]. Snail-1 misexpression is sufficient for breast cancer recurrence in a mouse model in vivo, and high levels of *Snail-1* predict the relapse of human breast cancer [47]. Snail-2 is necessary for the chicken primitive streak and neural crest EMTs [48]. One way in which Snail-1 or Snail-2 causes decreases in cell−cell adhesion is by repressing the *E-cadherin* promoter [21]. This repression requires the mSin3A co-repressor complex, histone deacetylases, and components of the Polycomb 2 complex [49]. Snail-1 is also a transcriptional repressor of the tight junction genes *Claudin* and *Occludin* [21] and the polarity gene *Crumbs3* [50]. The misexpression of Snail-1 and Snail-2 further leads to the transcription of proteins important for cell motility, such as fibronectin, vimentin [51], and RhoB [52]. Moreover, Snail-1 promotes invasion across the basal lamina. In Madin−Darby Canine Kidney (MDCK) cells, the misexpression of Snail-1 represses laminin (basement membrane) production [53] and indirectly upregulates *mmp-9* transcription [54]. Snail and Twist also make cancer cells more resistant to senescence, chemotherapy, and apoptosis, and endow cancer cells with "stem cell" properties [6]. Hence, Snail-1 or Snail-2 is necessary and sufficient for bringing about many of the steps of an EMT, including loss of cell−cell adhesion, changes in cell polarity, gain of cell motility, invasion of the basal lamina, and increased proliferation and survival.

Other zinc finger transcription factors important for EMTs are Zeb homeobox 1 (Zeb1; also known as δEF1), and Zeb2 (also known as Smad-interacting protein-1; Sip1). Both Zeb1 and Zeb2 bind to the *E-cadherin* promoter and repress transcription [21]. Zeb1 can also bind to and repress the transcription of the polarity proteins Crumbs3, Pals1-associated tight junction proteins, and Lethal giant larvae 2 [55]. Zeb2 is structurally similar to Zeb1, and Zeb2 overexpression is sufficient to downregulate E-cadherin, dissociate adherens junctions, and increase motility in MDCK cells [56].

The lymphoid enhancer-binding factor/T-cell factor (LEF/TCF) transcription factors also have an important role in EMTs. For instance, the misexpression of Lef-1 in cultured colon cancer cells reversibly causes the loss of cell−cell adhesion [57]. LEF/TCF transcription factors directly activate genes that regulate cell motility, such as the L1 adhesion molecule [58], and the *fibronectin* gene [59]. LEF/TCF transcription factors also upregulate genes required for basal lamina invasion, including *mmp-3* and *mmp-7* [60].

Other transcription factors that have a role in promoting EMTs are the class I basic helix-loop-helix factors E2-2A and E2-2B [61], the forkhead box transcription factor FOXC2 [62], the homeobox protein Goosecoid [63], and the homeoprotein Six1 [64,65].

Transcription factors that regulate an EMT often do so by directly repressing cell adhesion and epithelial polarity molecules and by upregulating genes required for cell motility and basal lamina invasion.

Regulation at the Promoter Level

Given the importance of the Snail, Zeb, and LEF/TCF transcription factors in orchestrating the various phases of an EMT, it is essential to understand the upstream events that regulate these EMT-promoting transcription factors.

The activation of *Snail-1* transcription in *Drosophila* requires the transcription factors Dorsal (nuclear factor κB [NF-κB]) and Twist [21]. The human *Snail-1* promoter also has functional NF-κB sites [66], and blocking NF-κB reduces *Snail-1* transcription [67]. In addition, a region of the *Snail-1* promoter is responsive to integrin-linked kinase (ILK) [21], and ILK can activate Snail-1 expression via poly-adenosine phosphate-ribose polymerase [68]. In mouse mammary epithelial cells, high-mobility group protein A2 and Smads activate *Snail-1* expression and subsequently *Snail-2*, *Twist*, and *Id2* transcription [69]. For *Snail-2* expression, myocardin-related transcription factors (MRTFs) interact with Smads to induce *Snail-2* [70] and MRTFs may have a role in metastasis [71] and fibrosis [72]. There are also several *Snail-1* transcriptional repressors. In breast cancer cell lines, metastasis-associated protein 3 binds directly to and represses the transcription of *Snail-1* in combination with the Mi-2/nucleosome remodeling deacetylase complex [73], as does lysine-specific demethylase [74]. The Ajuba LIM proteins (Ajuba, LIMD1, and WTIP) are additional transcriptional corepressors of the Snail family [75].

The transcription of LEF/TCF genes such as *Lef-1* are activated by Smads [76]. The misexpression of Snail-1 results in the transcription of *δEF-1* and *Lef-1* through a yet unknown mechanism [21].

Posttranscriptional Regulation of Epithelial–Mesenchymal Transition Transcription Factors

The activity of EMT transcription factors is also regulated at the protein level, including translational control, protein stability (targeting to the proteasome), and nuclear localization. Noncoding RNAs are emerging as important regulator EMTs. In a breast cancer model, Myc activates the expression of microRNA-9 (miR-9), and miR-9 directly binds to and represses the *E-cadherin* promoter [77]. Members of the miR-200 family repress the translation of *Zeb1*, and the expression of these miR-200 family members is repressed by Snail-1. In addition, *Zeb2* transcription can be activated by naturally occurring RNA antisense transcripts [78]. It is not yet known whether there are noncoding RNAs that regulate Snail family members. However, the Y-box binding protein-1 is important for the selective activation of *Snail-1* translation [79].

Protein stability is another layer of EMT control. Snail-1 is phosphorylated by glycogen synthase kinase 3β (GSK-3β) and targeted for destruction [80]. Therefore, the inhibition of GSK-3β activity by Wnt signaling may have multiple roles in an EMT, leading to the stabilization of both β-catenin and Snail-1. Some proteins that prevent GSK 3β–mediated phosphorylation (and thus promote Snail-1 activation) are lysyl oxidase–like proteins (LOXL)2, LOXL3 [81], and ILK [82]. A Snail 1–specific phosphatase (Snail-1 activator) is C-terminal domain phosphatase [83]. Snail-2 is targeted for degradation by the direct action of p53 and the ubiquitin ligase Mdm2 [84].

In addition to protein translation and stability, the function of Snail-1 depends on nuclear localization mediated by Snail-1's nuclear localization sequence. The phosphorylation of human Snail-1 by p21-activated kinase 1 promotes the nuclear localization of Snail-1 (and therefore Snail-1 activation) in breast cancer cells [85]. In zebrafish, LIV-1 promotes the translocation of Snail-1 into the nucleus [86]. Snail-1 also contains a nuclear export sequence (NES) that depends on the calreticulin nuclear export pathway [87]. This NES sequence is activated by the phosphorylation of the same lysine residues targeted by GSK-3β, which suggests a mechanism whereby phosphorylation of Snail-1 by GSK-3β results in the export of Snail-1 from the nucleus and subsequent degradation.

LEF/TCF activity is also regulated by other proteins. β-Catenin is required as a cofactor for LEF/TCF-mediated activation of transcription, and Lef-1 can also associate with cofactor Smads to activate the transcription of additional EMT genes [88]. In colon cancer cells, thymosin β4 stabilizes ILK activity [89].

EMT transcription factors such as Snail-1, Zeb1, and Lef-1 are regulated by a variety of mechanisms at both the transcriptional and posttranscriptional levels by noncoding RNA translation control, protein degradation, nuclear localization, and cofactors such as β-catenin.

MOLECULAR CONTROL OF THE EPITHELIAL–MESENCHYMAL TRANSITION

The initiation of an EMT or MET is a tightly regulated event during development and tissue repair because deregulation of cellular organization is disastrous to the organism. A variety of external and internal signaling mechanisms coordinate the complex events of the EMT, and these same signaling pathways are often disrupted or reactivated during disease. EMTs or METs can be induced by either diffusible signaling molecules or ECM

components. We next discuss the role of signaling molecules and ECM in triggering an EMT, and then present a summary model for EMT induction.

Ligand-Receptor Signaling

During development, five main ligand-receptor signaling pathways are employed: TGF-β, Wnt, receptor tyrosine kinase (RTK), Notch, and Hedgehog. These pathways, among others, have a role in triggering EMTs. Although the activation of a single signaling pathway can be sufficient for an EMT, in most cases an EMT or MET is initiated by multiple signaling pathways acting in concert.

Growth Factor-β Pathway

The TGF-β superfamily includes the TGF-β, activin, and bone morphogenetic protein (BMP) families. These ligands operate through receptor serine/threonine kinases to activate a variety of signaling molecules including Smads, mitogen-activated protein kinase (MAPK), PI3K, and ILK. Most EMTs studied to date are induced in part, or solely, by TGF-β superfamily members [90]. During embryonic heart development, TGF-β2 and TGF-β3 have sequential and necessary roles in activating the endocardium to invade the cardiac jelly and from the endocardial cushions [91]. In the avian neural crest, BMP4 induces *Snail-2* expression [92]. In the EMT that transforms epithelial tissue into metastatic cancer cells, TGF-β acts as a tumor suppressor during early stages of tumor development, but as a tumor/EMT inducer at later stages [90,93]. TGF-β signaling may combine with other signaling pathways to induce an EMT. For example, in cultured breast cancer cells, activated Ras and TGF-β induce an irreversible EMT [94], and in pig thyroid epithelial cells, TGF-β and epidermal growth factor (EGF) synergistically stimulate the EMT [95].

One outcome of TGF-β signaling is to change epithelial cell polarity immediately. In a TGF β—induced EMT of mammary epithelial cells, TGF-βRII directly phosphorylates the polarity protein, Par6, leading to the dissolution of tight junctions [34]. TGF-β signaling also regulates gene expression through the phosphorylation and activation of Smads. Smads are important cofactors in the stimulation of an EMT. For example, Smad3 is necessary for a TGF β—induced EMT in lens and kidney tissue in vivo [96]. The Smad3/4 also complex with Snail-1 and co-repress the promoters of cell—cell adhesion molecules [97]. Furthermore, TGF-βRI directly binds to and activates PI3K [98], which in turn activates ILK and downstream pathways.

ILK is emerging as an important positive regulator of EMTs [99]. ILK interacts directly with growth factor receptors (TGF-β, Wnt, or RTK), integrins, the actin skeleton, PI3K, and focal adhesion complexes. ILK directly phosphorylates Akt and GSK-3β, and results in the subsequent activation of transcription factors such as AP-1, NF-κB, and Lef-1. Overexpression of ILK in cultured cells causes the suppression of GSK-3β activity [82], translocation of β-catenin to the nucleus, activation of Lef-1/β-catenin transcription factors, and the downregulation of E-cadherin [100]. Inhibition of ILK in cultured colon cancer cells leads to the stabilization of GSK-3β activity, decreased nuclear β-catenin localization, the suppression of *Lef-1* and *Snail-1* transcription, and reduced invasive behavior of colon cancer cells [101]. ILK activity also results in Lef 1—mediated transcriptional upregulation of MMPs [60]. Hence, ILK (inducible by TGF-β signaling) is capable of orchestrating most of the major events in an EMT, including the loss of cell—cell adhesion and invasion across the basal lamina.

Wnt Pathway

Many EMTs or METs are also regulated by Wnt signaling. Wnts signal through seven-pass transmembrane proteins of the Frizzled family, which activates G-proteins and PI3K, inhibits GSK-3β, and promotes nuclear β-catenin signaling. For example, during zebrafish gastrulation, Wnt11 activates the GTPase Rab5c, which results in the endocytosis of E-cadherin [102]. Wnt6 signaling is sufficient for increased transcription of *Snail-2* in the avian neural crest [103]. Snail-1 expression increases Wnt signaling [104], which suggests a positive feedback loop.

One of the downstream signaling molecules activated by Wnt signaling is β-catenin. β-Catenin is a structural component of adherens junctions. Nuclear β-catenin is also a limiting factor for the activation of LEF/TCF transcription factors. β-Catenin is pivotal for regulating most EMTs. Interfering with nuclear β-catenin signaling blocks the ingression of sea urchin PMCs [105], and in β-catenin mouse knockouts, the primitive streak EMT does not occur and no mesoderm is formed [106]. β-Catenin is also necessary for the EMT that occurs during cardiac cushion development [107]. In breast cancer, β-catenin expression is highly correlated with metastasis and poor survival [108], and blocking β-catenin function in tumor cells inhibits invasion in vitro [109]. It is unclear whether β-catenin overexpression alone is sufficient for all EMTs. If β-catenin is misexpressed in cultured cells, it causes apoptosis [110]. However,

the misexpression of a stabilized from of β-catenin in mouse epithelial cells in vivo results in metastatic skin tumors [111].

Signaling by Receptor Tyrosine Kinase Ligands

The RTK family of receptors and the growth factors that activate them also regulate EMTs or METs. Ligand binding promotes RTK dimerization and activation of the intracellular kinase domains by autophosphorylation of tyrosine residues. These phosphotyrosines act as docking sites for intracellular signaling molecules, which can activate signaling cascades such as Ras/MAPK, PI3K/Akt, JAK/STAT, or ILK. We will cite a few examples of RTK signaling in EMTs and METs.

Hepatocyte growth factor (HGF; also known as scatter factor) acts through the RTK c-met. HGF is important for the MET in the developing kidney [112]. HGF signaling is required for the EMT that produces myoblasts (limb muscle precursors) from somite tissue in the mouse [10]. In epithelial cells, HGF causes an EMT through MAPK and early growth response factor-1 signaling [113].

Fibroblast growth factor (FGF) signaling regulates mouse primitive streak formation [114]. FGF signaling also stimulates cell motility and activates MMPs [115,116].

EGF promotes the endocytosis of E-cadherin [117]. EGF can also increase Snail-1 activity via the inactivation of GSK3-β [118], and EGF promotes increased *Twist* expression through a JAK/STAT3 pathway [119].

Insulin growth factor (IGF) signaling induces an EMT in breast cancer cell lines by activating Akt2 and suppressing Akt1 [120]. In prostate cancer cells, IGF-1 promotes Zeb-1 expression [121]. In fibroblast cells, constitutively activated IGF-IR increases NF-κB activity and Snail-1 levels [122]. In several cultured epithelial cell lines, IGFR1 is associated with the complex of E-cadherin and β-catenin, and the ligand IGF-II causes the redistribution of β-catenin from the membrane to the nucleus, activation of the transcription factor TCF-3, and a subsequent EMT [123].

Another RTK known for its role in EMTs is the ErbB2/HER-2/Neu receptor, whose ligand is heregulin/neuregulin. Overexpression of HER-2 occurs in 25% of human breast cancers, and the misexpression of HER-2 in mouse mammary tissue in vivo is sufficient to cause metastatic breast cancer [124]. Herceptin (antibody against the HER-2 receptor) treatment is effective in reducing the recurrence of HER 2–positive metastatic breast cancers. HER-2 signaling activates *Snail-1* expression in breast cancer through an unknown mechanism [47]. The RTK Axl is also required for breast cancer carcinoma invasiveness [125].

Vascular endothelial growth factor (VEGF) signaling promotes Snail-1 activity by suppressing GSK3-β [126] and results in increased levels of *Snail-1*, *Snail-2*, and *Twist* [127]. Snail-1 can also activate the expression of VEGF [128]. RTK signaling is important for many EMTs.

Notch Pathway

The Notch signaling family also regulates EMTs. When the Notch receptor is activated by its ligand Delta, an intracellular portion of the Notch receptor ligand is cleaved and transported to the nucleus, where it regulates target genes. Notch1 is required for cardiac endothelial cells to undergo an EMT to make cardiac cushions, and the role of Notch may be to make cells competent to respond to TGF-β2 [129]. In the avian neural crest EMT, Notch signaling is required for the induction and/or maintenance of *BMP4* expression [130]. Similarly, Notch signaling is required for the TGF β–induced EMT of epithelial cell lines [131], and Notch promotes *Snail-2* expression in cardiac cushion cells [132] and cultured cells [133].

Hedgehog Pathway

The hedgehog pathway is also involved in EMTs. Metastatic prostate cancer cells express high levels of hedgehog and *Snail-1*. If prostate cancer cell lines are treated with the hedgehog-pathway inhibitor, cyclopamine, levels of *Snail-1* are decreased. If the hedgehog-activated transcription factor, Gli, is misexpressed, *Snail-1* expression increases [134].

Additional Signaling Pathways

Other signaling pathways that activate EMTs include inflammatory signaling molecules, lipid hormones, ROS species, and hypoxia. Interleukin-6 (inflammatory and immune response) can promote Snail-1 expression in breast cancer cells [135], and Snail-1, in turn, can activate interleukin-6 expression [136], providing a link between inflammation and EMTs [137]. The lipid hormone prostaglandin E2 (PGE2) induces Zeb1 and Snail activity in lung cancer cells [138], and Snail-1 can also induce PGE2 expression [139]. ROS species can also activate EMTs by PKC and

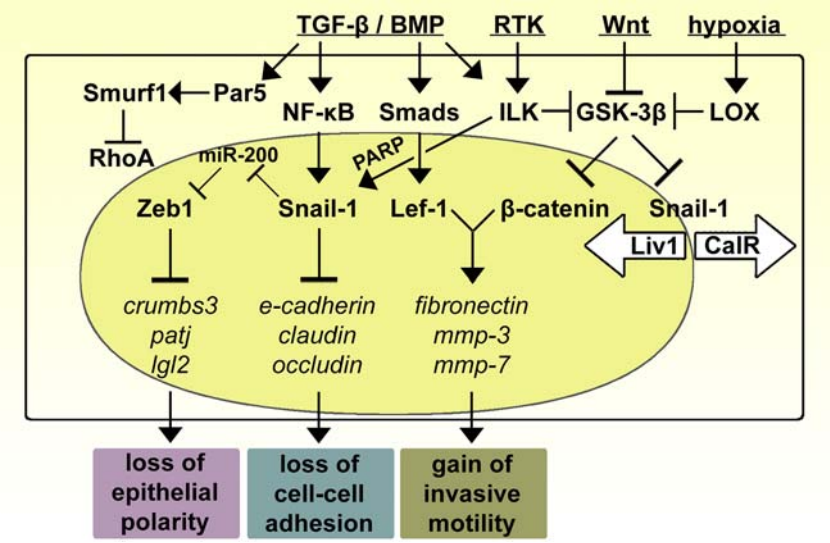

FIGURE 1.2 **Induction of an epithelial–mesenchymal transition (EMT).** This figure summarizes some of the important molecular pathways that bring about an EMT. Many of the signaling pathways converge on the activation of Snail-1 and nuclear β-catenin signaling to change gene expression, which results in the loss of epithelial cell polarity, the loss of cell–cell adhesion, and increased invasive cell motility. *BMP*, bone morphogenetic protein; *CalR*, calreticulin; *GSK-3β*, glycogen synthase kinase 3β; *Igl2*, immunoglobulin 2; *ILK*, integrin-linked kinase; *LOX*, lysyl oxidase; *miR-200*, microRNA-200; *mmp*, matrix-metalloprotease; *NF-κB*, nuclear factor κB; *RhoA*, Ras homolog gene family, member A; *RTK*, receptor tyrosine kinase; *TGF-β*, transforming growth factor-β; *Zeb1*, zinc finger E-box-binding homeobox 1.

MAPK signaling [140]. Hypoxia is important for initiating EMTs during development [141] and disease [137], often through hypoxia-inducible factor-1, which directly activates *Twist* expression [142]. Hypoxia also activates lysyl oxidases, which stabilize Snail-1 expression [143] by inhibiting GSK-3β activity [144].

In addition to diffusible signaling molecules, ECM molecules regulate EMTs or METs. This was first dramatically demonstrated when lens or thyroid epithelium was embedded in collagen gels, and then promptly underwent an EMT [2]. Integrin signaling appears to be important in this process [145] and involves ILK-mediated activation of NF-κB, Snail-1, and Lef-1 [146]. Other ECM components that regulate EMTs include hyaluronan [147], the γ-2 chain of laminin 5 [148], periostin [149], and podoplanin [150,151]. A variety of diffusible signals and ECM components can stimulate EMTs or METs.

A Model for Epithelial–Mesenchymal Transition Induction

Many experimental studies on EMT mechanisms are piecework, and although great progress has been made in discovering EMT pathways, the entire signaling network is still incomplete. Fig. 1.2 shows many of the various signaling mechanisms, although in actuality only a few of the inductive pathways will be used for individual EMTs. From experimental evidence, it appears that many EMT signaling pathways converge on ILK, the inhibition of GSK-3β, and stimulation of nuclear β-catenin signaling to activate Snail and LEF/TCF transcription factors. Snail, Zeb, and LEF/TCF transcription factors then act on a variety of targets to suppress cell–cell adhesion, induce changes in cell polarity, stimulate cell motility, and promote invasion of the basal lamina.

CONCLUSION

Since the term "EMT" was coined [10], important insights have been made in this rapidly expanding field of research. EMT and MET events occur during development, tissue repair, and disease, and many molecules that regulate the various EMTs or METs have been characterized, thanks in large part to the advent of cell culture models. However, the EMT regulatory network as a whole is still incomplete. An improved understanding of EMT and MET pathways will lead to more effective strategies for tissue engineering and novel therapeutic targets for the treatment of disease.

Zeb Zinc finger E-box-binding

Glossary

Apical Surface of the epithelial layer where adherens junctions and tight junctions are located. This is opposite the basal surface.
Basal Surface of the epithelial layer where the basal lamina is found. This is opposite the apical surface.
Basal Lamina Consists of extracellular matrix components such as collagen type IV, fibronectin, and laminin. The basal lamina functions to stabilize the epithelium and is a barrier against migratory cells.
Epithelial Epithelial cells adhere tightly to each other at their lateral surfaces and to an organized extracellular matrix at their basal domain, thereby producing a sheet of cells resting on a basal lamina with an apical surface.
Epithelial−Mesenchymal Transition The conversion of epithelial cells into mesenchymal cells.
Mesenchymal Mesenchymal cells are individual cells with a bipolar morphology that are held together as a tissue within a three-dimensional extracellular matrix.
Mesenchymal−Epithelial Transition The conversion of mesenchymal cells into epithelial cells.

Cell–Extracellular Matrix Interactions in Repair and Regeneration

Melissa Petreaca[1], *Manuela Martins-Green*[2]

[1]DePauw University, Greencastle, IN, United States; [2]University of California, Riverside, CA, United States

INTRODUCTION

For many years, the extracellular matrix (ECM) was thought to serve only as a structural support for tissues. Several studies conducted in the latter half of the 20th century dispelled this notion, providing evidence that matrix molecules promote the conversion of myoblasts to myotubes and facilitate the morphogenesis of multiple glands and organs [1]. Data from these and other studies collectively implicated the ECM in embryonic inductions and suggested the presence of matrix binding sites on the surface of cells responding to specific matrix molecules. These ideas opened an entire field of inquiry investigating the detailed mechanisms through which ECM molecules influence cell behavior. Bissell et al. proposed the model of "dynamic reciprocity," in which ECM molecules transmit signals across the cell membrane via cell surface receptors, stimulating signaling pathways that change expression of specific genes whose protein products then affect or alter the ECM [1]. It has become clear that this concept is correct, because cell–ECM interactions activate intracellular signaling, modulate cytokine and growth factor activities, and regulate cell adhesion, migration, growth, differentiation, and programmed cell death.

Much of our current understanding of the molecular basis of cell–ECM interactions in these events comes from in vitro cell or organ cultures and in vivo experiments involving changes in the composition or function of matrix molecules. Here, we will first briefly discuss the composition and diversity of some of the better-known ECM molecules and their receptors, and then discuss selected examples that illustrate the dynamics of cell–ECM interactions during regenerative (scarless) and nonregenerative (scar-forming) wound healing, as well as the potential mechanisms through which matrix-induced signaling affects wound repair. Finally, we will discuss the implications of cell–ECM interactions in regenerative medicine.

COMPOSITION AND DIVERSITY OF THE EXTRACELLULAR MATRIX

The ECM is a molecular complex with many components, including, but not limited to, collagens, hyaluronan, proteoglycans, glycosaminoglycans (GAGs), and elastins. These molecules interact with each other and with growth factors, cytokines, and matrix-degrading enzymes and their inhibitors. The distribution and organization of matrix molecules are not static, but rather vary from tissue to tissue and, during development and tissue repair after injury, from stage to stage, conferring distinct properties and functions on the tissue in question [1,2]. For example, mesenchymal cells are immersed in an interstitial matrix that confers specific biomechanical and functional properties to connective tissue, whereas epithelial and endothelial cells contact the specialized matrix of the basement membrane via only their basal surfaces, conferring mechanical strength and specific physiological properties to the epithelia [3]. The temporal and spatial presence and distribution of specific matrix molecules are critical for the function of both mature tissues and new tissues generated by development or repair, as shown by the impact of mutations in matrix molecules and their associated receptors on these processes [3]. This diversity of composition, organization, and distribution of ECM among different tissues and the same tissue under different conditions results from changes

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00002-3

in gene expression, splicing, and posttranslational modifications of matrix molecules. For example, alternative splicing or proteolytic cleavage may change the binding potential of matrix proteins to their receptors or to other matrix molecules, whereas altered patterns of glycosylation affect cell adhesion and migration [4–6].

Changes in the structure, organization, and components of the ECM also can affect the distribution and function of growth factors and cytokines that interact with the ECM, influencing downstream signaling in multiple ways. Through its binding to growth factors and cytokines, matrix molecules can protect these molecules from degradation, regulate their local concentrations, facilitate their formation of stable gradients within a tissue, and/or present them more effectively to their receptors, all of which increase downstream signaling and thereby alter signaling-induced cell behaviors [4,7–10]. One example of this matrix-facilitated growth factor signaling involves the binding of vascular endothelial growth factor (VEGF) to fibronectin or heparin sulfate proteoglycans, which increases endothelial proliferation and migration [9]. However, matrix molecules can also bind and sequester growth factors, thereby preventing ligand–receptor interactions and downstream signaling. Binding of heparan sulfate proteoglycans (HSPGs) to heparin-binding endothelial growth factor (EGF)-like factor growth factor (HB-EGF) prevents receptor binding and downstream signaling until proteolytic release of the ligand from the HSPGs [11].

Further complicating the impact of matrix molecules on growth factor signaling, some matrix molecules and matricryptins, proteolytic fragments of matrix molecules, can bind directly to growth factor receptors and either activate or inhibit downstream signaling [4]. For example, specific domains of matrix molecules, including the epidermal growth factor (EGF)-like repeats of laminin-332 and tenascin C, bind and activate the epidermal growth factor receptor (EGFR) [12]. These EGF-like repeats may function as matricryptins after their proteolytic release from their molecules of origin, allowing EGF-like matrix-derived peptides to function as soluble ligands that activate the EGFR, or the EGF-like repeats may function as EGFR ligands in the context of the intact matrix molecule [8,12]. If these EGF-like repeats can induce signaling as part of intact matrix molecules, these repeats could function as persistent, stable inducers of EGFR signaling that could regulate cell function over long periods [8]. In contrast, some matrix molecules and many matricryptins inhibit growth factor receptors, suppressing or antagonizing their downstream effects on cell survival, proliferation, and migration. For example, the proteoglycan decorin binds multiple growth factor receptors and interferes with downstream signaling, whereas fragments of collagen XVIII (endostatin), collagen IV (tumstatin), and the proteoglycan perlecan (endorepellin) bind and inhibit or downregulate VEGF receptors, decreasing endothelial cell survival and migration [10,12].

RECEPTORS FOR EXTRACELLULAR MATRIX MOLECULES

To establish the direct effects of ECM molecules on cell behavior, it was important to identify transmembrane receptors for the specific sequences present on these molecules. Early investigations of salivary gland morphogenesis showed that intracellular microfilaments contracted near the sites of glycosaminoglycan deposition, which suggested that the matrix could regulate microfilament function through the binding of matrix molecules with cell surface receptors [12a]. Later experiments demonstrated that ECM molecules contain specific amino acid motifs enabling their direct binding to cell surface receptors, the best-characterized of which is the tripeptide RGD, first found in fibronectin but later identified in many other matrix molecules [8].

The RGD motifs found in multiple matrix molecules serve as ligands for a subset of receptor proteins called integrins. Integrins, a family of heterodimeric transmembrane proteins composed of α and β subunits, were the first ECM receptors to be identified [13]. The 18 α and 8 β integrin subunits interact with each other in multiple combinations to generate a diverse family of matrix-binding receptors (Fig. 2.1). Some integrins have restricted ligand specificity; others bind multiple epitopes located on the same or different ECM molecules (Fig. 2.1) [13]. In contrast to the extracellular ligand-binding domains of the integrin heterodimers, the intracellular domains of these receptors are relatively small. Despite the relatively short length of their cytoplasmic domains, integrins interact with an array of intracellular signaling proteins that facilitate integrin-associated, matrix-induced signal transduction [14]. The simultaneous binding of some integrins, including integrins $\alpha_v\beta_3$ and $\alpha_5\beta_1$, to both a matrix ligand and a growth factor receptor attached to its growth factor ligand facilitates growth factor receptor signaling, expanding the role of integrin–matrix binding in the regulation of cell behavior [15].

Although not as extensively studied as the integrins, several proteoglycans, including members of the syndecan family, CD44, and RHAMM (receptor for hyaluronate-mediated motility) also function as ECM receptors [6]. The extracellular domains of syndecans interact with multiple ligands, including growth factors and matrix molecules

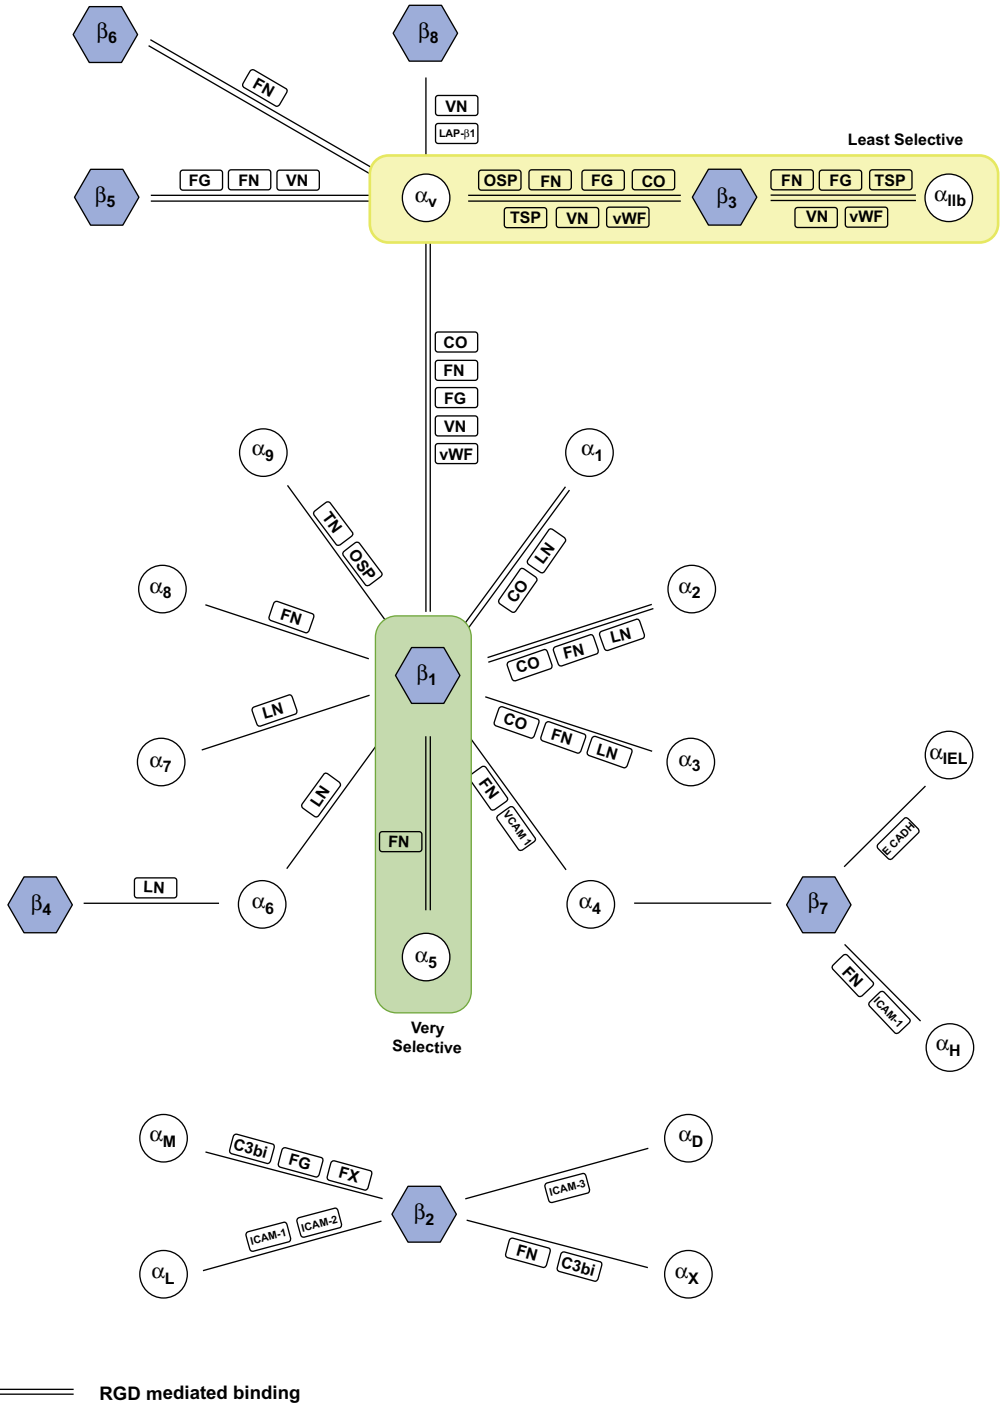

FIGURE 2.1 **Representative members of the integrin family of extracellular matrix (ECM) receptors and their respective ligands.** These heterodimeric receptors are composed of one α and one β subunit and are capable of binding a variety of ligands, including immunoglobulin superfamily cell adhesion molecules, complement factors, and clotting factors, in addition to ECM molecules. Cell–cell adhesion is largely mediated through integrin heterodimers containing the β_2 subunits, whereas cell–matrix adhesion is mediated primarily via integrin heterodimers containing the β_1 and β_3 subunits. In general, the β_1 integrins interact with ligands found in the connective tissue matrix, including laminin, fibronectin, and collagen, whereas the β_3 integrins interact with vascular ligands, including thrombospondin, vitronectin, fibrinogen, and von Willebrand factor. *CO*, collagens; *C3bi*, complement component; *FG*, fibrinogen; *FN*, fibronectin; *FX*, Factor X; *ICAM-1*, intercellular adhesion molecule-1; *ICAM-2*, intercellular adhesion molecule-2; *ICAM-3*, intercellular adhesion molecule-3; *LN*, laminin; *OSP*, osteopontin; *TN*, tenascin; *TSP*, thrombospondin; *VCAM-1*, vascular cell adhesion molecule-1; *VN*, vitronectin; *vWF*, von Willebrand factor.

such as fibronectin and multiple collagens, via chondroitin- and heparan-sulfate GAGs, whose composition varies based on the specific syndecan family member and the tissue in which it is expressed [16]. In contrast to the variable extracellular domain, the syndecan transmembrane and intracellular domains are small and relatively conserved, interacting with the actin cytoskeleton and several associated signaling molecules, including kinases in the Src and PKC families as well as Tiam1, a guanine nucleotide exchange factor for and activator of the Rho GTPases [17]. Although these intracellular signaling molecules are likely responsible for syndecan-mediated cytoskeletal reorganization, syndecan binding to nonmatrix molecules, including growth factors, growth factor receptors, and integrins, makes the identification of matrix-specific, syndecan-mediated signal transduction challenging [16].

Like syndecans, the CD44 receptor carries chondroitin sulfate and heparan sulfate chains on its extracellular domain and undergoes tissue-specific splicing and glycosylation to yield multiple isoforms [6]. Although hyaluronan is its primary ligand, CD44 interacts with other matrix molecules, including fibronectin, laminin, collagen IV, and collagen XIV. Furthermore, the ability of the heparan- and chondroitin-sulfate GAGs on CD44 to bind growth factors, combined with the interactions of CD44 with growth factor receptors, such as EGFR and transforming growth factor-βR (TGFβR), suggests a role for CD44 in modulating growth factor signaling [6,18]. In contrast to the transmembrane CD44 and syndecan proteoglycans, RHAMM, another proteoglycan able to both bind matrix molecules and induce signaling, is associated with the cell membrane through a glycosylphosphatidylinositol (GPI) linkage and not a transmembrane domain. As such, RHAMM located on the cell surface likely activates intracellular signaling through indirect mechanisms, via interactions with transmembrane receptors such as CD44 or growth factor receptors [19]. Interestingly, a variant of RHAMM lacking the GPI anchor resides in the cytoplasm and/or nucleus, where it affects intracellular signaling and cytoskeletal organization through its binding to intracellular signaling molecules and the cytoskeleton, expanding the role of RHAMM as a regulator of cell signaling [19].

Cell surface receptors other than integrins or proteoglycans, including the elastin receptor complex (ERC), CD36, annexin II, Toll-like receptors, and discoidin domain receptors (DDRs) can also serve as receptors for ECM molecules. The ERC is a complex of proteins, including elastin-binding protein (EBP), a splice variant of β-galactosidase, as well as neuraminidase 1 and cathepsin A, that serves as a receptor for elastin, laminin, fibrillin, and peptides derived from these ECM molecules. Signaling activated by this receptor is necessary for elastin deposition and participates in signaling induced by elastin and laminin during mechanotransduction [20]. Another nonintegrin, nonproteoglycan receptor, CD36, better known for its function as a scavenger receptor for long-chain fatty acids and oxidized low-density lipoprotein, binds thrombospondin, collagen I, and collagen IV [21]. CD36-thrombospondin binding activates a variety of signal transduction molecules, ultimately leading to inhibition of angiogenesis via increased endothelial cell apoptosis [22]. Cell surface annexin II, yet another matrix receptor, interacts with alternative splice variants of tenascin-C and facilitates proliferative and migratory effects of these tenascin C splice variants [23]. Although not a matrix receptor per se, Toll-like receptors can function as receptors for fragments of multiple matrix molecules, including fibronectin and low–molecular weight fragments of hyaluronan, which suggests that such fragments may function as danger signals that induce inflammation in response to matrix degradation [18,24].

Receptor tyrosine kinases can also serve as receptors for matrix molecules, as described earlier for EGFR, which binds matrix molecules through their EGF-like domains, as well as the collagen-binding discoidin domain receptors DDR1 and DDR2. Whereas the DDR proteins, like all receptor tyrosine kinases, promote receptor phosphorylation in response to ligand binding, DDRs form constitutive dimers required for ligand binding, unlike most of this receptor family, which dimerize after ligand binding [25]. Also, in contrast to other receptor tyrosine kinase activation, DDR activation by their collagen ligands induces prolonged rather than transient signaling events [26]. The combination of long-lived collagen ligands and the relatively long-term signaling induced by these ligands through the DDRs could provide sustained regulation of cell survival, proliferation, and/or migration in cells expressing these receptors.

In the next section, we will focus on ways in which ECM molecules and their various receptors affect signal transduction, the multiple cell behaviors regulated by this signaling, and the impact of this signaling on wound healing under both nonregenerative and regenerative conditions.

SIGNAL TRANSDUCTION EVENTS DURING CELL–EXTRACELLULAR MATRIX INTERACTIONS

As a result of interactions between ECM molecules and their receptors, as described previously, signals can be transmitted directly or indirectly to signaling molecules within the cell, activating a cascade of events and the coordinated expression of a variety of genes involved in cell adhesion, migration, proliferation, differentiation, and

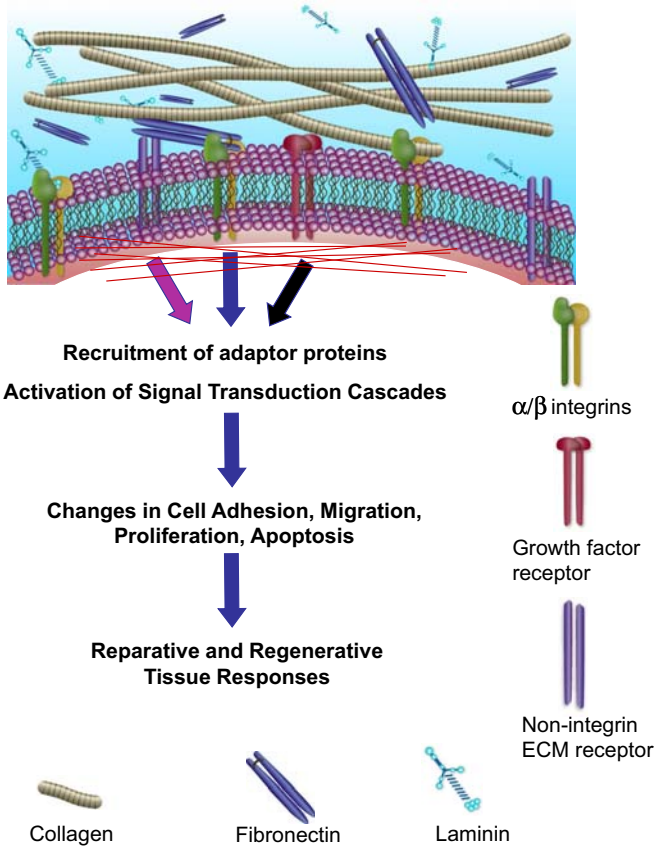

FIGURE 2.2 **Schematic diagram of cell–extracellular matrix (ECM) interactions present during healing and regenerative responses.** Such interactions between the ECM receptors and their respective ligands initiate signal transduction cascades culminating in a variety of cellular events important in repair and regeneration, including changes in cellular adhesion and migration and altered rates of proliferation and apoptosis. The presence and/or extent of such changes may influence the balance of repair and regenerative responses to favor one outcome over another; thus, interventions that alter ECM signaling events may shift this balance to favor tissue regeneration and decrease scarring.

programmed cell death (Fig. 2.2). Some of the increasing evidence that cell–ECM interactions through multiple types of matrix receptors activate a variety of signaling pathways affecting these specific cell outcomes is described subsequently.

Adhesion and Migration

When considering the importance of cell–matrix interactions in adhesion and migration, it is important to recognize that some receptors for ECM molecules, such as the integrins, can participate in both traditional "outside-in" signaling, leading to the activation of intracellular signaling, and "inside-out" signaling, in which intracellular signaling activates the receptor by increasing its affinity for an ECM molecule. This is further complicated by the fact that receptor activation and ligand binding can also initiate outside-in signaling. In the following section, the signaling events refer to outside-in signaling unless otherwise specified.

The outside-in signaling activated by integrin binding to its ligand requires the indirect interaction of the integrin cytoplasmic domain with the cytoskeleton, through a variable group of proteins that collectively comprise the integrin adhesion complex [14]. Some of the proteins of the integrin adhesion complex facilitate integrin-mediated mechanotransduction, whereas other proteins connect the integrins to other types of downstream signal transduction pathways [14]. Integrin-mediated ECM signaling uses these associated proteins to induce changes in cell shape and lead to proliferation, migration, and/or differentiation [27]. Some of the best-known components of the integrin adhesion complex include the signaling adaptor proteins focal adhesion kinase (FAK) and paxillin, the mechanotransducing proteins vinculin and talin, the actin regulatory proteins zyxin and VASP, and the actin-binding protein α-actinin [14]. When the integrin heterodimer interacts with its matrix ligand, FAK, which is associated with the

membrane-proximal portion of the integrin cytoplasmic domain, becomes autophosphorylated on tyrosine 397 (Y387) [28]. The Y397 autophosphorylation may be associated with mechanosensation, as shown by the positive correlation between Y397 phosphorylation and adhesion to fibronectin of increasing stiffness [29]. However, the role of mechanosensation in FAK Y397 phosphorylation may depend on both the matrix molecule and the integrin in question, because soluble collagen but not soluble fibronectin can induce FAK autophosphorylation in suspended cells [29]. Upon integrin–matrix binding and FAK activation, the phosphorylated Y397 serves as a binding site for the SH2 domain of the nonreceptor tyrosine kinase c-Src, which then enhances FAK activity by phosphorylating additional tyrosine residues [28,30]. Src-mediated FAK phosphorylation on tyrosine 925 generates a binding site for the Grb2/Sos complex, with subsequent activation of Ras and the mitogen-activated protein kinase (MAPK) cascade, which may be involved in adhesion/deadhesion and migration [28,31].

In addition to activation of the Ras/MAPK pathway, the FAK/Src complex phosphorylates and regulates the activity of other components of the integrin adhesion complexes, including paxillin, p130Cas, vinculin, and tensin [32]. All of these proteins are associated with cell migration, as shown by the migration defects observed in cells either lacking these molecules altogether and/or expressing mutants affecting their activity or localization [33–36]. For example, paxillin-deficient fibroblasts exhibit both reduced phosphorylation of signaling molecules downstream of integrin ligation and decreased cell motility [33]. The phosphorylation of paxillin by the FAK/Src complex promotes paxillin binding to the SH2 domain of the Crk/DOCK180/ELMO complex. DOCK180, a guanine nucleotide exchange factor (GEF) for Rac1, then activates Rac1 and promotes cell migration [37]. Similarly, p130Cas phosphorylation by the FAK/Src complex promotes Rac1 activation and migration through Crk/DOCK180/ELMO-mediated Rac activation [28]. Beyond their activation of Rac, phosphorylated integrin adhesion complex components regulate other members of the Rho GTPase family. For example, phospho-paxillin also appears to activate p190RhoGAP, leading to localized inhibition of RhoA activity [37]. Additional regulators of RhoA and Rac activity in migrating cells include members of the tensin family, which, like paxillin and p130Cas, are phosphorylated by FAK/Src complexes. In contrast to the RhoGAP-activating function of phosphorylated paxillin, however, tensin1 increases RhoA activity by inhibiting the RhoGAP activity of DLC1 [34]. The conventional understanding of Rac and RhoA dynamics during cell migration suggests that the combination of enhanced Rac1 activity and decreased RhoA activity at the leading edge of migrating cells decreases cell adhesion and promotes protrusion formation, thereby facilitating cell migration. However, Förster resonance energy transfer–based sensors demonstrate both RhoA and Rac activity at the leading edge of migrating cells, suggesting a more complex relationship between these GTPases and membrane protrusion than previously thought and demonstrating the need for more research in this area [38].

Although FAK and c-Src are best known for their roles in outside-in signaling, as described earlier, these kinases are also involved in inside-out signaling, which promotes integrin–ligand binding. FAK promotes integrin activation, cell adhesion to fibronectin, and strengthening of focal adhesions [39]. These effects appear to require Src binding and/or activity, because a Y397 F mutation that prevents FAK autophosphorylation and Src binding at this site also prevents FAK-mediated adhesion [39]. FAK-induced integrin binding to ECM molecules can then initiate outside-in signaling, leading to more FAK activation, FAK-Src interaction, and downstream signaling that promotes deadhesion and migration. This suggests a cycle of FAK and Src activity, in which they initially promote deadhesion and migration, followed by the formation of new adhesions at the leading edge. In support of this FAK/Src cycle of activity, active Src moves from the focal adhesions to the membrane ruffles at the leading edge during cell migration [39a]. The activation of integrins downstream of FAK/Src signaling may mediated by talins and kindlins, two families of proteins that bind directly to the cytoplasmic domains of β integrins. FAK is necessary for talin recruitment to integrins at newly forming adhesion sites, and cells either lacking specific talin family members or expressing mutants that abolish talin–integrin interactions prevent integrin activation induced by various stimuli, leading to defects in integrin-mediated adhesion [40]. Deficiencies in kindlin expression are associated with similar defects in integrin activation and cell adhesion, which suggests the possibility that talins and kindlins work together, potentially downstream of FAK, to activate integrins and promote cell adhesion [41]. However, kindlin signaling is not limited to inside-out signaling; it also participates in outside-in signaling after integrin engagement with matrix ligands. The interaction of kindlin-2 with Src is not required for inside-out signaling and cell adhesion to fibronectin but is necessary for paxillin phosphorylation downstream of integrin ligation and for platelet-derived growth factor (PDGF)-induced mesangial cell proliferation and migration [42]. These findings suggest that kindlin-2 may have multiple roles in integrin-mediated signaling, both promoting integrin-mediated adhesion and facilitating integrin-induced signaling after matrix adhesion, underscoring the interplay between inside-out and outside-in integrin signaling.

A separate form of integrin activation occurs downstream of growth factor receptors. VEGF binding to the VEGFR2 in endothelial cells activates c-Src, which directly phosphorylates β_3 integrin, increasing endothelial cell

adhesion to the $\alpha_v\beta_3$ ligand vitronectin [43]. Interestingly, Src is also necessary for integrin $\alpha_v\beta_3$ interaction with VEGFR2, which is also required for maximal VEGFR2 phosphorylation and VEGF-induced endothelial cell migration in vitro and angiogenesis in vivo [43]. Furthermore, VEGF-induced endothelial cell migration requires FAK activity [44]. These data suggest that the interactions between VEGFR2 and integrin $\alpha_v\beta_3$ couple integrin activation with VEGFR2 signaling, promoting FAK activation and signaling downstream of FAK (described earlier), thereby linking cell–matrix adhesion with promigratory signaling.

Beyond integrin signaling in cell adhesion and migration, nonintegrin ECM receptors, including proteoglycan receptors such as syndecans, CD44, and RHAMM, as well as the elastin-laminin receptor, the EGFR, and DDR1, also participate in cell adhesion and migration through a variety of mechanisms. For example, syndecans facilitate migration through both activation of signaling through the cytoplasmic domains of the syndecans themselves and syndecan-mediated activation of growth factor receptors and integrins [17]. The PDZ-binding motif, located on syndecan intracellular domains, binds several signaling proteins with PDZ domains, including the Rac1 GEF Tiam1, which suggests a mechanism by which syndecan binding to matrix ligands directly regulates cell migration [17]. Syndecans also collaborate with integrins and growth factor receptors in the induction of cell adhesion and migration. In the case of integrins, syndecan-4 regulates the formation and generation of specific integrin adhesion complexes by promoting the internalization and degradation of some integrin heterodimers while increasing surface levels of different heterodimers [16,45]. These alterations in integrin composition induced by syndecan-4 may affect both cell adhesion and integrin-induced signaling important in cell migration. In support of this idea, syndecan cooperation with integrin heterodimers mediates cell adhesion to vitronectin and laminin and induces cell migration, and syndecan-4 promotes Rac1 activation and localization to the leading edge of migrating cells, facilitating directional cell migration in response to fibronectin [46]. Syndecans also participate in growth factor receptor signaling through a complex web of interactions in which the syndecans bind growth factors and prevent receptor binding until proteolytic release (e.g., HB-EGF) or bind both growth factor and its receptor to promote receptor activation (e.g., fibroblast growth factor [FGF] and VEGF) [16]. These growth factor–proteoglycan interactions may provide a stable growth factor gradient that facilitates directional cell migration [8,9].

Two non-syndecan proteoglycan receptors, CD44 and RHAMM, both bind hyaluronan and collaborate to promote hyaluronan-induced signaling. Hyaluronan is a matrix molecule that is generally produced in a high–molecular weight form that can cross-link its cell surface receptors, promoting cell adhesion and inhibiting cell migration [19]. However, lower–molecular weight hyaluronan fragments found in injured and/or inflamed tissues promote cell migration associated with inflammation and angiogenesis [47]. Some of these differences in function between high– and low–molecular weight hyaluronan likely result from differences in receptor selection, because low–molecular weight forms are more likely to bind Toll-like receptors, which can then promote inflammation through nuclear factor κB–induced expression of cytokines and chemokines [47]. However, the angiogenesis induced by hyaluronan fragments requires CD44, which suggests that hyaluronan fragments of different sizes may induce different conformational changes in CD44 or selectively bind different CD44 splice or glycosylation variants, in either case inducing different downstream signaling pathways that either promote angiostatic or angiogenic outcomes [47,48]. Some of these CD44 variants can interact with growth factors and/or their receptors, modulating downstream signaling. For example, the splice variant CD44v6 binds both to VEGF isoforms and to VEGFR2, and CD44v6 inhibition decreases VEGF-induced activation of VEGFR2 and downstream phosphorylation of ERK in endothelial cells [49]. Furthermore, CD44v6 inhibition significantly decreases VEGF-induced endothelial cell migration in vitro and angiogenesis in vivo, which underscores the importance of this CD44 variant in promigratory VEGFR2 signaling [49].

Fragments of matrix components, likely generated under proteolytic conditions such as those occurring during wound healing and inflammation, bind multiple matrix receptors in addition to the receptors described earlier, including the EGFR and the elastin receptor, thereby promoting cell adhesion and migration in various cell types. The EGF-like repeats in tenascin-C, laminin 332, thrombospondin, and secreted protein acidic and rich in cysteine protein (SPARC) can decrease cell–matrix adhesions and promote cell migration [12]. Although receptor binding and signaling induced by these matrix molecules are complicated by their ability to bind and activate integrins, there is compelling evidence that the EGF-like repeats of tenascin C and laminin 332 promote changes in cell adhesion and motility in an EGFR-dependent manner [12]. Another matrix fragment-binding receptor, the ERC, binds fragments of elastin, laminin, and fibrillin. Although ERC binding to ligands initially promotes cell adhesion by promoting elastin deposition into the ECM, interaction of the EBP component of the ERC with elastin-derived peptides can promote migration of multiple cell types, including monocytes, keratinocytes, fibroblasts, smooth muscle cells, and endothelial cells [50]. The proliferative and migratory effects of elastin-derived peptides may result from the activation of multiple MAPK cascades downstream of the ERC [51].

In contrast to the ERC and EGFR, which can bind matrix fragments, DDR1 and DDR2 bind intact collagen molecules rather than fragments [25]. Signaling induced by collagen through the DDRs seem to have cell type–specific effects, promoting migration in some cell types while repressing it in others [25]. In the case of DDR2, collagen binding promotes the movement of fibroblasts through matrix, likely through induction of matrix metalloproteinase (MMP)-2 expression and activation, suggests a role in tissue invasion [26]. Because collagen induces relatively long-term DDR2 activation, DDR2-induced cell behaviors, such as matrix invasion, could be maintained over substantial periods [26].

Proliferation and Survival

ECM interaction with its receptors can promote cell proliferation and survival, as is demonstrated clearly by the anchorage dependence of cell growth. Even in the presence of growth factors, cells will not enter the S phase of the cell cycle without matrix adhesion [52]. In addition, cell detachment from the matrix or expression of matrix receptors in the absence of their intact ligands often promotes apoptosis, a process known as anoikis [15]. Thus, adhesion of cells to ECM molecules has an important role in regulating cell survival and proliferation. Because much of our understanding of matrix-induced proliferation and survival is related to matrix interaction with integrins, we will begin with integrin-associated proliferation and survival.

Multiple studies in which integrins are either inhibited or deficient demonstrate that integrin signaling is critical for cell proliferation [52]. For example, the fibroblasts of mice lacking the $\alpha_1\beta_1$ integrin, a primary collagen receptor, have reduced proliferation even though they exhibit normal adhesion [53]. The loss of integrin-mediated adhesion inhibits cell survival by inducing the movement of the proapoptotic protein Bax from the cytoplasm to the mitochondria, promoting apoptosis [54]. Integrin-mediated, adhesion-induced cell survival requires FAK activity, as shown by the Bax translocation and apoptosis of cells expressing dominant negative FAK and the survival of detached cancer cells overexpressing FAK [28,54]. Integrin–matrix binding activates the FAK–Src complex, which interacts with and activates PI3K, leading to the downstream activation of Akt [52]. Akt then alters the ratios of proapoptotic and antiapoptotic Bcl-2 family members, increasing the levels of the antiapoptotic Bcl-xl and Mcl-1 and decreasing the levels of proapoptotic Bax and Bak, thereby promoting cell survival [55]. Whereas the prosurvival signals downstream of Fak in epithelial cells require Src activity, as described previously, prosurvival signaling in fibroblasts instead involves p130Cas activation, which suggests that the mechanisms involved in FAK-induced survival are cell type specific [56].

Although maintenance of cell survival by integrin-mediated matrix adhesion is necessary for cell division, it is not sufficient. Many signaling pathways induced by integrin-ECM binding, notably the activation of MAPK pathways, promote cell division rather than simply survival [52]. As mentioned in an earlier section, FAK-induced p130Cas activation is upstream of Rac1, and once Rac1 is activated by this pathway, it can promote cell proliferation downstream of multiple effectors [28]. For example, Rac1-induced JNK activity promotes cell division through c-Jun-induced cyclin expression, whereas Rac1-mediated activation of Pak1 induces proliferation through its phosphorylation of Raf and downstream activation of extracellular signal-regulated kinase (ERK) [52]. Integrin ligation also activates ERK1/2 through FAK-mediated recruitment of Shc, an adaptor protein that binds Grb2/Sos and induces the Ras/ERK cascade [57]. Furthermore, cell-ECM binding and Rac activation promote the degradation of cyclin-dependent kinase (CDK) inhibitors, which would otherwise block cell proliferation [52].

Matrix molecules can also induce cell proliferation through cooperation with growth factor receptor signaling [8]. Such cooperative effects may occur in a direct manner, because some matrix molecules bind and activate growth factor receptors, leading to cell proliferation, whereas other matrix molecules bind growth factors and regulate their interaction with their receptors [23]. The matrix molecules that bind growth factor receptors directly can promote receptor activation and downstream signaling. For example, laminin and tenascin-C can bind and activate EGFR and associated downstream signaling through their EGF-like domains [12], which suggests the possibility that they or their proteolytic fragments may promote cell division downstream of EGFR. In contrast, decorin binding to EGFR and VEGFR2 inhibits proliferation induced by VEGF and EGF, potentially through internalization or degradation of the receptors, which has been shown for EGFR [12,58].

Although there is some evidence, described earlier, that matrix–growth factor receptor engagement can promote cell proliferation, substantially more evidence demonstrates the importance of growth factor binding to matrix molecules on growth factor receptor activation and induction of cell proliferation. Multiple ECM molecules are able to bind to either growth factors or their receptors to regulate their activity [8]. For example, VEGF binding to vitronectin promotes the formation of a VEGFR2/integrin $\alpha_v\beta_3$ complex that greatly increases VEGF-induced VEGFR2

phosphorylation and endothelial cell proliferation, and the binding of VEGF to fibronectin has a similar effect on VEGFR2/integrin $\alpha_5\beta_1$ complex formation, VEGFR2 activation, and cell proliferation [43,59]. Several growth factors, including FGFs, VEGFs, PDGFs, and TGFβ, can interact with HSPGs, which can either sequester these factors within the matrix, such that they are released upon matrix degradation, or can present them to their receptors [16]. For example, FGF binding to heparan sulfate moieties on syndecans facilitates FGF binding to and activation of FGFR, increasing the duration of signaling downstream of FGFR and promoting cell proliferation [16,45]. Similarly, VEGF binding to HSPGs increases binding to VEGFR2 and promotes cell proliferation [45].

In addition to matrix binding to growth factor receptors and growth factor binding to matrix, matrix–growth factor cooperation can occur through direct interactions between integrins and growth factors or growth factor receptors. VEGF binds directly to integrin $\alpha_9\beta_1$, which is necessary for VEGF-induced angiogenesis in vivo [59]. Other growth factors are also able to bind integrins directly; for example, insulin-like growth factor (IGF)-1 and FGF-2 both interact with integrin $\alpha_v\beta_3$, which is necessary for the cell proliferation induced by both factors [57]. Growth factor receptor binding to integrins may also enhance growth factor–induced signaling. Both PDGFRβ and VEGFR2 physically interact with integrin subunits, and concomitant integrin-mediated cell adhesion further increases both receptor activation and mitogenicity [52,59]. In the case of VEGFR2, integrin binding participates in FAK-induced Ras/ERK activation in endothelial cells, providing a likely mechanism for the role of integrin binding in proliferation [60].

Nonintegrin ECM receptors, including the hyaluronan receptor CD44, the ERC, and the collagen-binding DDRs, have also been implicated in cell proliferation and survival. Whereas high–molecular weight hyaluronan inhibits cell proliferation, the lower–molecular weight forms present in sites of injury and inflammation induce proliferation of multiple cell types, including fibroblasts and smooth muscle cells [19,47]. Hyaluronan-induced proliferation in fibroblasts appears to be mediated, at least in part, by CD44 and its downstream activation of ERK and Akt [61]. Similarly, binding of hyaluronan fragments to CD44 promotes smooth muscle cell proliferation via downstream activation of the Ras–ERK pathway [47]. The binding of elastin-derived peptides to the ERC promotes smooth muscle cell proliferation by activating multiple signaling pathways that culminate in activation of the MAPK cascade and upregulation of multiple cyclins and CDKs [62]. The ERC may also inhibit proliferation induced by growth factor receptors, because the neuraminidase subunit of the ERC desialylates cell surface growth factor receptors, preventing growth factor–receptor binding and downstream signaling, complicating the role that the ERC has in regulating proliferation [63]. Finally, both DDR2, a collagen receptor, and annexin II, a tenascin C receptor, can promote division in some cell types [23,26]. To date, we have few clues regarding signaling activated in matrix-induced proliferation via nonintegrin receptors, which suggests the need for more research in this area.

Differentiation

Interaction of cells with ECM molecules, hormones, and growth factors is required to activate genes needed for the differentiation of multiple cell types, including keratinocytes, endothelial cells, and fibroblasts. Differentiation of keratinocytes is carefully regulated by multiple cell–matrix and cell–cell interactions. Keratinocytes in contact with the basement membrane proliferate and do not express proteins associated with terminal differentiation, whereas those cells that are not attached to the basement membrane in suprabasal layers begin to express these markers of terminal differentiation. This suggests that keratinocyte differentiation is repressed by adhesion to the basement membrane. In support of this idea, integrin activation in cultured cells inhibits differentiation, whereas impaired adhesion promotes differentiation [64]. In contrast, keratinocytes of mice deficient in various integrins can still differentiate, which suggests that there may be some redundancy in the system [65]. There may be additional cues provided by matrix molecules present within the epidermis itself that regulate differentiation. For example, hyaluronan is present within the epidermis, where it facilitates keratinocyte terminal differentiation in a CD44-dependent manner [66]. These results are contradicted by separate studies suggesting that epidermal hyaluronan prevents premature keratinocyte differentiation [18]. One potential explanation for this discrepancy is that enzymatic digestion of hyaluronan may have generated hyaluronan fragments with binding and/or signaling differences from intact hyaluronan. Regardless, it appears that hyaluronan and CD44 are involved in the keratinocyte differentiation process.

Other differentiated phenotypes also require integrin-mediated signaling events. TGFβ-mediated differentiation of fibroblasts into myofibroblasts, contractile cells that produce ECM, requires cell integrin-mediated adhesion to extra domain A (EDA) of fibronectin [27]. Integrins $\alpha_v\beta_5$ and $\alpha_v\beta_6$ and integrin heterodimers containing the β_1 subunit are associated with TGFβ activation and are thus important in myofibroblast differentiation

[27,65]. Because integrin $\alpha_5\beta_1$ interacts with the EDA of fibronectin and integrin β_1-deficient mice exhibit defective myofibroblast differentiation, the connection between integrin $\alpha_5\beta_1$ and the fibronectin EDA may be particularly important in myofibroblast differentiation [27]. Pathways downstream of integrin–fibronectin interaction, including FAK and integrin-linked kinase activation, are necessary for TGFβ-induced myofibroblast differentiation, providing some potential mechanisms for its observed dependence on EDA-containing fibronectin [27]. Myofibroblast differentiation is also associated with matrix stiffness; increasing matrix stiffness is associated with increasing differentiation, which suggests a role for integrin-mediated mechanotransduction, likely involving FAK activation, in this differentiation process [2,5]. However, the roles of hyaluronan and CD44 activation in myofibroblast differentiation remain unclear owing to conflicting evidence in which both decreased hyaluronan production and hyaluronan-induced CD44 activation increase myofibroblast differentiation [18]. This discrepancy may result from differences in the ability of CD44 to engage in cross-talk with the TGFβ receptor under different circumstances [18].

Differentiation of endothelial cells is more difficult to identify than is differentiation of keratinocytes or myofibroblasts, both of which have specific protein markers of differentiation. In contrast, endothelial cell differentiation occurs when endothelial cells form mature vascular structures, which is challenging to mimic in vitro. Early experiments involving cultured endothelial cells demonstrated growth of endothelial cells on an ECM comparable to the basement membrane, Matrigel, induced the formation of capillary-like tubes whose formation could serve as an in vitro proxy for endothelial cell differentiation [67]. These results suggested that the adhesion of endothelial cells with some component or components of Matrigel could promote their differentiation. The main matrix components of both Matrigel and basement membranes in blood vessels in vivo are laminins, heterotrimeric proteins composed of α, β, and γ subunits [68]. In Matrigel, the primary laminin is laminin-111 ($\alpha_1\beta_1\gamma_1$), which, in the absence of other matrix components, can promote endothelial tube formation in vitro [69]. The basement membranes of intact vessels in vivo contain laminin-411 ($\alpha_4\beta_1\gamma_1$) primarily, rather than laminin-111, and laminin-411 participates in endothelial tube formation in vitro and angiogenesis in vivo; the latter is shown by the formation of abnormal vessels in laminin α_4- and γ_1-deficient mice [68]. Peptides derived from laminins α_1 and γ_1 promote angiogenesis through integrins $\alpha_v\beta_3$ and $\alpha_5\beta_1$, which suggests the potential role of laminin degradation in new vessel formation [68]. After the formation of these nascent vessels, they must be stabilized and matured by the deposition of new basement membrane and the recruitment and differentiation of pericytes, smooth muscle cells that increase endothelial barrier function and participate in depositing a new basement membrane [9,70]. Fibronectin, laminin-411, collagen IV, and HSPGs are all required for the formation of the new basement membrane, whereas integrin-mediated interactions between the developing matrix and pericytes is necessary for continued deposition of basement membrane matrix molecules [68,71]. As such, matrix–integrin interactions are critical for the deposition of the basement membrane and recruitment of pericytes, which, in turn, are necessary for new vessel maturation.

Apoptosis

Many cell types undergo apoptosis, or programmed cell death, through well-known signal transduction pathways involving the activation of proteases from the caspase family. Cell-matrix signaling tends to promote cell adhesion and survival, repressing apoptosis. However, even when cells remain attached to some ECM molecules, the inability of some integrins to bind their matrix ligands induces a specific form of apoptosis called integrin-mediated death through integrin-mediated recruitment and activation of caspase 8 [72]. In addition to promoting apoptotic signaling, the activation of caspase 3 downstream of caspase 8 may prevent prosurvival integrin signaling from separate matrix-bound integrins by cleaving paxillin and kindlin-3, blocking prosurvival outside-in signaling downstream of these proteins [37,41]. Integrin ligation by soluble, rather than intact, ligands also promotes apoptosis through the recruitment and activation of caspase 8 by the clustered integrins [73]. Such soluble ligands may be created by matrix degradation during tissue remodeling. A fragment of collagen XVIII, endostatin, binds to $\alpha_5\beta_1$ integrin and decreases the expression of Bcl-xl and Bcl-2, prosurvival Bcl family members, promoting endothelial cell apoptosis [10]. Similarly, a fragment of collagen IV, tumstatin, induces apoptosis in endothelial cells via integrin $\alpha_v\beta_3$ [74]. Fragments of matrix molecules can also induce apoptosis through nonintegrin receptors. Low–molecular weight fragments of hyaluronan can induce apoptosis in some cells through CD44, likely by interfering with prosurvival signaling downstream of CD44 [19]. Similarly, elastin-derived fragments promote fibroblast and lymphocyte apoptosis through the ERC [22,51]. Taken together, these pieces of evidence suggest that disrupting normal matrix–receptor adhesions can promote apoptosis in various cell types.

CELL–EXTRACELLULAR MATRIX INTERACTIONS DURING HEALING OF CUTANEOUS WOUNDS

Interactions of cells with ECM molecules have a crucial role during wound healing and regeneration. Continuous cross-talk between cells and the surrounding matrix environment contributes to the processes of clot formation, inflammation, granulation tissue development, and remodeling; during regeneration, matrix interactions are important in restoring damaged tissue. Many lines of experimental evidence demonstrate that the basic cellular mechanisms resulting in wound healing involve cell adhesion–deadhesion, migration, proliferation, differentiation, and apoptosis (Fig. 2.2).

Adhesion and Migration

Shortly after tissue damage and during the early stages of wound healing, multiple factors and blood cells enter into the wound area, activating the coagulation cascade when coagulation factors from the blood encounter tissue factor expressed on endothelial cells, tissue factor expressed by nonvascular cells exposed by injury, or collagen, also exposed by injury [75]. This cascade ultimately results in the activation of thrombin, an enzyme that cleaves fibrinogen to generate fibrin, which polymerizes to form a fibrin clot. Injury to the endothelium simultaneously promotes the adhesion of platelets to subendothelial von Willebrand Factor and ECM components, causing platelet aggregation, activation, and adhesion to fibrin, trapping them within the fibrin clot [75]. Activated platelets release additional coagulation factors that promote and stabilize the fibrin clot, which serves as a vascular plug. In addition, to fibrin and platelets, the fibrin clot contains matrix components including plasma fibronectin and a variety of chemokines, cytokines, and growth factors released by activated platelets [7,76]. As such, in addition to its hemostatic function, the fibrin clot facilitates wound healing by serving as a provisional matrix for cell migration and a reservoir of cytokines, thrombin, and growth factors that collectively promote the later phases of inflammation and granulation tissue formation [77].

During the clotting process, platelets and activated mast cells degranulate, releasing vasodilating and chemotactic factors that chemoattract inflammatory leukocytes to the wound site, initiating the inflammatory response. Leukocyte extravasation from blood vessels requires several adhesion and signaling events, including the binding of leukocyte integrins with endothelial intercellular cell adhesion molecules and vascular cell adhesion molecules rather than matrix molecules, and the binding of leukocyte chemokine receptors with chemokines associated with endothelial cell surface HSPGs [27,78]. Some of the first matrix molecules that the leukocytes encounter during emigration from the bloodstream are located within the endothelial basement membrane and the provisional matrix. Neutrophils adhere to and migrate within the basement membrane as they move through the blood vessel, where they encounter laminins-411 and -511, fibronectin, and vitronectin, and subsequently interact with fibrin and fibronectin in the provisional matrix [76,79]. Neutrophils also secrete laminin-411, which likely participates in their extravasation through integrin $\alpha_M\beta_2$, because inhibition of this integrin blocks leukocyte extravasation [79].

After leukocyte extravasation from the vasculature, the leukocytes are directed to the site of injury by the chemokines that form relatively stable gradients through interactions with endothelial cell surface proteins and ECM molecules, thereby promoting directional cell migration through the provisional matrix [6]. The fibrin–fibronectin provisional matrix serves as substrate for the migration of leukocytes and later keratinocytes during the early stages of healing when inflammation and reepithelialization occur. Leukocyte interactions with ECM molecules via integrin receptors affect many of the functions of these cells, in particular those associated with cell adhesion, migration, the production of inflammatory mediators, and antimicrobial functions. As mentioned, neutrophils interact with fibronectin in the basement membrane and the provisional matrix, and several types of inflammatory cells interact with fibrinogen, the primary component of the provisional matrix, through integrins $\alpha_M\beta_2$ and integrin $\alpha_X\beta_2$ [77,80]. Neutrophil binding to thrombospondin 4, another ligand of integrin $\alpha_M\beta_2$, also induces expression of the chemokine CXCL8, whereas monocyte interactions with fibrin in the provisional matrix induces expression of multiple proinflammatory cytokines and chemokines, including TNFα, interleukin (IL)-6, IL-1β, and several CC chemokines [80,81]. Intact ECM molecules then facilitate additional leukocyte chemotaxis into the inflamed area by binding these chemokines, thus creating a stable chemotactic gradient to promote specific directional migration [7,82].

Although intact ECM molecules regulate inflammation in multiple ways, matrix fragments also participate in this process. Inflamed tissues contain many proteases that can cleave matrix molecules, generating fragments with

altered matrix binding, downstream signaling, and effects on inflammatory processes. For example, platelet-derived hyaluronidase cleaves hyaluronan, generating low–molecular weight hyaluronan fragments; neutrophil elastase cleaves elastin, fibronectin, and collagen XVII; and urinary plasminogen activator– and tissue plasminogen activator–induced plasmin activation promote cleavage of collagen XIX, laminin-332, SPARC, and syndecan-4 [4,6,47]. Several of the fragments generated in this manner then promote inflammation in a positive feedback loop. For example, low–molecular weight hyaluronan fragments induce cytokine and chemokine production through CD44, and collagen XVII and elastin fragments generated by neutrophil elastase promote neutrophil chemotaxis [4,19]. Ultimately, the matrix molecules encountered by leukocytes substantially influence the course of inflammation.

The inflammatory phase of wound healing is followed by a proliferative phase. Shortly after wounding, activated platelets secrete a variety of growth factors, including EGF and TGFβ, that stimulate the keratinocytes at the wound edge to proliferate and migrate to cover the wounded area, a process known as reepithelialization [83]. FGFs and EGFs are produced and/or released from sequestering matrix molecules at later times by neutrophils, macrophages, endothelial cells, and fibroblasts, and may maintain the proliferative and promigratory signals needed for reepithelialization. During reepithelialization, the keratinocytes migrate beneath the provisional ECM, composed primarily of fibrin and fibronectin [27,65]. The lack of keratinocyte migration on top of the fibrin-based clot may result from their lack of integrin $\alpha_v\beta_3$ expression as well as the ability of fibrin to prevent keratinocyte adhesion to other provisional matrix components, including fibronectin [77]. These cells instead migrate on the nascent, provisional basement membrane composed largely of including laminin-332, fibronectin, and tenascin-C, through the $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_1$, $\alpha_9\beta_1$, $\alpha_2\beta_4$, and α_v integrins expressed by these cells [27]. That these matrix–receptor interactions are critical for reepithelialization is clear from studies investigating keratinocyte migration and reepithelialization in cultured keratinocytes migrating on specific matrices, in mice lacking these molecules, and in human patients with matrix mutations. Interestingly, keratinocytes at the migration front produce laminin-332, facilitating the migration of keratinocytes behind the migration front on this matrix component [27]. Because the keratinocytes migrate between the fibrin-based clot and the underlying tissue, their migration is also associated with the activity of multiple proteases, including MMPs and plasmin [27,84]. These enzymes may facilitate keratinocyte migration by promoting their deadhesion from matrix molecules that would otherwise promote adhesion over migration and/or through releasing matrix-bound growth factors, or EGF-like domains from matrix molecules themselves, that then induce promigratory signaling [65,84].

At the same time as reepithelialization, granulation tissue, a provisional connective tissue containing nascent blood vessels and multiple types of ECM molecules, including tenascin-C, cellular fibronectin, SPARC, and various collagens, begins to form [7,26,27]. Granulation tissue serves as substrate for the migration of the keratinocytes (see earlier discussion), the endothelial cells that form the vasculature of the wound bed, fibroblasts, myofibroblasts, and leukocytes that are chemoattracted to the wound site by chemokines secreted by multiple cells within the wound [26]. Chemokine-mediated chemoattraction of cells involved in granulated tissue formation, in conjunction with the interaction of these cells with ECM via cell surface receptors, participates in functions during the formation of the granulation tissue. For example, the neutrophil chemoattractant CXCL8, produced by multiple cell types in the wound environment, induces fibroblast recruitment to the granulation tissue and their deposition of tenascin-C, fibronectin, and collagen I [85].

Interactions of both intact matrix molecules and their degradation products with endothelial cells facilitate their migration through the nascent connective tissue to generate new blood vessels during the formation of granulation tissue [27]. As described in more detail previously, fibronectin and vitronectin may promote endothelial cell migration and angiogenesis by enhancing VEGF-induced promigratory signaling through the formation of integrin–VEGFR2–VEGF–matrix molecule complexes [59]. Proteoglycans may promote endothelial cell migration and angiogenesis through their association with angiogenic factors, including VEGF, CXCL8, and FGF-2, generating a stable gradient to promote directional migration and vessel formation [9,22,85]. During angiogenesis, endothelial cells release and activate matrix-degrading enzymes, including MMPs and cathepsins, which can facilitate the migration and invasion of endothelial cells into the surrounding tissue and generate bioactive matrix fragments that provide additional angiogenic stimuli [4]. Complicating the role of matrix fragments in angiogenesis is that some matrix fragments promote angiogenesis whereas others inhibit angiogenesis by inhibiting endothelial cell migration and/or inducing their apoptosis [4]. This raises the possibility that after angiogenic matrix molecules and fragments induce angiogenesis, these molecules could be cleaved further to generate antiangiogenic fragments that then promote vessel stabilization, basement membrane deposition, and maturation [86]. Therefore, the way matrix molecules are locally cleaved and/or factors are locally released could have important consequences for the formation of the granulation tissue.

Proliferation

During wound reepithelialization, keratinocytes trailing behind those at the front edge of migration replicate to provide a source of cells that cover the wound. Basement membrane-type ECM still present on the basal surface of these keratinocytes may be important in maintaining this less migratory, proliferative state. In a dermal wound model, basement membrane matrices are able to sustain the proliferation of keratinocytes for several days [87]. One component of the basement membrane involved in this proliferation is likely laminin. For example, laminin-511 and -521 can promote keratinocyte proliferation in vitro, and keratinocyte proliferation requires the laminin receptor integrin $\alpha_6\beta_4$ [52,68]. Integrin $\alpha_9\beta_1$, which binds several matrix molecules, is critical for keratinocyte proliferation during wound healing and thus in reepithelialization [65]. In contrast, specific cell–matrix interactions may prevent excessive proliferation. For example, the keratinocytes of mice deficient in either fibrinogen or emilin-1, a matrix ligand for integrins $\alpha_4\beta_1$ and $\alpha_9\beta_1$, hyperproliferate during reepithelialization, which suggests the importance of these molecules in limiting proliferation during normal reepithelialization [27,52].

As described earlier, granulation tissue forms at the same time as reepithelialization. In the granulation tissue, several types of cells proliferate, including fibroblasts and endothelial cells of the microvasculature. The ECM molecules present in the granulation tissue, in conjunction with growth factors released by the platelets and secreted by the cells present in this tissue, provide signals to promote cell proliferation [8]. ECM molecules themselves, including fibronectin and specific fragments of fibronectin, tenascin-C, laminins, collagen VI, SPARC, and hyaluronan, can stimulate fibroblast and endothelial cell proliferation [2]. For example, fibroblast proliferation requires collagen-induced activation of DDR2, a tyrosine kinase receptor, as shown by the reduced proliferation of DDR2$^{-/-}$ in vitro and decreased numbers in wound granulation tissue in vivo, although the decreased numbers in vivo could result from a combination of decreased proliferation and migration [26]. ECM molecules may cooperate with growth factors to promote fibroblast and endothelial cell proliferation. In fibroblasts, proliferation induced by TGFβ1 requires fibronectin [88]. Angiogenesis requires both endothelial cell migration (described previously) and proliferation, and angiogenic factors such as VEGFs and FGFs associate with ECM molecules, increasing their ability to activate their receptors and thereby stimulate the proliferation of endothelial cells, which then migrate to form the new microvessels [9,59,85]. Some antiangiogenic molecules, including thrombospondin and endostatin, may inhibit angiogenesis by competing with these growth factors for either growth factor receptor binding or matrix binding [9,10]. In contrast, ECM molecules and/or peptides derived from their proteolysis can have inhibitory effects on cell proliferation. Intact decorin and SPARC, as well as peptides derived from decorin, SPARC, collagens XVIII and XV (endostatin), collagen IV (tumstatin), and tenascin-C have antiangiogenic effects owing to their inhibition of endothelial cell proliferation [4,22].

Differentiation

As healing progresses, the healing wound shifts from granulation tissue formation to matrix remodeling, gradually removing the provisional matrix molecules of the granulation tissue and replacing them with a more mature connective tissue rich in collagen I [2]. This process is associated with the differentiation of some fibroblasts into myofibroblasts, acquiring the morphological and biochemical characteristics of smooth muscle cells by expressing α-smooth muscle actin [84]. This differentiation process requires specific growth factors and/or chemokines, including TGFβ and CXCL8, as well as fibroblast interactions with multiple types of matrix molecules [84,85]. TGFβ1-induced myofibroblast differentiation requires adhesion to the EDA-containing splice variant of fibronectin, likely mediated by integrin $\alpha_4\beta_7$ [5,89]. However, the combined presence of EDA-containing fibronectin and TGFβ1 is not sufficient to induce myofibroblast differentiation, which also requires fibroblast adhesion to stiff collagen matrices [2]. After myofibroblast differentiation, these cells secrete copious amounts of matrix molecules, particularly multiple isoforms of collagens, release enzymes that cross-link and thereby stiffen collagen fibrils further, and contract to promote wound closure [26,84]. These myofibroblast activities could cause more fibroblasts to differentiate into myofibroblasts in a positive feedback loop that, if unchecked, could promote excessive fibrosis and abnormal scarring that interferes with normal tissue function [84]. Decorin, a small proteoglycan present in normal wound healing, decreases TGFβ1 and collagen production, providing a possible mechanism that could limit myofibroblast differentiation and function to prevent excessive scarring [84].

Differentiation of keratinocytes, endothelial cells, and pericytes is also regulated by cell–matrix interactions. In keratinocytes, some matrix–integrin interactions seem to inhibit terminal differentiation and promote proliferation of basement membrane–associated cells, whereas hyaluronan–CD44 binding may promote terminal differentiation [64,66]. The differentiation of endothelial cells in mature blood vessels requires physical interactions with basement

membrane components such as laminin-411, as well as interactions with pericytes [68]. Pericyte differentiation, in turn, requires integrin β_1–dependent cell–matrix interactions [90].

Apoptosis

In healing wounds, many cells that are needed for one specific phase of the healing process undergo apoptosis after completing their respective functions. In fact, the persistence of some cells, including inflammatory cells and myofibroblasts, is detrimental, and apoptosis is needed to prevent chronic inflammation and excessive scarring, respectively [89,91]. ECM molecules regulate some of the inflammatory cell apoptosis after their activation. For example, low–molecular weight hyaluronan promotes neutrophil and macrophage apoptosis, likely through CD44 [19,47]. However, apoptosis in neutrophils is primarily regulated by a constitutive signaling pathway that can be delayed by inflammatory signaling or by fibrinogen binding, but otherwise seems little affected by matrix interactions [91,92].

Apoptosis also participates in the wound remodeling phase, because the granulation tissue evolves into a relatively acellular scar tissue [89]. In this remodeling phase, apoptotic cell death eliminates many types of cells at the same time without causing tissue damage. Within the granulation tissue, the number of cells undergoing apoptosis increases around days 20–25 after injury, dramatically reducing wound cellularity after day 25 [89a]. This coincides with the release of mechanical tension after myofibroblast-mediated wound contraction, which triggers apoptosis of human fibroblasts and myofibroblasts, which suggests the importance of interstitial collagens, their receptors, and mechanotransduction in myofibroblast apoptosis [7]. This myofibroblast apoptosis may be required to both promote wound healing and prevent scarring. Indeed, a type of excessive, abnormal scar called a hypertrophic scar exhibits reduced fibroblast/myofibroblast apoptosis, resulting in excessive fibrosis and scarring [84]. This apoptotic failure in hypertrophic scars likely results from an overexpression of tissue transglutaminase, leading to increased matrix breakdown and decreased collagen contraction [2].

CELL–EXTRACELLULAR MATRIX INTERACTIONS DURING REGENERATIVE FETAL WOUND HEALING

True tissue regeneration after injury rarely occurs in vertebrate species, but it occurs in specific instances, including fetal cutaneous wound healing, liver regeneration, and urodele amphibian limb regeneration. Unlike wound healing in normal adult animals, which is characterized by scarring, fetal cutaneous wounds heal without fibrosis and scar formation, leading to regeneration of the injured area. The contribution of cell–ECM interactions to regeneration in fetal healing is discussed subsequently (Fig. 2.3).

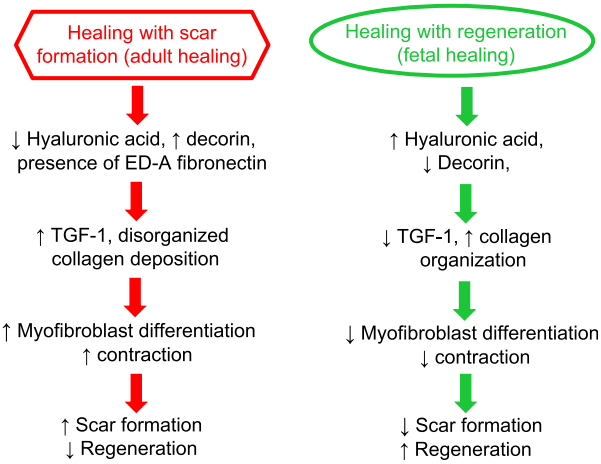

FIGURE 2.3 Comparison of particular cell–extracellular matrix (ECM) interactions occurring in scar-forming adult healing versus those occurring during regenerative fetal healing. As shown in this diagram, unique subsets of ECM molecules are associated with scarring versus regenerative healing. As such, therapeutic alteration of ECM composition may allow physicians to modulate healing to promote tissue regeneration. Additional therapeutic approaches may be generated upon further investigation into the importance of additional cell–ECM interactions in scarring and regenerative responses. *ED-A*, extra domain A; *TGF-1*, transforming growth factor-1.

Adhesion and Migration

Fetal wounds, at least these relatively early in fetal development, heal without scarring, in contrast to most adult healing, which heals with at least some scarring [89]. One major difference between scarless fetal healing and adult healing is the lack of an inflammatory response before embryonic day (E)15–16 in mouse development, and the attenuated inflammatory response seen after E18 [7]. Indeed, the onset of scarring in fetal healing at later embryonic stages coincides with the substantial appearance of mast cells and neutrophils in fetal wounds [2,93,94]. Mast cells after E18 have much larger mast cell granules, which contain higher levels of proinflammatory cytokines that may then contribute to the increased inflammatory response after this stage of development [95]. This lack of neutrophils in early fetal wounds is also associated with the low expression of neutrophil adhesion molecules, decreasing extravasation coupled with low levels proinflammatory cytokines chemokines such as TNFα, IL-6, and CXCL8, and increased levels of antiinflammatory cytokines such as IL-10 [96]. Experimental increases in IL-10 in adult wounds reduced inflammation and promoted regenerative healing, providing important evidence for the role of inflammation in the neutrophil recruitment and scarring present in adult wounds [89,96].

Scarless fetal wounds also differ from scarring adult wounds in cell–ECM interactions owing to differences in the composition of the ECM molecules, the timing of their appearance after wounding, and their duration in the wound area. One crucial ECM molecule in fetal wound healing is hyaluronan, which appears to be necessary for the regenerative response, because its removal from fetal wounds promotes a healing response more similar to that of adults, and treatment of normally scarring wounds or wound organ cultures with hyaluronan decreases scarring [97–99]. High–molecular weight hyaluronan is more abundant in fetal skin wounds than in adult wounds, where low–molecular weight hyaluronan is more abundant; the latter possibly results from increased hyaluronidase activity in adult wounds [2,83]. Fetal fibroblasts also express higher levels of the hyaluronan receptors CD44 and RHAMM after injury, thus increasing receptor–ligand interactions that promote fibroblast migration [98].

Tenascin C, fibronectin, and collagen levels also differ in adult and fetal wounds. Tenascin C is expressed at higher levels in fetal skin than in adult skin and is induced more rapidly and to a greater extent in fetal wounds, modulating cell adhesion to fibronectin and promoting migration within matrices containing fibronectin [27]. Fibronectin production increases more rapidly in fetal wounds, although the fibronectin produced does not contain the profibrotic EDA domains [2,27]. This increased expression of tenascin and fibronectin is associated with concomitant increases in the expression of integrins that serve as their receptors. In particular, α_5 subunit, $\alpha_v\beta_3$, and $\alpha_v\beta_6$ integrins, which bind fibronectin and/or tenascin, are upregulated in the wounded fetal epithelium [100]. The combined rapid increases in fibronectin and tenascin, coupled with increased expression of their respective integrin receptors in epithelial cells, are likely important in facilitating cell migration and reepithelialization in fetal wounds. In contrast to the increased levels and/or rate of tenascin C and fibronectin production in fetal wounds, these wounds contain reduced levels of total collagen compared with adult wounds. However, fetal wounds contain a greater proportion of collagen III compared with collagen I than do their adult counterparts [84]. The observed changes in the collagen I/III ratio in fetal wounds and their relative lack of collagen deposition and fibrosis may result from changes in the deposition, organization, and cross-linking of collagen at the wound site or rapid turnover of these ECM components by protease-mediated degradation [84,98]. Related to increases in matrix turnover, fetal wounds have increased levels and activity of multiple MMPs, with decreased levels of their endogenous inhibitors, tissue inhibitor of metalloproteinases, ultimately promoting matrix degradation and turnover [84]. Not only does the resulting matrix degradation and turnover prevent fibrosis, it also likely facilitates cell migration by reducing matrix density and increases the generation of proteolytic matrix fragments that modulate various stages of wound repair.

Proliferation

Increased levels of hyaluronan present during fetal wound healing likely decrease fetal fibroblast proliferation [101]. Fetal fibroblasts also exhibit decreased proliferation in response to growth factors compared with that of adult cells. For example, IGF-1, which induces ERK signaling, proliferation, and matrix synthesis in postnatal fibroblasts, induces proliferation to a much lesser extent and fails to induce significant ERK signaling or matrix synthesis in fetal fibroblasts [102]. Furthermore, whereas TGFβ1 induces proliferation in postnatal fibroblasts, it does not do so in fetal fibroblasts, possibly because of the ability of TGFβ1 to induce hyaluronan synthesis in fetal but not postnatal fibroblasts [103].

Differentiation

Fetal wounds have a decreased number of myofibroblasts, which appear in the wounded site earlier and remain a shorter time than in adult wounds [89,98]. Fetal fibroblasts produce more type III collagen and less type I collagen than adult cells, and the diameter and organization of the fibrils in the fetal wound are comparable to unwounded skin, whereas those of the adult wound exhibit a disorganization indicative of scarring [98,104]. Adult wound tissue is stiffer than fetal tissue, likely resulting from increased collagen I levels in adult wounds, facilitating myofibroblast differentiation that depends on stiff collagen matrices [2]. In contrast, fetal wounds have a decreased number of myofibroblasts, which appear in the wounded site earlier and are more transient than in adult wounds [89,98]. The low number of myofibroblasts in fetal wounds may result, at least in part, from a lack of collagen matrix stiffness [83]. Because myofibroblasts are themselves responsible for much of the collagen I production and tissue contraction in adult wound tissue, their relative absence in fetal wounds may be responsible for the reduced collagen I levels and lower contraction in fetal wounds [89].

Increased fetal hyaluronan may also prevent myofibroblast differentiation by increasing expression of TGFβ3, which is antifibrotic, in contrast to TGFβ1, which increases collagen I deposition and promotes scar formation [84,98]. Indeed, adult wounds treated with hyaluronan healed more rapidly with a significant decrease in TGFβ1 levels, which suggests that the large amounts of hyaluronan in fetal wounds may thus explain, at least partly, the greatly reduced levels of TGFβ1 in fetal wounds [83]. Downregulation of TGFβ1 in adult wounds produces a decrease in scarring similar to that observed with hyaluronan treatment, whereas addition of TGFβ1 to normally scarless fetal wounds induces a more scarring phenotype, with myofibroblast differentiation, wound contraction, and fibrosis [98,105]. Thus, hyaluronan-mediated inhibition of TGFβ1 expression may be critical in scarless fetal healing. The relatively small amount of TGFβ1 present during fetal wound healing may be regulated by inhibitory ECM molecules present in the injured area. One such inhibitor is the proteoglycan decorin, which is capable of binding TGFβ1 and preventing receptor activation and is expressed to a greater extent in fetal wounds than in adult wounds [2]. Decreased activity of this growth factor, combined with low levels of expression in fetal wounds, likely results in decreased fibrosis, myofibroblast differentiation, and wound contraction, leading to regeneration rather than scarring.

Apoptosis

Less is known about the apoptotic process in fetal wounds than in adult wounds, which makes it difficult to compare cellular apoptosis under these conditions. An investigation of apoptotic induction at very early time points after wounding in both scarless (E15) and scar-forming (E18) fetal mouse wounds found lower apoptosis in scar-forming wounds than scarless wounds [106]. Some of these cells disappearing from scarless wounds may be myofibroblasts, because any myofibroblasts that differentiate from fetal fibroblasts, either in vivo or in vitro, disappear rapidly, perhaps owing to an altered rate of apoptosis in these wounds [106]. If changes in apoptotic efficiency indeed occur, they may result from the decreased contraction, and thus decreased mechanical tension, in fetal wounds, as well as altered collagen levels within the collagen matrix [7]. However, myofibroblasts may disappear from fetal wounds through dedifferentiation back to fibroblasts, which complicates the picture [89]. Perhaps apoptosis is not as critical in the healing of fetal wounds as in adult wounds, because leukocyte influx and myofibroblast differentiation appear to be minimal in fetal wounds, and thus may not require large numbers of cells to undergo apoptosis for regeneration to occur [7,89].

IMPLICATIONS FOR REGENERATIVE MEDICINE

One primary goal of studies comparing differences in cell–ECM interactions, and thus changes in signaling, that accompany regenerative and nonregenerative healing is to determine which types of interactions promote and which inhibit tissue regeneration (for an example, see Fig. 2.3). After elucidating the functions of particular interactions, it may be possible to increase the regenerative response through (1) the induction of proregenerative ECM molecules or signaling events in the wounded area combined with (2) the antagonism of antiregenerative–scarring interactions or signaling events using specific inhibitors. This discussion of regenerative medicine will focus on possible strategies to promote regeneration in adult scarring wounds, thus causing adult wounds to resemble more closely fetal scarless wounds. Such an increased regenerative response would be particularly useful in treating wounds that heal with increased scar formation, such as keloids and hypertrophic scars.

Different types of approaches may be used to increase proregenerative ECM levels in the wounded area, including direct application of the matrix molecules themselves, the addition of agents that increase their expression, the addition of cells producing these types of ECM that have been prepared to minimize immunogenicity, the introduction of biomaterials modified to contain adhesive, proregenerative regions of these ECM molecules, or wound treatment with inhibitors of their proteolysis.

Several different ECM molecules are present at higher levels in fetal wounds than in adult wounds, including hyaluronan, tenascin, fibronectin, and collagen III, which may have important roles in the regeneration process [2,27,98]. Thus, altering the levels of these molecules in a scarring wound may improve regeneration. In keeping with the substantial evidence supporting a role for hyaluronan in scarless healing, multiple types of biomaterials currently used to promote healing incorporate hyaluronan in the presence or absence of other matrix molecules or various cell types, although the antiscarring outcomes of these biomaterials vary [107]. One potential reason for the observed variability lies in the rapid degradation of hyaluronan caused by hyaluronidase activity in vivo, and a biomaterial containing modified, more hyaluronidase-resistant hyaluronan mimics improved healing in multiple contexts [99]. Other biomaterials have been used with some success, including those with substantial amounts of collagen III and "natural" scaffolds containing multiple matrix molecules and proteoglycans [99,108]. Combinations of hyaluronan with other matrix molecules, including tenascin, embryonic fibronectin, and/or collagen III, should mimic the fetal wound environment better and may lead to more regenerative healing. Alternatively, various matrix scaffolds could be combined with growth factors that promote healing and reduce scarring, using the matrix molecules to deliver growth factor more effectively to the wound and thereby better facilitate a regenerative response [76]. Alterations in the biomaterial formulation, such as adding molecules that bind and release growth factors or engineering growth factors that associate more effectively with biomaterials, could regulate the timing of growth factor release, allowing their release over a relatively long period to promote more effective healing [76]. These or other biomaterials may be useful for the delivery of proregenerative ECM molecules and/or growth factors to the injured area, thereby promoting healing and reducing scar formation.

When attempting to promote regeneration, it is also imperative to inhibit events associated with scarring, including excessive ECM deposition, fibrosis, and contraction. During the adult healing process, these scar-associated processes are primarily controlled by the myofibroblast, a differentiated cell type that arises during the adult healing process, but which is largely absent throughout fetal wound healing. Therefore, inhibition of myofibroblast differentiation or function in combination with the addition of proregenerative molecules may facilitate a stronger regenerative response. Inhibition of differentiation could be accomplished by blocking factors that normally stimulate myofibroblast differentiation, such as TGFβ1 and CXCL8, by preventing fibroblast−ECM interactions that facilitate myofibroblast differentiation, such as EDA-containing fibronectin, and by the delivery of antifibrotic molecules such as TGFβ3 and IL-10 [84,85,96]. It is also possible that the application of one molecule may promote more regenerative healing by affecting multiple parts of the healing process. For example, insulin interaction with its receptor affects multiple aspects of keratinocyte behavior, stimulating cell motility, increasing expression of the cell surface adhesion molecule integrin α_3, enhancing secretion of the ECM molecule laminin-332, and improving epidermal differentiation during wound healing [109]. Furthermore, we have shown that insulin stimulates the formation of regenerative rather than scarring matrix [110].

The surge in research regarding ECM molecules themselves and their interactions with particular cells and cell surface receptors has led to the realization that such interactions are many and complex, and that they are of the utmost importance in determining cell behavior during events such as wound repair and tissue regeneration. Therefore, the manipulation of specific cell−ECM interactions has the potential to modulate particular aspects of the repair process and thereby promote a regenerative response.

CHAPTER

3

Mechanisms of Blastema Formation and Growth in Regenerating Urodele Limbs

David L. Stocum

Indiana University-Purdue University, Indianapolis, IN, United States

INTRODUCTION

The limbs of larval and adult urodele amphibians are unique among tetrapod vertebrates in their ability to regenerate from any level of the limb after amputation. Limb regeneration can be divided into two major phases: (1) formation of a blastema that resembles the early embryonic limb bud and (2) blastema redevelopment, which involves growth and redifferentiation. Blastema formation refers in this chapter to events leading to the establishment of an accumulation of undifferentiated cells under a thickening of the distal wound epidermis, the apical epidermal cap (AEC). Pattern formation, in which the spatial relationships of the structures to be regenerated are determined and specified, is a process that spans both phases. The ability to form a blastema after amputation is what distinguishes the limbs of urodeles from those of anuran amphibians, reptiles, birds, and mammals, and is the primary focus of this chapter. Blastema formation is a reverse developmental process realized partly by cell dedifferentiation in tissues local to the amputation plane [1] and partly by a contribution of muscle stem cells [2].

Blastema development is similar to that of the embryonic limb bud, with one major exception: blastema cell proliferation depends on an interaction between the limb nerves and the AEC, whereas proliferation of embryonic limb bud cells relies on an epithelial−mesenchymal interaction among the counterpart of the AEC, the apical ectodermal ridge, and the subjacent mesenchymal cells. The musculoskeletal and skin tissues of the new limb parts derived from the blastema redifferentiate in continuity with their parent tissues, whereas blood vessels and nerves regenerate by extension from the cut ends of the preexisting blood vessels and axons, respectively. The growing blastema goes through several morphological/histological stages to attain a cone of cells that then broadens and initiates differentiation in proximal to distal and anterior to posterior directions, ending in distal bifurcations of the digits.

If we were able to understand why some animals such as urodele amphibians are able to form a regeneration-competent blastema after amputation whereas others such as adult anurans, birds, and mammals are not, it might be possible to design chemical approaches to inducing blastema formation in human appendages. At the least, such knowledge might improve our ability to deal with nonamputational injuries to musculoskeletal, vascular, and neural tissues. With this in mind, I review here what is known about blastema formation in the regeneration-competent limbs of urodeles and compare it with blastema formation in the regeneration-deficient anuran, *Xenopus laevis*.

BLASTEMA FORMATION

Blastema formation in regenerating urodele limbs can be subdivided into three phases: (1) hemostasis and reepithelialization, (2) histolysis and dedifferentiation, and (3) blastema cell migration and accumulation (Fig. 3.1). The latter two phases overlap with one another.

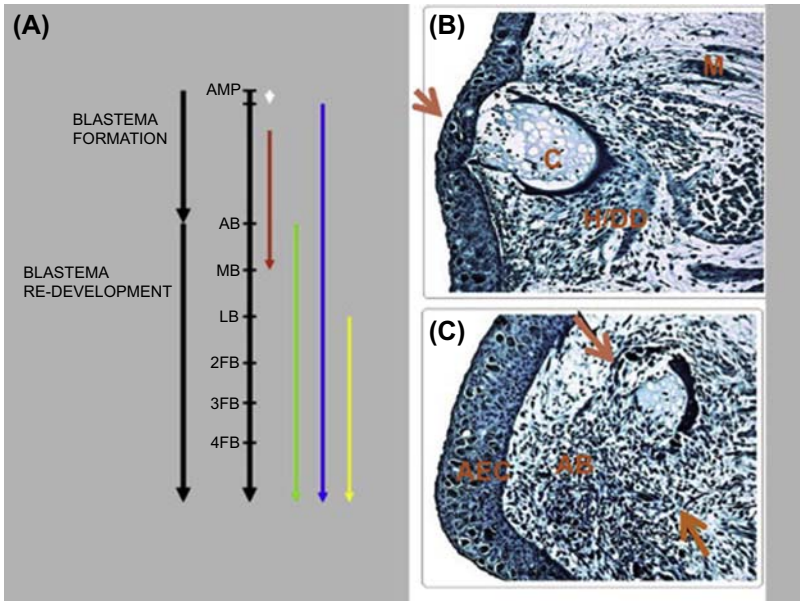

FIGURE 3.1 (A) Diagram of phases and stages of regeneration after amputation of a urodele limb. The two *black lines* indicate the two major phases of regeneration (blastema formation and blastema redevelopment) and the stages of regeneration after amputation (AMP). *2FB, 3FB, 4FB*, finger bud stages; *AB*, accumulation blastema; *LB*, late bud; *MB*, medium bud. The *colored lines* indicate different subphases of blastema formation and redevelopment. *Blue*, pattern formation; *green*, blastema growth; *orange*, histolysis and dedifferentiation; *white*, hemostasis and reepithelialization; *yellow*, redifferentiation. (B) Longitudinal section of regenerating axolotl hindlimb 4 days after amputation through the midtibia-fibula. *Arrow* points to the thickening apical epidermal cap (AEC). The cartilage (C), muscle (M), and other tissues are breaking down in a region of histolysis and dedifferentiation (H/DD) under the wound epithelium. Magnification ×10, light green and iron hematoxylin stain. (C) Longitudinal section of regenerating axolotl hindlimb 7 days after amputation through the midtibia-fibula. An accumulation blastema (AB) has formed by the migration of dedifferentiated cells under the AEC. *Arrows* mark the junction between the accumulation blastema and the still-active region of histolysis and dedifferentiation proximal to it. magnification ×10, light green and iron hematoxylin stain.

Hemostasis and Reepithelialization

After limb amputation or after making skin wounds in amphibians, vasoconstriction occurs and a thrombin-catalyzed fibrin clot forms within seconds to protect the wound tissue and provide a temporary matrix from which repair or regeneration is initiated. An epithelium two to three cells thick covers the wound surface within 24 h after amputation, depending on limb size. The basal epidermal cells at the cut edge of the skin migrate as a sheet that is extended by mitosis of cells adjacent to the wound edges [3]. The fibrin clot contains significant amounts of fibronectin, which the epithelial sheet uses as a substrate for migration [4]. Within 2–3 days postamputation (dpa), the wound epidermis thickens to form the AEC.

The basal cells and gland cells of the wound epidermis/AEC have secretory functions, as evidenced by their more extensive endoplasmic reticulum and Golgi network [5]. WE3, 4, and 6 are three secretory-related antigens expressed specifically by dermal glands and wound epidermis/AEC [6]. Two other antigens, 9G1 [7] and NvKII [8], are also specific to the wound epidermis, but their functions are unknown.

The early wound epidermis has an important function in generating early signals for limb regeneration. Na^+ influx in the amputated newt limb and H^+ efflux in the amputated tail of *Xenopus* tadpoles generate ionic currents across the wound epidermis essential for regeneration. Na^+ influx is via sodium channels [9]. H^+ efflux in the amputated tail is driven by a plasma membrane adenosine triphosphatase (ATPase) in the epidermal cells [10] and is likely to be important for urodele limb regeneration as well, given that a gene encoding a v-ATPase was the most abundant clone in a suppressive subtraction complementary DNA library made from 4-dpa regenerating limb tissue in the axolotl [11]. Drug-induced inhibition of either Na^+ or H^+ movements during the first 24 h or so after amputation results in failure of blastema formation [10,12].

Inositol triphosphate (IP_3) and diacylglycerol (DAG) are the products of phosphatidylinositol bisphosphate (PIP_2), which in turn is derived from inositol. IP_3 synthase, a key enzyme for the synthesis of inositol from glucose-6-phosphate, is upregulated during blastema formation in regenerating axolotl limbs [13]. IP_3 stimulates a rise in cytosolic Ca^{2+} that results in the localization of protein kinase C (PKC) to the plasma membrane, where PKC is activated by DAG and regulates transcription [14]. During blastema formation, there is a general

downregulation of proteins involved in Ca^{2+} homeostasis, which suggests that IP_3 might signal a rise in cytosolic Ca^{2+} in regenerating limbs to localize PKC to the plasma membrane [13]. Other studies have shown that IP_3 is generated from PIP_2 within 30 s after amputation in newt limbs [15] and that PKC rises to a peak by the accumulation blastema stage [16]. How these early signals are linked to the next phase of blastema formation, histolysis, and dedifferentiation, is unknown.

Histolysis and Dedifferentiation

Histolysis is the loss of tissue organization resulting from the enzymatic degradation of the extracellular matrix (ECM). Dedifferentiation is the reversal of a given state of differentiation to an earlier state via nuclear reprogramming and loss of specialized structure and function.

All of the tissues subjacent to the wound epidermis undergo intense histolysis (ECM degradation and tissue disorganization) for 1–2 mm, resulting in the liberation of fibroblasts, Schwann cells of the peripheral nerves, and skeletal cells [1]. Myofibers fragment at their cut ends and break up into mononucleate cells while releasing satellite cells (the stem cells that effect muscle regeneration). The liberated cells lose their phenotypic specializations and revert to mesenchymal-like cells with large nuclei and sparse cytoplasm that exhibit intense RNA and protein synthesis. Histolysis and dedifferentiation begin within 2–3 dpa in larval urodeles and within 4–5 days in adults.

Mechanisms of Histolysis

Degradation of tissue ECM is achieved by acid hydrolases and matrix metalloproteinases (MMPs) [17]. Acid hydrolases identified in regenerating urodele limbs include cathepsin D, acid phosphatase, β-glucuronidase, carboxyl ester hydrolases, and *N*-acetyl-glucosaminidase. Osteoclasts are abundant in the region of histolysis, where they degrade bone matrix via hydrochloric acid, acid hydrolases, and MMPs. Upregulated MMPs include MMP-2 and -9 (gelatinases), and MMP-3/10a and 10b (stromelysins) [18]. Macrophages are a major source of MMPs, particularly MMP-9 [19]. The basal layer of the wound epidermis is a source of MMP-3/10a and 10b in the newt limb, as well as of a novel MMP with low homology to other MMPs [20]. These MMPs are responsible for maintaining contact between the wound epidermis and the underlying tissues by preventing reassembly of a basement membrane. Chondrocytes are a source of MMP-2 and -9 in the newt limb, and these enzymes diffuse outward from the degrading skeletal elements [20]. The importance of MMPs to histolysis, and the importance of histolysis to the success of regeneration, are underscored by the failure of blastema formation in amputated newt limbs treated with an inhibitor of MMPs (GM6001) [21].

Histolysis continues to contribute blastema cells until the medium bud stage; then it ceases owing to the activity of tissue inhibitors of metalloproteinases (TIMPs) [18,22]. TIMP1 is upregulated during histolysis, when MMPs are at maximum levels, and exhibits spatial patterns of expression congruent with those of MMPs in the wound epidermis, proximal epidermis, and internal tissues undergoing disorganization.

Mechanisms of Dedifferentiation

Dedifferentiation is a complex and poorly understood process involving epigenetic reprogramming that suppresses the transcription of differentiation genes, while activating transcription of genes associated with stemness, reduction of cell stress, and remodeling internal structure. Inhibition of these transcriptional changes by actinomycin D does not affect histolysis, but it prevents or retards dedifferentiation, leading to regenerative failure or delay [23]. This suggests that at least part of the proteases involved in histolysis are not regulated at the transcriptional level, but that proteins effecting dedifferentiation are thus regulated. Dedifferentiated cells express a more limb bud–like ECM in which the basement membrane is absent, type I collagen synthesis and accumulation are reduced, and fibronectin, tenascin, and hyaluronate accumulate [24–26].

The molecular details of transcriptional regulation during dedifferentiation are largely unknown. Degradation of the ECM by proteases would break contacts between ECM molecules and integrin receptors, leading to changes in cell shape and reorganization of the actin cytoskeleton that might activate epigenetic reprogramming. Stemness genes upregulated during blastema formation are *msx1*, *nrad*, *rfrng*, and *notch* [17]. *Msx1* inhibits myogenesis [27] and its forced expression in mouse myotubes causes cellularization and reduced expression of muscle regulatory proteins [28]. Inhibition of *msx1* expression in cultured newt myofibers by anti-*msx* morpholinos prevents their cellularization [29]. Newt regeneration blastema extract stimulates mouse myonuclei to reenter the cell cycle, cellularize, and reduce their expression of muscle regulatory proteins [30]. *Nrad* expression is correlated with muscle

dedifferentiation [31], and *Notch* is a major mediator of stem cell self-renewal [32]. A micro-RNA gene regulatory circuit has been identified in regenerating axolotl limbs and fish fins [33].

Three of the six transcription factor genes (*klf4*, *sox2*, and *c-myc*) used to reprogram mammalian adult somatic cells to induced pluripotent stem cells (iPSCs) [34,35] are upregulated during blastema formation in regenerating newt limbs, and also during lens regeneration [36]. The Lin 28 protein, the product of a fourth transcription factor gene used to derive iPSCs [35], also is upregulated during blastema formation in regenerating axolotl limbs [13]. Thus, transcription factors that reprogram fibroblasts to iPSCs may also gave a role in nuclear reprogramming during limb regeneration. The further molecular characterization of transcription factors, micro-RNAs, and changes in epigenetic marks via chromatin-modifying enzymes will be crucial for understanding the mechanism of dedifferentiation in regenerating amphibian limbs.

The differential regulation of pathways that protect cells from stress and apoptosis also have a role in dedifferentiation. Proteomic analysis suggests that reduced metabolic activity, upregulation of pathways that accelerate protein folding or eliminate unfolded proteins (the unfolded protein response), and differential regulation of apoptotic pathways may largely prevent apoptosis [13], which is known to be minimal in regenerating limbs [37,38]. This idea is consistent with other studies on cultured chondrocytes, β cells, and Muller glia cells of the retina showing that cells dedifferentiate as part of a mechanism to combat apoptotic cell stress [13].

The molecular details of internal cellular remodeling are poorly understood. Dismantling of the phenotypic structure and function is most visible in myofibers, but the molecular details of the process are largely uninvestigated for any limb cell type. Two small molecules, one a trisubstituted purine called myoseverin and the other a disubstituted purine dubbed reversine, have been screened from combinatorial chemical libraries and have been found to cause cellularization of C2C12 mouse myofibers [39,40]. Myoseverin disrupts microtubules and upregulates genes for growth factors, immunomodulatory molecules, ECM remodeling proteases, and stress-response genes, which is consistent with the activation of pathways involved in wound healing and regeneration, but it does not activate the whole program of myogenic dedifferentiation in newt limbs [41]. Reversine treatment of C2C12 myotubes resulted in mononucleate cells that behaved like mesenchymal stem cells, i.e., they were able to differentiate in vitro into osteoblasts and adipocytes as well as muscle cells [42]. Myoseverin and reversine might be useful in analyzing the events of structural remodeling, and may have natural counterparts that can be isolated.

Differential Tissue Contributions to the Blastema

Individual tissues of the limb make differential contributions to the blastema. In the axolotl limb, dermal fibroblasts represent 19%, and chondrocytes 6%, of the cells present at the amputation surface [43]. Dermal fibroblasts contribute nearly half of the blastema cells; fibroblasts of the periosteum and myofiber/nerve sheath interstitial connective tissue, Schwann cells, and myogenic tissue contribute the rest. Experiments transplanting green fluorescent protein (GFP) cartilage into a limb wound induced the formation of a supernumerary limb, which suggests that chondrocytes make no contribution to the blastema [44]. Transplants of other GFP-labeled tissues have shown that the redifferentiation of blastema cells is largely lineage-specific, i.e., they are constrained to reproduce their parent cell types. The exception is connective tissue fibroblasts, which after dedifferentiation are able to transdifferentiate at high frequency into cartilage [45–47]. Lineage-restricted redifferentiation is also reflected in stably maintained histone methylation patterns of parent cells [48]. Thus, although transcription factors that reprogram fibroblasts to iPSCs have a role in nuclear reprogramming during limb regeneration, other factors clearly ensure that dedifferentiated cells reverse their transcription programs only far enough to attain a state that can respond to proliferation and patterning signals while maintaining their phenotypic memory of origin.

There are developmental and species differences in muscle contributions to the blastema. Muscle regenerates in larval and adult axolotl and larval newt limbs by $Pax7^{+}$ satellite cells, whereas in adult newts, muscle regenerates via fragmentation of the ends of cut myofibers and dedifferentiation of the resulting mononucleate cells [49,50]. Whether the switch from muscle regeneration via satellite cells in newt larvae to dedifferentiation of myofiber fragments in adults is all-or-none or gradual is unknown.

Cell Cycling During Blastema Formation

Tritiated thymidine (^{3}H-T) labeling studies have shown that cells of amputated urodele limbs initiate cell cycle entry coincident with their liberation by histolysis. The pulse-labeling index reaches 10–30% during formation of the accumulation blastema [51,52]. However, the mitotic index is low, between 0.1% and 0.7% (average of about 0.4%, or 4 in

1000 cells) in both *Ambystoma* larvae [53] and adult newt [54]. The low mitotic index during establishment of the accumulation blastema suggests that it forms primarily by accumulating dedifferentiated cells rather than their mitosis.

The fact that cells readily enter the cell cycle during formation of the accumulation blastema but divide only infrequently suggests that a large proportion of dedifferentiating cells arrest in G_2 (M51). Further indirect evidence for G_2 arrest is the strong upregulation of the ecotropic viral integration factor 5 (Evi5) throughout blastema formation in regenerating axolotl limbs [13]. Evi5 is a centrosomal protein that accumulates in the nucleus during early G_1 in mammalian cells and prevents them from prematurely entering mitosis by stabilizing Emi1, a protein that inhibits cyclin A degradation by the anaphase-promoting complex/cyclosome [55]. At G_2, Emi1 and Evi5 are phosphorylated by Polo-like kinase 1 and targeted for ubiquitin-driven degradation, allowing the cell to enter mitosis. Thus, high levels of Evi5 during blastema formation may restrain cells from entering mitosis until they are fully dedifferentiated and present in enough numbers to form an accumulation blastema [13]. To test this hypothesis, it will first be necessary to determine the spatiotemporal expression pattern of Emi1 and Evi5. The hypothesis predicts that these proteins would be expressed at high levels in both wound epidermis and blastema mesenchyme, and that expression would decrease as the cells transited a normal cell cycle.

The signals that drive liberated cells to enter the cell cycle have been studied in detail in myofibers of the regenerating newt limb. Entry into the cell cycle of muscle-derived blastema cells appears to be initiated by the muscle LIM protein (MLP), a member of the MARCKS family that has a role in muscle differentiation [56]; whether MLP initiates cell cycle entry of blastema cells derived from other limb tissues is unknown. Progression through G1 and S in cultured newt and mouse myoblasts and newt myofibers is promoted by a thrombin-activated factor present in the serum of all vertebrates tested thus far, including mammals, that deactivates the Rb protein [57]. Mouse myofibers do not respond to this factor. Newt blastema extract promotes DNA synthesis in both newt and mouse myofibers [30], which suggests that mouse myofibers lack an essential signal pathway ingredient that is supplied by newt blastema extract but not by serum. Although the thrombin-activated protein is both necessary and sufficient to stimulate the entry of myonuclei into the cell cycle, it is not sufficient to drive them through mitosis, and myonuclei arrest in G_2. Cell cycle reentry is independent of myofiber cellularization, because cell cycle−inhibited myofibers implanted into newt limb blastemas break up into mononucleate cells [58]. However, mitosis appears to require mononucleate cell status. The mechanism of myofiber fragmentation into single cells is not known, nor is it known whether the thrombin-activated protein is also necessary to drive cells such as dedifferentiating fibroblasts and Schwann cells into the cell cycle or whether this is a feature unique to myofibers. Biochemical evidence suggests that the thrombin-activated factor may be a potent growth factor required in very small amounts [57].

Macrophages Have an Important Role in Blastema Formation

Macrophages of the innate immune system are important mediators of wound repair in mammals via their bactericidal and phagocytic activities and their secretion of growth factors and cytokines that modulate inflammation and initiate structural repair by fibroblasts [17]. Studies emphasize the importance of the immune system, particularly macrophages, for the events of blastema formation during urodele limb regeneration [59−61].

Proinflammatory and antiinflammatory cytokines are upregulated during blastema formation in regenerating limbs of adult axolotls, coincident with a significant enrichment of macrophages, which produce both types of cytokines as well as MMPs. Macrophage depletion by liposome-encapsulated clodronate during blastema formation results in regenerative failure and scarring of the limb stump. The epidermis closes the wound but does not develop an AEC, and dermal scar tissue is interposed between the wound epidermis and underlying tissues [19]. By contrast, depletion after a blastema enters the growth phase only delays regeneration. These results suggest a central role for macrophages in resolving inflammation and the degradation of ECM. Macrophages have also been shown to have a role in removing senescent cells during urodele limb regeneration. In mammals, senescent cells accumulate in tissues with age. Few cells undergoing apoptosis are detected in regenerating urodele limbs [37]. Cell senescence is induced during blastema formation in regenerating urodele limbs, but senescent cells are cleared by macrophages and do not accumulate [62].

Blastema Cell Migration and Accumulation

The AEC appears to direct the migration of blastema cells to aggregate beneath it [1]. This was shown by experiments in which shifting the position of the AEC laterally caused a corresponding shift in blastema cell accumulation, and transplantation of an additional AEC to the base of the blastema resulted in supernumerary blastema

formation. Nerve guidance of blastema cells to form eccentric blastemas appeared to be ruled out, because similar experiments on aneurogenic limbs resulted in eccentric blastema formation.

The redirected accumulation of blastema cells in these experiments results from the migration of the cells on adhesive substrates produced by the eccentric AEC. Transforming growth factor (TGF)-β1 is strongly upregulated during blastema formation in amputated axolotl limbs [63]. A target gene of TGF-β1 is fibronectin, a substrate molecule for cell migration that is highly expressed by basal cells of the wound epidermis during blastema formation [13,64]. Inhibition of TGF-β1 expression by the inhibitor of SMAD phosphorylation, SB-431542, reduces fibronectin expression and results in failure of blastema formation [63]; this suggests that fibronectin provided by the AEC provides directional guidance for blastema cells.

BLASTEMA GROWTH

There are two synergistic requirements for cells of the accumulation blastema to break G_2 arrest, enter mitosis, and proliferate. The first is the production of mitogens via an interaction of the AEC with nerve axons. The second is that cells of the accumulation blastema derived from opposite positions on the limb circumference must migrate toward one another and interact. Unless these two conditions, along with vascularization, are met, the accumulation blastema will not persist and will regress.

The Apical Epidermal Cap–Nerve Interaction

Neither denervation at the time of amputation nor deprivation of wound epidermis prevents histolysis and formation of blastema cells, but the blastema cells do not persist [65]. The ^{3}H-T labeling index is the same as that of controls during formation of the accumulation blastema in both epidermis-free and denervated limbs, which suggests that neither the nerve nor the wound epidermis is required for DNA synthesis during this time [53,66–68].

The AEC of the accumulation blastema is invaded by sprouting sensory axons as it forms, whereas other sensory axons and motor axons make intimate contact with mesenchyme cells of the blastema [69]. Coincident with innervation of the AEC, the labeling and mitotic indices of the accumulation blastema rise as much as 10-fold (Fig. 3.2) and the blastema enters the phase of growth and patterning [51,52]. These increases do not take place in denervated or wound epidermis–deprived limbs. ^{3}H-T pulse labeling studies indicate that the final cycling fraction of blastema cells is between 92% and 96% in larvae and over 90% in adults [70,71]. These results are consistent with the idea that blastema formation results from cell migration and aggregation, not mitosis.

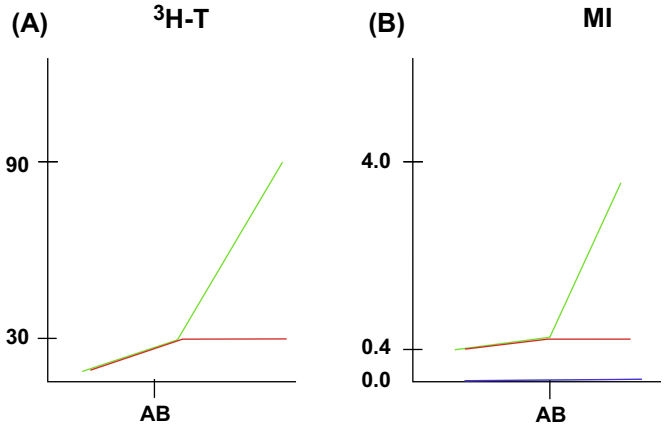

FIGURE 3.2 Diagram of changes in tritiated thymidine (^{3}H-T) labeling and mitotic index (MI) during blastema formation and growth, expressed as percentages of the total cell number on the ordinate. AB on the abscissa represents the accumulation blastema stage. The growth phase is to the right of the AB. (A) Before the accumulation blastema stage, the ^{3}H-T labeling index is the same in control (*green line*) and in epidermis-free and denervated limbs (both represented by the *red line*). These indices in deprived limbs fail to rise in concert with the controls during blastema growth and an accumulation blastema does not form. (B) Before the accumulation blastema stage, the basal mitotic index of controls (*green line*) and epidermis-free limbs (*red line*) are nearly identical, but the MI does not increase with the controls during blastema growth. In contrast, the MI in denervated limbs (*blue line*) does not achieve the basal level and remains near zero. An accumulation blastema does not form in either denervated or epidermis-free limbs.

When the growing blastema achieves a critical mass of cells, it becomes independent of the nerve for its differentiation and morphogenesis, but its individual cells remain nerve-dependent for mitosis [72,73]. Thus, a blastema denervated at the medium bud stage will form a morphologically normal but miniature regenerate owing to the lack of further mitosis. An established blastema mesenchyme stripped of its epidermis by chelation and denervated by implanting it in a dorsal fin tunnel such that its distal end becomes recovered by fin epidermis also forms a morphologically normal but miniature regenerate. Consistent with this result, the ^{3}H-thymidine labeling and mitotic indices of epidermis-free newt limb blastemas cultured in the presence of dorsal root ganglia are reduced three- to fourfold [74]. If the mesenchyme is implanted completely into the fin tunnel, however, a miniature regenerate forms that is distally truncated [75]. This result suggests that the AEC has a role in proximodistal (PD) patterning in addition to proliferation.

As in other vertebrate embryos, the amphibian limb bud requires signals from the AEC for outgrowth that are generated by a reciprocal interaction between mesenchyme and AEC. It becomes nerve-dependent for regeneration only after it has differentiated and become innervated [76]. Urodele limb buds rendered aneurogenic are AEC-dependent for growth but do not become nerve-dependent for regeneration [77,78], although this dependence can be instituted by allowing the limbs to become reinnervated [79]. These facts suggest a model for blastema growth in which the AEC supplies mitogens to subjacent blastema cells but requires factors supplied by the nerve to perform this function (Fig. 3.3).

If this model outlined is correct, putative AEC and nerve factors should meet several criteria, in addition, to being expressed by the AEC and nerves. For AEC candidates, these are expression of their receptor in the blastema mesenchyme, loss of AEC expression by denervation, and the ability to support regeneration of denervated or AEC-deprived limbs to digit stages. Neural factors should be transported from nerve cell bodies along limb nerve axons to the AEC where they bind to their receptor, denervation should prevent blastema cell mitosis by abolishing AEC factors, and they should support regeneration to digit stages in denervated limbs.

Many factors expressed by the AEC stimulate blastema cell proliferation in vitro and in vivo. Fibroblast growth factor (Fgf)1, Fgf2, and the anterior gradient (AG) protein are expressed by the AEC in vivo [80,81], and mesenchymal cells express receptors for Fgfs and AG [81,82]. Fgf1 elevated the mitotic index of cultured blastema cells [83], and Fgf2 elevated the mitotic index of blastema cells in amputated limbs covered by full-thickness skin [84]. However, only two factors expressed by the AEC have been shown to be downregulated by denervation and to substitute for the nerve in supporting regeneration to digit stages. These are Fgf2 [85] and AG [81]. AG is involved in head development of the *Xenopus* embryo and has been the more thoroughly investigated of the two. It is strongly

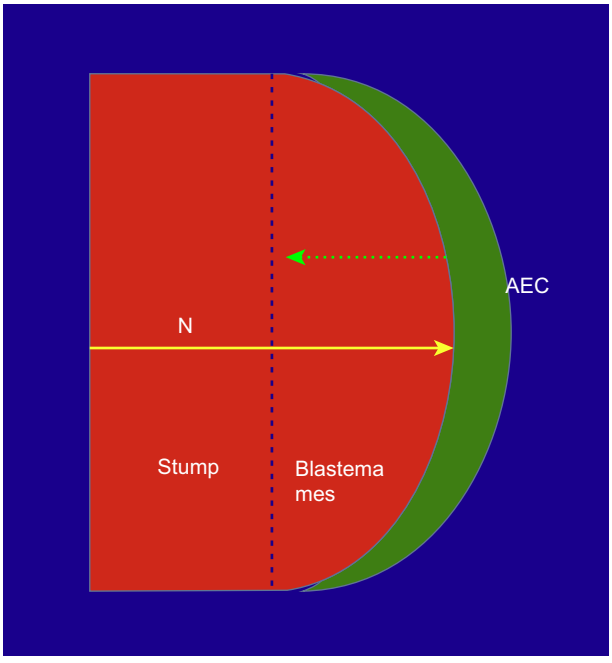

FIGURE 3.3 Model of apical epidermal cap (AEC)—neural (N) interaction for mitotic growth of the blastema. The function of the AEC is to secrete mitogens into the subjacent blastema mesenchyme (mes) (*green dashed line*); this function depends on factors made by dorsal root ganglion neurons (*solid yellow line*). *Dashed blue line* indicates level of amputation.

expressed in Schwann cells insulating the axons of regenerating newt limbs at 5 and 8 dpa, when initial dedifferentiation is under way. By 10 dpa, AG expression shifts to the gland cells of the AEC, coincident with formation of the accumulation blastema. Denervation abolishes AG expression, indicating that it is induced by axons.

The AG gene supports regeneration to digit stages when electroporated into denervated newt limbs at 5 dpa. The receptor for AG is the blastema cell surface protein Prod1, a member of the Ly6 family of three-finger proteins anchored to the cell surface by a glycosylphosphatidylinositol linkage [86]. Conditioned medium of Cos7 cells transfected with the AG gene stimulates 5-bromo-2′-deoxyuridine incorporation into cultured blastema cells; this incorporation is blocked by antibodies to Prod1, which suggests that AG acts directly on blastema cells through Prod1 to stimulate proliferation [81]. The dependence on nerves for mitosis throughout blastema growth implies that this action is continuous, an implication that could be confirmed or refuted by examining expression patterns of AG in control and denervated limbs at successively later stages of blastema redevelopment. As would be predicted by the nerve−AEC model, AG is expressed in developing urodele limb buds and regenerating aneurogenic limbs [87]. Fgf2 expression in the AEC of aneurogenic limbs has not been examined.

Factors expressed by DRG neurons that promote blastema cell proliferation in vitro include transferrin, substance P, Fgf2, and glial growth factor 2 (Ggf-2) [17,88]. Ggf-2 was reported to rescue regeneration to digit stages in denervated axolotl limbs when injected intraperitoneally during blastema formation [89], but this has not been investigated further. New nerve factor candidates are combinations of Fgf8 and bone morphogenetic protein. Both are expressed in DRG neurons and are detectable in peripheral limb nerve axons [90]. Furthermore, they can substitute for the nerve in inducing a supernumerary limb [91].

Interaction of Cells From Opposite Sides of the Limb Circumference

Blastema cells also fail to persist unless they are derived from opposite positions on the limb circumference and interact. This was shown by experiments in which the normally asymmetrical (anteroposterior [AP] or dorsoventral [DV]) skin of the newt limb was made symmetrical by rotating a longitudinal strip of skin 90 degrees, grafting it around the circumference of an irradiated limb, and then amputating through the strip [92]. This led to failure of blastema cell mitosis, which indicates that mitosis requires an interaction between blastema cells with opposite positional identities. Normal regeneration ensued, however, when this requirement was met by grafting short longitudinal skin strips from two or more opposite points of the circumference.

Lheureux [93] devised an experimental model to show the synergistic effect on mitosis of nerve-induced mitogen expression by the AEC with the interaction between cells of opposite positional identities. He made a wound on one side of an adult newt limb, deviated a nerve to the wound site, and juxtaposed a graft of skin from the opposite side of the limb to the skin of the wound. By themselves, nerve deviation or juxtaposing opposite positional identities resulted in the formation of blastema cells that failed to persist. Together, however, they stimulated the formation of a supernumerary blastema that grew and regenerated a complete limb. The Lheureux model was later used by another group to evoke supernumerary blastema formation in axolotl limbs under the name “Accessory Limb Model” [94]. Supernumerary limbs can be induced in the same way by reversing the AP or DV axis of the blastema with respect to the limb stump.

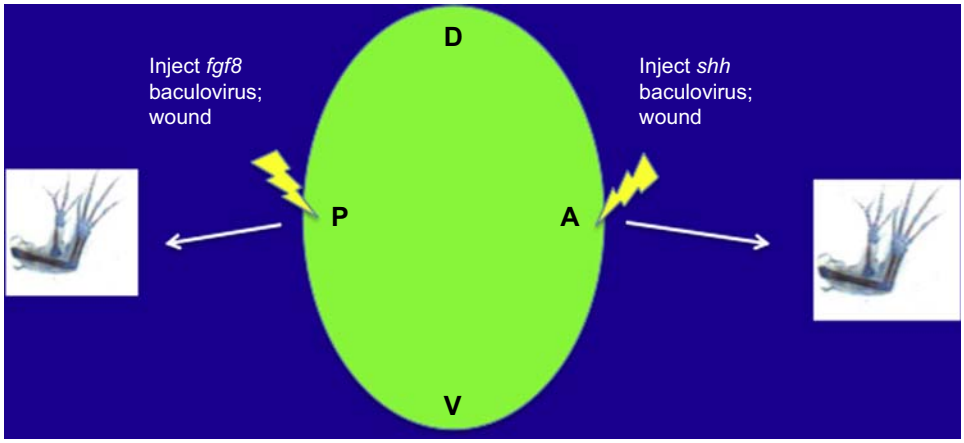

FIGURE 3.4 Cross-section of axolotl stylopodium and result of injecting baculovirus constructs containing *Fgf8* under posterior skin and *Shh* under anterior skin, followed by wounding and nerve deviation. *Fgf8* and *Shh* substitute for anterior and posterior skin, respectively, in evoking supernumerary limb formation. *A*, anterior; *D*, dorsal; *P*, posterior; *V*, ventral.

The Lheureux system has been used to investigate several aspects of limb regeneration. One of these has been to define the signals passing between cells of opposite positional identity. Nacu et al. [95] injected the sonic hedgehog (*shh*) gene under anterior skin of the stylopodium and the *fgf8* gene under posterior skin using a baculoviral vector system (Fig. 3.4). Shh and Fgf8 have been implicated in AP patterning of the limb bud and regeneration blastema [96,97]. A wound was then created in the skin and a nerve deviated to the site. The gene transfections substituted for cells of opposite positional identity, which indicated that Shh and Fgf8 signal opposite cells to drive some aspect of mitosis. The AEC does not persist in the absence of polar juxtaposition, which suggests that proliferating blastema cells may also be essential for AEC maintenance.

Positional identity in the PD axis of the limb is associated with a proximal (low) to distal (high) gradient of cell adhesion [98–100]. Prod-1 is expressed in an opposite gradient; antibodies to Prod1, or its removal from the blastema cell surface by phosphatidylinositol-specific phospholipase C inhibit the recognition of adhesive differentials between distal and proximal blastemas [86]. These results suggest that Prod-1 has a role in integrating mitosis with patterning through its AG ligand [101]. The PD segments of the regenerating limb appear to be specified in a proximal to distal direction [102], but how the positional identities reflected in cell surface adhesion are generated is not clear. There is evidence that PD patterning of the chick limb bud switches from an extrinsic signaling mechanism to an intrinsic timing mechanism that is reflected in intrinsic changes in cell affinities in the distal limb bud mesenchyme [103]. Whether blastema patterning uses a similar mechanism is unknown but would be worth investigating.

List of Acronyms and Abbreviations

AEC Apical epidermal cap
AG Anterior gradient
AP Anteroposterior
DRG Dorsal root ganglion
DV Dorsoventral
ECM Extracellular matrix
GFP Green fluorescent protein
IP_3 Inositol triphosphate
MMP Matrix metalloproteinase
PD Proximodistal
PKC Protein kinase C
Shh Sonic hedgehog
TIMP Tissue inhibitor of metalloproteases

Glossary

Aneurogenic limb A limb that develops without innervation.
Blastema The collection of undifferentiated cells that forms after amputation of a limb.
Dedifferentiation The process by which differentiated cells revert to progenitor cells.
Fibroblastema A blastema composed of fibroblastic cells instead of dedifferentiated cells.
Growth factors Proteins that promote cell proliferation and differentiation.
Histolysis The breakdown of extracellular matrix to release cells.
Satellite cell The progenitor cells that regenerate injured muscle.
SMAD Proteins phosphorylated by activation of TGF-b/BMP receptors that participate in activating or repressing transcription.
Stem cell Undifferentiated cells that maintain or repair tissue structure.
Transdifferentiation The differentiation of one cell type into another cell type.

CHAPTER

4

The Molecular Circuitry Underlying Pluripotency in Embryonic and Induced Pluripotent Stem Cells

Rachel H. Klein, Paul S. Knoepfler

University of California Davis, Davis, CA, United States

INTRODUCTION

Multiple criteria are employed to characterize cellular pluripotent potential, including (1) the expression of molecular markers, in particular, transcription factors known to regulate embryonic stem cell (ESC) potency and self-renewal; (2) the absence of molecular and morphological markers defining specific lineages that are typically referred to as "differentiation-associated genes"; and (3) the ability to form all three embryonic germ layers including ectoderm, endoderm, and mesoderm upon induction of differentiation in vitro or in vivo. Upon injection into immunocompromised mice, ESCs and induced pluripotent stem (iPS) cells will rapidly and reproducibly form teratomas containing differentiated cells from the three germ layers. Ultimately, the most rigorous pluripotency assay, but one not currently amenable to studying human cells, for ethical reasons, is that upon implantation of ESCs into blastocysts there is a subsequent contribution of these cells to all tissue types of the adult chimeric animal. Although some stem-like cells have been isolated from many organisms, including zebrafish, dogs, chickens, mice, rats, and humans, to date only stem cells from a few species have demonstrated this ultimate and most stringent capability associated with pluripotency by which they can be defined concretely as ESCs.

In this review, we describe the mechanistic details of the molecular circuitry that regulates the maintenance of the pluripotent state at the level of signal transduction, chromatin dynamics, and transcription factor control. We also discuss the reprogramming of somatic cells into iPS cells that possess essentially all ESC-like properties, and how the processes that govern their production and maintenance relate to ESC maintenance. Analyses of the rewiring of the molecular circuitry involved in going from a somatic to pluripotent state have reinforced the identities and roles of core pluripotency mechanisms.

GROUND STATE AND PRIMED EMBRYONIC STEM CELLS HAVE UNIQUE SIGNALING NETWORKS UNDERLYING PLURIPOTENCY

The initial protocols employed to isolate and maintain murine ESCs involved plating inner-cell mass cells onto a feeder cell layer of embryonic fibroblasts in a medium containing serum proteins [1,2]. The complex mixture of exogenous factors released by fibroblasts into the medium maintains ESCs in their pluripotent state and allows for the undifferentiated self-renewal and proliferation of these cells. Despite the complex composition of fibroblast-conditioned medium containing serum components, several key growth factor signaling pathways essential for subsequent pluripotency have been identified and extensively characterized, including leukemia inhibitory factor (LIF)/signal transducer and activator of transcription 3 (Stat3), and bone morphogenic protein (BMP) signaling. Upon removal of the feeder cells, or medium conditioned by the feeder cells, ESCs spontaneously differentiate into all three germ layers of the developing organism. More recent protocols have been developed and used

alternative media options, including 2i and 3i media that allow for feeder-independent growth of mouse ESCs (mESCs) [3]. Development of these media was based on the idea that inhibition of intrinsic differentiation signals could maintain pluripotency, similar to the application of exogenous factors (from fibroblast feeders and serum). For instance, 2i medium uses an inhibitor of mitogen activated protein kinase (MAPK)/extracellular signal–regulated kinase (ERK) (MEK) combined with an inhibitor of glycogen synthase kinase 3β (Gsk3β) and does not require LIF for stem cell maintenance [4].

Human ESCs (hESCs) can be grown on feeder cells in media conditioned by fibroblasts or in chemically defined media [5]. Interestingly, studies with these human cells revealed striking differences in signaling pathway requirements for stem cell maintenance compared with mESCs, which led to the hypothesis that despite the high levels of conservation in development across widely divergent species, pluripotent stem cell maintenance is at least partially a unique process in different organisms. This line of thinking has been challenged by more recent findings that distinguish two main states of ESCs: naive and primed. It was found that under commonly used derivation and culture conditions, mESCs are maintained in the naive state whereas hESCs acquire and maintain the primed state [6]. Primed mESCs, which are derived from the mouse embryo after implantation and are typically called epiblast stem cells (EpiSCs), share many of the same signaling pathway requirements as do hESCs grown under standard conditions [7]. Several articles reported the development of media and conditions that allow for culturing of naive hESC [8,9] and found in this context that the pathway requirements are much more similar to those required by naive mESC, including the dependency on LIF. These findings suggest LIF signaling is a key aspect of naive pluripotent stem cell self-renewal across species. Thus, apparent differences in human and murine ESCs may be largely a function of the developmental state related to how the cells are cultured, which signaling pathways are modulated in the process, and thus which cell fate–related transcription factors are activated or repressed downstream.

INDUCED PLURIPOTENT STEM CELLS

An additional type of pluripotent stem cells, iPS cells, can be derived from human or mouse somatic cells through related protocols mainly based on exogenous expression of a select group of pluripotency-related transcription factors. In 2006, Yamanaka and colleagues reported that by introducing four transcription factors necessary for ESC self-renewal including *Oct4*, *Sox2*, *Klf4*, and *c-Myc* into the genome of mouse fibroblasts, some cells underwent complete reprogramming to a state of pluripotency [10]. Further work including studies by Yu et al. found that *Klf4* and *c-Myc* can be substituted by *Nanog* and another transcription factor *Lin28* [11], or that the entire reprogramming process in humans and mice can be accomplished through the expression of a single cluster of microRNAs (miRNAs), mir302/367 [12]. These results indicate that multiple combinations of transcription factors or other regulators can reprogram cells to the same primitive developmental state [11]. A year later, Yamanaka and other teams reported successful human somatic cell reprogramming to make iPS cells [13]. These human iPS cells possess all of the hallmarks of hESCs in their functional abilities to differentiate into all cell types of an organism [10]. Importantly, these distinct pluripotent cells also require the same signaling pathways to maintain their undifferentiated state and respond appropriately to growth factors and cytokines eliciting specific lineages [14].

Reprogramming methods have been developed including the use of nongenetic methods that do not leave a genomic fingerprint via episomal vectors, nonintegrating virus, messenger RNAs (mRNAs), proteins, and even in an entirely chemical cocktail [15–17]. Although the reprogramming protocols are well-established, large fluctuations remain in efficiency and the probability that any given cell will become an iPS cell. Even among a clonally selected somatic cell population infused with the same copy number of reprogramming factors, heterogeneity abounds, with a minority of cells reprogramming within a few weeks while others require longer periods [18]. Part of the answer to the heterogeneity may reside in the concept of nongenetic heterogeneity and random fluctuations in protein expression levels among a clonal population of cells; heterogeneity in any number of transcription factors, signaling proteins, or epigenetic marks may place a cell in a state either relatively amenable or resistant to proper manipulation by the reprogramming factors.

LEUKEMIA INHIBITORY FACTOR AND BONE MORPHOGENIC PROTEIN SIGNALING PATHWAYS REGULATE MOUSE EMBRYONIC STEM CELL SELF-RENEWAL

mESCs derived from permissive strains can maintain their undifferentiated state with a combination of signaling from LIF and BMPs (Bmp4) [19,20]. LIF receptor activation leads to receptor dimerization with gp130 subunits and subsequent tyrosine phosphorylation and nuclear localization of the transcriptional activator Stat3 (Fig. 4.1) [21].

	LIF/STAT	FGF/MAPK	BMP	TGF-β	WNT
naive mESC	+	-	+	-	+
primed mESC (EpiSC)	-	+	-	+	-
naive hESC	+	+	-	+	+
primed hESC	-	+	-	+	+

FIGURE 4.1 **Signaling circuitry regulating mouse and human embryonic stem cell (ESC) pluripotency.** The Wnt pathway is a highly conserved regulator of pluripotency and is active in both mouse and human ESCs. Different signaling pathways are required to maintain pluripotency, depending on the state of the stem cells and species. Naive mESCs require leukemia inhibitory factor (LIF) and bone morphogenic protein (BMP) signals to maintain self-renewal, whereas primed mESCs require transforming growth factor β (TGFβ) and fibroblast growth factor (FGF) signaling. Naive human ESCs (hESCs) have been derived using various media formulations, but in general they require LIF, FGF, TGFβ, and WNT signaling. Primed hESCs depend on the activity of TGFβ and FGF signals. These pathways ultimately function at multiple levels to maintain the pluripotent state by inhibiting differentiation and feeding into the core transcriptional regulatory circuitry of ESCs. *ALK*, anaplastic lymphoma kinase; *EpiSC*, epiblast stem cells; *ERK*, extracellular signal—regulated kinase; *GSK*, glycogen synthase kinase; *MAPK*, mitogen activated protein kinase; *MEK*, MAPK/ERK; *mESC*, mouse ESC; *STAT*, signal transducer and activator of transcription; *TCF*, transcription factor

Whereas LIF also activates the phosphatidylinositol-3-kinase/protein kinase B and MAPK signaling pathways in mESCs, only Stat3 activation is required for pluripotency [22]. One of the key downstream targets of LIF/Stat3 is the transcription factor *Myc* (Fig. 4.1) [23]; high levels of *Myc* expression even in the absence of LIF signaling allows for self-renewal of mESCs [23], which suggests that the main downstream target of the LIF/Stat3 signaling pathway in mESC is *c-Myc*.

BMPs are transforming growth factor β (TGFβ) superfamily members that bind to type I TGFβ receptors anaplastic lymphoma kinase (ALK)1, ALK2, ALK3, or ALK6 (Fig. 4.1). Upon ligand binding, type I receptors form heterodimers with type II receptors, which recruit and phosphorylate receptor activated SMADs 1, 5, and 8 (R-SMADs). Serine/threonine phosphorylation of R-SMADs allows association and complex formation with SMAD4, which can subsequently enter the nucleus and initiate transcription (Fig. 4.1) [24]. Among the targets of BMP signaling is Inhibitor of Differentiation 1 (*Id1*), a key factor that can maintain ESC self-renewal when overexpressed even in the absence of BMP signaling [19]. In addition, chromatin immunoprecipitation (ChIP)-sequencing (Seq) studies revealed that Smad1 colocalizes with octamer binding protein 4 (Oct4), SRY-box 2 (Sox2), Nanog, and Stat3 at a number of pluripotency gene targets [25].

Whereas ERK has generally been considered to promote differentiation of mESCs (it promotes Kruppel-like factor 4 (Klf4) ubiquitination and degradation [26] and reduces Nanog's activating ability [27], and inhibitors of upstream factor MEK are used to maintain mESC pluripotency), it has also been shown to have an important role in maintaining genomic stability, promoting proliferation, and suppressing apoptosis in mESCs [28]. This suggests a more complex role for this factor in stem cell dynamics.

TRANSFORMING GROWTH FACTOR β AND FIBROBLAST GROWTH FACTOR SIGNALING PATHWAYS REGULATE HUMAN EMBRYONIC STEM CELL SELF-RENEWAL

As discussed earlier, hESCs cultured on fibroblast feeder cells with serum exist in a more primed state, with similarities to mouse EpiSCs. LIF/STAT3 signaling does not stimulate self-renewal in this state; rather, TGFβ/activin and fibroblast growth factor (FGF) signaling are required to maintain hESC pluripotency [14,29]. In contrast to naive-state mESCs, BMP signaling actually promotes hESC differentiation [30,31]. TGFβ and activins account for the second branch of the TGFβ superfamily of ligands, and binding to receptors ALK4, ALK5, and ALK7 triggers serine/threonine phosphorylation of the C-terminal region of SMAD2 and SMAD3, which also dimerize with SMAD4 to allow nuclear entry and transcription (Fig. 4.1) [24]. FGFs function through tyrosine receptor dimerization upon ligand binding and subsequent activation of phosphorylation events in the MAPK cascade (Fig. 4.1) [32]. FGF signaling can further phosphorylate both BMP and TGFβ-mediated R-SMADs at the "linker" domain of the proteins. This phosphorylation has been associated with signal termination, because linker phosphorylation allows recognition of SMAD proteins by the ubiquitin ligase SMURF1 [33,34]. Polyubiquitination of the SMAD proteins by SMURF1 leads to subsequent degradation of the SMAD proteins and termination of the signal. Hence, an intricate balance of antagonistic signaling inputs may exist in the maintenance of hESC pluripotency. Among their definitive roles in proliferation and survival, FGF signals may also act to inhibit differentiation promoting BMP signals in hESCs by promoting degradation of any active SMAD 1/5/8 proteins [33]. Alternatively, FGF signals may also fine-tune the amount of active TGFβ-mediated SMAD 2/3 proteins to produce the proper threshold of activity necessary to maintain pluripotency, because an excess of TGFβ/activin signaling can lead to definitive endoderm differentiation of ESCs [35].

Studies demonstrating the necessity of these pathways to maintain self-renewal have followed two strategies. First, small molecule inhibition of TGFβ/activin receptors results in the rapid differentiation of hESCs even in fibroblast-conditioned medium, which illustrates the necessity for TGFβ signals to maintain pluripotency [29]. Second, defined medium with select growth factors and cytokines has been developed to substitute fibroblast-conditioned medium, which contains a diverse milieu of undefined components. These studies revealed that TGFβ or activin plus FGF-2 at defined concentrations is a necessary component for self-renewal, and removal of either of these factors results in differentiation of ESCs [14,36]. For both mouse and human iPS cells, the same media and growth factor pathway activities are required for culture and maintenance of their pluripotency as for the respective comparable types of ESCs, which further supports the important nature of these pathways in pluripotency.

WNT SIGNALING CONTRIBUTES TO MAINTENANCE OF PLURIPOTENCY IN MOUSE EMBRYONIC STEM CELLS AND TO THE NAIVE HUMAN EMBRYONIC STEM CELL STATE

Although activation of LIF and BMP signaling are sufficient to maintain mESC self-renewal, the highly conserved Wnt pathway is also an important modulator of these signaling pathways; it can contribute to the maintenance of mESC pluripotency [37–39]. In the presence of Wnt ligand, a receptor complex forms between receptors Frizzled

and Lrp5/6. This complex recruits and sequesters Axin and Gsk3β, releasing their inhibitory interaction with β-catenin, which subsequently can accumulate in the nucleus, where it serves as a coactivator to activate Wnt-responsive genes (Fig. 4.1) [40]. β-Catenin also interacts with chromatin remodeling factor Brg1 to remodel chromatin during gene activation in response to Wnt signaling [41]. β-Catenin is important for maintaining stem cell identity and inhibiting neuronal differentiation, because mESCs that lack this factor show decreased expression levels of stem cell genes *Dppa4*, *Dppa5*, and *Rex1*, and increased expression of *Oct6*, a marker of neuronal differentiation [42].

Functional studies demonstrating the importance of Wnt signaling have employed small molecule inhibitors of Gsk3β, which destabilizes β-catenin. Inhibition of Gsk3β results in increased Wnt activity, and cells cultured in the presence of Gsk3β inhibitors have increased propensity to maintain their pluripotent state even under differentiation conditions [19,37]. Furthermore, the role of Wnt ligands in supporting stemness has been demonstrated in experiments that show that Wnts secreted by feeder cells or Wnt-conditioned media maintain pluripotency in mESCs [38,39].

Extensive cross-talk has been documented between the LIF and Wnt signaling pathways; when LIF is removed from culture media, mESCs reduce levels of nuclear β-catenin [43]. In addition, Wnt signaling molecules Wnt3a, Wnt5a, and Wnt6 can upregulate Stat3 signaling (downstream of LIF), and upregulation of Wnt signaling can compensate for low levels or the complete absence of LIF; LIF presence can also compensate for the loss of β-catenin [38]. Because β-catenin knockout mESCs have been shown to be able to self-renew in the presence of LIF, it appears not to be absolutely essential to the maintenance of pluripotency; rather, it acts in concert with other factors to enhance stem cell self-renewal. This idea is supported by the finding that Wnt signaling is also important in reprogramming differentiated cells into iPS cells, because Wnt3a can improve reprogramming efficiency [44].

Transcription factor 3 (Tcf3) is a transcription factor and binding partner for β-catenin. It has been shown to bind to many pluripotency genes and act as a repressor. It is also commonly found in complex with Oct4, Sox2, and Nanog, where it is thought to have a role in tempering the level of activation by these factors at pluripotency genes [45,46]. Upon stimulation of Wnt signaling by Wnt3a in mESCs, β-catenin enters the nucleus and binds to Tcf3, promoting its phosphorylation and degradation, thereby relieving the repression of at least a subset of Tcf3 targets and promoting stem cell self-renewal [47,48].

Seemingly conflicting reports exist on the role of Wnt signaling in promoting differentiation of mESCs and in maintaining pluripotency. These differences can potentially be explained by the vast number of transcriptional regulators that can associate with β-catenin. In addition to the TCF family, β-catenin can bind with p300, cyclic adenosine monophosphate response element binding protein (CBP), the histone methyltransferase Mll1, and numerous transcription factors of the SOX, SMAD, FOXO, and nuclear receptor families [49]. Some work suggested that although β-catenin can form a complex with p300 and with CBP, the β-catenin/CBP complex is specifically essential for mESC maintenance, whereas p300 is dispensable, and that the complex specificity can determine the activity of β-catenin [50,51]. An interesting open question is how complex specificity itself is controlled.

The mechanisms of Wnt signaling action on cell fate appear to be highly time- and context-dependent. For example, Wnt signaling activated early in mESC differentiation leads to the promotion of mesoderm development toward heart; however, the same Wnt signaling activated at a later stage of differentiation actually inhibits this fate [52]. Many of the conflicting ideas about Wnt function in differentiation and in pluripotent cells may also arise from cross-talk and interactions of Wnt with different signaling pathways that are selectively active either in ESCs or in a lineage differentiation context influenced by temporal factors.

The role of Wnt signaling in hESCs has not been fully elucidated, partly because most work has focused on hESCs under standard culture conditions, which promote a more primed cell state. Studies of cells under these conditions indicated that Wnt signaling might not be essential for hESC maintenance. However, a study looking specifically at hESCs in the naive state concluded that whereas Wnt signaling was not required for the expression of pluripotency factors in this context, it contributes to cell proliferation and colony-forming ability, and that blocking Wnt signaling led to the acquisition of a metabolic and transcriptional profile more similar to hESC in the primed state, which suggests that the role of Wnt signaling in naive hESCs is to prevent transition to the primed state [53].

THREE TRANSCRIPTION FACTORS, OCTAMER BINDING PROTEIN 4, SRY-BOX 2, AND NANOG, FORM THE CORE PLURIPOTENCY TRANSCRIPTIONAL NETWORK

The previously discussed growth factor signaling pathways that regulate pluripotency could do so through a number of different mechanisms, as outlined earlier. The most widely accepted model is that they function coordinately to inhibit differentiation-associated factors and induce expression of pluripotency-related transcription

factors. Among the many transcription factors identified and characterized as having critical roles in stem cells, a core set of three pluripotency transcription factors has been shown to form the backbone of the pluripotency gene regulatory network. These three, OCT4, SOX2, and NANOG, act together downstream of the key signaling pathways and function in part through positive feedback loops to maintain each other's expression as well as that of the wider pluripotency gene expression program. The three are thought to be central to transcriptional regulation of ESC identity because of their essential roles during early development, including in the inner cell mass (ICM), and their ability to maintain the ESC state [6,54–56]. Disruption of *Oct4* in knockout embryos and ESCs results in the inappropriate differentiation of ICM and ESC to trophectoderm, whereas *Nanog* mutants develop into extraembryonic endoderm [6,55,56]. *Sox2* loss-of-function mutants also divert to trophectoderm [54]. Notably, the phenotype of mESCs overexpressing *Oct4* resembles that of *Nanog* loss of function, forming embryonic endoderm, whereas cells with *Nanog* overexpression are highly resistant to differentiation [55]. These findings suggest a higher level of complexity in core pluripotency transcription factor functional interactions where they do not always simply work together coordinately to promote a blanket state of pluripotency and in which they can sometimes be antagonistic in specific contexts. Furthermore, they also highlight the need for exquisite fine-tuning of gene expression circuitry to promote pluripotency without completely blocking eventual differentiation capacity. Nevertheless, genome-wide analysis has revealed that these three transcription factors generally form an autoregulatory network and do so by binding to each other's promoter regions and enhancing each other's expression [57]. Furthermore, these factors regulate the expression of large numbers of downstream genes governing aspects of differentiation, cell cycle, and self-renewal [57]; and as mentioned earlier, these core factors are integral to the reprogramming process to make iPS cells.

MYC LINKS CELL SIGNALING TO PLURIPOTENCY GENE REGULATION

In addition to core pluripotency transcription factors, *c-Myc* was also found by Yamanaka initially as one of the four main reprogramming cocktail factors. Whereas *c-Myc* was subsequently determined not to be essential for reprogramming, it can potentiate efficiency of the process by one or two orders of magnitude [58]. In stem cells, MYC factors have a broader role in regulating many unique properties associated with stemness and pluripotency, including specific states of metabolism, cell signaling, cell cycle dynamics, and the epigenetic landscape. Because MYC can regulate all of these cellular functions (even if in distinct ways) in somatic and progenitor cells, where it is also expressed, it is probably not an actual "pluripotency factor" in the narrowest sense of that term. Three MYC family members have been identified and characterized: MYC, MYCN, and MYCL. In stem cells, there is a high level of redundancy between MYC and MYCN; however, knockout of both causes a loss of pluripotency and promotes differentiation [59]. Reportedly, loss of *Mycl* causes no detectable defects in stem cells and does not appear to be able to compensate for loss of the other two MYC family members [60].

MYC represents one connection point between cell signaling and the core pluripotency transcriptional network. Stem cell maintenance requires active Wnt signaling and repression of high levels of MAPK signaling. When MYC is expressed, it acts to suppress MAPK signaling by transcriptionally upregulating the ERK inhibitors, dual-specific phosphatases (DUSP2/7); it also acts to promote Wnt signaling through upregulation of WNT receptors and suppression of WNT antagonists. In mESCs, LIF is also required to activate the JAK/Stat3 pathway with *c-Myc* as a key downstream target that is activated by LIF [23].

MYC has been shown to act as both a transcriptional activator and a repressor in hESCs. In ChIP experiments, MYC is primarily associated with active histone modifications, but it also has an important role in promoting pluripotency through repressing the expression of differentiation genes including the HOX gene clusters in hESCs [61]. This is consistent with findings that loss of MYC does not have a strong effect on the expression of core pluripotency genes; the most dramatic effects instead manifest as upregulation of early differentiation genes [59]. Similarly, during reprogramming, MYC may act to suppress differentiation-specific gene expression [62]. In the repressive context in hESCs, MYC interacts with MIZ1 and repressive chromatin-modifying complexes including DNMT3A, and histone deacetylases (HDACs) [61]. The interaction between MYC and MIZ-1 appears to be antagonistic: whereas the two co-bind many targets, their effects on transcription are often in opposite directions [61]. This opposing relationship may serve to balance the contradictory forces of stem cell self-renewal and differentiation; when external signals alter the balance of MYC and MIZ-1, one force can dominate and either promote commitment to differentiation or maintain pluripotency.

MYC also influences stem cell potency in part through regulating the cell cycle, where it acts to promote S-phase progression [59]. Among MYC targets are numerous cyclins and cyclin-dependent kinase enzymes, as well as the miRNA cluster miR-17-92 [63], which targets and suppresses cell cycle inhibitors including those in the retinoblastoma family [25,64]. Because ESCs have unique cell cycle properties, it has been suggested that the effect on the cell cycle and proliferation upon loss or downregulation of MYC could trigger ESC differentiation [59].

Numerous sources of evidence indicate that whereas MYC is frequently found at gene promoters with the core pluripotency factors, some of its mechanisms of action are unique compared with other transcription factors. In fact, ChIP-microarray (ChIP-chip) and ChIP-Seq studies generally point to unique modules of gene targets for MYC compared with core pluripotency factors such as OCT4, SOX2, or NANOG. MYC also has an important role in releasing transcriptional pausing of RNA polymerase II and the transcription machinery at gene promoters, a function that is unique from core pluripotency transcriptional regulators [65].

MYC has been found to interact with a number of different epigenetic modifying enzymes in both activating and repressing conditions. These include histone acetyltransferases (HATs), HDACs, DNA helicases RUVBL-1 and -2, which are essential for ESC morphology, and histone demethylase LSD1 [66]. In addition to a role in repressing lineage specific and differentiation factors, MYC has been shown to regulate global levels of euchromatin in a number of cell types, an uncommon function for a transcription factor. This may relate to the proposed model in which MYC acts as a general activating factor at certain types of gene promoters that are already primed for gene expression by binding specific transcription factors. In this context, MYC has been shown to interact with a number of HAT complexes to promote histone H3 and H4 acetylation. Although MYC is not generally considered a pioneer factor that can bind and remodel chromatin, it has an important and early job during reprogramming to promote euchromatin by regulating global levels of histone modifications. MYC frequently binds to regions where OCT4, SOX2, or KLF4 are already bound, and then increases local euchromatin formation and transcriptional activity [67]. Thus, overall, the contributions of MYC to pluripotency are pleiotropic and mediated by a number of distinct epigenetic and transcriptomic mechanisms. MYC's importance in both stem cells and cancer further points to specific downstream pathways shared among these cell types. For instance, inhibition of differentiation-related genes, maintenance of rapid cell cycling, and an elevated metabolic state are also features of tumorigenesis, and tumorigenesis and reprogramming appear to be related phenomena [68].

A SPECIFIC EPIGENETIC PROGRAM HELPS MAINTAIN PLURIPOTENCY

The importance of chromatin modification states in regulating pluripotency is evidenced by the fact that perturbations of the expression level or function of many different epigenetic enzymes can impair stem cell self-renewal and lead to the loss of pluripotency, events that are followed by differentiation [69–72]; these enzymes are necessary for specific chromatin structural and functional states. In addition, modulation of epigenetic enzyme activity can promote cellular reprogramming. For example, the use of HDAC inhibitors, or the H3K9 methyltransferase inhibitor G9a, makes reprogramming more efficient, implicating H3K9 methylation in the process [73,74]. Other histone marks and histone-modifying enzymes are implicated as well. For example, the polycomb group complex polycomb repressive complex 2 (PRC2) is responsible for the H3K27me3 mark that acts to repress gene expression; in ESCs, this mark is found in many differentiation genes and prevents premature expression (Fig. 4.2) [75]. Loss of PRC2 complex components causes a dramatic reduction in H3K27me3 and impairs pluripotency by upregulating differentiation genes [69]. PRC2 also has a role in maintaining bivalent domains, characterized by the presence of both active H3K4me3 and repressive H3K27me3 marks together in discrete chromatin domains in developmental genes that allow for rapid activation upon commitment of the pluripotent cell to differentiation (Fig. 4.2).

Heterochromatin, marked by H3K9me3, is generally less common in ESCs than in differentiated cells. Consistent with this, the H3K9 methyltransferase G9a is important for early differentiation and development, and has been shown to recruit DNA methyltransferase enzymes Dnmt3a and Dnmt3b to downregulate pluripotency genes including *Oct4* (Fig. 4.2) [76,77]. Conversely, enzymes that remove the H3K9 methylation marks are important for maintaining pluripotency. These include Jumanji domain enzymes *Jmjd1a* (*Kdm3a*) and *Jmjd2c* (*Kdm4c*), which are upregulated by Oct4 and function to remove H3K9 methylation to maintain the pluripotency of ESCs [71].

A number of interesting differences exist between DNA methylation levels and patterns in pluripotent cells compared with differentiated cells. For example, in looking at cytosine guanine (CpG) methylation, differentiated cells frequently have enrichment of methylation in sites where there is a high density of CpG dinucleotides. In contrast, in pluripotent cells, higher methylation levels are observed in regions with lower concentrations of CpG dinucleotides [78]. These low-density CpG regions that are methylated in pluripotent cells are associated with

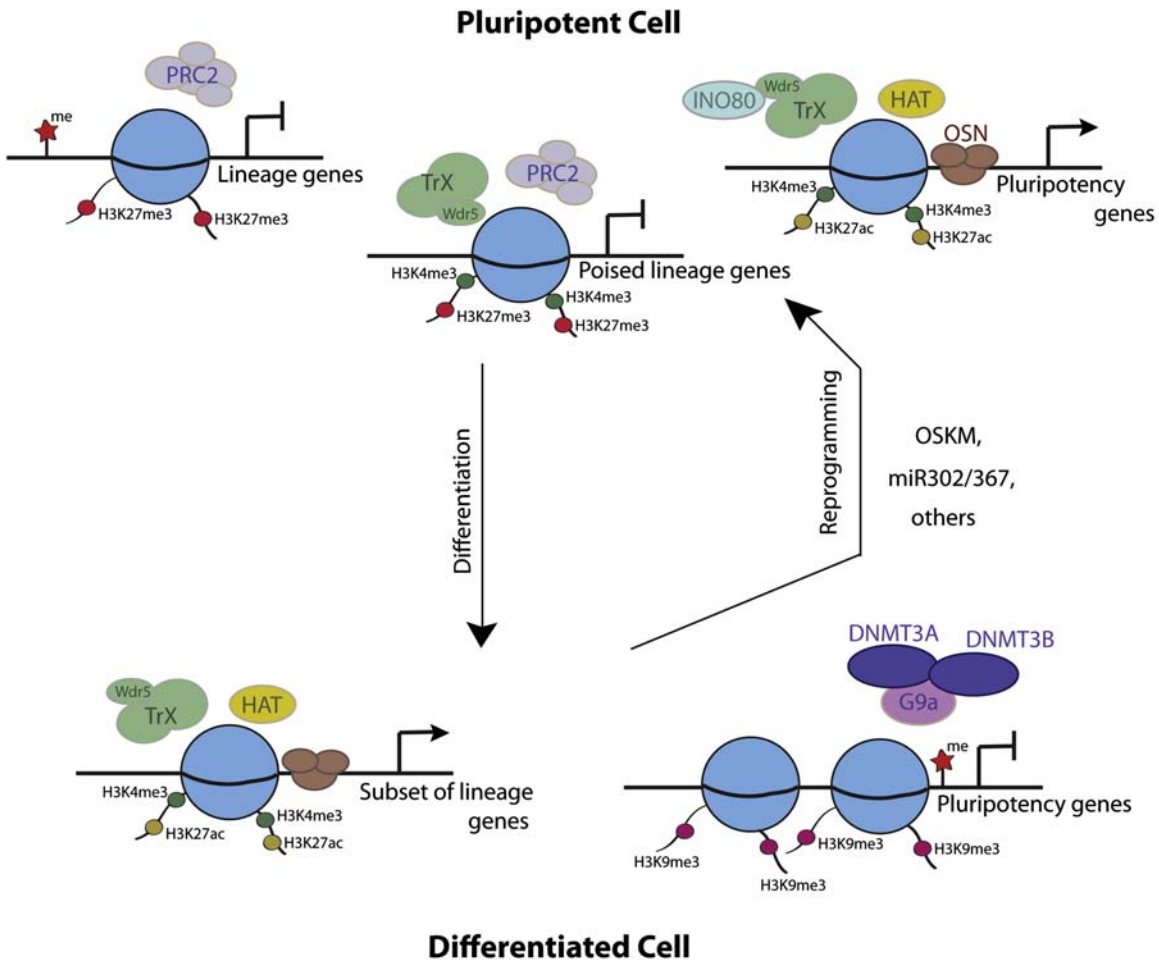

FIGURE 4.2 **Chromatin dynamics of pluripotency and stem cell differentiation.** In pluripotent cells, lineage genes are maintained in two states: repressed by polycomb complexes and DNA methylation or poised for rapid activation based on histone modifications mediated by polycomb and trithorax complexes. Pluripotency genes are maintained by octamer binding protein 4, SRY-box 2, and Nanog complex binding, as well as recruitment of active chromatin-modifying complexes. Upon differentiation, a specific subset of lineage genes is activated in each cell type by lineage-specific transcription factors that recruit activating chromatin complexes. Pluripotency genes are repressed by DNA methylation and heterochromatin associated histone marks. *HAT*, histone acetyltransferase; *OSKM*, gene expression of octamer binding protein 4, SRY-box 2, Kruppel-like factor 4, and MYC; *OSN, octamer binding protein 4, SRY-box 2, and Kruppel-like factor 4*; *PRC2*, polycomb repressive complex 2; *TrX*, trithorax; *Wdr5*, WD repeat domain 5.

bivalent chromatin marks [79] and are thought to function by being able to respond rapidly and dynamically to signals that modulate chromatin remodeling, leading to efficient activation of genes with low-density CpG methylation in their promoters.

There are three DNA methyltransferase enzymes: DNMT1, DNMT3A, and DNMT3B. DNMT1 is mainly involved in maintaining methylation over DNA replication events, whereas DNMT3A and DNMT3B modulate de novo methylation events. Deletion of any one Dnmt enzyme in mice results in embryonic or neonatal lethality [80–82], which indicates an important role in development, but mESCs deleted for one or all three Dnmt enzymes retain their pluripotency, despite losing DNA methylation globally. This suggests that in mice, DNA methylation is not required to maintain pluripotency, at least in vitro [83]. In hESCs grown under standard primed conditions, loss of both *DNMT3* enzymes does not affect stem cell self-renewal, but loss of *DNMT1A* results in cell death [84]. These findings may indicate differences in the role of DNA methylation in maintenance between human and mouse ESCs, or it may reflect the fact that hESCs are usually grown under more primed conditions, whereas mESCs are maintained in a more naive state. *DNMT3A* and *3B* are also not strictly required to generate iPS cells from differentiated cells [85].

In addition to the three DNMT enzymes, DNMT3L is a catalytically inactive DNMT protein that is highly expressed in mESCs and hESCs [86]. Its high expression in this context led to its inclusion in the 24 factors originally tested by Yamanaka for their reprogramming ability in differentiated cells. Although it does not possess enzymatic activity in itself, DNMT3L has been shown to dimerize with DNMT3A and significantly increase its enzymatic

activity [87]. DNMT3L can also interact with the N terminal tail of histone H3, and several studies have suggested that it can discriminate among different H3K4 methylations [88,89]. DNMT3L knockdown alters the methylation landscape in ESCs and affects differentiation, but it does not appear to have a strong effect on pluripotency gene expression or stem cell self-renewal [90].

DNA demethylation can occur through a series of steps in which the 5mC is converted to 5-hydroxymethylcytosine through an oxidation reaction and then further modified to 5-formylcytosine and finally 5-carboxylcytosine, which can be removed by the cell through base excision repair [91]. The methylation intermediate 5fC is often found in gene regulatory elements, including poised enhancers, and in regions associated with p300 binding [92], which suggests a regulatory function for these methylation intermediaries. The main steps of this demethylation reaction are carried out by the TET family of enzymes. TET family members *Tet1* and *Tet2* are strongly expressed in mESCs and decrease in expression during cell differentiation. Loss of *Tet1* reduces the expression of important pluripotency genes including *Klf4*, *Nanog*, and *Esrrb*, among others [93,94]. In addition, the expression of *Tet1* and *Tet2* is regulated by Oct4 [95]. During reprogramming, Tet1 has a role in removing methylation at the promoter and enhancer of *Oct4* and interacts directly with Nanog [96]. Loss of *Tet1* reduces the efficiency of iPS cell induction, whereas early activation of *Tet1* increases reprogramming efficiency [96]. Although TET proteins appear to have important roles in modulating DNA methylation in ESCs, whether they are required to maintain pluripotency is not clear: *Tet1* knockout mice survive and are fertile, and mESCs from these mice display no defects [97]. Less work has been done on TET proteins in hESCs, but knockdown of *TET2* did not affect pluripotency markers although it skewed the differentiation of hESCs toward neuroectoderm at the expense of mesoderm and endoderm [98].

The chromatin in ESCs is characterized as being more open and containing more euchromatin relative to heterochromatin, compared with more differentiated cell types. Therefore, it is unsurprising that histone modifications enriched in euchromatin and associated with more active transcriptional states have also been shown to have an important role in maintaining the pluripotent state by promoting euchromatin. Histone acetylation neutralizes the charge affinity between DNA and histone proteins, leading to more open chromatin that is found at active chromatin domains [99]. That a variety of HDAC inhibitors consistently increase reprogramming efficiency [74] also indicates that open, active chromatin is an important feature of pluripotency. Trithorax group complexes are responsible for the H3K4me3 mark that is strongly enriched at active promoters, and core trithorax complex member *Wdr5* is most highly expressed in pluripotency [70]. *Wdr5* expression decreases as differentiation progresses, and it can aid in reprogramming [70]. It is also a downstream target of Oct4, Sox2, and Nanog [70]. WD repeat domain 5 protein interacts directly with OCT4 and chromatin remodeler INO80 to increase activation of self-renewal genes [100].

In addition to the interaction of cell signaling molecules with transcription factors, there are also extensive interactions between cell signaling and chromatin itself. For example, JAK signaling results in phosphorylation of tyrosine 41 on histone H3, leading to reduced affinity of heterochromatin protein 1α binding at pluripotency genes and promoting gene expression [101]. The chromatin remodeling factor Brg1 acts in Stat3 target genes in pluripotent cells [102]. The embryonic stem cell Brg1/hBrm associated factor complex, an SWI/SNF chromatin remodeling complex that contains Brg1 as a subunit and has a crucial role in mESCs, has also been shown to be an integration point for multiple signaling pathways and transcriptional regulators. Not only does it associate with Oct4, Sox2, and Nanog, it binds with Stat3 and Smad1, linking chromatin remodeling to both the LIF and BMP signaling pathways [102–104].

MICRORNAS INTEGRATE WITH CELL SIGNALING AND TRANSCRIPTION FACTORS TO REGULATE STEM CELL PROLIFERATION AND DIFFERENTIATION

Noncoding RNAs represent an additional level of regulation of gene expression and have an important role in stem cell maintenance as well as cellular differentiation. MicroRNAs, a class of noncoding RNAs, are short single-stranded RNA molecules that are usually 20–30 nucleotides in length and function by targeting a specific set of mRNA transcripts, interfering with their transcription. The most common mechanism for miRNA processing involves a series of cleavage steps mediated by enzymes Drosha and Dicer [105]; the resulting miRNA is incorporated into a protein complex known as the RNA-induced silencing complex [106].

Relatively few miRNAs are expressed in ESCs compared with differentiated cells [107–109]. Despite this, studies have identified several clusters of miRNAs that are highly enriched in ESCs. For instance, the miR302 cluster is selectively expressed in both mESCs and hESCs compared with differentiated cells, whereas mESCs also express the

miR290 cluster and hESCs express the miR17 family, and miRNAs from the chromosome 19 miRNA cluster and miR-371-373 cluster (thought to be orthologous to mir290 in mESC) [110–112]. Core pluripotency transcription factors Oct4, Sox2, and Nanog can bind the promoters of most of these ESC-enriched miRNAs [113]. The importance of these miRNAs to ESC maintenance was demonstrated by deleting miRNA processing enzymes Drosha and Dicer. *Dicer* knockout resulted in embryonic lethality in mice [114], which indicated an important role for miRNA in development. In addition, in mESCs, knockout of *Dicer* or the Dicer binding partner DiGeorge syndrome critical region gene 8 caused proliferation defects and prevented proper differentiation; however, stem cell self-renewal appeared to be preserved [115–117]. Similarly, in hESCs, knockdown of *DICER* or *DROSHA* caused reductions in cell proliferation [118]. These results indicate that miRNAs function in ESCs to regulate the cell cycle: in particular, the shortened G1-S transition that uniquely characterizes stem cells. More broadly, it is hypothesized that pluripotency is facilitated by short cell cycle gap phases and that gap phases represent specific windows of opportunity for stem cells to initiate the differentiation process.

Another interesting aspect of miRNA is their ability to contribute to reprogramming during iPS cell formation. Expression of miR290 cluster members or several other miRNAs can increase the efficiency of reprogramming [119–121], whereas knockdown of *Dicer* or *Drosha* reduces efficiency [119]. Reportedly, reprogramming was completely inhibited by the deletion of the miR302 cluster in human fibroblasts [122]. ESC-expressed miRNAs have also been shown to influence cell signaling; miR290 members can repress Wnt signaling inhibitor Dkk1 in mESC [123], and mir302 targets Lefty, an inhibitor of the TGFβ/Nodal signaling pathway in hESCs [124].

CHROMATIN STRUCTURE DETERMINES REGULATORY ACTIVITY OF TRANSCRIPTION FACTOR BINDING TO PLURIPOTENCY GENES

Two-dimensional views of chromatin (such as strictly linear perspectives on transcription factor control of nearby target genes) do not reflect its unique three-dimensional (3D) structure accurately. The major roles of 3D chromatin structure in pluripotency have come into focus. Regulation of chromatin structure and the formation of chromatin loops are essential aspects of pluripotency; the proper expression of members of the cohesin and mediator complexes is required for stem cell maintenance, and the preexisting chromatin structure in somatic cells has been shown to have a strong influence on the reprogramming efficiency of these cells into iPS cells [125]. In fact, the expression of transcriptional factors that regulate reprogramming and their binding to gene promoters of pluripotency targets such as *Oct4* is not enough on its own to activate gene transcription; the proper chromatin structure must also be in place. In the case of *OCT4* in hESCs, it has been shown that in addition to the binding of transcription factors such as OCT4 and NANOG, activation requires a downstream enhancer to be in close proximity to the promoter, and that this structure depends on the mediator and cohesin protein complexes [126].

The intersection of transcription factor binding and chromatin structure is also evident in long-range interactions that are present at the *Nanog* locus. In mESCs and iPS cells, it has been shown that mediator and cohesin are responsible for approximately 40% of the observed long-range genomic interactions with the *Nanog* locus, and that Med1 and Smc1a interact directly with pluripotency and reprograming factors Oct4, Sox2, Klf4 [127]. A separate study showed that tethering Nanog to a region of the genome in mESCs was sufficient to induce a number of chromatin loops between pluripotency genes, which artificially created a Nanog binding site [128]. In addition, Klf4 is required for cohesin complex recruitment to *Oct4* and for the resulting loop between enhancer and promoter [129].

Together, these results suggest that pluripotency and reprograming factors are involved in mediating chromatin looping and in the recruitment of cohesin and mediator complexes to gene targets where chromatin looping has essential roles in pluripotency. From some of these studies, it is also evident that chromatin looping at pluripotency genes tends to occur before gene activation. For example, during the reprogramming process, it is striking that pluripotency-specific genomic interactions of the *Nanog* locus occur several days before activation of *Nanog* expression [127]. These data support a model in which reprogramming factors bind and act to recruit cohesin and mediator complexes to restructure the chromatin, forming loops that place enhancers and promoters in proximity, and group coexpressed genes together, before these factors then can activate gene expression.

CONCLUSIONS

The molecular basis of pluripotency is a complex coordination of extracellular and environmental factors with intracellular signal transduction and transcriptional regulation via specific epigenomic events. We have seen significant leaps in understanding of how signaling cascades converge upon core transcriptional circuitry to coordinate

maintenance and induction of pluripotency. Furthermore, understanding of the intricate mechanisms through which signaling pathways create the multitude of cell types and tissue lineages remains paramount to understanding basic human development as well as to manipulating and controlling lineage specification for the purposes of regenerative medicine. The rapid advent of induced pluripotency by reprogramming differentiated cells into an embryonic state through cocktails of transcription or chemical factors has opened significant doors to the concept of personalized regenerative medicine. Understanding the fundamental mechanisms of this process may ultimately provide us with unprecedented control to reprogram somatic cells into iPS cells or directly to any desired cell type for the purpose of cell transplantation. Toward that goal, new technologies such as clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR−associated protein 9 gene editing and pluripotent stem cell−based organoids are likely to accelerate new discoveries further.

List of Acronyms and Abbreviations

BMP Bone morphogenic protein
EpiSC Epiblast stem cell
FGF Fibroblast growth factor
GSK3β Glycogen synthase kinase 3β
HDAC Histone deacetylase
hESC Human embryonic stem cell
iPS cell Induced pluripotent stem cell
LIF Leukemia inhibitory factor
MEK mitogen activated protein kinase/extracellular signal−regulated kinase
mESC Mouse embryonic stem cell
OCT4 Octamer binding protein 4
PRC2 Polycomb repressive complex 2
SOX2 SRY-box 2
TCF3 Transcription factor 3
TGFβ Transforming growth factor β

Acknowledgment

The authors thank Ali Brivanlou and Harvir Singh, who were the authors of the previous edition of this chapter, as some of their work in that previous version of the chapter has been carried over to the current version.

Scarless Wound Healing: From Experimental Target to Clinical Reality

Alessandra L. Moore[1,2], *Clement D. Marshall*[1], *Allison Nauta*[1,3], *Hermann P. Lorenz*[1], *Michael T. Longaker*[1]

[1]Stanford University School of Medicine, Palo Alto, CA, United States; [2]Brigham and Women's Hospital, Boston, MA, United States; [3]Oregon Health and Sciences University, Portland, OR, United States

INTRODUCTION

Though scarring is the normal outcome of wound healing in adults, little is talked about its long-term consequences. For instance, because skin and other organs scar rather than regenerate after injury, several physiologic sequelae often occur. After bowel surgery, the visceral and parietal peritoneum develop dense scar tissue known as adhesions, which cause postoperative bowel obstructions [1]. After traumatic injury to soft tissue, ligaments, and tendons, scarring can cause contractures that limit movement and cause functional restriction [2]. Scarring in the nervous system results in loss of function because neuronal connections are destroyed [3]. In the cornea, scarring limits visual acuity [4]. Cardiac myocytes are also severely affected by scarring, as seen by the number of arrhythmias associated with impaired conduction after infarct [5]. The only exceptions to the rule of fibrosis after injury in adults are found in bone, oral mucosa, and hepatic tissue, which are capable of partial regeneration [6,7].

The most significant phenotype in skin scar formation can be found in burn injuries [8,9]. Approximately 500,000 patients in the United States undergo medical treatment for burn injuries annually; over one-third of patients have burns that exceed 10% of the total body surface area (American Burn Association Burn Incidence Fact Sheet, 2016). In addition, many of these patients are children, a population that is particularly vulnerable to the negative physical and psychological effects of scarring; 10,000 children are permanently disabled each year from burn injury and fibrosis [8–12]. Perhaps the most dramatic consequence of burns are hypertrophic scars, which afflict up to 70% of burn patients in their lifetime. These dense, fibrous scars can limit range of motion severely and can negatively affect quality of life through pain, itching, and irritation rendered from the scar tissue itself [13]. All of this, of course, does not account for the long-term psychological impact caused by delayed reintroduction to society after hospitalization, partly from disability but also from issues related to confidence and cosmetic appearance [13].

As mentioned, not only normal scars cause problems for adult and pediatric patients. Issues with underhealing and overhealing also cause significant morbidity. Nonhealing chronic ulcers and excessive fibroproliferative scarring are the most common examples of dysfunctional wound healing, each of which is prevalent in certain pediatric and adult populations. Often, dysfunctional wound healing will cause pain, functional restriction, and severe psychological outcomes [14,15]. In patients with chronic illnesses, dysfunctional wound healing usually falls into the category of "underhealing". In this situation, wounds fail to heal for numerous reasons, including infection, impaired blood flow, severe malnutrition, and inadequate wound care. These patients have become an increasing concern, particularly as the population ages and more health care resources are allocated to treat chronic diseases and their associated complications.

Diabetic patients are a dramatic example of the burden of chronic wounds on society. The following statistics, obtained from the Centers for Disease Control and Prevention's 2014 National Diabetes Statistic Report, illustrate the magnitude of diabetic nonhealing wounds: 29 million people in the United States have diabetes, which makes diabetic patients approximately 10% of the US population. In addition, 65% of diabetic patients have at least one other

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00005-9

co-occurring illness. In 2010, 73,00 nontraumatic lower limb amputations were performed in patients with diabetes. A total of 23% of all patients with diabetes have foot problems ranging from numbness to amputations. From 25% to 50% of all hospital admissions for diabetes are for nonhealing ulcers, which are the cause of most nontraumatic extremity amputations performed in the United States each year [16].

On the other extreme, excessive healing is also a serious clinical burden. Pathological scarring causes hypertrophic scars and keloids. Whereas hypertrophic scars eventually abate with management and time, keloids continue to grow as a type of soft tissue tumor that may persist for life after excision [17]. These scarring processes cause functional impairment and symptoms such as burning, itching, and pain. Ultimately, hypertrophic scars and keloids are difficult to treat medically or surgically, particularly because uniform treatment algorithms do not exist [18].

As is noted from these examples of normal and dysfunctional wound healing, the burden of wound healing is substantial in the United States and on patients. As such, research in the field is urgently needed to help patients regain functional abilities and limit morbidity after injury. Here, we discuss the normal mechanism of adult wound healing and explore the remarkable ability of fetal skin to regenerate. Current and future therapeutics will be discussed, with the hope of highlighting the potential of regenerative healing.

ADULT SKIN

Anatomy of Adult Skin

Adult skin is made up of two layers, the epidermis and dermis. The epidermis is a type of keratinizing stratified squamous epithelium that has five distinct layers, each characterized by the level of keratinocyte maturation. Keratinocytes originate from a thin sheet of stem cells in the basal epidermis and migrate to the surface over 4 weeks to become soft keratin, which eventually sloughs off.

Epidermal appendages, which are epithelial structures that extend intradermally, are an important source of cells for reepithelialization in skin wound healing. Epidermal appendages include sebaceous glands, sweat glands, apocrine glands, and hair follicles. Appendages can extend deep into the dermis or through the dermis into the subcutaneous tissue/hypodermis.

The hair follicle is an important appendage composed of an external outer root sheath attached to the basal lamina that is contiguous with the epidermis. The hair follicle also contains a channel with a hair shaft. Together, the hair follicle and its attached sebaceous gland are called the pilosebaceous unit. The base, or bulb, of the hair follicle contains a committed but proliferating progenitor cell population, as well as the matrix encasing the dermal papilla. The dermal papilla contains specialized mesenchymal cells. From this region, the hair shaft and its channel will grow.

Sweat glands (or eccrine glands) produce sweat, a mixture of water and salts, which functions to cool the body by evaporation. The sweat gland is distinct in that it contains a coiled intradermal portion that extends into the epidermis by a relatively straight distal duct. These glands, too, have an important role in normal skin, as well as physiologic homeostasis.

Below the epidermis lie two distinct layers of the dermis: the more superficial papillary layer and the deeper, more fibrous reticular layer. The papillary dermis is highly vascular, sending capillaries (dermal papillae) superficially. The reticular dermis contains densely packed collagen fibers and tends to be less vascular, except where sweat glands and hair follicles traverse through the tissue. Reticular dermis is also rich in elastic fibers and contains some macrophages, fibroblasts, and adipose cells that participate in skin wound healing [19] (Fig. 5.1).

Adult Wound Healing and Scar Formation

Adult wound healing is traditionally described as a sequence of temporally overlapping phases: inflammation, proliferation, and remodeling. Disruption of the vascular network within cutaneous wounds results in platelet aggregation and the formation of a fibrin-rich clot, which protects from further extravasation of blood or plasma. Aggregation of platelets initiates the coagulation cascade [20–22]. In addition to providing hemostasis, platelets modulate fibroblast activity through degranulation and secretion of multiple cytokines and growth factors, such as platelet-derived growth factor (PDGF), platelet factor 4, and transforming growth factor β1 (TGF-β1). These growth factors and cytokines remain elevated throughout the process of normal wound healing [23,24].

Largely under the influence of platelet-derived inflammatory molecules, neutrophils and monocytes initiate their migration to the wound. Because of the high concentration of neutrophils in circulation, these cells are the first to enter the area of injury and quickly reach high concentrations, becoming the most dominant influence in early wound healing. Neutrophils primarily produce degradative enzymes and phagocytose foreign and necrotic material, but they also produce vascular endothelial growth factor (VEGF), tumor necrosis factor α, interleukin 1 (IL-1),

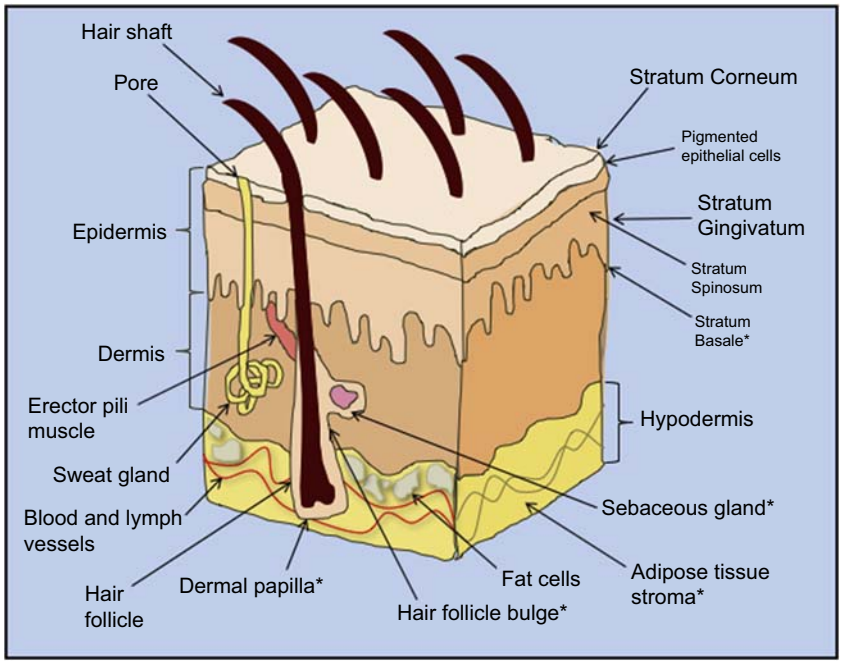

FIGURE 5.1 **Normal skin anatomy.** Normal skin anatomy is composed of two layers, the epidermis and dermis, with a layer of subcutaneous fat known as the hypodermis below. Contained within the dense array of epithelial cells and extracellular matrix are many specialized structures including sebaceous glands, sweat glands, and hair follicles. In wound healing, normal tissue homeostasis, and tissue engineering, skin stem cells have an important role. Areas where resident adult stem cells are located are indicated by an *asterisk*. Not pictured are interfollicular epidermal stem cells.

and other growth factors that assist in wound healing [25]. Interestingly, studies show that neutrophil infiltration is not essential to normal healing, which demonstrates one of many redundancies in the repair process [26].

The level of inflammation in a wound ultimately depends on the presence or absence of infection. In the presence of infection, neutrophils continue to be active in high concentration throughout later stages of wound healing, leading to further inflammation and fibrosis [22]. In the absence of infection, neutrophils greatly diminish activity by day 2 or 3, as monocytes increase in number in response to both extravascular and intravascular chemoattractants. Monocytes differentiate into macrophages that bind to the extracellular matrix (ECM), which induces phagocytosis and allows for debridement of necrotic cells and fractured structural proteins. During the late inflammatory phase, tissue macrophages release cytokines and scavenge dead neutrophils, then elevate macrophages as the dominant leukocyte in the wound bed. In contrast to neutrophils, studies on tissue macrophage and monocyte-depleted guinea pigs demonstrated macrophages to be essential to normal wound healing through their stimulation of collagen production, angiogenesis, and reepithelialization [27]. However, like neutrophils, if macrophages persist in the wound environment, the result is excess scar formation. Under these circumstances, macrophages produce cytokines that activate fibroblasts to deposit excessive amounts of collagen [28] (Fig. 5.2).

The presence of macrophages in the wound marks the transition between the inflammatory phase and the proliferative phase of wound healing, which begins around day 4–5 after injury. Granulation tissue begins to form and is described as a loose network of collagen, fibronectin, and hyaluronic acid embedding a dense population of macrophages, fibroblasts, and neovasculature. During the deposition of granulation tissue, macrophages and fibroblasts move into the wound space as a unit while new blood vessels sprout from adjacent exposed endothelium [22].

The rate of granulation deposition depends on many factors, including the interaction between fibronectin and fibroblast integrin receptors [29]. Fibroblasts in the wound bed deposit collagen and a proteoglycan-rich provisional matrix, a process that is stimulated by TGF-β1 and TGF-β2 in adult wounds. Studies have shown that exogenous administration of these molecules leads to increased collagen and inflammatory cells at the wound site, which potentially implicates this subfamily of growth factors as a source of overactive scar formation [30,31].

During the proliferative phase of wound healing, which occurs from approximately day 5 to day 14 after wounding, collagen is deposited more densely in the wound. Once a threshold level of collagen is reached, collagen synthesis and fibroblast accumulation are suppressed by an unknown negative-feedback mechanism [32]. The balance

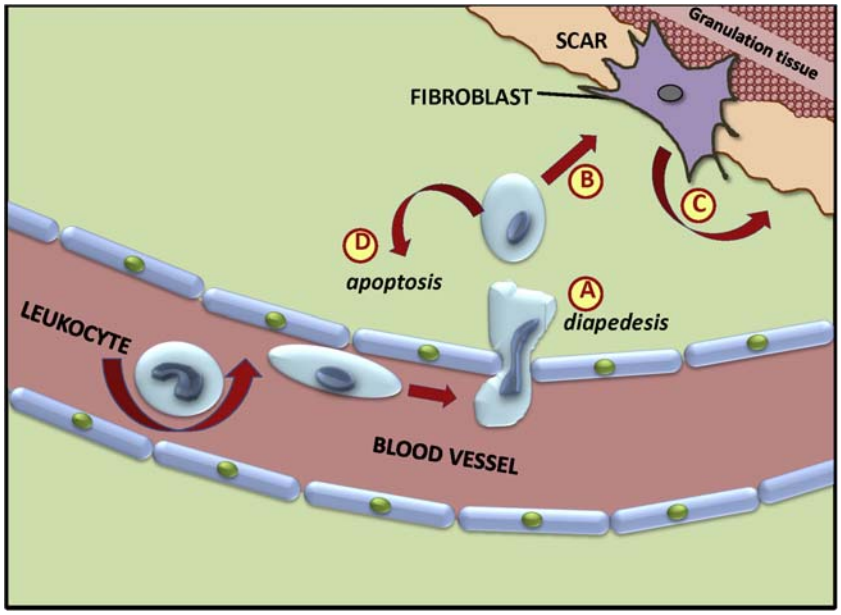

FIGURE 5.2 **Inflammatory cell recruitment to the site of tissue damage.** Therapeutic intervention aimed at dampening the immune response could target any of the steps along the pathway of inflammatory cell recruitment. (A) Leukocytes in blood vessels adjacent to the site of tissue damage emigrate through the vessel wall by diapedesis and (B) migrate to the site of tissue damage in response to chemotactic signals. Inflammatory cells activate resident fibroblasts and attract other bone marrow–derived cells to the wound, where the repair outcome is (C) scar formation. After acting at the wound site, the activated repair cells disperse, differentiate, or (D) apoptose, thus ending the repair response.

of collagen synthesis and degradation is controlled by collagenases and tissue inhibitors of metalloproteinases. When this negative feedback does not occur appropriately, pathological scars form with the deposition of densely packed, disorganized collagen bundles [22].

Reepithelialization begins in the first 24 h after wounding, with the goal of creating a new protective, natural skin barrier. Initially, basal keratinocytes at the border of the wound, which under normal circumstances are linked together by desmosomes, detach from each other and the ECM and migrate laterally to fill the void in the epidermis. Through this process, keratinocytes are exposed to serum for the first time. As they are subjected to new and increased levels of inflammatory cytokines and growth factors, keratinocytes are signaled to further migration, proliferation, and differentiation [33].

Neovascularization also occurs during the proliferative phase and is influenced by multiple cytokines, circulating endothelial progenitor cells, and the ECM [34]. The formation of new blood vessels can also be stimulated by lactic acid, plasminogen activator, collagenases, and low oxygen tension [22]. New blood vessels in the wound bed bud and grow at an exceptional rate during skin wound healing, eventually giving the wound bed adequate oxygenation and its characteristic pink hue. Once apoptotic pathways become active again as the granulation tissue matures, angiogenesis eventually desists and the numerous new blood vessels reduce to only a few major tributaries [35].

The maturation phase of wound healing consists of collagen remodeling beginning during the second week of healing. At this point, fibroblasts differentiate into myofibroblasts, which are characterized by greater expression of smooth muscle actin and the ability to contract wounds. Fibroblasts eventually decrease in number from the proliferative phase, and the scar tissue becomes less vascular and paler as vessels involute [36].

Scar tissue finally gains tensile strength as collagen cross-links increase during remodeling, largely owing to the action of myofibroblasts. Maturation involves the replacement of the initially randomly oriented types I and III collagen by predominantly type I collagen organized along the lines of tension. Eventually the process completes; however, scar tensile strength will never reach that of unwounded skin [37] (Fig. 5.3).

Fibroproliferative Scarring

Fibrosis is defined as "the replacement of the normal structural elements of the tissue by distorted, nonfunctional, and excessive accumulation of scar tissue" [38]. Many medical problems are linked to excessive fibrosis, in addition to a number of deaths each year in the United States and across the globe [37,39]. As previously

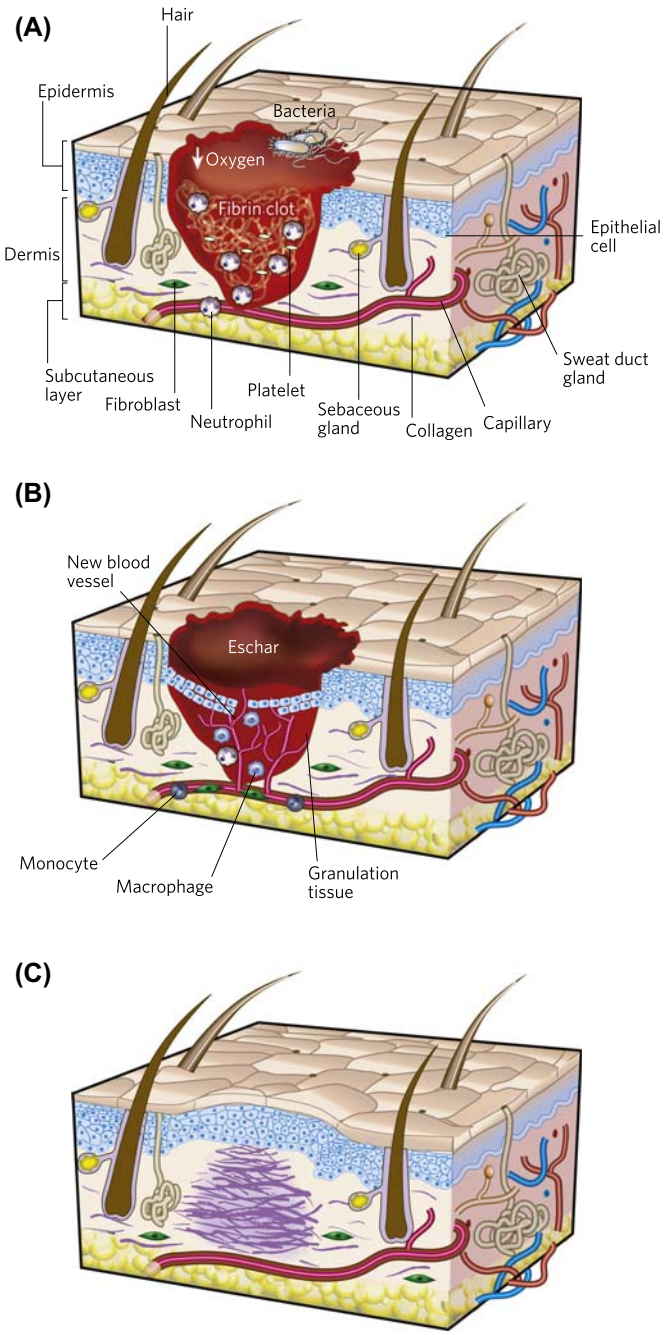

FIGURE 5.3 **Classic stages of wound repair.** There are three classic stages of wound repair: inflammation (A), new tissue formation (B), and remodeling (C). (A) Inflammation. This stage lasts until about 48 h after injury. Depicted is a skin wound at about 24–48 h after injury. The wound is characterized by a hypoxic (ischemic) environment in which a fibrin clot has formed. Bacteria, neutrophils, and platelets are abundant in the wound. Normal skin appendages (such as hair follicles and sweat duct glands) are still present in the skin outside the wound. (B) New tissue formation. This stage occurs about 2–10 days after injury. Depicted is a skin wound at about 5–10 days after injury. An eschar (scab) has formed on the surface of the wound. Most cells from the previous stage of repair have migrated from the wound and new blood vessels now populate the area. The migration of epithelial cells can be observed under the eschar. (C) Remodeling. This stage lasts for a year or longer. Depicted is a skin wound about 1–12 months after repair. Disorganized collagen has been laid down by fibroblasts that have migrated into the wound. The wound has contracted near its surface and the widest portion is now the deepest. The reepithelialized wound is slightly higher than the surrounding surface and the healed region does not contain normal skin appendages. *Reproduced with permission from Gurtner GC, Werner S, Barrandon Y, Longaker MT. Wound repair and regeneration. Nature 2008; 453(7193):314–21.*

mentioned, excessive fibroproliferative scarring occurs when the mechanisms of wound healing fail to respond to inhibitory cues at any one of the phases of wound healing. In essence, abnormal scar formation is an excess accumulation of unorganized collagenous ECM. Although the appearance of scars is often unpredictable, several factors influence the severity of scarring. These include not only genetics but also tissue site, sex, race, age, magnitude of injury, and wound contamination. Generally, skin sites with thicker dermal tissue tend to heal with thicker scars. Also, estrogen is believed to promote scarring; premenopausal women have denser scar tissue than do postmenopausal women. Patients with darkly pigmented skin are also more prone to thicker scarring, as are young people. Larger, deeper, and more contaminated wounds tend to produce larger resultant scars, as well [40–44].

Keloids

Over months to years, some scars will develop benign but locally aggressive tumors known as "keloids" [45]. This extreme example of fibroproliferative scarring is characterized by "cauliflower" nodules that extend well beyond the area of original injury and continue to grow, sometimes into significant masses [45]. Symptoms can range from irritation and pain to severe disfigurement and functional restriction owing to the appearance, size, color, and location of lesions [17,18,28,39,46–48]. In addition to being disfiguring, keloids tend not to regress. Instead, they can continue to grow slowly over many years, and their growth rate tends to correlate with symptoms. The most common areas affected by keloids are upper-body sebaceous areas, whereas the extremities are less commonly involved [49]. Aside from being involved in areas with a high density of sebaceous glands, tension may have a role in their development over time [45].

Histologically, keloids are characterized by thick, large, closely packed bundles of disorganized collagen. In addition, the scar tissue is colonized by mast cells, eosinophils, plasma cells, and lymphocytes with a stark absence of macrophages [45]. Unlike hypertrophic scars, keloids have nodules in the mid to deep dermis containing densely packed collagen with a few myofibroblasts. Mucin is deposited focally in the dermis, and hyaluronic acid expression is confined to the thickened, granular/spinous layer of the epidermis. Finally, an amorphous and unidentified mucopolysaccharide surrounds the dense collagen bundles in keloidal scars that is not found in other scar tissue types [18].

Interestingly, in keloids, more than one mechanism of dysfunctional healing may be at play. Fibroblasts in keloids tend to respond abnormally to wound healing growth factors, secreting collagen, elastin, and fibronectin with little response to inhibitory compounds. Moreover, the ability for fibroblasts to proliferate in keloids is increased. In addition, dysfunctional apoptosis has been observed as keloidal wounds enter the remodeling phase of wound healing [50]. It is possible that this is partly the result of central scar ischemia and ongoing release of VEGF, hypoxia inducible factor 1α, and other growth factors that promote proliferation [17,18,28,39,46–48]. Finally, although a number of therapies exist for the treatment of keloids, including surgical excision, laser therapy, cryotherapy, and chemotherapy, keloids remain remarkably resistant and recur over time [51–54]. Because of these features, it is possible that keloid tumor cells are mutated skin progenitor cells which are known to display a similar resilience [55] (Fig. 5.4A).

Hypertrophic Scars

The incidence of hypertrophic scars, another type of fibroproliferative scar, is significantly higher than keloids. This is partly because of the large number of young adults with initially hypertrophic scars that eventually regress with age (35%) [56]. Hypertrophic scars are raised, similar to keloids; however, they are usually no more than 4 mm from the surface of skin. Visually, hypertrophic scars are erythematous or brown-red in color, but they can become pale over time. Also, hypertrophic scars will sometimes regress spontaneously. Yet, also unlike keloids, which are predominantly over skin containing sebaceous glands, hypertrophic scars usually occur on extremity joints such as the elbows and knees [48].

Histologically, hypertrophic scars are characterized by the expansion of collagen bundles that are fine, well-organized, and parallel to the epidermis. Hypertrophic scars do not have the nodal collagen bundles seen in keloids, but they have islands of hypercellularity in the deep dermis that upon closer inspection contain aggregates of fibroblasts, collagen, and neovasculature. Mucin is absent and hyaluronic acid is a major component of the papillary dermis [18,49].

The purported mechanism of hypertrophic scar formation is increased and ongoing collagen deposition with decreased collagenase activity. In addition, fibroblasts in hypertrophic scars are more likely to assume a myofibroblast phenotype, which may contribute to collagen deposition and scar contracture without addressing scar remodeling. Because 70% of burn victims are affected, initial wound depth may have a significant impact on the development of hypertrophic scars, because they appear to be most common in patients with delayed healing or

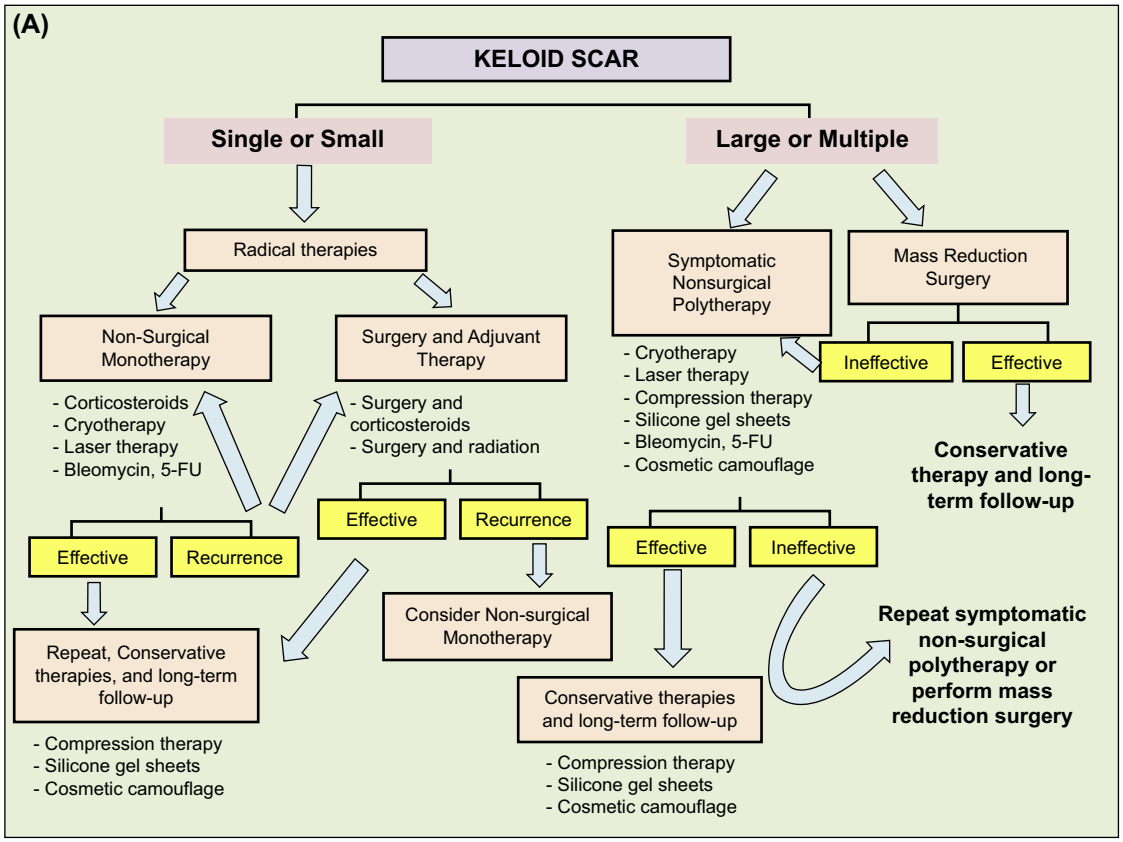

FIGURE 5.4 **Scar reduction strategies: algorithms for (A) keloids and (B) hypertrophic scars.** *Modified from Ogawa R. The most current algorithms for the treatment and prevention of hypertrophic scars and keloids. Plast Reconstr Surg 2010; 125(2):557–68.*

a prolonged inflammatory phase. In deeper and larger wounds, fibroblasts assume a myofibroblast phenotype, which renders them less capable of reducing type I collagen in scars during the remodeling phase [56] (Fig. 5.4B).

Underhealing: Chronic Skin Ulcers

Many types of chronic nonhealing dermal ulcers exist, such as pressure ulcers, diabetic lower-extremity ulcers, and venous stasis ulcers. Besides causing pain and disfigurement, chronic ulcerations often lead to infection as well as amputation. In patients with chronic ulcerations such as those who have diabetes, often the single most important life-saving measure is limb salvage to preserve mobility and function [57]. In those who are immobile, pressure ulcers predominate, as seen by their commonality among debilitated or institutionalized patients, those with spinal cord injuries, and patients with cerebrovascular infarcts. The total cost of wound care per hospitalization for pressure ulceration is estimated to be $130,000, a figure expected to grow as the population ages [58].

Interestingly, nonhealing wounds have distinct histologic hallmarks too, as do keloid and hypertrophic scars have their own set of unique histologic hallmarks. In chronic ulcers, there is excessive neutrophil infiltration, and wounds seem to remain in the inflammatory phase. Likely, the abundance of neutrophils is responsible for the lingering inflammation seen in chronic ulcers. As neutrophils release enzymes, such as collagenase (matrix metalloproteinase [MMP] 8), connective tissue is digested as fast as new matrix is deposited [59]. Neutrophils also release elastase, an enzyme known to destroy PDGF and TGF-β, which are important growth factors for normal wound healing [60]. The environment of chronic ulcers is also known to contain an abundance of reactive oxygen species that damage healing tissue [61]. The result of this nonhealing mechanism is a wound that not only fails to heal but perpetuates its existence.

FETAL SKIN

Development of Fetal Skin

The skin's superficial layer, the epidermis, is derived from surface ectoderm, whereas the dermis is generated from mesenchyme. The epidermis starts as a single layer of ectodermal cells covering the embryo, which begins to emerge at gestational day 20 in humans. In the second month, cell division takes place, at which time the periderm (epitrichium) emerges as a thin superficial layer of squamous epithelium overlying the basal germinative layer. Over the next 4–8 weeks, the epidermis becomes highly cellular. New cells are produced in the basal germinative layer and are continuously keratinized and shed to replace cells of the periderm. Together, these cells are part of the vernix caseosa, a greasy white film that covers fetal skin. In addition to desquamated cells, the vernix caseosa contains sebum from sebaceous glands. With sebum and desquamated cells mixed together, this slippery substance serves as a protective barrier during gestation and facilitates passage through the birth canal at delivery.

Replacement of the periderm continues until the 21st week, at which point the periderm has been replaced by the stratum corneum. Through a series of stages of differentiation, the epidermis stratifies into four layers by the end of the fourth month, including the stratus germinativum (derived from the basal layer), the thick spinous layer, the granular layer, and the most superficial stratum corneum. By the time these four layers emerge, interfollicular keratinization has begun and the epidermis has developed buds that become epidermal appendages. Melanocytes of neural crest origin have also invaded the epidermis, synthesizing melanin pigment that can be transmitted to other cells through dendritic processes. By the end of the 21st week, the fetal epidermis has many of the components that it will maintain into adulthood. After the 21st week, the dermis begins to mature from a thin and cellular structure to a thick and fibrous one. By 24 weeks of gestation, fetal skin matures and thickens to become histologically distinct from its embryonic beginnings [62].

Fetal Scarless Wound Repair

Whereas adult wounds heal with fibrous tissue (scarring), early-gestation fetal skin wounds heal scarlessly. Fetal wounds are capable of healing with restoration of normal skin architecture and preservation of both tissue strength and function. This observation has been confirmed in multiple animal species, including mice, rats, rabbits, pigs, sheep, and monkeys. The mechanisms responsible for fetal scarless wound healing are intrinsic to fetal tissue and are independent of environmental or systemic factors such as bathing in sterile amniotic fluid, perfusion with fetal serum, or the fetal immune system [63–65]. To support this point, studies in which human fetal skin

that was transplanted subcutaneously into the dorsolateral flank of athymic mice healed without a scar further suggested that the scarless wound phenotype depends on characteristics intrinsic to fetal tissue [66].

Ultimately, scarless fetal wound repair outcomes depend on two factors: the gestational age of the fetus and the size of the wound. Excisional wound healing studies performed on fetal lambs showed that at a given gestational age, larger wounds healed with an increased incidence of scar formation. Likewise, the frequency of scarring increased with increasing gestational age [67]. Since the publication of these studies, transitional periods have been found for humans (24 weeks' gestation) [68], rats (between gestation days 16.5 and 18.5) [64], and mice [69]. Extensive research has been dedicated to determining the culprit for the shift to adult wound healing. Eventually, instead of depositing bundles of ECM in a normal basket-weave pattern, organisms begin to heal breaches in skin integrity with scarring.

Interestingly, as fetuses develop and enter the early period of scar formation, the wound phenotype has been described as a "transition wound." At this point, the repair outcome is tissue that retains the reticular organization of collagen characteristic of normal skin but is devoid of epidermal appendages [70]. The skin does not truly regenerate, but the dermis does not form a scar.

In addition, although the fetal ECM was once thought to be inert, evidence suggests that it is a dynamic structure that has a pivotal role in cellular signaling and proliferation. The fetal ECM is now known to be a reservoir of growth factors essential to development [71]. The fetal ECM also has a structural protein composition different from that of adult skin. For example, the collagen content of the ECM changes as the fetus ages, starting with a relatively high type III to type I collagen ratio and shifting to the type I collagen-predominated adult phenotype. Another structural difference between fetal and adult ECM can be found in the hyaluronic acid content. Hyaluronic acid, the negatively charged, extremely hydrophilic, nonsulfated glycosaminoglycan of the ECM, has been shown to be in higher concentration in the ECM during rapid growth processes such as cellular migration and angiogenesis. In vitro studies show that hyaluronic acid can cause fibroblasts to increase the synthesis of collagen and noncollagen ECM proteins [72]. During adult repair, hyaluronic acid initially increases dramatically, and then decreases from days 5 to 10, after which the concentration remains at a low level. Interestingly, this hyaluronic acid profile is not the case in fetal wound ECM, in which the hyaluronic acid level remains high. Similar to the concentration of type III collagen, the ECM hyaluronic acid content decreases from the fetal to the postnatal period [63].

The concentration of other substances such as decorin, fibromodulin, lysyl oxidase, and MMPs further sets the fetal ECM apart from the adult ECM [71]. These substances are proteoglycan ECM modulators that have a role in the development and maturation of collagen. Lysyl oxidase cross-links collagens whereas MMPs degrade collagen. In addition, decorin content and the expression of lysyl oxidase and MMPs increase as fetal tissue matures. Fibromodulin modulates collagen fibrillogenesis and has been shown to bind and inactivate TGF-βs. Fibromodulin decreases with gestational age, paralleling the shift from scarless fetal wound healing to scarring adult repair [73] (Fig. 5.5).

REGENERATIVE HEALING AND SCAR REDUCTION THEORY

Targeting the Inflammatory Response

Initial research into the mechanisms responsible for scar formation led investigators to focus on the inflammatory phase of wound healing as a target for reducing the incidence and magnitude of scar formation. This choice was based on observations that regenerative wound healing is replaced by scarring as the immune system develops in the embryo [65]. Interestingly, many studies have shown that reduction of inflammation in postnatal skin wounds correlates with reduced scarring [74].

One example of reduced inflammation and scarring can be found in enhanced healing in mice devoid of mothers against decapentaplegic homolog 3 (Smad3), a protein known to transduce TGF-β signals. These mice exhibited more rapid reepithelialization and decreased inflammation (blunted monocyte activation) [43]. In another example, PU.1 null mice devoid of functional neutrophils and macrophages heal wounds over a time course similar to that of their wild-type counterparts but exhibit scar-free healing similar to embryonic wound healing [75]. These two studies support the contention that the inflammatory response may be deleterious to normal wound repair by contributing to increased fibrosis. Experiments performed on athymic mice [74] and experiments involving antisense downregulation of connexin43, a protein involved in gap junctions and inflammation, support these findings [74,76]. Furthermore, other studies have provided evidence that wound inflammatory cells from the circulation

An in vivo mouse excisional wound model of scarless healing. Plast Reconstr Surg 2006; 117(7):2292–96.*

produce signals that either directly or indirectly induce collagen deposition and granulation tissue formation, which increase scarring [77].

Although this research points to the inflammatory phase of wound healing as a cause of scar tissue formation, studies have provided evidence that the inflammatory phase and scarring might not be as directly linked as previously believed. Cox-2, an enzyme involved in prostaglandin production, is a mediator of inflammation. Two studies

show conflicting evidence regarding the effect of Cox-2 inhibition; one study reported decreased scar formation and the other claimed no difference in wound healing or scar formation [78,79]. Likewise, a study that transiently induced neutropenia in mice accelerated wound closure but failed to show a difference between collagen content in neutrophil-depleted wounds compared with wild-type controls [80].

Although other possible mediators of scar formation exist, the inflammatory response remains a major target for ongoing research aimed at preventing or reducing the appearance of scars. As Stramer et al. illustrated, many points exist at which interventions could dampen the inflammatory response. The first target could be leukocytes, at any point as they migrate (1) through the vessel wall from the bloodstream, (2) from outside the vessel to the wound, or (3) as they transmit a signal to fibroblasts, inducing the fibrotic response. A second target could be the fibroblasts themselves, and interventions could be designed to block the action of these cells as they respond to leukocyte signaling [81].

An interesting development in the scar theory was the discovery of heterogeneous fibroblast populations, with certain fibroblasts being responsible for the entirety of scar collagen production. *Engrailed-1*, a gene for a homeobox protein, was used to trace a lineage of fibroblast appearing at the transition from regenerative to scarring phenotype in the dorsal skin of fetal mice, and was also found to deposit all skin scar collagen in adults. This discovery may have uncovered the elusive element behind scar formation and may offer a specific cellular target to achieve regenerative healing. Also, along with the discovery of *Engrailed-1* positive fibroblasts was the discovery of specific inhibitors of these fibroblasts, offering already a potential therapy to achieve reliable scar reduction. Through targeting scar fibroblasts rather than inflammatory cells, perhaps other phases of wound healing, such as the proliferative and remodeling phases, may also be investigated having potential therapeutic benefit [82].

Cytokines and Growth Factors

Transforming Growth Factor β Superfamily

Though there is an abundance of knowledge pertaining to the TGF-β pathway, the development of clinical tools targeting this growth factor have largely arrested. The TGF-β superfamily includes several proteins, the most important are which are TGF-β1, TGF-β2, and TGF-β3; all of them have been shown to influence adult wound healing [83]. These cytokines are secreted by keratinocytes, fibroblasts, platelets, and macrophages, which act to influence their own and other cell populations to migrate into the wound bed [84]. The TGF-β superfamily has also been implicated in matrix remodeling and collagen synthesis [85]. Partly, this comes from evidence that TGF-β1 activates myofibroblast differentiation to influence wound contraction and the synthesis of collagen and fibronectin in granulation tissue [86].

Investigators have compared the TGF-β isoform profiles of fetal and adult skin. Results showed that injured fetal epidermis contains a greater amount of TGF-β3, derived from keratinocytes and fibroblasts, and less TGF-β1 and TGF-β2, derived from degranulating platelets, monocytes, and fibroblasts, compared with healing adult skin [87,88]. Since this cytokine profile was discovered, isoforms TGF-β1 and TGF-β2 have generally been thought to be pro-fibrotic, whereas TGF-β3 is thought to support scarless healing [84]. Discovery of the relative ratios of these isoforms prompted experiments aimed at mimicking the embryonic profile, using antibody neutralization of TGF-β1 and TGF-β2 and treatment with exogenous TGF-β3 [89]. Although antibody neutralization of TGF-β1 or TGF-β2 has no effect on wound healing, experiments showed that antisense RNA knockdown of TGF-β1 does in fact reduce scar formation [90]. Likely, the length of time that TGF-β1 is neutralized over the course of wound repair influences scarring, with longer neutralization needed for greater influence on scar reduction [84]. In addition, the coordinated actions of TGF-β1 and TGF-β3 in wound healing may be more complicated and necessary than originally hypothesized, because alterations in the ratio of TGF-β1 and TGF-β3 fail to produce significant results [91].

Interestingly, clinical trials with recombinant TGF-β3 failed to demonstrate diminished scarring. Avotermin, which received acclaim and investment in early clinical trials, failed to meet its Phase III end points [92]. Since then, Avotermin and its alternative were abandoned, perhaps highlighting the importance of integrating TGF-β with tissues, cells, or other cell signaling molecules. Now, with the expansion of wound healing biomaterials, the TGF-β superfamily is being targeted as a therapeutic to be delivered via biomimetic scaffolds [93]. Engineered as well as dermal composite scaffolds are emerging as potential therapies, with some promising in vivo studies [94].

Connective Tissue Growth Factor

Connective tissue growth factor (CTGF), like many other growth factors in wound healing, is capable of influencing fibroblast differentiation and inflammatory cell migration [95]. It is also considered profibrotic by a mechanism related to TGF-β, and through its influence on fibroblasts to deposit scar ECM matrix [95], as evidenced by its

increased expression in scleroderma patients [96]. CTGF is a TGF-β target gene that is activated by Smad proteins after TGF-β binds to and activates its receptors. Once activated, this cysteine-rich matricellular protein binds to integrin and proteoglycan receptors activating pathways such as wingless type (Wnt), bone morphogenic protein, VEGF, and TGF-β [97], which highlights the redundancy in many important wound healing signaling cascades.

Adult fibroblasts have higher expression of CTGF than fetal fibroblasts, which makes this an attractive therapeutic target. Studies on fetal fibroblasts stimulated by TGF-β show increased expression of CTGF, suggesting that scarless fetal repair may be partially a result of lower CTGF expression [98]. Following this evidence, CTGF was found to have a positive vulnerary effect in diabetic wound healing, accelerating the time to wound closure in diabetic foot ulcers [95]. In a rabbit ear model, hypertrophic scarring improved using messenger RNA (mRNA) antisense inhibition of CTGF [99]. Like TGF-β, CTGF may be involved in too many overarching signaling cascades to influence wound healing by solitary treatment with recombinant or inhibitory compounds, although its predominant temporal influence in wound healing may be limited to the early inflammatory phases [97].

Vascular Endothelial Growth Factor

There are four isoforms of VEGF, VEGF A through D. Keratinocytes, fibroblasts, and macrophages all produce VEGF, which is thought to be one of the main regulators of angiogenesis and vasculogenesis in wound healing. VEGF acts through two receptors in endothelial cells, VEGF-R1 and VEGF-R2.

In adult wound healing, VEGF increases over time and has been associated with angiogenesis [71]. Also, direct and indirect targets of VEGF can affect wound healing [100,101]. However, through studies on fetal rats, scarless healing has an increase in VEGF expression three times higher than what is observed in late-gestation fetal wounds [73]. This work suggests that increased VEGF expression is partially responsible for the accelerated wound healing that occurs early in gestation, but ultimately its role may not be in regulating scarless wound repair.

Fibroblast Growth Factors

Embryonic wounds contain lower levels of fibroblast growth factors (FGFs), growth factors involved in skin morphogenesis [88]. The expression of FGFs, including keratinocyte growth factors 1 and 2, increases as the fetus ages, which suggests that these growth factors are profibrotic, similar to CTGF and TGF-β [102]. Many isoforms have been studied, including FGF-5, which doubles in expression at birth, FGF-7, which multiplies more than sevenfold at birth, and FGF-10, which doubles at the transitional period [71]. In general, downregulation of the FGF isoforms occurs during scarless wound healing, whereas the opposite is true during adult wound healing, which suggests that FGF upregulation is likely partially responsible for scar formation or at least managing cell differentiation and proliferation [71].

Studies suggest that FGFs, as well as Wnts, also have a role in organizing and differentiating embryonic organs [103–106]. Moreover, FGFs may be stored in the ECM by binding to proteoglycans, becoming a reservoir during tissue injury, when serum proteases cleave FGFs into functionally active isoforms and begin their signaling cascade [104]. In injured murine skin, FGF-9 initiates wound-induced hair follicle neogenesis through a feedback loop including two different fibroblast subtypes, the Wnt2a/β-catenin pathway, and FGF-10 [107]. Although studies in electroporation may provide an example of dermal appendage regeneration through ECM maintenance [108], these studies have not been verified, which makes FGF-9 the only single-cell signaling molecule capable of restoring some normal skin architecture during adult skin healing.

Platelet-Derived Growth Factor

Like FGF, PDGF has been identified as a profibrotic growth factor. Adult wounds contain high amounts of PDGF, whereas this growth factor is virtually absent in embryonic wounds. However, this is largely the result of inhibition of platelet degranulation in embryonic wounds [88]. Experiments involving the administration of PDGF to fetal wounds show that this growth factor induces scarring through increased inflammation, fibroblast recruitment, and collagen deposition [109].

Wingless Type Signaling

Wnts are a critical regulatory cell signaling molecule existing in the form of secreted glycoproteins. Wnts, which are usually tethered to a lipid moiety such as a palmitate tail, usually have limited diffusion capacity and function in local tissue environments [110]. In embryos, Wnts have a major role in axial differentiation. In adults, Wnt responsive cells are found in all major tissue types and origins, which suggests Wnts continue to have important roles in adult tissue organization [111]. In adult skin, Wnt-responsive cells can be found in the epidermis and dermis. By expert opinion, Wnt signaling cascades in adult stem cells are thought to be responsible for ongoing cell fate, spatial

recognition, and cell polarity, the importance of which is often understated [111]. In addition, specific Wnt proteins such as Wnt2a may be involved in the cell-to-cell communication necessary for specialized dermal structures to develop, such as new hair follicles in wounded adult skin, as was previously discussed [107].

Wnt expression in fetal tissue is usually higher than in adult tissue at baseline and often gradated [111,112]. With wounding, the expression of Wnts in fetal dermal tissue, as with many other growth factors and inflammatory cells, changes very little [112]; instead, the overwhelming number of organizational growth factors and *Hox* gene products leads to scarless tissue regeneration. In adults, Wnts increase during skin wound repair. However, their role in skin wound healing is less certain because Wnts (1) function mostly as a signal transducer and (2) are difficult to study [112]. Ultimately, Wnts are a promising although enigmatic choice for studying wound healing. Their only foreseeable barriers in clinical translation are appropriate dosing and delivery modalities, because Wnts also have a role in cancer development [106,107].

Interleukins

The interleukins (ILs) are a class of cytokines involved in activating the inflammatory cascade; they are frequently targeted as wound healing adjuvants. IL-8 stimulates neovascularization and attracts neutrophils. IL-6 is produced by adult fibroblasts in response to stimulation by PDGF, and then activates macrophages and monocyte chemotaxis. With an insult to skin integrity, IL-6 and IL-8 rapidly increase expression to facilitate recruitment of circulating inflammatory cells to the wound. This elevated expression is maintained over 72 h during adult repair but is suppressed after 12 h during scarless fetal repair. Early fetal fibroblasts express lower levels of both IL-6 and IL-8 than do their adult counterparts at baseline and in response to PDGF stimulation. Therefore, these proinflammatory cytokines are thought to promote scarring. In addition, studies on the administration of IL-6 to fetal wounds induces scarring, which further supports this theory [65,113].

However, IL-10 is thought to be antiinflammatory, based on its antagonism of IL-6 and IL-8. Evidence for this comes from fetal embryonic day (E)15 skin in IL-10 knockout mice grafted to syngeneic adult mice. Incisional wounds on these skin grafts showed scar formation, whereas similar wounds in 15-day gestation wild-type skin grafts on adult wild-type mice healed scarlessly. These results suggest that IL-10 is essential for scarless fetal healing owing to its ability to dampen the inflammatory response [65,113]. In a supporting study, administration of an IL-10 overexpression adenoviral vector reduced inflammation and induced scarless healing in adult mouse wounds [114].

CURRENT THERAPEUTIC INTERVENTIONS

No currently available therapy can induce postnatal regenerative healing. Although many therapeutic interventions are used to reduce scar formation, research has not adequately demonstrated efficacy or safety for many of these treatments, because of small treatment groups and a lack of well-designed studies. However, the following treatments are used clinically to reduce scarring symptoms and scar formation.

Topical and Intralesional Corticosteroid Injections

Corticosteroids are commonly used to treat symptomatic scars; triamcinolone is the most commonly used agent. The mechanism of action is multifactorial. The inflammatory response is globally decreased, which secondarily decreases collagen synthesis and increases collagen degradation. Corticosteroids also inhibit fibroblast proliferation and TGF-β1 and β2 expression by keratinocytes [115,116]. Although 50−100% symptom improvement has been reported, studies are limited by a lack of appropriate controls and poor design [115,117].

The use of corticosteroids is limited by reported adverse consequences in 63% of patients. These effects include delayed wound healing, hypopigmentation, dermal atrophy, and scar widening [117]. Based on successful studies combining corticosteroid injections with 5-fluorouracil therapy and laser therapy, polytherapy may be the best method with which to use steroids, because lower dosing and fewer adverse effects occur [117,118]. Overall, an agent with global reduction in cell protein synthesis and proliferation is not ideal for achieving tissue regeneration.

5-Fluorouracil

In the treatment of fibroproliferative scars, 5-fluorouracil (5-FU) has been used since the 1990s, with some promising clinical results [119]. This therapy, which represents a middle ground between the low side-effect profile of

silicone gel sheeting and the morbidity of surgery, has emerged as a promising alternative for patients who wish to avoid surgery or who have failed conventional treatment algorithms. 5-FU has gained some negative attention because of its use as a chemotherapeutic agent. When given systemically, it has potent side effects though a long-established safety profile. Its mechanism of action involves inhibiting the synthesis of the pyrimidine thymidine, thus inhibiting DNA synthesis in dividing cells and inevitably causing apoptosis [119].

In glaucoma and other proliferative diseases (such as keloids), 5-FU offers promising results when administered locally. When used alone, 45–78% of patients saw improvement in their scar appearance. However, when combined with triamcinolone, the efficacy of local administration improved scar appearance in 50–96% of patients [119]. It may also be combined with surgery to reduce fibroproliferative scar recurrences. Unfortunately, most clinical trials recruit small numbers or are confined to populations inherently at risk for fibroproliferative scarring [120,121]. Further research analyzing the efficacy of 5-FU in scarring is needed, but given its relatively benign local side effects and demonstrated benefits, it should remain an alternative for patients with recalcitrant scarring disorders [18,119,121–123].

Imiquimod

Originally marketed as a treatment for verruca, actinic keratosis, and basal cell skin cancer, imiquimod may be used in low-morbidity settings for the treatment of hypertrophic scars and keloids. This Toll-like receptor-7 agonist functions by stimulating dermal inflammatory cells to secrete interferons, ultimately recruiting activated leukocytes to skin when applied topically. There, the effect is mostly mediated by the immune system. This medication represents an exciting, minimally toxic, and targeted method of immune modulation with few systemic side effects, and mostly blistering or skin irritation as the major local side effect.

A few small, randomized controlled trials evaluated the efficacy of imiquimod in the treatment of acute surgical incisions in the breast [124] and in minor dermatologic surgeries [124]. However, the most trials failed to show a difference in scar appearance and potentially may have worsened outcomes by potentiating inflammation [124]. In the case of already formed keloids and hypertrophic scars, imiquimod could be tested in select patients wishing to try nonsurgical therapies, but ultimately this product does not appear to have a role in acute wound healing.

Laser Therapy

In the 1990s, pulsed dye laser therapy emerged as a potential treatment for fibroproliferative and acute scars [125,126]. Like other disorders of aberrant proliferation, the mechanism proposed involves destruction of new blood vessels to limit, at a minimum, the erythematous appearance of some scars [126]. The idea behind targeting fibroproliferative scars with laser treatment comes from the principle that vascularity is partially responsible for their erythematous appearance. Although some case studies showed positive results in the treatment of keloids, the ischemic mechanism of keloid progenitor cell differentiation and proliferation is concerning [127].

Laser therapy has relatively few adverse effects (hyperpigmentation in 1–24% of patients and transient purpura in some). However, more research is needed to support its efficacy.

Bleomycin

Another potent chemotherapeutic being used in dermal fibroproliferative disorders is bleomycin. This antibiotic has profound antibacterial, antiviral, and antitumor activity through DNA strand scission [128]. The exact mechanism of action is not entirely understood, but it is generally accepted that bleomycin induces cell death by forming complexes with iron and other metals that generate free radicals that eventual cleave both double- and single-stranded DNA, as well as degrade RNAs [128]. In resistant hypertrophic scars, keloids, and warts, bleomycin has been used off-label by dermatologists via intradermal injections [129]. Similar to other off-label use products, there are few clinical trials testing its efficacy [129]. However, if monitored closely with an experienced practitioner, it may be effective and safe. Side effects from treatment with bleomycin may be as minor as skin irritation, to as severe as skin necrosis and eschar formation [129]. When giving systemically, bleomycin notoriously causes pulmonary and skin fibrosis in humans and mice [130]. As such, it is often used to induce both conditions in an effort to create mouse models of pulmonary fibrosis and scleroderma [130]. Like other chemotherapeutic agents exploited in wound healing, development of a targeted therapy would be more attractive.

Silicone Gel Sheets

Maintaining tissue hydration in the base of wounds has long been known to improve outcomes in acute and chronic wound healing. Silicone, in either sheets or gels, emerged in the 1980s as a potential vulnerary agent by providing a hydrating barrier to open wounds. For decades, silicone has been used in deeper tissues, in the form of breast implants or as an interface for matrices used in hernia repair and large tissue defects; which highlight its safety [131,132]. Silicone gel sheets are hypothesized not only to hydrate wounds but also to inhibit collagen deposition and downregulate TGF-β2. Its development came from a series of studies that implicated dehydration of deep dermal fibroblasts as the mechanism for inducing scar collagen production. This therapy has been studied for both treatment and prophylaxis of excessive scarring [133]. Initial studies showed conflicting results in terms of efficacy [134,135], requiring further study. A review emphasized the weak evidence surrounding the use of silicone gel sheets in the treatment of keloids and hypertrophic scars [136]. However, silicone gel sheets will likely continue to be used because they are a noninvasive treatment with few adverse effects. In clinical practice, silicones are usually found as a component to a complex matrix or as a topical therapeutic dressing for chronic wounds [132]. Although the efficacy is unknown, they are safe to continue using and investigating.

Pressure Dressings and Negative-Pressure Wound Therapy

Despite being in clinical use since the 1970s [137], pressure dressings have not been validated by experimental trials to be efficacious in prophylaxis or in the treatment of scars [138]. These treatments may be efficacious in reducing the appearance of a scar if used in polytherapy, but further investigation is warranted. Pressure earrings have been used in earlobe keloid excisions but have not been shown to eliminate recurrence.

Pressure is also used in the form of negative-pressure wound therapy. Most surgeons are familiar with this technique, in which a vacuum is applied to an open wound (chronic or acute) to activate mechanotransducers in cells and potentiate cell proliferation and eventual wound closure by secondary intention [139]. The application of negative pressure in wound therapy appears to be ever increasing, with promising results as a treatment for acute wounds [140], chronic wounds [141], burns [142], and for the closure of large contaminated incisions [143]. Many modifications have been made to the vacuum system, such as the application of silicone sheets or foam pads, which ultimately make minor improvements in the overall technology.

Radiation Therapy

Radiation therapy can also be used as an adjunct to surgical excision in the treatment of keloids. Mechanistically, it is thought to decrease collagen production by reducing fibroblast proliferation and neovascular bud formation. Radiation therapy is most effective for recurrent keloids if a single dose is given within 24 h of surgical excision, but studies have attempted short courses of radiation after healing with positive results, as well [144]. Radiation treatment appears to decrease recurrence rates after surgical excision from 45–100% to 16–27% of patients [145–147]. The magnitude of difference from these studies clearly highlights their limited power.

One limitation of radiation therapy is that standardized dosing, fractionation, time period, and frequency after surgical procedures has not been developed. Reish et al. reported good results in treating recurrent keloids after surgery with 300–400 Gy in three to four fractions or 600 Gy in three fractions [138]. However, like many other studies in wound therapy, large, randomized, controlled studies are required to evaluate the role of radiation further in wound healing. Ideally, therapy that may cause oncogenesis should be avoided. Given the morbidity of radiation, this is not a popular method to reduce scar tissue formation.

Cryotherapy

Cryotherapy has been studied in conjunction with surgical excision to treat keloids and hypertrophic scars. Many of these studies are limited by small sample size and poor controls, but the largest study reported a 79.5% response rate with 80% reduction in scar volume [148,149]. Cryotherapy is thought to decrease collagen synthesis and mechanically destroy scar tissue. Side effects include hypopigmentation and depressed atrophic scar formation [150]. This therapy can be used as an adjunct to surgery or as monotherapy, but studies question its efficacy in large recalcitrant keloids [151].

Extracellular Matrix Substitutes and Scaffolds

As the extracellular matrix is researched, it is becoming increasingly apparent that once regarded "inert" structural proteins such as collagen, vimentin, fibronectin, hyaluronic acid, proteoglycans, and glycosaminoglycans are in fact functional and can regulate cell growth [152]. With this discovery, scaffolds mimicking the ECM targeting acute or dysfunctional wound healing have emerged at a rapid rate. The most basic ECM scaffolds are made of single ECM compounds such as collagen or hyaluronic acid, at times integrated in bilayers with synthetics. Examples include Hyalomatrix, Promogran, and Biocol [152]. Acellular dermal matrices, human amniotic membranes, and porcine intestinal mucosa, which once were used for large incision closures and hernias, are also emerging in the market as wound healing adjuvants. These, too, can be combined with a number of additional therapies, from impregnated pharmaceuticals to cultured stem cells [153]. Generally, results are promising in the treatment of chronic and diabetic wounds [152]. However, large randomized controlled trials have not been performed comparing different ECM substitutes.

Tension Offloading

An important field of study in wound healing focuses on mechanical forces. There are multiple examples of pressure, suction, or stretch that result in rapid cell proliferation, as is seen with vacuum-assisted wound closure and pregnancy [139,154]. In adult wound healing, tension initiates a signaling cascade leading to the proliferation of local cells typically in a symmetric pattern. Both keratinocytes and fibroblasts have mechanosensors imbedded in their cell membrane. These sensors, with other molecules that bind to the ECM such as integrins, are ion channels that open only when stretched [155]. In the case of fibroproliferative wounds, this may be an inciting factor leading to aberrant cell growth [139]. In fetal wound healing, the loss of dermal architecture leads to the deposition of actin protrusions that will contract and recruit local cells to close gaps in tissue and eventually regenerate lost structures [156]. This is perhaps the most stark difference in wound healing between prenatal and postnatal organisms, in which similar filaments and structures are involved but ultimately are used in entirely different ways [156].

In surgical patients, tension can have a severe impact on wound healing. On the back, chest, sternum, and tibia, incisions naturally stent open and can be predisposed to prolonged healing, infection, and dehiscence whereas areas with low tension and redundant tissue, such as the eyelid, heal with minimal scarring. A clinical trial tested an external tension offloading device known as "embrace®" in acute scar revision [157]. Patients achieved significantly diminished scarring with its use.

Surgery

Remodeling is a process that can last 1–2 years. During this time, scars can lose their dark pigmentation, flatten, soften, and contractures can lessen. Because scars can often behave unpredictably, surgery is usually reserved until after this period has passed. There are many options for surgical treatment for scarring, including excision with direct closure, local skin flap coverage, or more extensive vascular flap coverage. These treatments are generally considered before surgical treatment or as an adjunct. For fibroproliferative scars, surgical treatment is usually a simple excision, with or without flap closure, depending on the size of the resulting defect. In chronic wounds, burns, and pressure ulcerations, surgery may consist of creating local or pedicled tissue flaps, split-thickness skin grafts, or repeated surgical debridements to encourage healthy wound healing.

FUTURE THERAPEUTIC INTERVENTIONS

Growth Factors and Cell Signaling Molecules

As mentioned earlier, targeting individual cell signaling molecules has not translated to effective clinical treatments. In the case of recombinant TGF-β, clinical trials were arrested when the treatment failed to affect wound healing [92]. Monotherapy with solitary ECM components also usually leads to some treatment effect, but none that regenerates normal dermal architecture. Studying the signals influencing cell polarity and differentiation, however, has been more fruitful. FGF-9 is being developed as a therapy for hair loss [107] whereas its target, Wnt2a, may prove to be important in generating new hair placodes. WNt3a has already proved to be valuable in regenerating tissues, and in a mouse model of tissue regeneration, full-thickness excisional wounds taken from the ears closed whereas

placebo treatments did not [158]. It is likely that if signaling cascades are targeted specifically via receptor agonists and antagonists, polytherapy will be needed to circumvent redundancies in the inflammatory pathway and signals leading to collagen deposition. These few examples represent the most promising monotherapies currently in use.

Targeting Gap Junctions and Connexins

Gap junctions are hypothesized to function during wound repair by transferring injury signals from cell to cell, coordinating the inflammatory response, mediating wound closure, and regulating scar tissue formation in response to injury [46,159–161]. Many connexins (Cx) are present in the skin; the most extensively studied connexin is Cx43, which is expressed in both the epidermis and dermis [76]. Cx43 has decreased expression at the wound edge by the first 1 or 2 days after injury [159]. During wound repair, increased phosphorylation of Cx43 by protein kinase C may cause decreased gap junctional communication through a decrease in unitary channel conductance. This inhibition then initiates the injury-related response by the involved cell, which recognizes injury via reduced cell-to-cell communication [162].

When Cx43 antisense oligonucleotides were applied to mouse skin wounds, decreased inflammatory cell infiltration, fibrotic tissue deposition, and accelerated wound healing were observed [163]. Other studies showed that transient inhibition of Cx43 decreases scarring after burn injury in wild-type mice and increases reepithelialization after burn injury in human diabetic patients [163,164]. To further support these data, Cx43 knockouts have accelerated wound closure [165] and decreased collagen type I synthesis in the presence of chemicals that uncouple communication between cells. Interestingly, these treatments did not affect the levels of collagen type I mRNA [46]. Based on these data, the application of lithium chloride, a substance known to enhance signal propagation through gap junctions, produced the opposite effect: enhancing the deposition of granulation tissue, increasing open wound closure time, and increasing scar [166].

Given the strong correlation between Cx inhibition and improved wound healing, other therapies aimed at blocking signal transduction from cell to cell are under investigation. For example, a group at the Medical University of South Carolina synthesized a membrane permanent peptide containing a sequence designed to inhibit interaction of the ZO-1 protein with Cx43. This peptide, known as ACT1 peptide, decreases the rate of channel organization in gap junctions [167]. Through further investigation, researchers found that this peptide interacts with more than one portion of Cx43 and enhances cutaneous wound healing through decreased inflammation and scarring [160]. The advantage of this novel protein is that overall Cx43 expression is not altered. Moreover, the expression of other genes is not directly altered, unlike with antisense therapy and gene knockdown modalities.

As with the TGF-β superfamily, several commercial companies are attempting to develop Cx-related scar reduction therapies. These therapies include Cx43 antisense-based gene therapy and ACT peptide bioengineering [167], which are in the early stages of testing and will not be available for some time.

Other Drugs and Biologics

Additional strategies increase the expression of intrinsic antiscarring molecules at the wound site, including fibromodulin, hyaluronic acid, and hepatocyte growth factor [168–170]. Other approaches include treatment with inhibitors of MMP [171], inhibitors of procollagen C-proteinase [172], inhibitors of dipeptidyl peptidase IV enzymes [173], as well as treatment with angiotensin peptides [174]. Adenovirus-p21 overexpression has also been linked to scar reduction [175].

Stem Cells

True skin regeneration at sites of injury has not been accomplished by single molecule–specific therapy. As such, regenerative repair may require a cell-based approach. Stem cell therapy, with the ability to differentiate cells into various necessary cell types, is a promising approach to regenerative repair (Fig. 5.6).

Embryonic Stem Cells

Embryonic stem (ES) cells are those that may be isolated from the embryo and possess both pluripotency and the capacity for unlimited self-renewal. The discovery of ES cells was the result of work in the 1970s involving transplanting embryonic cells into ectopic sites, which inevitably resulted in teratomatous tumor formation [177]. The discovery of specific embryonic cells that self-renew indefinitely in culture and can generate an entire organism

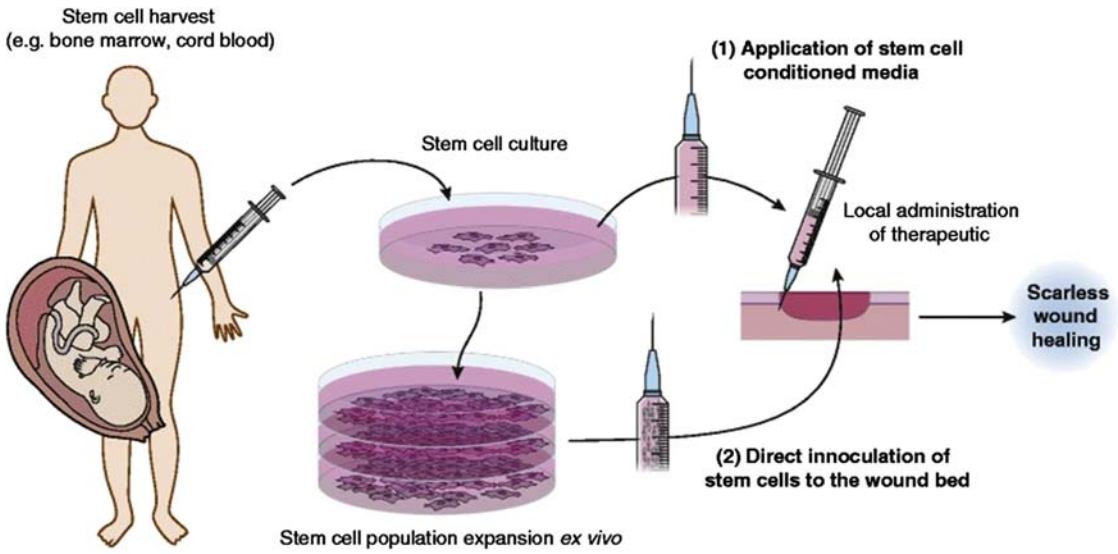

FIGURE 5.6 **Stem cell–based therapies to promote scarless wound healing.** Representation showing general principles of two cell-based therapeutic methodologies: (1) application of stem cell–conditioned media, and (2) direct application of stem cells to the wound bed. The poor survivability of mesenchymal stem cells (MSCs) transplanted to the wound bed has prompted the development of other novel therapies that take advantage of the paracrine mechanisms of action of these cells. Application of conditioned media from umbilical cord blood–derived MSC culture is one such example [178]. *Reproduced with permission from Leavitt T, Hu MS, Marshall CD, Barnes LA, Lorenz HP, Longaker MT. Scarless wound healing: finding the right cells and signals. Cell Tissue Res 2016; 365(3):483–93.*

or specific cell types led to the concept of the totipotent ES cell [179,180]. It was immediately recognized that these cells held the potential to be used for regenerating dysfunctional organs and tissue. Equally obvious were the potential ethical problems related to using cells from human embryos. Whereas other types of stem cells have been used successfully in clinical therapies, such as hematopoietic stem cell transplantation for hematologic diseases and malignancies, therapies involving ES cells remain entirely experimental.

In an early attempt at tissue regeneration using ES cells, Fraidenraich and colleagues injected wild-type ES cells into mice predisposed to death by cardiac failure. The remarkable result of this experiment was that the mice were rescued from their lethal phenotype through a mechanism that appeared to involve signaling factors released by the ES cells [181].

A potential barrier to using therapeutic ES cells in humans is the host immune response against these foreign cells. Immunocompetent mice mount a robust immune response against human ES cells, leading to limited ES cell survival, although this response can be mitigated with the use of immunosuppression [182].

Another difficulty with using ES cells in human therapy is the formation of teratomas; this is unsurprising because the origin of the ES cell's discovery was in the study of teratoma-forming embryonic cells. Undifferentiated ES cells transplanted into ectopic sites, such as the heart, consistently form teratomas [183]. However, advances in the directed differentiation of ES cells toward specific fates should make teratoma formation less of a concern [184].

Improvements in the purifying and characterizing ES cells have allowed for trials testing their efficacy in human diseases. In a phase I/II clinical trial, patients with macular degeneration were treated with retinal pigment epithelium cells derived from human ES cells and with immunosuppression [185]. Several patients experienced improvements in visual acuity up to 12 months after treatment, a result that would not be expected in the absence of treatment.

Human oligodendrocyte precursor cells derived from human ES cells showed promise in treating spinal cord injury in preliminary rodent experiments [186]. However, human spinal cord injury patients treated with similar cells in a phase I trial showed no improvement after treatment [187]. These results highlight that promising results in animal models are not easily translated to human applications, and that novel stem cell therapies must be tested rigorously in human trials. In addition to macular degeneration and spinal cord injury, diabetes, myocardial infarction, and Parkinson disease are among human diseases that are the subjects of ongoing clinical trials involving ES cells [187].

Mesenchymal Stem Cells

Mesenchymal stem cells (MSCs) are nonhematopoietic bone marrow stromal cells that were initially isolated based on their ability to adhere to plastic culture plates. These cells are unique in that they differentiate into

mesenchymal lineages such as cartilage, fat, muscle, and bone [188]. MSCs are a heterogeneous group of cells that have had populations isolated not only from the bone marrow but also from adipose tissue and amniotic fluid. Based on their ability to expand in vivo and differentiate into multiple mesenchymal tissue types, these cells are thought to be an ideal source of autologous stem cells used for promoting wound healing and/or scar-reducing therapies [189]. MSC therapy avoids rejection and the ethical and moral concerns associated with ES cell therapies.

MSCs may affect wound healing and tissue regeneration through many different avenues. Once transplanted, these cells migrate to the site of injury or inflammation, where they may stimulate the proliferation and differentiation of resident progenitor cells, secrete growth factors, participate in remodeling [188,190], and modulate the immune and inflammatory responses in the wound bed [191].

A wealth of clinical data attest to the safety of bone marrow–derived MSCs, and emerging data support adipose-derived mesenchymal cells as possessing a similar safety profile to bone marrow–derived MSCs [192,193]. Therefore, MSCs could be used to affect various pathways involved in wound healing, including inflammation, aging, and cellular senescence.

Several examples of human wound healing investigations exist using MSCs. The first was a small trial using a fibrin glue vehicle in both acute and chronic wounds. This study demonstrated that topical application of autologous passage 2–10 bone marrow–derived MSCs, combined with fibrin spray, allowed acute surgical wounds and chronic lower extremity ulcers to heal faster. The wound healing speed increased in a manner directly proportional to the number of cells applied [194].

A larger study evaluated patients with various nonhealing wounds. Bone marrow–derived MSCs were applied with a dermal scaffold to wounds, with or without autologous skin grafts. Results showed accelerated healing in wounds treated with MSCs [195]. A limitation of this study was that the cells were not passaged and flow cytometry was not used for isolation. MSCs are known to represent only 0.001% of nucleated cells in the bone marrow; therefore, the cell population used in these experiments was likely heterogeneous and may have contained tissue macrophages that would also assist in wound healing [188].

In a randomized controlled trial in which patients with critical limb ischemia received injections of either allogeneic circulating MSCs or control solution, no difference in outcomes was seen [196]. In a later randomized trial, 24 patients with nonhealing ulcers were randomized to receive autologous cultured MSCs or control treatment [197]. Those treated with MSCs experienced greater symptom improvement and ulcer healing compared with the control group.

Several small, nonrandomized human pilot studies suggested improved healing rates in patients with limb ischemia after treatment with bone marrow–derived mononuclear cells [198–205]. Designed to expand on these results, the JUVENTAS trial is perhaps the most prominent clinical investigation to date based on bone marrow–derived cell therapy [206]. This trial included 160 patients with critical limb ischemia thought to be nonrevascularizable. Subjects received either injections of bone marrow–derived MSCs or placebo injections. There was no significant difference between groups in rates of amputations or quality of life measures. These results confirm the importance of verifying promising preliminary results with well-designed, randomized trials.

Adipose-derived stromal cells (ASCs) are a potentially promising source for therapeutic cells because they are easily isolated from a patient's own fat tissue and exhibit osteogenic and adipogenic activity in vivo and in vitro [207]. Data from animal models indicate that autologous and allogeneic ASCs can regenerate tissue after injury [208]. Two noncontrolled human trials with small numbers of patients demonstrated improved wound healing after the administration of ASCs [209,210]. However, these results must be interpreted with caution because of the absence of control groups. In a small randomized human trial, a product containing ASCs and fibrin glue accelerated closure of perianal fistulae, which share similarities with nonhealing skin wounds [211]. However, a larger follow-up study showed no improvement with ASC administration compared with control treatment [212].

Further research is needed to characterize MSCs and their niches. As purification and enrichment techniques improve, the role of MSCs in wound healing will gain clarity. Defining the direct role of MSCs in wound repair, as well as their effects on other cells, will guide their future therapeutic potential.

Epidermal Stem Cells

As mentioned previously, the epidermis in humans is a dynamic structure undergoing constant renewal. Epidermal turnover is estimated to take place over 60 days in humans, a process that requires a continuous supply of differentiated cells. Epidermal stem cells have a high capacity for self-renewal, as evidenced by the number of daughter cells that undergo terminal differentiation into keratinocytes [213]. Several stem cell niches are present in the epidermis. The best-characterized are the interfollicular epidermal stem cells and the hair follicle bulge region.

The interfollicular epidermis (IFE) is the region of epidermis located between hair follicles. Under normal homeostatic conditions, IFE stem cells defined by expression of the gene *Lrig1* of the basal layer of the epidermis divide at a steady rate to provide new keratinocytes to populate the epidermis [191,214]. These cells may also contribute to the growth of hair follicles and sebaceous glands [214] Whereas the IFE can receive contributions of cells from other structures, such as the hair follicle, it is also capable of repairing and renewing itself after injury in the absence of these other cells [191].

A separate population of epidermal stem cells defined by embryonic expression of *Lgr6* represents a primitive stem cell population that establishes all lineages of the skin, including cells of the hair follicle, sebaceous gland, and interfollicular dermis. In postnatal life, *Lgr6*-expressing cells reside above the hair follicle bulge and contribute to maintaining the sebaceous gland and the IFE [215].

The hair follicle is a complex structure with several distinct regions whose cellular composition has been exceptionally well-studied. Each regions appears to contain a unique population of hair follicle stem cells (HFSCs). It is clear that HFSCs can repair the hair follicle itself after injury. However, an unresolved question is to what extent HFSCs are critical for regenerating the injured epidermis.

The first hair follicle stem cells to be discovered were those residing in the hair follicle bulge region. These cells are characterized by expression of the genes *Krt15*, *Lgr5*, and *Gli1* [191,216]. Initial experiments showing that these cells are present in the epidermis after a scratch injury suggested that they may participate in epidermal repair [217]. However, subsequent experiments showed that the presence of bulge cells in the epidermis is short-lived. It is likely that the contribution of these cells to long-term skin repair is minimal, and that their main role is to regenerate the hair follicle [191].

The junctional zone of the hair follicle is located above the bulge and adjacent to the sebaceous gland. It contains a complex population of stem cells that generally express *Lrig1* but otherwise have different gene expression profiles and roles in regeneration [191,214]. Those that express *Lgr6* in the embryo form the hair follicle, sebaceous gland, and interfollicular dermis. Postnatally, these cells contribute to repair of IFE and hair follicles. Because these *Lgr6*-positive cells are capable of forming several skin structures, they may represent a primitive skin stem cell [215].

Given the important role of epidermal stem cells in skin formation and regeneration after injury, the possibility of using them in a therapeutic role after injury is intriguing [216,218]. Preliminary experiments in animal models have yielded some promising results, such as epidermal stem cells transplanted onto rat wounds [216,218]. However, a major limiting factor in the therapeutic use of epidermal stem cells is their scarce availability and the difficulty in obtaining them. In patients most in need of new keratinocytes, burn victims, there may not be enough autologous cells left in certain situations to make this a viable clinical tool. At this point, the therapeutic potential for epidermal stem cells is largely theoretical, but research continues to develop at a rapid pace [219].

Induced Pluripotent Stem Cells

Difficulties inherent in deriving and using human ES cells led to interest in generating pluripotent cells from other sources. In a landmark paper, Takahashi and colleagues described the transformation of adult dermal fibroblasts into induced pluripotent (iPS) cells using a specific combination of transcription factors [220]. Generation of iPS cells has been achieved from other human cell types, such as keratinocytes [221]. Using similar processes, fibroblasts may be transformed directly into functional, differentiated cell types such as neurons and cardiac myocytes [222,223]. The potential to derive iPS cells from adult tissue avoids the logistical and ethical problems associated with ES cells. Theoretically, iPS cells may also be used in an autogeneic fashion, avoiding the issue of immune rejection.

Translating the potential of iPS cells into human therapies has been challenging. In the only human trial to date involving the therapeutic use of iPS cells, sheets of retinal pigment epithelium cells derived from iPS cells were implanted into the retina of a patient with macular degeneration. Although the patient reportedly experienced improved vision, the trial was halted owing to concerns about mutations detected in the iPS cells [224].

Advances in molecular biology have the potential to refine and improve methods for generating therapeutic iPS cells. For example, the ability to edit specific genetic sequences using clustered regularly interspaced short palindromic repeats—Cas nuclease 9 may allow for the generation of iPS cells with specific traits that could increase their utility in specific disease processes [225]. In addition, the ability to generate functional organoids from iPS cells may prove to be useful for replacing dysfunctional organs in humans. Various groups have used iPS cells to generate organoids resembling cerebral cortex [226], intestine [227], and kidney [228], among others [229] (Fig. 5.7).

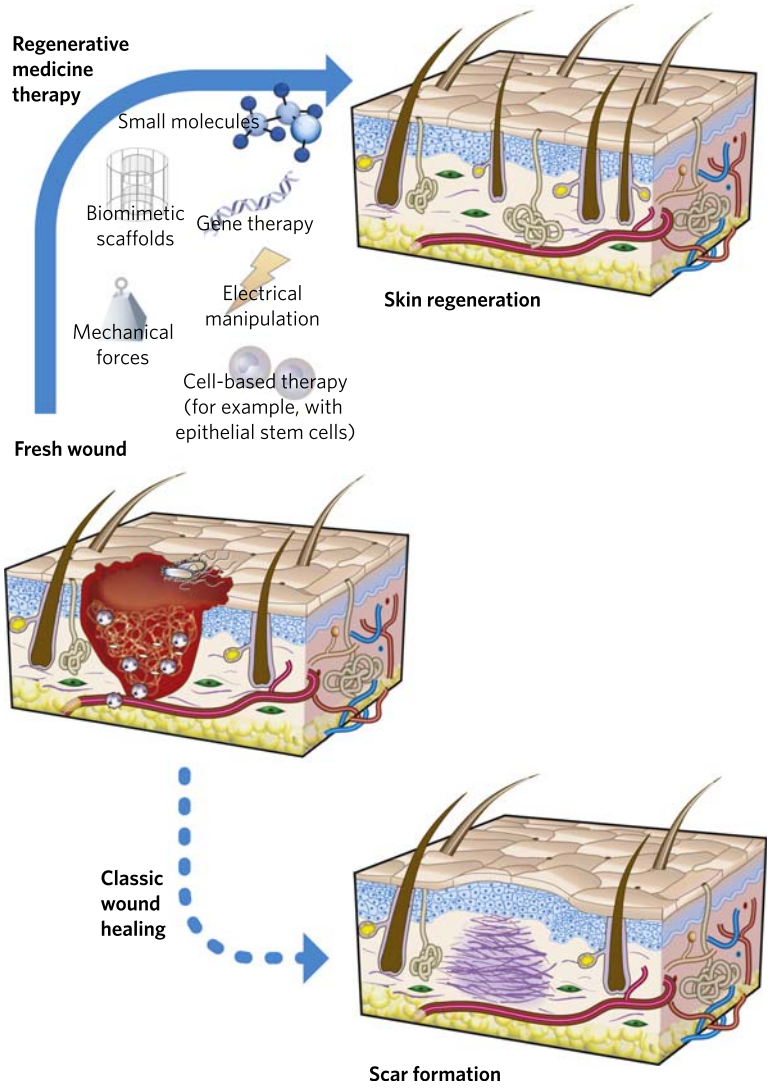

FIGURE 5.7 **Potential therapies for reducing scar formation during wound repair.** To manipulate wound repair to become more regenerative than scar forming, strategies include the use of biomimetic scaffolds, manipulation of the mechanical environment (for example, negative-pressure wound therapy to increase healing) or the electrical environment, the administration of small molecules, the use of gene therapy approaches, and the use of cell-based strategies (including administration of epithelial stem cells). All of these elements have been demonstrated to have an effect on in vitro and in vivo models of wound healing as single-agent therapies. In theory, many of these elements could be combined to recreate a receptive environment (or "soil") to promote regeneration. Combining these with the appropriate stem cells (or "seed") will undoubtedly alter the result of wound healing in humans. *Reproduced with permission from Gurtner GC, Werner S, Barrandon Y, Longaker MT. Wound repair and regeneration. Nature 2008;453(7193):314–21.*

PERSPECTIVE

Our understanding of adult stem cell populations, the complexity of embryonic development, and the redundancy of the adult skin wound healing mechanism has revealed that targeting a single-cell signaling cascade will not be sufficient to recreate scarless wound healing in adult mammals. Rather than the depth of our understanding leading to radical innovations, research has revealed a complex web of interactions among tissue types, structural proteins, developmental and highly evolutionarily conserved growth factors, external forces, and cell-to-cell interactions. On an optimistic note, the number of products for improved wound healing, both acute and chronic, has exploded, giving patients new options and hopes for improved outcomes and wound closure. Unfortunately, however, skin regeneration remains elusive.

With the US population aging and accumulating comorbidities, new solutions are needed that combine scar treatment strategies to prevent the cost of wound healing complications from increasing. Perhaps most exciting, our

understanding of stem cell niches and engraftment issues has improved to the point where autologous and allogenic stem cell therapy may become a therapeutic reality. If scarless wound healing cannot be accomplished in healthy adults by activating appropriate "self" signals, it is possible that engineered and cultured grafts may provide the necessary leap to accomplish regenerative healing.

CHAPTER

6

Progenitor and Stem Cell Heterogeneity: Using Big Data to Divide and Conquer

Melanie Rodrigues, Paul A. Mittermiller, Jagannath Padmanabhan, Geoffrey C. Gurtner

Stanford University, Stanford, CA, United States

INTRODUCTION

Traditional analysis of cells has relied on pooling of RNA or protein from hundreds of thousands of cells and displaying aggregate or average expression of replicate samples. These tools, which include polymerase chain reaction (PCR), microarrays, and western blotting, have been powerful in unfolding transcriptional networks, signaling cascades, and metabolic pathways, to advance our knowledge of disease and therapy. However, the underlying assumption with these techniques is that the population average represents the dominant biological state within the population. This assumption is flawed in most cases because the activity of each cell of the population is not reflected by the population average. Importantly, population averages are unable to capture the activity of rare but critical cells such as stem cells, or transiently amplifying cells such as progenitor cells (Fig. 6.1A). Interrogation of these rare but critical cells could prove to be key regulators of disease progression and therapy.

With the evolution of single-cell technologies such as high-throughput sequencing (HTS), it is possible to evaluate single cells with a high degree of comprehensiveness. These technologies provide information about transcript expression, gene fusions, mutations, or single-nucleotide polymorphisms in individual cells. Outlier cells are no longer considered errors in measurement by default, but can be tested for the presence of a unique function. It is also possible to detect whether a cell population is homogeneous or if cells display heterogeneity by clustering the single-cell data into subpopulations of cells that exist in metastates. These subpopulations can then be tested for functional relevance in tissue homeostasis, repair, and disease (Fig. 6.1B).

In homeostasis, cellular subpopulations function in a stable yet adaptable population equilibrium [1,2]. For example, in the skin, epithelial cells that display a high turnover rate are maintained by distinct subpopulations of self-renewing epithelial stem cells [3]. Similarly, in the bone marrow, the transcriptional, epigenetic, and functional heterogeneity of hematopoietic stem cells determines their cell cycle potential and differentiation ability [4,5]. A second level of complexity arises in tissue injury and repair. After tissue injury, various cell types need to be activated in spatiotemporal concert to bring about healing. In wound repair, for example, multiple cell types within the epidermis, dermis, hypodermis, and circulation must coordinate to bring about healing [6]. Single-cell technologies have revealed heterogeneity within several of the cell types involved in this repair process [7]. However, in tissues such as the heart and the brain, resident cells are still largely considered homogeneous owing to limited access to these tissues in the normal human state.

Cellular heterogeneity also has a critical role in disease and consequences for how the diseased tissue is diagnosed and treated. In cancer biology, tumors display intertumor heterogeneity in which genetic and phenotypic variations are observed between individuals with the same type of tumor, or between tumors in different tissue types of the same individual. However, tumors also exhibit intratumor heterogeneity in which cells within the same tumor exhibit differences in gene expression, cellular morphology, motility, proliferation, metabolism, metastatic potential, and recurrence potential. Alterations in these cellular characteristics can be determined using next-generation HTS

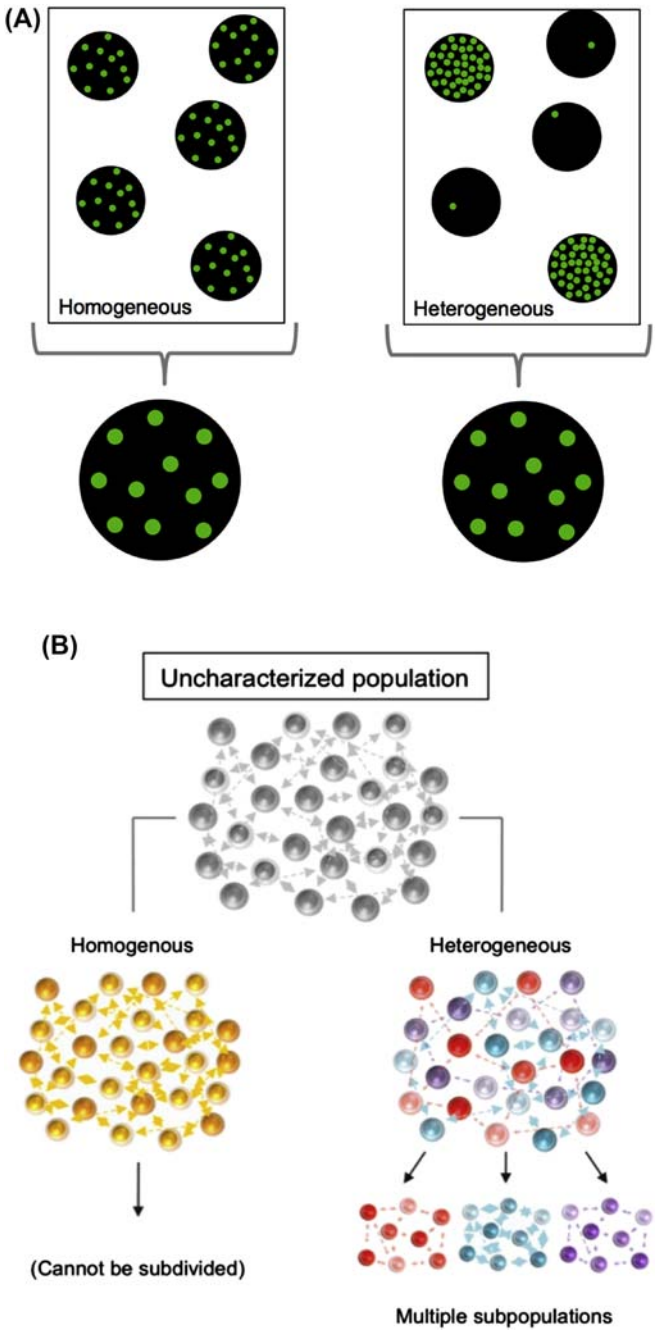

FIGURE 6.1 **Population assays versus single-cell assays.** In population-averaged techniques such as traditional microarray analysis, messenger RNA (*green*) from all cells (*black circles*) are pooled together and the aggregate expression level is reported. When studying heterogeneous populations, such as in cancer and stem cell biology, this approach can lead to considerable loss of information (A). Using single-cell analysis, it is possible to determine whether the population of cells can be further subdivided into subpopulations that are distinct from each other (B).

aided by computational analysis. These technologies have also made it feasible to detect mutational burden and the temporal order of mutations within tumors [8].

Traditional population assays cannot detect cellular heterogeneity because they obscure the response of individual cells and cellular subpopulations. Population assays also require hundreds of thousands of cells to be analyzed, which makes it difficult to study cellular heterogeneity in relatively small samples that are hard to obtain. In comparison, single-cell technologies can determine accurately and comprehensively differences at the genomic,

transcriptional, translation, or epigenetic level. These technologies can assay rare cells. In addition, they allow for analysis of cells in an unbiased manner without the use of markers a priori.

Although single-cell technologies are associated with several advantages, it is necessary to determine the need for resolution at the single-cell level. This is critical considering that the human body is composed of approximately 37.2 trillion cells [9] and each cell generates large datasets of information that must be analyzed computationally and mathematically. Once the need for single-cell analysis is established, it is essential to understand whether the biologic question requires a broad net to be cast to capture information about cellular behavior, or whether a targeted approach is required to reveal only certain cellular features with accuracy and precision. Thus, accuracy, precision, and comprehensiveness determine which technique is selected to answer the biologic question. Accuracy is the measure of certainty or validity that the measured value is close to the true value [10]. It is estimated by comparing the measurements generated by the single-cell technique with a reference standard technique (such as quantitative PCR for transcriptomic analysis). Precision is the ability to replicate or reproduce a measurement. In transcriptomics, high precision is associated with a narrow distribution of gene expression values [10]. Comprehensiveness or sensitivity is the amount of information obtained per cell. In transcriptomics, comprehensiveness refers to the total number of genes that can be detected [10,11]. Advanced single-cell technologies such as RNA sequencing (RNA seq) can detect more than 5000 genes per cell [12]. In addition to these three criteria, considerations such as cost-efficiency, sample size effects, and false discovery are also important for deliberation when comparing and developing HTS techniques [11,13].

This chapter describes the rapidly evolving single-cell technologies that have been used to study cellular heterogeneity. It explains how cellular subpopulations are discovered without prior bias. Finally, it addresses the impact of single-cell technologies on biology, regenerative medicine, and cellular therapy.

SINGLE-CELL ISOLATION

To study heterogeneity and gather data on a single-cell level, cells need to be isolated with accuracy. Most genomic and transcriptional analyses assay nuclear content from individual cells and do not require the isolated cells to be alive. On the other hand, proteomic and metabolic measurements require live cells, which makes single-cell isolation a more challenging process. The classic method of isolating single cells involves manual pipetting followed by serial dilutions. Manual pipetting works only on microliter volumes, is cumbersome, and is difficult to scale. This has led to the use of robots such as the Mosquito HTS, which ensures repeatable nanoliter pipetting irrespective of the viscosity of the cell suspension or environmental conditions [14]. Automated liquid handlers can also scale experiments with ease, converting a 96-well assay into a 1536-well format [14].

In situations in which cells need to be isolated directly from a tissue sample or a surface, laser-capture microdissection can be used [15]. This technique requires a trained histologist to isolate the cells of interest accurately based on morphological properties or changes in fluorescence. To increase the speed of this technique, an automated laser microdissection technique called laser-enabled analysis and processing has been developed [16]. However, laser microdissection can be cumbersome, it may rupture surrounding cells, and it may isolate individual cells incompletely. For these reasons, this technique is not frequently used to obtain cells for HTS.

For decades, fluorescence-activated cell sorting (FACS) has been the default technique to sort cells into well-defined populations. It has become the most widely used technique to isolate single cells for high-throughput studies. FACS can rapidly sort single cells at a high level of purity into 96- or 384-well plates at 10,000 cells per second, a pace that is impossible to match manually [17]. FACS systems work by passing cell suspensions through a small nozzle (70-100 μm in diameter) that creates a continuous stream of droplets, each droplet of which contains a single cell. Electrically charged plates are then used to deflect the droplets containing cells of interest into a microwell plate based on the physical, chemical, or optical properties of the cells that are enhanced using antibodies conjugated to fluorescent probes [15]. Sorting single cells through FACS requires a priori knowledge of surface markers for specific cells and can be difficult to perform in scenarios in which there are limited cells, such as early-stage reproduction and characterization of stem cells (Fig. 6.2). Moreover, the high flow rate and pressure can potentially damage delicate or large cells such as adipocytes as they move through the machine [18]. Most important, FACS does not allow for tracking an individual cell over time, which makes it difficult to determine the dynamic behavior of a cell.

Microfabrication, precision engineering, and rapid prototyping techniques have led to the development of microfluidic devices that allow for sorting low cell volumes on miniaturized devices with rapid throughput [19]. These devices contain thousands of integrated fluid channels, valve control surfaces, and reservoir chambers to separate individual cells [2]. In addition, they reduce the size of the sorting equipment and eliminate biohazardous aerosols

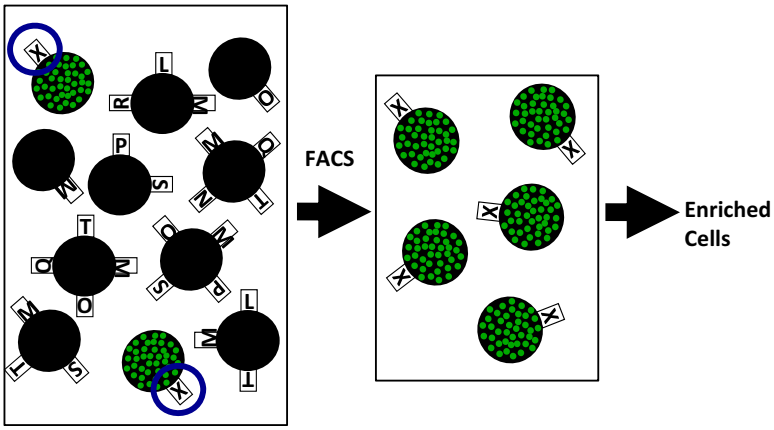

FIGURE 6.2 **Enriching single cells using fluorescence-activated cell sorting (FACS).** FACS can reliably test up to 15 proteins allowing for determination of signaling pathways and enrichment of cells based on surface markers. However, surface markers for enrichment are selected a priori and it is important to determine the best surface marker that can reliably enrich cells for therapeutic use.

[20]. Microfluidic technologies can be either active or passive. Active systems use external fields such as acoustics, electric, magnetic, or optical to displace individual cells into microchambers. The commercially available dielectrophoresis array, for example, uses a nonuniform electric field to exert forces on cells suspended in a liquid and trap them into "cages." This allows for the separation of cells of interest from complex, heterogeneous samples. Passive systems, on the other hand, use inertial forces, filters, and adhesion mechanisms to sort cells [18,20,21]. The commercially available C1 chip from Fluidigm Corporation (South San Francisco, CA) is an example of a passive system in which hydrodynamic traps in a microfluidic channel allow for the isolation of a single cell from a heterogeneous sample. The cell is then subjected to RNA isolation and complementary DNA (cDNA) synthesis within the trap. This system can be scaled to accommodate many traps (up to 800 for the C1 chips), but the largest disadvantage is that the cell pool must be homogeneously sized because the microfluidic traps are sized for an average cell. If the cells are too large, they will rupture before reaching the trap. If the cells are too small, the traps will capture doublets or multiplets [22].

Droplet microfluidics is an emerging field of microfluidic technology in which active or passive systems are used to capture cells within discrete micrometer-sized aqueous (micro)droplets. The flow rate of the aqueous fluid determines the number of droplets that are unoccupied by cells. Each occupied droplet acts as a miniaturized reaction vessel and allows thousands of single cells to be analyzed in parallel every second. Whereas the droplets allow for fluorescent imaging and PCR analysis, they can also keep the cells live for a few hours to enable the analysis of dynamic cellular behavior such as enzyme kinetics or the response to drugs, antibiotics, biologic, and environmental factors. The commercially available 10X platform for example, uses droplet technology for single-cell genome sequencing and RNA seq [23]. In the RNA seq platform, cells are run through a microfluidic chip and single cells are individually encapsulated within gel beads. Each bead has a unique bar code to identify the source cells. The cells then undergo reverse transcription to create bar-coded cDNA. All cDNA from a single cell share the same bar code. The cDNA is then fragmented, amplified, and sequenced. Full sequences are reconstructed from the short-read sequences and expression levels for single cells are determined based on the number of transcripts expressed with the same unique bar code. This technology has been employed to investigate chimerism in immune cell populations, screening for Clustered Regularly Interspaced Short Palindromic Repeats interference, and testing single nucleotide polymorphisms in noninvasive prenatal testing, among other applications [23–25].

ACQUIRING SINGLE-CELL DATA

Once individual cells are collected, single-cell analysis can be performed. The flow of biological information in cells is from DNA to RNA to protein, with DNA containing the genetic information of all cellular organisms, with RNA functioning as the messenger of this information and proteins acting as the working force to determine the phenotype of the organism. Random mutations bring about changes to the DNA. Injury and disease bring about changes in the transcribed RNA and protein. Sometimes there are modifications in the phenotype with no changes to the DNA sequence owing to changes in gene expression. These alterations, called epigenetic changes, can be

influenced by various conditions including age, the cellular microenvironment, or disease states. This section describes the various high-throughput techniques developed to study changes in the DNA, RNA, protein, or epigenetics of individual cells.

Single-Cell Genomics

Next-generation DNA sequencing allows for the comprehensive study of minute amounts of DNA from an individual cell. This technology has uncovered the evolutionary history of cells, genomes of unculturable microorganisms, and genetic mosaicism in normal physiology, disease, and cancer [26,27]. Genetic mosaicism is the presence of two or more populations of cells with different genotypes within the same individual, developed from a single fertilized egg. Although it has long been known that cancer is a mosaic disorder, in somatic tissues, early studies of genetic mosaicism were limited to abnormalities in skin development such as epidermolysis bullosa and ichthyosis. However, the advent of single-cell DNA sequencing unearthed variations in the chromosome, copy number, and single nucleotide sequences in a variety of tissue types, and mosaicism is now seen in a diverse range of clinical disorders that can be gonadal, somatic, or gonosomal [28].

To obtain single-cell genomic data, single cells are isolated and subjected to whole-genome amplification. This can be achieved through either PCR amplification or isothermal methods such as multiple displacement amplification [18]. The isothermal methods have greater coverage or comprehensiveness compared with the PCR-based methods; however, they display lack of uniformity or accuracy and precision [26]. Therefore, most single-cell genomic approaches use a hybrid method that consists of a limited isothermal amplification step followed by PCR amplification. These hybrid techniques include displacement degenerate oligonucleotide-primed (DOP)-PCR and multiple annealing and looping-based amplification cycles (MALBAC) and differ based on whether degenerate primers or random primers are used for amplification. DOP-PCR and MALBAC have uniform coverage that results in greater sensitivity and accuracy [29,30].

Once the genome is amplified, it is subjected to single-cell exome sequencing or entire-genome sequencing [31]. An important consideration while sequencing is that false variants increase as the size of the genome region increases. Furthermore, errors can be introduced in any stage, including the single-cell isolation and whole-genome amplification steps. Hence, it is imperative to develop tools that differentiate technical aberrancies and noise. The quality metrics include visual conformation of isolated cells as well as quantification of the whole-genome amplification product.

Single-Cell Transcriptomics

Whereas genomics allows for the identification of genetic alterations within cells, transcriptomics allows the investigator to understand changes in the function of cells. Single-cell transcriptional studies emerged with the integration of single-cell quantitative polymerase chain reaction (qPCR) into microfluidic platforms, allowing for massively parallel qPCR reactions on a small chip [32]. The Biomark chip from Fluidigm Corporation, for example, provides a highly sensitive platform that allows for probing of individual cells for the expression of 96 select genes, providing a readout in less than 24 h after sample collection. This platform enables cDNA volumes to be detected that are 1000 times less than those required for traditional qPCR reactions. In this method, a single cell is sorted by FACS into a well of a 96-well plate. The cDNA conversion step is combined with a low-cycle reverse-transcriptase (RT)-PCR step that preamplifies the cDNA with the select 96 primers before it is loaded onto a microfluidics chip. The microfluidics chip is subjected to qPCR in a Biomark machine (Fluidigm Corporation) where the cDNA from each cell is amplified by each of the 96 primers, which results in 9216 data points (Fig. 6.3A). This microfluidic-based qPCR technology generates highly accurate and precise gene expression data and has been used to determine heterogeneity among a wide range of cell types including fibroblasts, adipose stromal cells, glioblastomas, and hematopoietic stem cells [2,33–36]. The main downside of this method is that the number of genes that can be evaluated depends on the size of the microfluidics chip [37].

HTS of whole transcriptomes through RNA seq enables profiling of the transcriptome. This technology enables the detection of absolute levels of gene expression, gene fusions, single nucleotide variants, insertions, deletions, and weakly expressed genes. Unlike hybridization methods such as microarrays, RNA seq does not require prior knowledge about the organism (species or transcript-specific probes), which enables the identification of both known and novel transcripts. It also provides a signal-to-noise advantage over microarrays by eliminating cross-hybridization, nonideal hybridization, and DNA contaminants. DNA contaminants are negated by unambiguously mapping DNA

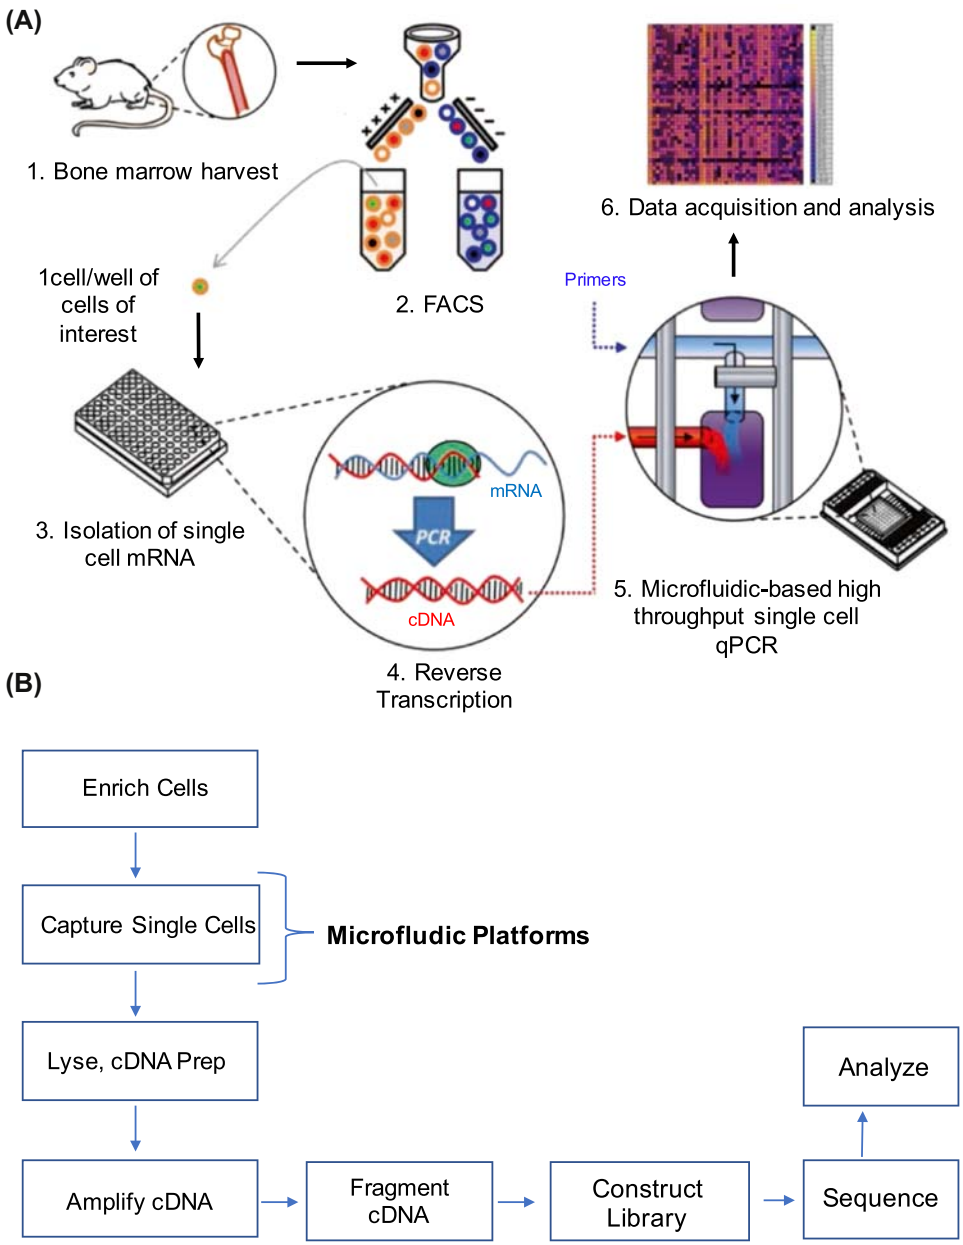

FIGURE 6.3 **Single-cell transcriptomics.** Schematic of high-throughput, microfluidic chip-based, single-cell transcriptional analysis demonstrates how a single cell is sorted by fluorescence-activated cell sorting (FACS) into each well of a 96-well plate that has been preloaded with reverse transcriptase–polymerase chain reaction (RT-PCR) reagents. A low-cycle RT-PCR preamplification step creates complementary DNA (cDNA) for each individual cell. Single-cell cDNA is then loaded onto the microfluidics chip along with the primer-probe sets for 96 gene targets and quantitative polymerase chain reaction is performed in the Biomark machine, leading to 9216 data points per chip (A). Schematic of single-cell RNA sequencing demonstrates that cells first need to be isolated and enriched by techniques such as FACS. Microfluidic technologies are then used to isolate single cells. Reverse transcription of messenger RNA is performed to produce cDNA that is amplified through PCR. The amplified cDNA is sheared to reduce the length of the sequences and the fragments are sequenced to the number of desired reads. Finally, the sequences are reconstructed and matched to a known library and the copy numbers of transcripts are determined (B).

sequences to unique regions of the genome. Based on its sensitivity and range of expression, there has been an overwhelming interest in using RNA seq on single cells to determine heterogeneity within cell populations, identify rare cells, and characterize poorly defined cells.

Although individual protocols vary slightly, the overall processing of single-cell RNA seq is similar. First, template switching by reverse transcription of messenger RNA (mRNA) is performed to produce cDNA that is amplified through PCR. The amplified cDNA is sheared to reduce the length of the sequences and the fragments are

sequenced to the number of desired reads. Subsequently, the sequences are reconstructed and matched to a known library and the copy numbers are determined [37]. This method allows sequencing of all mRNA molecules, resulting in an unbiased approach to evaluating the transcriptome and allowing for the discovery of novel transcripts or splice variants (Fig. 6.3B) [38–40].

Despite the comprehensiveness of the technique, single-cell RNA seq is associated with a myriad of technical issues that result in uncertainty of the generated data. Most microfluidic platforms require several thousands of cells to be loaded in highly concentrated solutions as starting material before the cells are distributed into individual traps or microdroplets. In most cases, these cells are freshly sorted by FACS to obtain a homogeneously sized population. Although tested for viability before loading into the microfluidic chamber, it is unlikely that all the FACS-sorted cells are live at the start of the assay. In addition, microfluidic separation of cells may cause cell rupturing or the microchambers may capture doublets or multiplets. Several technologies do not allow for the visualization of entrapped cells within the traps or microdroplets before cDNA synthesis. If doublets are captured, it is difficult to distinguish the data obtained from a single cell. Similarly, if the cells are ruptured and only part of the RNA becomes reverse transcribed, it is difficult to separate these data from those of an intact single cell. Many sequencing technologies use spike-in RNA controls (either external RNA controls consortium or custom) to determine the quality and success of the library constructed. These spike-ins provide transcripts at a known sequence, length, and concentration and serve as a quality control for the isolated single-cell RNA. Although used as controls, in several cases, the spike-ins compete and become reverse transcribed instead of the cellular mRNA. mRNA by itself is a delicate molecule and easily prone to degradation. Therefore, strict quality control measures of fragment range in the Bioanalyzer or Experion is helpful.

Single-Cell Proteomics

Proteomics provides information about the biochemical activation state of the translated protein. The activation of a protein is represented by its phosphorylation, acetylation, proteolytic cleavage, ubiquitylation, change in localization, conformation, or abundance within cells [41]. Traditionally, these processes have been analyzed by population assays such as western blotting and immunofluorescence imaging. However, the analysis of these changes in single cells is challenging because of the paucity of protein amplification techniques [18]. FACS has been the most well-established technique for determining the relative expression of surface proteins on single cells; it distinguishes individual cells within a mixed population of cells and enriches live cells based on surface markers [42]. FACS can reliably test up to 15 proteins and enables the determination of signaling pathways and networks within individual cells. However, these are markers selected a priori, and it is important to understand which is the best surface marker that can enrich cells before therapeutic use (Fig. 6.2). When the cells are fixed and permeabilized, FACS also helps in determining the intracellular activation state within individual cells. Most commercial flow cytometers require manual sample preparation of cells; however, improvements have been made in microfluidic platforms that allow for handling, sorting, and flow cytometry [42].

Groups of cells can also be fluorescently bar coded with unique signatures of fluorescent dyes, so that they can be mixed together, stained, and analyzed as a single sample. This results in the possibility of high-throughput FACS analysis. Fluorescent bar coding reduces antibody consumption by 10-fold to 100-fold and minimizes pipetting error, staining variation, and the need for normalization. The robustness of data is increased through the combination of control and treatment samples, and the speed of acquisition of data is enhanced [43].

Mass cytometry is a combination of flow cytometry with mass spectrometry and provides measurement of over 40 parameters simultaneously at a single-cell resolution. This process allows for millions of cells to be assayed, enabling sufficient sampling to identify major cell subsets from the heterogeneous cell sample [44]. Unlike conventional FACS, which uses fluorophores as reporters causing spectral overlap, mass cytometry uses unique, stable, heavy metal isotopes of atomic weights different from those employed in mass spectrometry. This allows for greater number of parameters to be analyzed with little signal overlap between parameters. The instrumentation used for mass cytometry is called cytometry by time-of-flight [44]. Disadvantages of mass cytometry are that it cannot determine forward and side scatter, and hence cannot determine cell size and shape; the acquisition rate is slower than FACS; and cells must be fixed before analysis. Thus, mass cytometry can be used to analyze subpopulations of cells but cannot be used to enrich subsets of live cells based on these markers.

A long-standing challenge in proteomic analysis is the transformation of high-resolution mass spectrometry as a cell population–averaging tool into a single-cell analyzer. Advancements have enabled the identification of 500–800 nonredundant protein groups from single cells using less than 0.2% of the total protein of the cell as starting material

[45]. However, the main drawback is a low signal-to-noise ratio when considering the low levels of protein within a single cell [42].

Single-Cell Epigenetics

Epigenetic modifications such as DNA methylation or histone modifications are functionally relevant changes to the genome that perturb gene expression without altering the DNA sequence. The best-studied epigenetic modification is DNA methylation, which consists of the addition of a methyl group to cytosine residues (5-methylcytosine). Usually, this alteration is inversely correlated with gene expression levels with implications for tumor biology, disease progression, resistance to standard drug treatments, and relapse.

Attempts have been made to study epigenetics at the single-cell level. Single-cell genome-wide bisulfite sequencing (scBS-seq) has been used to assess the epigenetic heterogeneity of DNA. In this technique, the DNA of a cell is treated with bisulfite, which results in DNA fragmentation and the conversion of unmethylated cytosines to thymine [46]. Complementary strands of the fragmented DNA are synthesized using adaptor sequences and random oligonucleotides. This step is repeated several times to obtain enough tagged DNA and copy numbers of each fragment. A second adaptor is integrated, PCR amplification is performed, and cDNA libraries are generated, which are subjected to sequencing [46]. The number of CpGs obtained from the analyzed data depends on the depth of sequencing.

Furthermore, to understand the complex relationship between DNA methylation and transcription in heterogeneous cell populations, scBS-seq of the genome and RNA seq of the transcriptome have been performed on the same cell. Such analyses have clinical implications in contexts such as in vitro fertilization, in which the number of cells for analysis is limited [47].

Advances in sequencing have cleared the way for many other methods to assess single-cell modifications. These include formaldehyde-assisted isolation of regulatory elements followed by sequencing, chromatin immunoprecipitation sequencing, DNase sequencing, Micrococcal nuclease followed by sequencing, and assay for transposase-accessible chromatin sequencing. The general principle of these technologies is fragmentation of DNA and sequencing of the regions that have been bound by DNA-binding proteins [48]. This has allowed for improved profiling of DNA-binding proteins, histone modifications, and nucleosomes [49].

ANALYZING SINGLE-CELL DATA

As detailed previously, single-cell technologies enable alterations in genes, gene expression profiles, and protein production within single cells to be determined [50]. However, single-cell sequencing technologies generate large amounts of data requiring computational infrastructure and expertise. For example, whole-genome sequencing of 100 individual cells at read lengths of 75 base pairs requires about 15 TB of storage space. Subsequently, the quality of these data needs to be assessed so that variations resulting from noise can be distinguished from true biological variations. The vetted data are then normalized and analyzed to reveal subpopulations of cells or information of clinical relevance. Thus, it is essential from the start to understand whether the biologic question requires a broad net to be cast to capture all information about individual cellular behavior, or whether a targeted approach is beneficial to reveal the most important cellular features affecting human health.

Reducing Noise in Single-Cell Data

Noise in data generated from single-cell technologies can be classified into two major types: technical and biological [10,51]. During sequencing, technical variations can occur as a result of insufficient amounts of isolated RNA/DNA, instability of the minute amounts of isolated RNA, problems in amplification of DNA/RNA, and bias during library preparation [51]. It has been estimated that over 80% of variation in expression patterns in single-cell RNA seq results from technical variations in measurement [51]. Biological noise can be caused by differences in the stages of the cell cycle, the epigenetic status of the cell, and the cellular microenvironment. It can also occur owing to the ineffective isolation of initial cells [26]. Biological confounders account for up to 18% of noise in single-cell RNA seq data and are especially problematic when analyzing rare subpopulations of cells [51].

To build accurate clinical models to guide diagnosis and treatment, it is important to minimize variability and noise in single-cell analysis techniques. This can be achieved by identifying and removing low-quality cells through

two major steps: (1) quality control measures at each experimental step, and (2) quality control during data analysis [50].

Quality control at the experimental level can be performed at various stages by testing for the viability and size of the isolated cells, visually inspecting entrapment of cells within microfluidic chambers, testing the quality of DNA/RNA, analyzing the size of the fragments generated, and quality testing the library preparation to ensure the data from each cell reaches a minimum threshold of usability. An interesting solution to detect doublets or multiplets is to mix cell populations from two different species. For example, when studying cardiomyocyte heterogeneity, cardiomyocytes from murine and human cells can be isolated and processed together. During data analysis, seemingly individual cells displaying mixed cDNA patterns can be discarded. The number of single cells analyzed can also be increased, resulting in a higher detection power [52]. However, this approach increases the amount of data generated when the same depth of sequencing is desired and requires greater computation capacity and resources. Another approach is to use nanoliter volumes of sample preparation to yield fewer false positives in gene expression studies compared with microliter formulations [10]. This method requires the use of automated liquid dispensers and robots.

Quality control at the data analysis level can be performed by excluding cells with minimal numbers of reads or excluding cells with a high number of poor-quality reads. Furthermore, research groups have attempted to create models to remove biological confounding factors. One group succeeded in determining where cells lay within their paths of differentiation by creating a model that adjusted for cell cycle−specific changes in gene expression [53].

Normalizing Single-Cell Data

Once clean data are identified, normalization can be performed to compare data from one cell with data from other cells. Normalization of data can be performed through a variety of techniques and can vary depending on the technology used [54]. This has proven to be challenging for all single-cell analysis methods. For bulk RT-PCR studies, housekeeping genes have been used to normalize gene expression against that of a gene with relatively constant expression across cells. However, at the single-cell level, there is significant variation between these housekeeping genes [55]. This has led to normalization with a combination of housekeeping genes or with genes that are best for the tissue being evaluated [56]. Some researchers even suggest using no normalization owing to these significant variations between cells [57].

As with single-cell RT-PCR analysis, there are also multiple methods for data normalization with RNA sequencing [54]. One method involves median normalization, in which the mean count for all cells of each gene is calculated and a size factor is created by determining the median of the fraction of each sample's count over the mean across all samples. The size factor is then applied to all samples. Another method to normalize the data that accounts for technical artifacts is the use of spike-ins [54]. This involves introducing synthetic transcripts into each cell's library at a known concentration. Knowledge of what the expected and observed counts are can then be used as a multiplicative factor to account for technical errors that occur during the process.

Mathematical Identification of Cellular Subpopulations

Once the data have been vetted, they can be used in various ways. One specific purpose is to find important subpopulations with unique functions [50]. Single-cell technologies have demonstrated that cells that were once thought to be homogeneous display significant variations in their functional profiles and instead exist as subpopulations. However, perfectly equivalent expression profiles between any two cells are highly unlikely, which pushes the biostatistician to determine how best to group cellular subpopulations.

A variety of techniques have been used to cluster cells within a population and reveal subpopulations. Two main categories of clustering include hierarchical and partition clustering. However, many variations exist within these groups [58].

Hierarchical clustering functions by combining or dividing groups and creating a hierarchical structure that demonstrates this order (Fig. 6.4). The two main methods within this technique include agglomerative nesting and divisive analysis [47]. Agglomerative nesting methods involve first arranging the data into a series of sets with one object in each set. For the purposes of single-cell analysis, an object would be considered the data profile from a single cell. A cost function is used to determine which of these sets is "cheapest" to combine. The two objects are then combined, removed from the list, and replaced with a combination of their components. The process is repeated until all items exist within a single group. Divisive analysis differs from agglomerative nesting in that it begins with one set

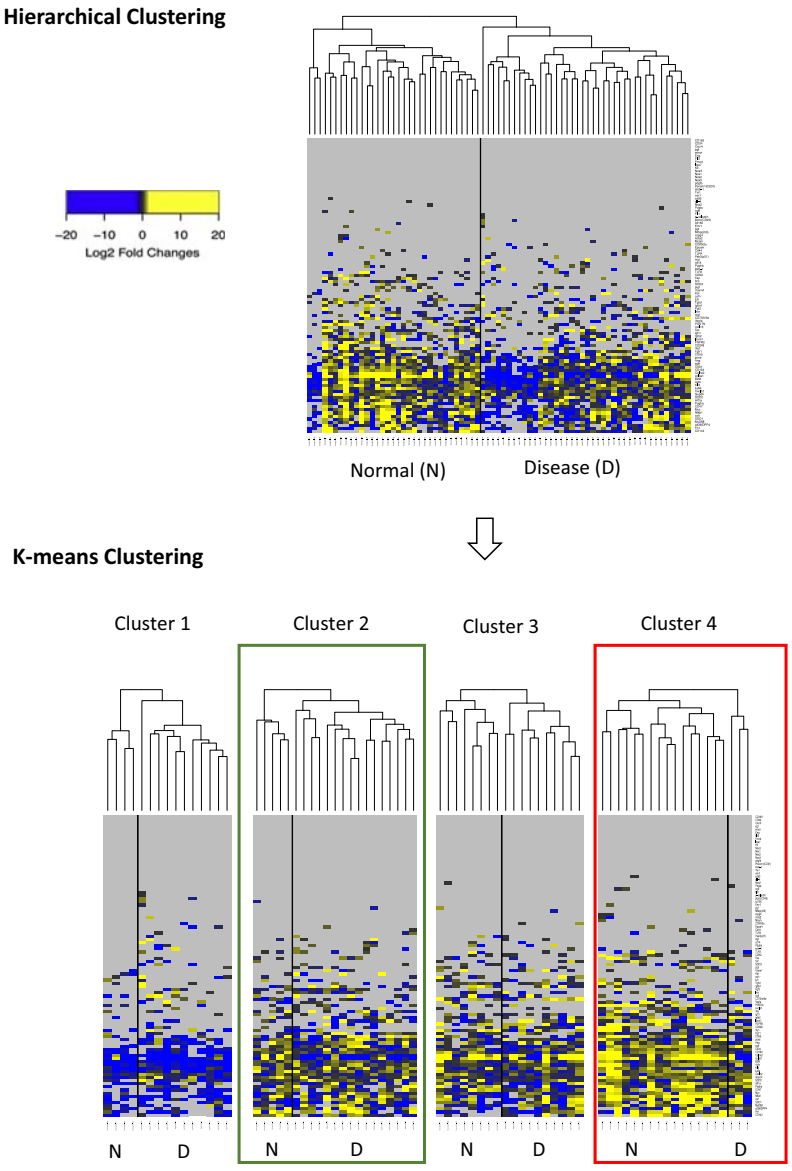

FIGURE 6.4 **Hierarchical clustering followed by k-means clustering can reveal novel subsets that are altered in disease.** Single-cell transcriptional data can be represented by hierarchical clustering with each cell, represented as a column, and each gene, represented as a row in the heat map. There data can further be clustered using k-means clustering to reveal subsets that are altered in disease. Cells in cluster 2 (*green box*) show an increased frequency in the diseased state, whereas cells in cluster 4 show a decreased frequency in the diseased state (*red box*). These cells can then be specifically targeted to test for therapeutic outcomes.

containing all objects. The object with the greatest dissimilarity from the rest of the objects is separated from the group. The remaining objects are then evaluated to see whether they should be included in this separated group. The process is repeated until there are as many clusters as there are objects. Each separation is demonstrated within a dendrogram to show the level of separation among the various groups. Once an object is placed into a group, it cannot be reassigned from that group. The specific mathematical approach to clustering can be varied based on the cost function used within the algorithm.

In contrast to hierarchical clustering, partition clustering involves a set number of clusters that are defined a priori [47]. This method involves placing objects into a cluster with the closest center. The goal is then to minimize dispersion within each cluster through iterative reallocation of the objects within clusters. Unlike hierarchical clustering, this method enables an object's cluster assignment to be changed at any step. Two specific examples of partition clustering are k-means clustering and partitioning around medoids (PAM). The difference between these two methods is that the cluster center in k-means is the average of the objects, whereas in PAM the center is an actual object.

A significant number of modifications have been made to both hierarchical and partition clustering. One example is demonstrated by the addition of fuzzy c-means clustering. The methods of partition clustering listed earlier involve placing an object into a single cluster, which is referred to as "hard assignment" [59]. Fuzzy c-means clustering uses a "soft assignment," which allows placement of an object into multiple clusters. This becomes useful for objects that lie between two clusters.

With partition clustering, a key requirement is to determine how many clusters one should create. Many methods have been presented to attempt to determine the optimal number of clusters, with none obviously superior to the others [59]. These include, but are not limited to, minimum message length criteria with a Gaussian mixture model, minimum description length, Bayes information criterion, Akaike information criterion, and gap statistics. Even with these objective measures, there is no perfect method to determine how many meaningful clusters exist within a given data set.

DETERMINING SUBPOPULATIONS

Although cells are defined by their intracellular characteristics (transcription, translation, epigenetics, metabolism, etc), the only way to isolate live cells is to use markers on their surface. Many of these surface markers defined in the literature may have little to no mechanistic relationship to the intracellular function of the cell, but they are selected by educated guesses. For the first time, single-cell technologies allow the correlation of surface markers to the intracellular cellular machinery to ensure that the best surface markers are selected to determine cellular subpopulations. However, to identify the best signature for the cell, a broad net needs to be cast encompassing all surface markers.

Single-cell RNA seq offers the widest resolution and can inform decision making. However, the large datasets generated by this technology contain high amounts of technical noise, masking, or amplifying cellular heterogeneity and make it difficult to define rare subpopulations accurately and precisely. This is like to finding a needle in a haystack [60]. From a technical perspective, it is unclear whether single-cell RNA seq will ever approach the accuracy and precision of single-cell qPCR. Such unreliability is not acceptable for prospectively isolating and functionally testing cell subpopulations and generating therapeutic products that will be used in humans. To overcome these shortcomings, a single-cell approach was developed and validated that leverages the comprehensiveness of single-cell RNA seq and the accuracy and precision of single-cell qPCR [60].

Specifically, this approach uses information from single-cell RNA seq, metaanalysis of publicly available microarray databases, and peer-reviewed literature to arrive at 96 genes with which to interrogate cells of interest (fibroblasts, hepatocytes, etc.). These genes include cell cycle, transcriptional, and cell-specific genes that appear to be sporadically expressed by the three screening analyses. The 96 genes are then transcriptionally analyzed in individual cells by qPCR on a reliable Fluidigm Biomark microfluidic chip. The single-cell transcriptional data are subjected to hierarchical and k-means clustering to validate expression of the 96 genes and accurately determine systematic variations within the cells. This is the first part of the analysis, which determines whether putatively homogeneous cells contain undiscovered subpopulations.

At this point, if there are subpopulations (i.e., autonomous clusters), it is still not clear whether these subpopulations have any differential function. It is possible that the transcriptional clusters are merely a descriptive curiosity. To determine functional relevance requires isolation of the subpopulations and prospective functional analysis. Only cells with differing functionality are considered "true" autonomous cell subpopulations. To prove functional relevance, the subpopulations need to be isolated with surface markers using existing FACS technology. To do this, single cells are subjected to transcriptional analysis for a second time. Mathematically, the original 96 genes can be winnowed to eight or nine "cluster defining" genes, which leaves 80 or more open channels on each chip. These open channels are used to correlate the cluster defining genes blindly with all known surface markers capable of being used for FACS sorting. This results in a surface marker combination with the highest specificity and sensitivity for each subpopulation (receiver operating characteristic curve closest to 1). The surface marker combination identified is used to isolate the subpopulations of interest accurately and precisely using FACS, and the cells are functionally tested (Fig. 6.5). This technology can be used to speciate any cell type, isolate rare cells, and study cellular alterations in any disease state [33].

This single-cell approach has been used to (1) study cellular heterogeneity in various cell types including fibroblasts, mesenchymal stem cells, hematopoietic stem cells, neural stem cells (NSCs), and glioblastomas [7,33,34,36,61]; (2) determine subpopulation alterations in a wide range of diseases such as diabetes, aging, fibrosis, and cancer [34,35,62,63]; and (3) identify surface markers accurately for the prospective isolation of cells for therapeutic use [33].

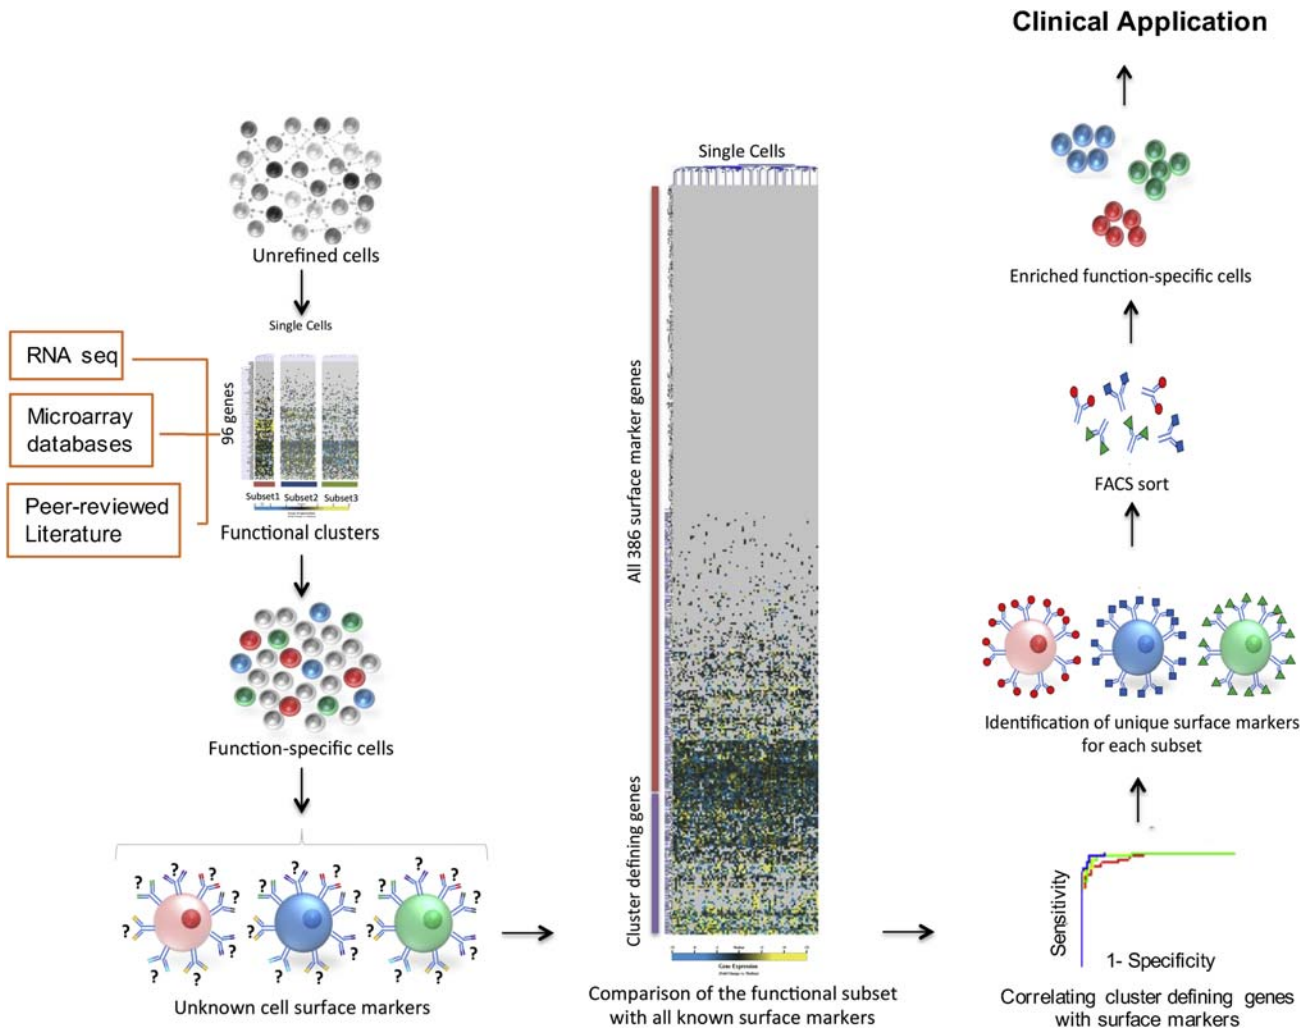

FIGURE 6.5 **Development of a rational framework for the identification and isolation of functional cell subpopulations.** Seemingly homogeneous cells within a population are subjected to single-cell transcriptional analysis to determine cell subsets based on differential gene expression across 96 genes. The 96 genes are selected from RNA sequencing, publicly available microarray databases, and peer-reviewed literature. The subsets are then probed with all 386 surface markers in parallel with the intracellular functional genes to determine the ideal surface markers that select for these clusters. Because the multiplex chip allows for the probing of only 96 genes, at least five chips are used and single-cell transcriptional data across these chips are displayed. Transcriptional data of the 386 surface markers is then blindly correlated with intracellular genes to determine the surface marker combination that identifies the cell with the highest sensitivity and specificity. Finally, antibodies for the selected surface markers are employed to fluorescence-activated cell sort (FACS) and enrich the functional subsets that can readily be used for investigation and therapy.

Development of Cell-Based Therapies

Cell-based therapies have been developed based on 'legacy' surface markers derived from the literature and from historical data. Thus, when trials fail, it becomes difficult to determine the best way in which to proceed. Customized therapies require an in-depth knowledge of both disrupted cellular pathways in diseased tissue and cell surface marker information on cells that can bring about the best therapeutic effect.

The effectiveness of the Needlestack platform was tested to identify and isolate single-cell subpopulations rationally for therapeutic use. Human subcutaneous adipose-derived stromal cells (ASCs) were selected as the cell therapy source [33]. These cells can easily be isolated from the subcutaneous tissue and were tested widely in preclinical trials based on their ability to produce growth factors and deposit extracellular cells. However, ASCs are a heterogeneous group of cells obtained from excluding hematopoietic cells and endothelial cells and enrich CD34-expressing cells from the stromal vascular fraction. If these cells are to be used therapeutically, it is imperative to understand the healing effects of the various cell subsets within this population.

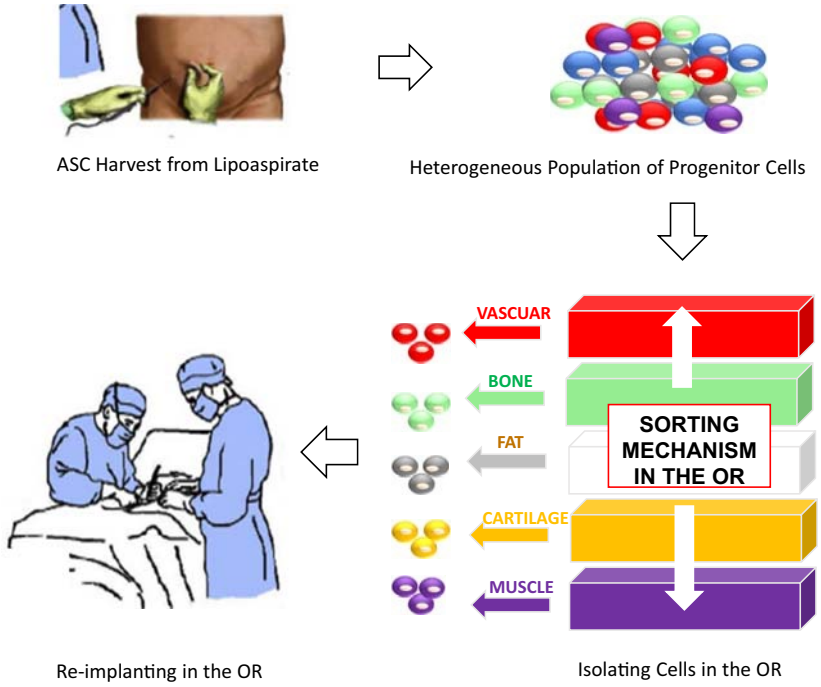

FIGURE 6.6 **Isolating the best cell for any given clinical application.** Single-cell technologies can identify which cells in a heterogeneous population will provide the best outcome for a specific clinical application. Thus, heterogeneous cells such as adipose-derived stromal cell (ASCs) that are obtained from lipoaspirates in the clinic can be enriched for these highly potent cellular subsets in the operating room (OR) and delivered immediately to patients who require therapy.

Hence, ASCs were individually isolated and subjected to single-cell qPCR against 96 genes involved in tissue repair. The gene list was informed from the literature and publicly available microarray databases. The resulting data were subjected to k-means clustering to identify subpopulations. The subpopulation most favorable to wound healing was selected. This subpopulation was defined by 18 genes, which left open 78 channels to interrogate cell surface marker expression in a second set of experiments. Upon combining five chips, it allowed for an unbiased and blinded correlation with 386 surface markers. This blinded correlation (mathematically performed by linear discriminant analysis) identified two surface markers that precisely selected the subpopulation of interest [33].

Next, these two surface markers were used to enrich the ASC subpopulation by FACS, and the cells were delivered to diabetic wounds. Diabetic wounds displayed a normalization of the healing response with the enriched ASCs. Interestingly, the application of ASCs depleted of this important subset demonstrated no effect on diabetic healing, whereas application of the unsorted, heterogeneous ASCs improved but did not normalize diabetic healing. This was the first cell-based targeted therapy to normalize diabetic wound healing in a preclinical setting and could be extended to the treatment of any disease (Fig. 6.6). Importantly, this single-cell method for selecting the best cellular subpopulation exists during a time when US Food and Drug Administration—approved cell-based therapies such as Apligraf and Carticel have shown efficacy and have resulted in reduced overall health care costs for patients.

CLINICAL IMPLICATIONS OF CELLULAR HETEROGENEITY IN TISSUE REPAIR AND DISEASE

Customized therapies need an in-depth analysis of impaired cellular pathways in disease and a granular understanding of cellular subpopulation changes that underlie disease. Although population-averaged assays cannot provide such resolution, the development of novel single-cell technologies provide great promise for targeted basic science and clinical discovery. This section summarizes advancements made using single-cell technologies in understanding the molecular and cellular changes that modulate diabetes, aging, wound healing, cancer, and fibrosis (Fig. 6.7).

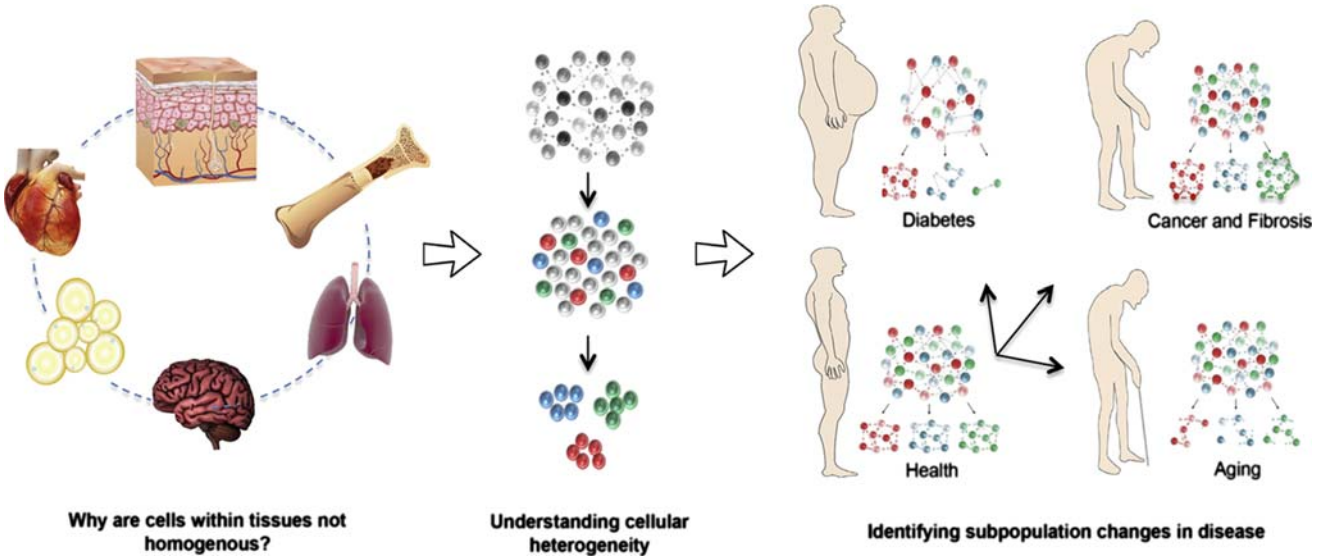

FIGURE 6.7 **Understanding the functional relevance of cellular heterogeneity.** The development of novel single-cell technologies offers great promise for targeted basic science and clinical discovery. These techniques allow for the comprehensive mapping of cells within various tissues in health and inform us about alterations in cellular subsets during aging or diseases such as diabetes, fibrosis, and cancer.

Cellular Heterogeneity in Diabetes

Diabetes brings about cellular and molecular impairments in a wide variety of cell types including stem and progenitor cells leading to tissue dysfunction. In many cases, owing to hyperglycemic memory, these cellular perturbations do not normalize even after a return to normoglycemia, resulting in persistence of tissue dysfunction [64]. Single-cell interrogation of subcutaneous ASCs in type 1 and type 2 diabetes has demonstrated that the global dysfunction in ASCs is brought about by the selective depletion of discrete ASC subpopulations, impairing wound healing in diabetes [33,62]. Similarly, type 1 and type 2 diabetes bring about intrinsic defects within bone marrow progenitor cells through selective depletion in provasculogenic subpopulations. These defects are not correctable by restoring glucose homeostasis [65]. Within the bone microenvironment, single-cell RNA seq has also revealed intrinsic skeletal stem cell impairments caused by hyperglycemic changes within the stem cell niche [66].

Interestingly, single-cell analyses revealed differences within insulin-producing pancreatic β cells, a population long considered to be homogeneous. These studies indicated that adult β-cell subpopulations can differ in size, insulin production, insulin secretion, and precursor cell potential with relevance to an understanding of diabetes and implications for enhancing cell replacement therapies for treating diabetes [67,68].

Cellular Heterogeneity in Wound Healing

Wound repair is an example of a highly heterogeneous tissue with several different cell types working in concert at distinct spatiotemporal stages to bring about healing [6]. Immediately after a wound is formed, neutrophils are recruited from the bone marrow as the first line of defense against bacteria. Classically, neutrophils have been considered a homogeneous population of terminally differentiated cells with a conserved function. Their limited proliferation ability, short life span, and low mRNA content (10–20 times lower than leukocytes) have made it difficult to tease apart the various subsets of neutrophils through population techniques [69]. However, single-cell technologies revealed both phenotypic and functional versatility in neutrophils that extend beyond their antimicrobial activity to their impact on disease and their ability to activate other cells such as macrophages [70–72].

With the evolution of single-cell technologies, the definition of a macrophage has evolved as a cell that engulfs and digests pathogens, particles, and dead cells. It is now accepted that tissue macrophages have the unique ability of plasticity, in which the cells modulate their activation state based on external cues such as the presence of infection, growth factors, and cytokines in their microenvironment [73]. The diversity within macrophages is seen at the phenotypic, genetic, and epigenetic levels, leading to subsets of macrophages that are proinflammatory, antiinflammatory, and provascular, or transitioning between these states. Furthermore, there are macrophages in the adult tissue that originate during embryonic development that are not derived from monocytes [74]. Thus, spatiotemporal

factors within the wounded tissue microenvironment determine the presence of macrophage subpopulations, each potentially with a unique function.

Neovascularization follows the inflammatory phase of repair in every tissue. During this phase, blood vessels are at various levels of maturity. Some vessels are intact and are maintaining blood fluidity, some are leaky and aiding the influx of inflammatory cells, and others are actively undergoing angiogenesis. During angiogenesis, endothelial cells are sprouting and proliferating, whereas pericytes within the basal lamina are activated to scaffold and provide structural integrity to the new vessels. Circulating progenitor cells from the bone marrow are also recruited to support new blood vessel formation. Appropriate synchronization of these cells is crucial for neovascularization and healing. However, population assays have been unsuccessful in definitively characterizing pericytes and circulating progenitor cells within the repairing wound.

In wound healing, active proliferation and reciprocal interactions of fibroblasts with other cell types in the wound environment, such as keratinocytes, endothelial cells, adipocytes, inflammatory cells, and resident stem cells, are important. Although reduced extracellular matrix deposition by fibroblasts can contribute to nonhealing wounds, excessive extracellular matrix deposition can lead to hypertrophic scarring and fibrosis [75]. Single-cell analyses have led to the identification of various fibroblast subpopulations with distinct functions after injury [7,76]. These technologies have identified unique subsets of fibroblasts that are responsible for the scar response.

Cellular Heterogeneity in Fibrosis

Tissue fibrosis is a common complication that underlies impaired tissue regeneration and tissue dysfunction in response to a variety of insults [6,75]. Fibrosis is a poorly understood process, but it is largely attributed to excessive extracellular matrix deposition by fibroblasts. However, fibroblasts are a heterogeneous population of cells [77]. To this end, single-cell technologies have been employed to interrogate fibroblast heterogeneity. It has been demonstrated that CD26+ fibroblasts constitute a distinct subpopulation of dermal fibroblasts, which is the primary cell type for excessive collagen deposition and scarring during wound healing associated with fibrosis [7]. Similarly, heterogeneity in fibroblasts mediating pathology such as pulmonary fibrosis and renal fibrosis have also been described in the literature [78,79]. Moreover, matrix stiffness cues from cross-linked collagen can induce other cells to turn into fibroblast-like cells, further contributing to fibroblast heterogeneity [80].

Macrophages are one of the cell types that deposit collagen in response to matrix stiffness. Thus, cellular heterogeneity in macrophage populations has formed the basis of many fibrosis studies. Traditionally, macrophages have been classified into proinflammatory M1 cells and antiinflammatory M2 cells [81,82]. Time-dependent shifts in relative proportions of M1/M2 macrophages underlie the reparative process as well as dysregulated excessive inflammation in the heart, kidney, and lungs. Comprehensive gene expression analysis of macrophages coupled with surface marker screening revealed that Ceacam1+/Msr1+/Ly6C−/F4/80−/Mac1+ cells, a distinct subpopulation of cells, is the chief contributor to bleomycin-induced fibrosis [83]. Similarly, subpopulations of macrophages that express CD34/CD68 have been found to be more prone to differentiate into myofibroblasts [84]. Single-cell transcriptional analysis has also been employed to study heterogeneity in fibrocytes, which are hematopoietic cells depositing collagen during tissue repair and fibrosis. This revealed the presence of a CD45+/CD11b+/F480+ macrophage subpopulation forming fibrocytes during wound healing [35]. Further research into tissue-specific cellular heterogeneity will help develop therapeutic strategies to control fibrosis. Enhanced understanding of cell heterogeneity in fibrosis could lead to strategies for cellular reprogramming, with implications in wound healing therapeutics, tissue engineering, and regenerative medicine [77].

Cellular Heterogeneity in Aging

Aging affects the regenerative capacity of most tissues. At the stem and progenitor cell level, these changes are attributed to both alterations of the intrinsic stem cell state and perturbations in the composition of stem cell subpopulations, which have been difficult to dissect in the past. Single-cell RNA seq has been used to differentiate between these cell-intrinsic and subpopulation differences in hematopoietic stem cells and progenitor cells. From a cell cycle perspective, these studies reveal a reduction in long-term HSCs (LT-HSCs) in the G1 phase with age. From a differentiation perspective, aged short-term-HSCs (ST-HSCs) resemble young LT-HSCs, which demonstrates that aged ST-HSCs fully self-renew and serve as the main source of hematopoietic maintenance in mice [85,86].

Single-cell qPCR has been used to evaluate the effects of aging on subcutaneous ASCs and influence their ability to support neovascularization in a wound healing setting. Although aging does not bring about changes in ASC

number, viability, or proliferative capacity, the single-cell study demonstrated that aging depletes a vasculogenic subpopulation of ASCs, leading to impairments in wound healing [63].

Single-cell RNA seq has been used to characterize adult NSC and progenitor cell populations, to determine heterogeneity within these cells. This resulted in the finding that NSCs can be clustered into early, mid-, and late-stage subpopulations along the stages of activation and differentiation. This study provides an integrative understanding of the NSC lineage with clinical implications in aging [87].

Tumor Cell Heterogeneity and Drug Resistance

Cells within tumors exhibit differential mutations and are derived from multiple lineages resulting in intratumor heterogeneity [52]. Tumor cell heterogeneity is a chief contributor to tumor invasion, metastasis, and resistance to drug therapy [52,88]. Two models have been proposed to drive this heterogeneity. The first, called the clonal evolution model, proposes that most neoplasms originate from a single cell, and the stepwise acquisition of mutations within this clone allows for the formation of more aggressive subclones, leading to tumor progression [89]. The second, theoretically opposing hypothesis, the cancer stem cell model, suggests that only a small subset of cells, called cancer stem cells, have tumorigenic potential, whereas their differentiated progeny have limited proliferation and tumorigenic potential. The elucidation of these two models had depended on xenograft limiting dilution assays and tumor markers from the literature [89]. Powerful single-cell technologies to discern this information had not yet been developed until now. These technologies might be able to suggest that the two tumor models are not mutually exclusive; cells within the tumor may display vast phenotypic plasticity and differentiated tumor cells undergoing dedifferentiation to acquire stemlike properties [90].

Single-cell RNA seq has been used to distinguish transcriptional diversity in genes regulating proliferation, immune response, and oncogenic signaling in cells isolated from human tumors [91]. In human glioblastomas, which is the most common and aggressive form of brain tumor, with an exceptionally low rate of survival, there has been a search for brain tumor−initiating cells. One study using single-cell qPCR identified a distinct DDR1+ subset from murine and human glioblastomas as the primary driver of aggressive tumorigenicity in vivo [34]. Although glioblastoma is a well-established example, there is limited information from other brain tumors. Single-cell RNA seq has been applied to study other brain tumors, such as from patients with oligodendroglioma, and has revealed stem/progenitor cell populations and unique differentiation programs within cells of these tumors [92].

In breast cancer, cancer stem cell subsets have been studied, with CD44high/CD24low cells representing a quiescent invasive mesenchymal state and ALDH+ cells representing a more proliferative epithelial state [93]. Advances in single-cell transcriptional profiling have taken these studies a step further and revealed novel targets such as calcium- and zinc-binding protein encoding gene (S100A9) to target breast cancer metastasis [94,95]. Similarly, single-cell sequencing of breast cancer cells has identified subpopulations that are resistant to chemotherapy. IGF1R+/KDM5A+/ITGA6+ breast cancer cells, for example, have been found to be resistant to drugs such as Paclitaxel [96]. In addition, in situ single-cell analysis suggested that chemotherapy before human epidermal growth factor receptor 2−targeted therapy can increase treatment resistance as a result of changes in intratumor diversity [97].

In a similar vein, single-cell RNA seq of lung adenocarcinoma cells revealed a unique subset of KRAS G12D+/high RS cells that are resistant to chemotherapy [98]. Single-cell analysis of human colon cancer samples identified cellular subsets with unique signatures such as $KRT20^{negative}$/$(CA1, MS4A12, CD177, SLC26A3)^{negative}$ that correlate with worse clinical prognosis [99]. Similar approaches have been used to identify POU5F1+ cells as a subpopulation of invasive cells in melanoma [100].

Therefore, new single-cell analysis techniques enable the identification of specific tumor cell subpopulations that are resistant to drugs, mediate tumor metastasis, and are responsible for tumor relapse. These novel targets can be used to develop targeted cell-specific treatments for cancer.

CONCLUSIONS

For a long time, our understanding of biology has been defined by measuring population averages of cellular behavior. However, in most cases, population averages do not result in accurate information, because cells within the same population exhibit heterogeneity. Rare but important cells such as stem and progenitor cells are almost unidentifiable in population-averaged studies. The evolution of single-cell technologies such as next-generation sequencing offers for the first time a comprehensive analysis of the entire genome and transcriptome of single cells,

and the ability to discover rare and previously unidentified cells. These technologies reveal changes within individual cells without previous bias from the literature. However, obtaining single-cell data is a challenging process in terms of time, resources, technical know-how, and the reliability of analyzed data. Moreover, a major concern that accompanies single-cell sequencing technologies is the presence of technical and biological noise that needs to be differentiated from biologic variation and heterogeneity. Whether these challenges can be overcome is doubtful. Thus, it is important to determine in what cases comprehensiveness of biological information is necessary. In clinical situations, particularly those in which patients must be diagnosed or in which therapeutic products must be used in patients, unreliability of data is unacceptable. In such situations, the use of accurate and precise technologies such as single-cell qPCR and FACS remains the norm. Platforms such as the Needlestack combine RNA seq, single-cell qPCR, and FACS to provide reliable single-cell readouts and validate the cellular subpopulations discovered. Development of such accurate and precise single technologies will aid in the fundamental understanding of human biology and guide therapeutic development.

Embryonic Stem Cells: Derivation, Properties, and Challenges

Irina Klimanskaya

Astellas Institute for Regenerative Medicine, Marlboro, MA, United States

INTRODUCTION

Embryonic stem cells (ESC) can be viewed as an immortal extension of short-lived pluripotent cells that exist in a preimplantation embryo. These pluripotent cells become all of the tissues of the body during embryo development, and cell lines created in vitro from these pluripotent cells retain important properties: self-renewal and the ability to differentiate into a variety of tissues of all three germ layers. An in vitro research model of these cells established in 1981 [1,2] immediately became indispensable for studying mechanisms of mammalian development, and when ESC were derived from human embryo in 1998 [3], regenerative medicine received a new and promising source of cells for tissue engineering.

Cells of any type intended for a therapeutic application have to be functional in vivo, nontumorigenic, and free of pathogens, and it is highly desirable to have a reliable long-lasting source of these cells. When such cells are isolated from donor tissues, their potential for expansion is limited, which restricts the use of this source. As a desirable off-the-shelf product, pluripotent cells seem to be an excellent source of differentiated derivatives: Their ability to self-renew allows for virtually limitless in vitro expansion, thus enabling large-scale manufacture, and they can be differentiated into a variety of derivatives that in turn can be purified and expanded.

DERIVATION OF EMBRYONIC STEM CELLS

Mouse Embryonic Stem Cells

In 1981, two independent research efforts resulted in the derivation of the first ESC lines from mouse embryos [1,2]. Both approaches used mitotically inactivated STO cells as feeders and based their assessment of cell morphology on the morphology of mouse embryonic carcinoma (EC) cells maintained in each laboratory. Evans and Kaufman considered critical factors for the success of derivation of pluripotent cell lines to be the window of embryonic development when pluripotent cells that would grow in culture existed in an embryo, the isolation of a sufficiently large number of such cells, and tissue culture conditions supportive of proliferation rather than differentiation of these cells. They first used an artificial delay in implantation induced by ovariectomy, which allowed late-stage embryos to remain free-floating in the uterus and to grow a large number of cells with no further development beyond primary ectoderm. After a 4- to 6-day delay, the blastocysts were recovered and cultured until egg cylinder-like structures formed that were isolated, trypsinized, and subcultured on mitotically inactivated STO cells, and selected for colonies resembling EC cells.

Martin based her work on the premise that teratocarcinoma stem cells are derived from pluripotent cells of the periimplantation embryo and produce pluripotency-supporting factors. She used conditioned medium from an established EC cell line as a source of such factors and plated the inner cell masses (ICMs) of mouse blastocysts isolated by immunosurgery [4] on the STO feeder layer in such conditioned medium. Resulting colonies with morphology resembling EC cells were selected and passaged until a high-density culture was established that no

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00007-2

longer depended on conditioned medium, because ESC were probably making pluripotency-supporting factors themselves.

Pluripotent cell lines from both studies had a normal karyotype and differentiated into cells of three germ layers. These works laid the foundation for the huge field of study in cell and developmental biology on pluripotent stem cells and their differentiation.

Mouse ESC are typically derived from mouse blastocysts with optional immunosurgery. They can be cultured indefinitely on mitotically inactivated STO cells or mouse embryonic fibroblast feeder layers in the presence of leukemia inhibitory factor (LIF) and fetal bovine serum (FBS), they express several markers of pluripotency, and they have high alkaline phosphatase activity [5]. Common pluripotency markers are transcriptional factor Oct-3/4, originally reported in the ICM of an early blastocyst [6,7], as well as Nanog [8], Sox-2, Rex-1, Dnmt3b, Lin-28 [9], and cell surface antigen SSEA-1, which is expressed on the surface of blastomeres of the eight cell−stage embryo and ICM [9a]. ESC have become a common tool for generating transgene mouse models, because they easily aggregate with the ICM of a blastocyst when injected, or with blastomeres, making aggregation chimeras. ESC could also be generated from a single blastomere of a multicell-stage embryo [10] and appear to have the same properties including germ line transmission.

Human Embryonic Stem Cells

In 1998, in a groundbreaking report from the group led by James Thomson at the University of Wisconsin [3], the derivation of human ESC was announced. The team used an approach similar to that for deriving mouse ESC: An ICM of a blastocyst, isolated by immunosurgery, was plated onto mouse embryonic fibroblast feeder cells in medium supplemented with LIF, basic fibroblast growth factor (bFGF), and knockout serum replacement (KSR) (Life Technologies) in place of FBS. Several human ESC (hESC) lines were generated and soon became available for use by other researchers worldwide. hESC have the capability of differentiating into any and all cell types of the human body; they immediately became recognized as a promising source of many cell types sought after by regenerative medicine. However, this discovery also evoked great controversy and led to heated discussions in the media because some considered the destruction of a preimplantation human embryo to be the same as killing a human.

The use of federal funds for research involving hESC lines is allowed for National Institutes of Health−registered cell lines; there were 378 eligible hESC lines as of January, 2017 (https://grants.nih.gov/stem_cells/registry/current.htm). Other examples of stem cell registries are the University of Massachusetts International Stem Cell Registry http://www.umassmed.edu/iscr/index.aspx and the European Human Embryonic Stem Cell Registry http://www.hescreg.eu/.

ESC retain the fundamental property of ICM cells: the ability to give rise or develop into all tissues of the human body. The same markers of pluripotency are found in both ICM and hESC: transcription factors Oct-4, NANOG, and Rex-1; cell surface antigens SSEA-3, SSEA-4, TRA-1-60, and TRA-1-81; and high endogenous alkaline phosphatase activity [11,12]. They retain high telomerase activity and can continue to self-renew indefinitely. Both in vitro and in vivo, when injected into immune-deficient mice, hESC form teratomas, tumors that contain derivatives of all three germ layers, with the most commonly seen ones being bone, cartilage, neural rosettes, and epithelium of the airways and gut.

SOURCES OF HUMAN EMBRYONIC STEM CELLS

Blastocyst

The first and most commonly used source of hESC is a blastocyst. Many groups noticed that fully expanded and spontaneously hatching blastocysts are not the best candidates for the derivation of ESC: their outgrowth is very prone to differentiation, probably because of some intrinsic commitments already made by the cells of the ICM. In addition, the growth of trophoblast cells can potentially overgrow ICM-originated cells. The latter can be avoided by performing immunosurgery [4], in which a zona pellucida−free blastocyst is incubated with antibodies that bind to the surface of trophectoderm, and then complement is added. This results in the lysis of trophoblast cells. The trophoblast-free ICM is plated for outgrowth. This procedure increases the efficiency of cell line derivation, but the success rate also depends on the quality and size of the ICM. Common impediments that may be encountered are spontaneous differentiation and apoptosis observed during the first week of ICM or blastocyst outgrowth. As mentioned earlier, Evans and Kaufman used delayed implantation of mouse embryos to achieve a larger ICM;

Stoikovic and coauthors used a similar approach. They cultured late-stage blastocysts in the presence of Buffalo rat liver (BRL) cell—conditioned medium through day 8, which allowed them to obtain larger ICM without its extensive further differentiation, and resulted in the successful derivation of hESC [13].

Morula

As an alternative to whole blastocyst, which represents a relatively late stage in preimplantation embryonic development when the specification of the cell fate starts, earlier-stage embryos (morulae) were successfully used [14] to create hESC lines with an efficiency comparable to that for ICM- or whole blastocyst—derived hESC lines. These hESC appeared to have the same properties as blastocyst-derived hESC, such as a pattern of expression of pluripotency markers, differentiation to all three germ layers, immortality in culture, and a normal karyotype.

Growth-Arrested Embryo

While many hESC cell lines have been created using leftover in vitro fertilization (IVF) embryos donated to research by couples undergoing infertility treatment, scientists kept working on alternative ways to make hESC without destroying the embryo. One of the first successfully executed approaches was the derivation of hESC lines from nonviable growth-arrested embryos [15,16]. This demonstrated that such embryos still have viable pluripotent cells that can be used to generate hESC lines.

Somatic Cell Nuclear Transfer

A highly publicized approach to hESC derivation is based on somatic cell nuclear transfer (SCNT). During a micromanipulation procedure, an unfertilized egg is enucleated and the nucleus of a donor cell is introduced into the egg via a micropipette. The egg with the donor nucleus then develops into a blastocyst that can be used to isolate ESC. Such ESC would have the same genotype as the donor of the nucleus and can be used to generate an autologous cell type for tissue repair. Several research groups [17,17a,18] succeeded in creating hESC by SCNT using fetal, neonatal, and adult fibroblasts as donor cells for somatic nuclei; the success rate was 25% [18a], which was comparable to that for hESC derivation from a naturally fertilized blastocyst. However, the efficiency of blastocyst formation and hESC derivation seemed to be different for eggs from different donors and can even correlate with the hormonal stimulation protocol [18]. In addition, it was discovered [18a] that a major SCNT reprogramming barrier was associated with the severe methylation of lysine 9 in histone H3 in a human somatic cell genome. The introduction of KDM4A, an H3K9me3 demethylase, during SCNT significantly improved the development and blastocyst formation of SCNT embryos, even when the authors deliberately used eggs from donors whose eggs had previously failed to produce SCNT blastocysts. Although the possibility of creating donor-matched hESC lines by SCNT remains attractive, it takes years for the operator to develop the skills required to perform this procedure with high precision and minimal disturbance to the egg or donor nucleus for successful outcome, so this approach to deriving hESC remains in the realm of only a few groups in the world.

Parthenogenesis

Another attractive possibility for generating pluripotent cells without destroying the embryos and overcome the problem of immune compatibility at the same time, is the generation of ESC and their derivatives from activated nonfertilized oocytes, or parthenotes [19], that would carry only maternal human leukocyte antigen (HLA) genes and thus allow to reduce the variability and number of lines required for immune match of the large number of patients. Due to genetic imprinting and the deficiencies of maternal and paternal haploid gene sets, their combined action is required for normal development. Parthenote mammalian embryos which do not have paternal genes are unable to develop to term; however, pluripotent cells produced from such parthenote human embryos seem to have phenotypes, behavior, and differentiation potential similar to those of hESC from blastocysts [20—23]. From an ethical viewpoint, parthenote hESC may be less controversial because no life is destroyed [23a]. A lot of progress has been made in generating human parthenote ESC and their derivatives [24—29], but data on the behavior of such derivatives in vivo are still limited. Several studies showed that a large percentage of parthenogenetic blastomeres was affected by an excessive number of centrioles, a high aneuploidy rate [30], and genetic and epigenetic

instability [31]. More studies demonstrating the safety and efficacy of parthenote hESC derivatives are needed before this attractive source of HLA-matched cells for regenerative medicine can be fully used.

Single Blastomere

To address the ethical controversy of hESC derivation from blastocysts, our group developed an approach based on single blastomere biopsy, a procedure commonly employed in preimplantation genetic diagnostics (PGD) in the course of IVF [32–34]. In this procedure, a hole is made in the zona pellucida of a morula stage embryo using acid Tyrode solution or with the help of a laser, and a single blastomere is extracted. The embryo continues to develop while the blastomere undergoes PGD tests, and a few days later, blastocysts that were "cleared" can be implanted. This procedure has been deemed safe and has resulted in hundreds of healthy babies being born. Using blastomere biopsy, we established several hESC lines from single blastomeres, whereas the parent embryos were allowed to develop to the blastocyst stage and then were cryopreserved [35]. Single blastomeres were first cocultured with the biopsied embryos and then were plated onto feeder cells in microdrops. Outgrowing colonies were treated in the same way as ICM outgrowths: with careful mechanical passaging followed by enzymatic dissociation when an appropriate number of colonies could be achieved. Established hESC lines had properties similar to ICM-derived hESC: they stained positively for Oct-4, SSEA-3, SSEA-4, TRA-1-60, TRA-1-81, and alkaline phosphatase; they had a normal karyotype and differentiated into derivatives of all three germ layers both in teratoma assays in nonobese diabetic/severe combined immunodeficiency (NOD-SCID) mice and in vitro. The success rates for hESC derivation from blastocysts and blastomeres can be similar, around 25%–30%. This technique was subsequently used by several other groups to derive hESC lines with high efficiency and/or without destroying the embryo under different conditions including human feeder cells, feeder-free, and even from growth-arrested embryos [36–41]. Single blastomere–derived hESC showed a transcriptional profile similar to "conventional" hESC [38], and several differentiated derivatives of single blastomere–hESC appeared functional in vitro and in vivo [42,43,43a]. By avoiding the destruction of human embryos, this approach has offered a way to address ethical concerns regarding hESC derivation and provided a way to overcome a major impediment in developing hESC-based therapies.

HUMAN EMBRYONIC STEM CELL MAINTENANCE

Similar to early mammalian development, when multiple cell–cell and cell–matrix interaction produce a variety of both inductive and permissive differentiation signals, ESC culture reproduces such signals with a certain degree of approximation: hESC readily differentiate into all three lineages, but the efficiency of their commitment to each lineage often depends on specific culture conditions, because this artificial system does not provide the same finely tuned orchestration as that which happens during in vivo pattern formation. The strong inclination of hESC to differentiate in culture makes it challenging to maintain hESC in a self-renewing state and is associated with the limitations of a two-dimensional cell culture environment and media components used as substitutes for the short-lived microenvironment of a preimplantation embryo. Meticulous attention to several key factors is required for the successful maintenance of hESC in a pluripotent state for multiple passages:

- Microenvironment: defined combination of media and matrix, with or without feeder cells
- Maintenance: frequent passaging using gentle and efficient cell–matrix disruption
- Morphology observation performed daily to assess the culture and avoid subculturing cells with signs of differentiation

Microenvironment

hESC are usually cultured on either a monolayer of mitotically inactivated feeder cells or a defined extracellular matrix (for example, Matrigel, vitronectin, laminin-521) in defined media that allow them to be propagated in culture virtually indefinitely, unlike cells of the ICM, which exist only transiently. Like the ICM of a developing blastocyst, which is programmed to differentiate once the implantation starts, pluripotent ESC in culture readily differentiate when the microenvironment changes. Even the most carefully selected and tested combinations of media and matrix will not allow hESC to keep growing in the same dish and remain pluripotent indefinitely, because when colonies

reach a certain size and become overcrowded, they form a second layer of cells, and then the cells in the colony begin to lose pluripotent marker expression and differentiate. Timely passaging prevents this loss of pluripotency because it releases single cells and small cell clumps, so any matrix–cell interactions that were formed during the first days after previous passage and begin to send differentiation signals to hESC are disrupted, and the cells can continue to self-renew.

The first hESC lines were derived and cultured under conditions similar to what is used for derivation and maintenance of mouse ESC: mitotically inactivated mouse embryonic fibroblasts (MEF) plated on gelatin, in a medium based on KSR, a proprietary serum substitute formulation. This medium was supplemented with LIF and bFGF [3,11,33,34]. Variations of this system include adding Plasmanate [33] or using a 1:1 mix of Knockout- Dulbecco's Modified Eagle Medium and F12 medium. However, it was reported that human hESC do not have an active signal transducer and activator of transcription 3 (STAT3) pathway and thus are LIF-independent [44,45], and many researchers stopped using it in the culture medium. Indeed, it appeared that using bFGF alone is sufficient to support the pluripotency of hESC over multiple passages. Other studies have shown the importance of LIF in maintaining hESC in what is called a naive state (discussed subsequently), so it is probably too early to make a conclusion about the need of this factor to maintain pluripotency.

Maintenance

It is commonly observed that cultures of hESC contain differentiating cells that, when there are only few of them, usually do not interfere with the successful maintenance of hESC in a pluripotent state or with their differentiation toward a desired derivative. However, if the colonies are allowed to overgrow, soon afterward they become multilayered or begin to touch each other, and spontaneous differentiation usually follows within hours. Although it is possible to rescue even extensively differentiated cultures (for instance, by carefully selecting undifferentiated colony pieces, or "mechanical picking," it is more practical to prevent the loss of pluripotency by timely passaging based on observing the colony morphology and confluency and by using high-quality reagents and good cell handling practices.

For an hESC subculture, there is a wide variety of commercially available dissociating agents. In the past, collagenase used by Thomson and colleagues [3] for hESC derivation and passaging was an enzyme of choice for many laboratories. It allowed the cells to be passaged as clumps rather than as single cells, but it required meticulous attention to colony morphology because when colonies of larger size are harvested, they are more prone to spontaneous differentiation. Trypsin is another popular enzyme, but because of its rapid action, it demands careful techniques during cell harvest to avoid cell damage and death. Mechanical colony dispersion and hand picking allows the selection of colonies of "proper" morphology with minimal stress to the cells and is the most commonly used method to derive new lines (when the outgrowth is small and the removal of differentiating cells is needed to prevent further differentiation of the remaining pluripotent cells). However, this method is operator-biased and demands sufficient experience to avoid selecting for aneuploid cells that may have a growth advantage and thus are the first to form good-sized and "good-looking" colonies. On the other hand, a skilled operator may be able to rescue an aneuploid culture by carefully selecting and dispersing colonies of the right morphology. Other available dissociation methods that allow hESC colonies to gently break into small cell clumps are Accutase, TrypLE (proprietary mix of enzymes, Life Technologies), and "Dissociation Buffer" (containing chelating agents, Life Technologies).

hESC can maintain normal karyotype over multiple passages, but they are prone to aneuploidy. There are not enough data to identify reliably which factors cause aneuploidy, although a study showed an association of aneuploidy with high-density culture [46]. The authors demonstrated that 33% of hESC became genetically abnormal after only 5 days of high-density culture. It seemed that lactic acid and acidification of the medium were the main reason for such abnormalities, but interestingly, laminin 521 used as matrix counteracted this effect. Frequent change of medium also prevented such aberrations. Some of most commonly seen chromosome abnormalities, such as trisomy in chromosome 12 or 17 [47], are known to result in hESC survival or growth advantage, so even an initial nonclonal aberration can quickly become prevalent. Other common abnormalities in hESC karyotype are seen with chromosomes 1, 14, and 20 [48]. Dissociating agents can contribute to the quick spread of abnormal cells throughout the population [48a]. This tendency of hESC to undergo clonal aneuploidy reinforces the importance of making frequent karyotyping a part of the routine maintenance of hESC. G-banding with the examination of a minimum of 20 cells complemented by fluorescence in situ hybridization (FISH) with probes for chromosomes 1, 4, 12, 17, and 20 can be considered appropriate karyotyping methods.

When choosing the most suitable combination of matrix, media, and passaging methods, it is important to remember that in addition to supporting pluripotency, a stable karyotype and reproducibility, the culture system needs to ensure the acceptable efficiency of the differentiation of hESC into the desired derivative under specific protocols. For instance, the formation of embryoid bodies (EB) (plating hESC into low-attachment cell culture plates, where they can aggregate and form cell clumps, differentiating into three germ layers) is frequently used to simulate early differentiation events in mammalian development. However, when hESC are dissociated into single cells, the formation of EB may be impeded by low cell survival, and the yields of EBs and differentiated cells can be much lower [48b].

Morphology

The morphology of individual hESC and of colonies was mentioned earlier with regard to the maintenance routine and the choice of culture conditions. hESC have been known to form colonies with sharp "shiny" borders when they are cultured on feeder cells, and cells in such colonies are small with a high ratio of nuclei to cytoplasts and visible nucleoli. When cultured feeder-free, hESC look larger and more spread-out [55]. The borders of the colonies may become sharp after only several days in culture, when the cells become almost "overgrown." Under these conditions, hESC inside the colonies look relatively large and flat for the first few days and may even resemble early stages of differentiation, which can be confusing to an inexperienced eye; however, after several days, the morphology of such colonies becomes more similar to typical hESC as cells become "packed," so they become smaller in diameter. However, larger and flatter cells can also indicate the beginning of differentiation, and daily follow-up of the same cell culture dish is important to better understand the nuances of cell morphology, to tell apart which deviations from the "ideal" morphology are associated with cell adaptation after passaging and which are early signs of differentiation.

Evolution of Human Embryonic Stem Cell Derivation and Culture Methods

There are several commercially available media with a proprietary blend of growth factors and nutrients that support the maintenance of hESC growth and pluripotency. Some examples are NutriStem (Biological Industries, Israel), TeSR media (Stem Cell Technologies), and E8 (Thermo Fisher Scientific). These media usually come with a detailed protocol prompting the researcher to use a certain matrix−media combination. Commonly used extracellular matrices are Matrigel, an extracellular matrix produced by Engelbreth-Holm-Swarm mouse sarcoma cells (BD Biosciences), laminin 521 or 511 (BioLamina Sweden), CELLstart, a human placenta-derived extracellular matrix (Life Technologies), and vitronectin. If a special matrix−media combination is desired, the conditions have to be carefully tested: hESC need to be subcultured for several passages under new conditions before it is known whether a certain combination works for the support of growth and pluripotency and ensures karyotype stability. MEF as feeder cells have been a reference standard for ESC culture for years. Since the beginning of hESC research, there has been great interest in using their derivatives clinically, but coculture of live human cells with live animal cells results in a xenogeneic product and requires more extensive testing for animal viruses. Thus is has been highly desirable to be able to derive and propagate hESC without feeder cells of animal origin or even make them feeder-free. Although xenogeneic cell products are allowed for transplantation in human patients, there are more stringent regulations. For instance, the patient's blood samples needs to be archived for a prolonged time, which adds to the costs and logistics of clinical applications. The first reports on using feeder cells of human origin demonstrated the feasibility of using cells from different donors and/or different tissues, although some cell types seemed to be more effective in supporting hESC derivation and growth [39,49−53].

Another step in the transition from a xenogeneic to a nonxenogeneic cell product was the feeder-free culture system [54], in which the MEF-conditioned cell culture medium allowed hESC to propagate on Matrigel or laminin and retained their pluripotency and normal karyotype. However, this work was done using cell lines established with live mouse feeder cells, so these feeder-free cultured hESC still classified as a xenogeneic product. We attempted to derive new cell lines from blastocysts that were completely feeder-free. We postulated that an important factor in establishing the outgrowth of pluripotent cells was interaction with an extracellular matrix that was produced and properly organized by feeder cells. MEF were cultured for several days to allow for this matrix to be produced and organized, and then sodium deoxycholate was used to lyse the MEF whereas the preassembled extracellular matrix was left intact. The blastocysts or ICMs were plated onto this matrix in KSR-based derivation medium supplemented with LIF and bFGF, and the outgrowing hESC colonies were dispersed using mechanical passaging or

trypsin–EDTA. hESC cell lines that showed normal karyotype, maintained pluripotency marker expression over multiple passages and differentiated into derivatives of all three germ layers in vivo and in vitro was established as a result of this work [55]. Although derivation of hESC is more challenging than propagation, more feeder-free hESC lines were established using novel defined media such as NutriStem [40].

NAIVE EMBRYONIC STEM CELLS

hESC and mouse ESC have many similarities, yet they are different. Mouse ESC have been shown to exist in two states: "naive" and "primed" [56–59]. Not only do naive pluripotent cells express markers of pluripotency such as Oct4, NANOG, Sox2, both X-chromosomes are active. Primed ESC coming from the epiblast (EpiSC) retain the expression of these markers, but only one X chromosome is active [60]. hESC resemble EpiSC rather than naive: the colonies they form are flat, not dome-like as is typical for naive cells, they are polarized [60a]; their metabolism is mostly glycolic whereas primed cells rely on oxidative phosphorylation [61,62]; only one X-chromosome is active; and they are sensitive to single-cell dissociation [57,63]. Naive cells survive single-cell dissociation much better, which allows for greater capacity for expansion (which could be highly desirable for large-scale manufacturing), their doubling time is much shorter, and they have been shown to differentiate more efficiently both in vivo and in vitro [64,65], a highly sought-after property when differentiation is aimed at making derivatives for regenerative medicine.

Mouse ESC are usually derived and exist in a naive state, and it takes special effort and culture conditions to isolate EpiSC from an epiblast. On the other hand, most hESC lines were derived and propagated in a primed state, until naive, or "ground state" pluripotent hESC were derived [66,67]. It has been shown that naive hESC can be derived de novo, or existing hESC lines can be converted into the naive state. In both cases, signaling pathways need to be activated or inhibited using a cocktail of bioactive substances and small molecules. Some examples are MEK inhibitor PD0325901, GSK inhibitor CHIR99021, STAT3 inhibitor NSC74859, ROCK inhibitor Y27632, LIF, FGF2, and TGFβ1. Interestingly, all such cocktails include LIF, which was once considered to be essential for hESC maintenance in the pluripotent state but then was abandoned after it was shown that hESC do not depend on it for pluripotency. It remains unclear whether the transition from naive to primed hESC happens during the first days, if not hours, of derivation from a naive ICM or whether such primed cells exist in the embryo. RNA sequencing analysis of single cells of human blastocysts showed that at least three types of cells can be identified, and that during derivation of hESC there are changes in gene expression as the cells adapt to culture conditions [68].

HUMAN EMBRYONIC STEM CELL DIFFERENTIATION AND MANUFACTURING FOR CLINICAL APPLICATION

Although hESC provide exciting research opportunities for studies related to the mechanisms of development, their biggest promise is in their differentiation potential. There are unmet medical needs for a variety of cell types, including but not limited to pancreatic β cells, hepatocytes, dopamine neurons, oligodendrocytes, retinal cells, cardiomyocytes, vascular cells, cartilage, and bone: derivatives of all three germ layers. Some of these cell types are frequently seen in hESC cultures left to differentiate spontaneously or in EB, and some require specialized derivation protocols for efficient yields. For instance, the neural path seems to be a default choice of ESC in the absence of other differentiating cues [69], and in spontaneously differentiating hESC cultures [69–71] the presence of various neural lineage cells is common. Perhaps this natural tendency of hESC to form derivatives of neural lineage endorsed derivation and studies of such derivatives, and oligodendrocyte progenitors were the first hESC-derived cells to enter clinical trials for spinal cord injury. More clinical trials followed using another hESC-derived progeny of the neural lineage: retinal pigment epithelium (RPE) cells to treat macular degeneration and Stargardt's disease in the United States and European Union [72,73].

RPE has a unique function: it provides support for the photoreceptor by delivering nutrients and removing shed outer segments. Its morphology is also unique which allow to easily detect these cells as pigmented cobblestone "islets" among various types of differentiating hESC. Unlike many terminally differentiated cell types, RPE retains its proliferation potential, so these pigmented epithelial cells can be relatively easily isolated with high purity and also be efficiently scaled up (Klimanskaya et al., 2004). Such hESC-derived RPE cells can fully differentiate and mature

after transplantation in animal models, fully integrate into the host's RPE layer, retain RPE morphology and molecular markers, and provide photoreceptor rescue [43a,73,74].

For this unique type of cells, a relatively small scale hESC culture can result in efficient production of the final product, and considering the small size of the macula and low cell numbers required for injection (in the range of several hundred thousand cells) [72,73], a relatively small-scale cell culture is needed to produce therapeutic doses. However, for other cell types considered for therapeutic applications that cannot undergo multiple population doublings while maintaining potency, or when large numbers of cells are required, various challenges can arise, such as using alternative cell culture systems including suspension culture, microcarrier- or microfluidics-based bioreactors at the hESC stage of the process, or isolation of progenitor type cells that can be expanded further.

Whereas there may be a variety of approaches to manufacturing different hESC-originated cell types, the same principles can be applied to producing all hESC derivatives to ensure their safety and efficacy. The US Food and Drug Administration issued a document on tissue donor regulations (*Guidance for Industry: Eligibility Determination for Donors of Human Cells, Tissues, and Cellular and Tissue-Based Products (HCT/Ps)*, https://www.fda.gov/downloads/biologicsbloodvaccines/guidancecomplianceregulatoryinformation/guidances/tissue/ucm091345.pdf), and these regulations apply to embryo donors. All raw materials used in manufacturing need to meet the safety criteria and be fully characterized. Standard tests performed on manufactured cells include sterility, mycoplasma, common and latent viruses, and endotoxins. Of utmost importance is the safety of the cell product. First, there should be solid proof that the manufacturing process does not result in the presence of residual pluripotent cells in the final product, which can lead to the formation of teratoma, and the assays used to detect such pluripotent cells have to have a high level of sensitivity. Animal studies may be required to confirm that transplantation of the hESC derivative does not lead to tumor formation in immune-suppressed animals. Cell growth in soft agar can be used as an additional in vitro tumorigenicity test, and an assay should be in place to confirm the desirable purity of the derivative. Cells intended for transplantation have to have a normal karyotype confirmed by a rigorous test. The potency of the final product has to be confirmed using physiologically relevant assays: For instance, it could be phagocytosis for RPE, glucose-responsive insulin production for pancreatic β-cells, and bone and cartilage formation for mesenchymal stem cells. For each cell type, the most relevant and technically feasible in vitro assay should be chosen.

CONCLUSIONS

ESC help to recapitulate early events in mammalian development and are an excellent system to study self-renewal and differentiation. Since hESC were derived, numerous studies have demonstrated that they could be a promising source of various cell types for regenerative medicine. There are several alternative sources of pluripotent stem cells: the ICM of a blastocyst, morula, single blastomere, parthenote embryos, embryos generated via SCNT, growth-arrested embryos, and induced pluripotent cells. The same principles established through many years of research using ESC can be applied to the culture and differentiation of all pluripotent cell lines of different origins and sources to ensure their robust propagation in self-renewal state and efficient differentiation. Since the first derivation of hESC the culture methods have been become increasingly more robust, and there is now a variety of approaches to propagating pluripotent stem cells including hESC. Human feeder cells or feeder-free conditions can be used along with several defined media−extracellular matrix combinations and a variety of dissociating agents, including xenogeneic-free reagents.

At the same time, many challenges are associated with our incomplete knowledge of the fine mechanisms of self-renewal and differentiation. Further studies should help us to better understand which components of the cell culture system and steps in the maintenance routine are most critical in supporting hESC self-renewal, a stable karyotype, and differentiation efficiency to advance the use of hESC derivatives in regenerative medicine.

Alternative Sources of Human Embryonic Stem Cells

Svetlana Gavrilov, Virginia E. Papaioannou, Donald W. Landry

College of Physicians and Surgeons of Columbia University, New York, NY, United States

INTRODUCTION

Human embryonic stem cells (hESC) are conventionally derived from viable preimplantation embryos produced by embryonic stem (IVF) [1]. The derivation of hESC is considered ethically controversial because of the typical destruction of the embryo during this process [2–5]. A human embryo constitutes an object of moral concern [6] owing to its identity as a human at the embryonic stage of development. In biological terms, a human embryo has a distinct, unique, and unambiguous status as a result of this identity. However, the political and moral status of human embryos are in a state of flux. Whereas there is universal opposition to reproductive cloning of humans by any method, there is diversity in opinion regarding the use of human embryos to derive hESC and, subsequently, potential therapies derived from them [7,8]. Ethical and cultural imperatives to respect human dignity from the moment of fertilization conflict with a utilitarian desire to relieve human suffering, even when this comes at the expense of embryonic human life. These conflicting perspectives have fueled an intense debate and have influenced legislative regulation of stem cell research in the United States and internationally [2–5,9,10]. US stem cell research policy was regulated on the federal level by the Dickey Amendment and President Obama's Executive Order 13,505 and by individual state laws (Box 8.1) [10]. The use of federal funding to derive new hESC that would entail destroying human embryos is forbidden. Also, in many European countries (Austria, Germany, Ireland, Italy, Lithuania, Norway, Poland, and Slovakia), the derivation of hESC from surplus embryos is prohibited [9]. Because stem cell biology is at the forefront of research, legislative acts change rapidly. (For up-to-date legislative regulation of human embryonic stem (ES) cell research, refer to links provided in Box 8.2) [9,10].

Another consideration is the constant demand to derive new human embryonic stem (ES) lines for both basic and clinical applications owing to the loss of genetic and epigenetic stability arising during hESC culture and manipulation [11–14]. Many available hESC lines had been exposed to animal material during derivation or culture [2,15]. It is acceptable to expose hESC lines to products of human origin, but it remains the ultimate goal to pursue hESC derivation under stringent xenogeneic-free conditions for eventual clinical use [2,15].

The debate on embryo-destructive derivation of ES cells often focuses on the moral sensibilities of investigators and their desires for research unfettered by ethical considerations. However, the goal of hESC research is to find therapies that would ease human pain or debilitation caused by illness or injury [2,16,17]. In the latter context, the sensibilities of many millions of the populace (the intended beneficiaries of this work) should be instructive. As a result, a variety of different derivation strategies have been proposed (Fig. 8.1) to avoid using an embryo as a source of human stem cells (detailed information can be found in appropriate chapters of this book or elsewhere) [2,3]. In this chapter, we will discuss two alternative approaches to yielding genetically unmodified hESC that do not interfere with the developmental potential of human embryos: single blastomere biopsy (SBB) and organismically dead embryos (Fig. 8.1) [2].

BOX 8.1

BRIEF OVERVIEW OF US FEDERAL STEM CELL POLICY

The US policy on stem cell research is shaped by the following legislative act and executive order:

- The "Dickey amendment," a rider issued in 1996 that framed all subsequent political discussions regarding human embryonic stem cells (hESC) research. The amendment stated that no federal funding may be employed for (1) the creation of a human embryo or embryos for research purposes or (2) research in which a human embryo or embryos are destroyed, discarded, or knowingly subjected to risk of injury or death (beyond that permitted for fetuses in utero under the Public Health Service Act).
- Executive Order (EO) 13,505, which removed barriers to responsible scientific research involving human stem cells. This EO was issued by President Obama on March 9, 2009 and stated that the Secretary of Health and Human Services, through the director of the National Institutes of Health, may support and conduct responsible, scientifically worthy human stem cell research, including human stem cell research, to the extent permitted by law. In addition, this EO revoked two items issued by President George W. Bush: (1) a presidential statement that permitted work only on hESC lines generated before August 9, 2001, and (2) EO 13,435, which favored all research on stem cells without harming a human embryo.

The page also contains public comments on draft NIH human stem cell guidelines that supplement Executive Order 13,505. http://stemcells.nih.gov/index.asp.

International Society for Stem Cell Research webpage: contains comprehensive information on international legislation on human embryonic stem cell research; periodically updated. http://www.isscr.org/.

Single Blastomere Biopsy

SBB for the purpose of deriving ES cells was developed by Lanza and colleagues [18–21]. HESC are created from a single blastomere that is removed from the embryo [20,21] by employing a technique that was originally developed for preimplantation genetic diagnosis (PGD) [2,22–24]. This procedure bypasses the ethical issue of embryo destruction, because biopsied embryos continue to develop and reach the blastocyst stage and beyond, as demonstrated by more than a decade of experience with PGD [2,24]. SBB of both murine and human eight-cell stage embryos has been used successfully as a source of material to derive ES cell lines (Fig. 8.1) [2,18–21]. The risk associated with embryo biopsy [25] is accepted by patients as part of the PGD procedure, but it would be considered unjustified in a research setting in the absence of a clinical indication [2]. In addition, US regulations forbid research on an embryo that imposes greater than minimal risk, unless the research is for the direct benefit of the fetus (Box 8.1) [26]. To date, none of the hESC lines derived by SBB have been approved for National Institutes of Health (NIH) funding [10].

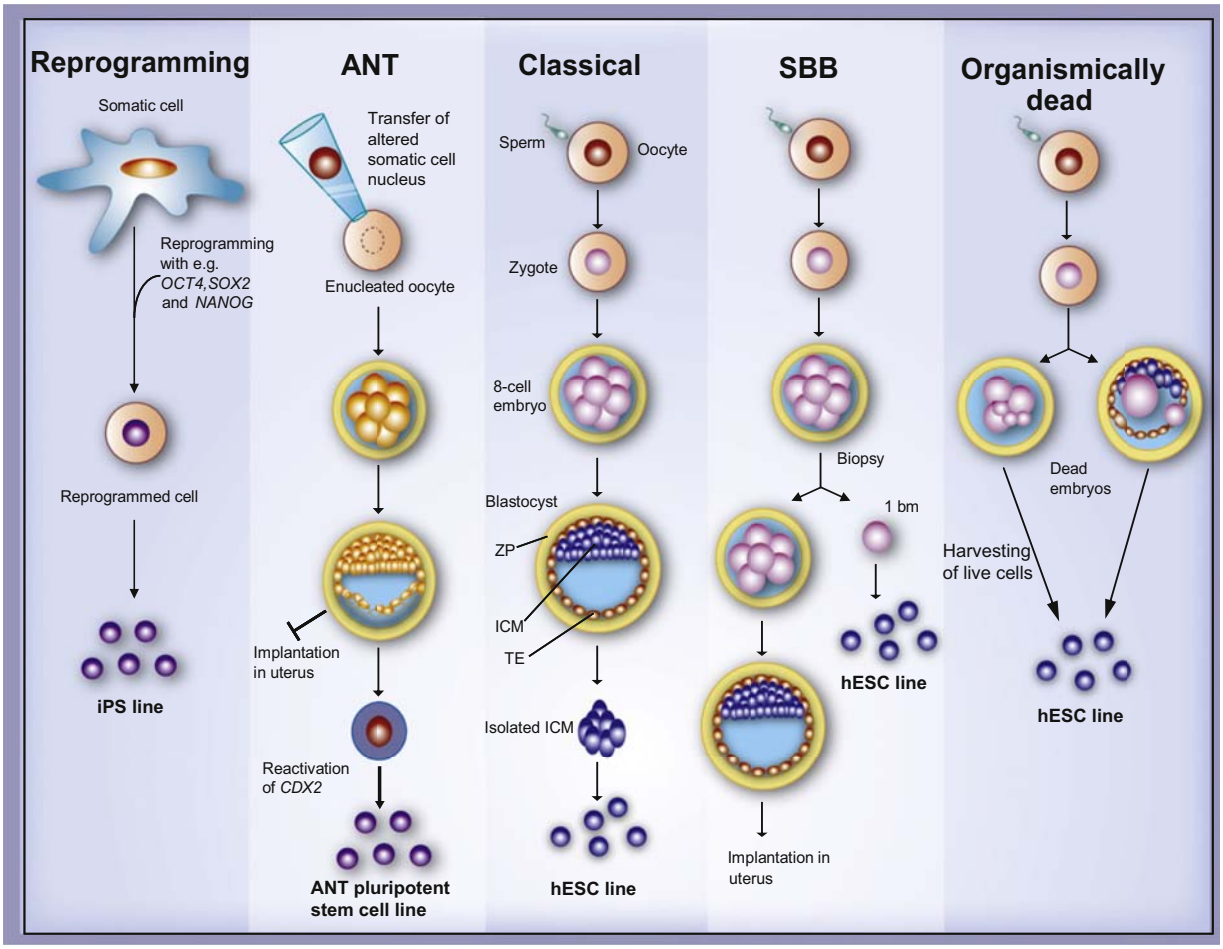

FIGURE 8.1 Classical and alternative strategies for the generation of human stem cells by reprogramming with exogenous genes (iPS), transfer of a genetically altered somatic cell nucleus into an oocyte (ANT), the classical derivation of human embryonic stem cells (hESCs) from blastocyst culture, the derivation of hESCs from a biopsied single blastomere (SBB), and the derivation from organismically dead embryos. *bm*, blastomere; *ICM*, inner cell mass; *iPS*, induced pluripotent stem cells; *TE*, trophectoderm; *ZP*, zona pellucida. *Reproduced with permission from Gavrilov S, Papaioannou VE, Landry DW. Alternative strategies for the derivation of human embryonic stem cell lines and the role of dead embryos. Curr Stem Cell Res Ther 2009a;4:81–6.*

ORGANISMICALLY DEAD EMBRYOS

Our group proposed the derivation of hESC from irreversibly arrested, nonviable human embryos that died, despite best efforts, during the course of IVF for reproductive purposes [2]. This proposal to harvest live cells from dead embryos is analogous to the harvesting of essential organs from deceased donors. We suggested that the established ethical guidelines for essential organ donation could be employed for the clinical application of this paradigm to generate new hESC lines [2,4,27,28].

Irreversibility as a Criterion for Diagnosing Embryonic Death

The modern concept of death is based on an irreversible loss of integrated organismic function [28,29]. Brain death is used as a reliable marker for irreversible loss of integrated function. Diagnosing the death of a patient before the

death of that patient's tissues is important for the appropriate application of medical resources and for the possibility of organ donation.

To apply this concept to a stage of development that precedes the development of the nervous system, we proposed that an irreversible arrest of cell division would mark an irreversible loss of integrated function. Thus, it was necessary to find criteria that would establish irreversible cessation of normal embryonic development before every cell of the embryo has died. Through retrospective analysis of early-stage embryos that had been generated for reproductive purpose but were rejected owing to poor quality and/or developmental arrest, we showed that many of these embryos were in fact organismically dead [28]. Our data showed that the failure of normal cell division for 48 h was irreversible, and despite the possible presence of individual living cells, they indicated an irreversible loss of integrated organismic function: the conceptual definition of death [2,28].

Furthermore, we conducted a prospective study to characterize embryonic death [3,30], in which the progression of arrested embryos, including abnormal blastocysts, was examined in extended culture [27]. Our data demonstrated that developmental arrest observed in some human embryos by embryonic day 6 (ED6) after IVF cannot be reversed by extended culture in conditions suitable for preimplantation embryos, because we saw no morphological changes indicative of developmental progression in most embryos and observed no unequivocal instances of further cell divisions [27]. Moreover, these observations are in line with standard IVF practice, which dictates that such embryos should not be transferred or cryopreserved because they are known not to produce live offspring [27,31–38]. In an attempt to correlate morphology with cell number, we categorized the embryos at ED6 on the basis of gross morphology (Fig. 8.2) [27]. We showed that morphological categorization was of limited value in predicting cell number. Nevertheless, the higher cell number associated with cavitation might predict greater potential for the success of hESC derivation [27]. In addition, we determined the proportion of living and nonliving cells in nonviable ED6 human embryos (Fig. 8.2) and showed that most irreversibly arrested embryos contain a high proportion of vital cells regardless of the stage of arrest, which indicates that harvesting cells and deriving hESC from such nonviable embryos should be feasible [27].

Human Embryonic Stem Cell Lines Derived From Irreversibly Arrested, Nonviable Embryos

In fact, the proof of principle for this alternative method has been obtained, because 14 hESC lines were successfully derived from nonviable embryos that were irreversibly arrested by our criteria (Table 8.1) [39,40,41]. The first cell line (hES-NCL9) was derived by Stojkovic and colleagues from 132 arrested embryos [40]. Subsequently, Daley and colleagues derived 11 lines from 413 poor-quality embryos rejected for clinical use [39]. In addition, our group derived two human ES lines: CU1 and CU2 from 159 ED6 irreversibly arrested, nonviable human embryos [41]. Although many arrested embryos might be expected to be aneuploid [42–46], all 14 hESC lines were karyotypically normal; moreover, pluripotency and differentiation potential were demonstrated in vitro and/or in vivo [39,40]; [41].

Morphological Criteria for Predicting the Capacity of Irreversibly Arrested, Nonviable Human Embryos to Develop Into a Human Embryonic Stem Cell Line

To define morphological criteria that could be used to predict the capacity of discarded, irreversibly arrested, nonviable embryos to develop into an hESC line, we carried out a retrospective analysis of the morphological progression from ED5 to ED6 in 2480 embryos that were rejected for clinical use [41]. Embryos were given a morphological category commonly used for clinical grading as per standard IVF practice (e.g., single-celled embryo, multicell, morula, blastocyst). If an embryo had reached the blastocyst stage (i.e., showing advanced cavitation), it was given an overall grade of good, fair, or poor, and was also scored for inner cell mass and trophectoderm quality. Our analysis showed that nonviable embryos defined as poor did not improve with extended in vitro culture but retained the capacity to yield hESC lines despite arrested development [41]. We postulated that if derivation efforts were targeted on this subgroup, the derivation success rate could be increased and the production of new hESC lines could be brought closer to clinical application [41].

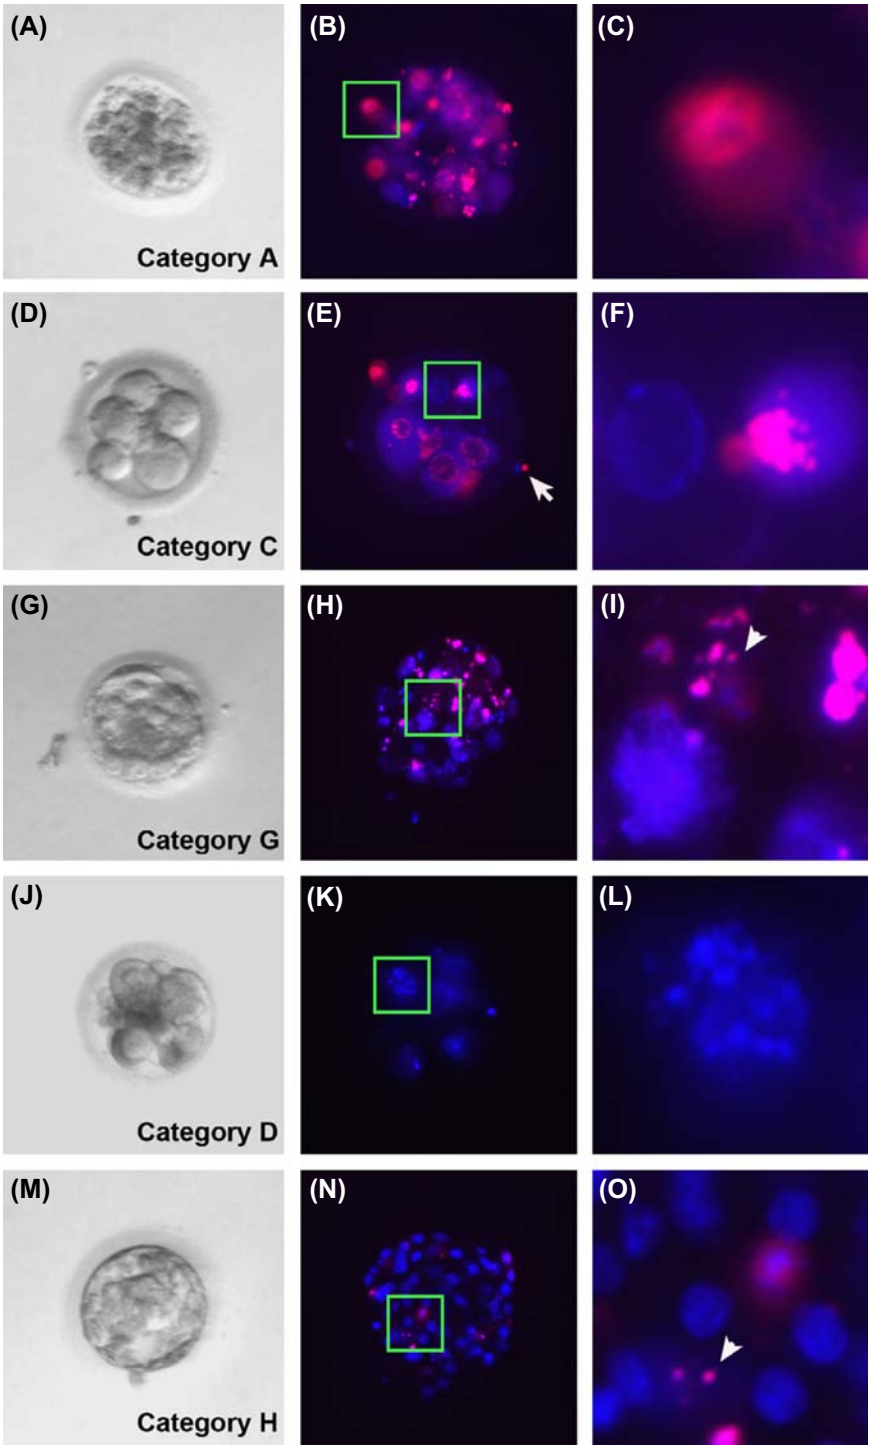

FIGURE 8.2 **Morphology and differential propidium iodide/Hoechst fluorescent nuclear staining of nonviable embryos at ED6.** Brightfield images (A, D, G, J, and M) with corresponding fluorescence images (B, E, H, K, and N), and enlarged details (C, F, I, L, and O) as indicated by the green squares (A–C). Category A embryo showing degeneration at embryonic day 6. All nuclei, including nuclear fragments, are pink, indicating that there are no living cells in the embryo. Detail shows pink nucleus from a dead cell (D–F). Category C embryo with living and dead cells is indicated by the blue and pink nuclei, respectively. Detail shows nuclei from one living and one dead cell. Arrow in E indicates a sperm nucleus outside the zona pellucida. (G–I) Category G embryo with living and dead cells as well as fragmented nuclei. Detail shows intact and fragmented nuclei (J–L). Category D embryo with all live cells. Detail shows blue fragmented nucleus (M–O). Category H embryo with many living and a few dead cells. Arrowheads in I and O indicate nuclear fragments. *Reproduced with permission from Gavrilov S, Prosser RW, Khalid I, MacDonald J, Sauer MV, Landry DW et al. CONCLUSION

The derivation of hESC from organismically dead embryos is a unique approach because it defines a common ground in the human ES debate. Harvesting live cells from dead human embryos has the likelihood of being accepted by the staunchest opponents of embryo-destructive ES derivation. ES cells generated by this approach appear to be suitable for clinical research. Thus far, 11 human ES lines derived by Daley and colleagues have been included in the NIH stem cell registry and are available for research with NIH funding [10]. Human ES lines generated from organismically dead embryos are of equal quality compared with lines derived by the classical, intracellular mass–derived approach, but further characterization of these lines is needed [2].

During routine IVF procedures, large proportions of embryos fail to develop properly [45,47,48] and are discarded as being unsuitable for clinical use [2,27]. Despite the low efficiency of isolation of hESC from organismically dead embryos, large-scale derivation is not limited because in the United States alone, nearly half a million such embryos are generated yearly as a by-product of assisted reproductive technologies [2,27]. The prospect of thousands of hESC lines generated by this method and deposited into stem cell banks renders clinical applications based on human leukocyte antigen matching feasible.

Stem Cells From the Amnion

Paolo De Coppi[1,2], *Anthony Atala*[2]

[1]UCL Institute of Child Health and Great Ormond Street Hospital, London, United Kingdom; [2]Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

INTRODUCTION

In this chapter, we provide an overview of the potential advantages and disadvantages of different stem and progenitor cell populations identified in the amnion and in the amniotic fluid (AF), along with their properties and potential clinical applications.

Placenta, fetal membranes (i.e., amnion and chorion), and AF have been extensively investigated as a potential noncontroversial source of stem cells. They are usually discarded after delivery and are accessible during pregnancy through amniocentesis and chorionic villus sampling [1]. Several populations of cells with multilineage differentiation potential and immunomodulatory properties have been isolated from the human placenta and fetal membranes; they have been classified by an international workshop [2] as human amniotic epithelial cells (hAECs) [3–7], human amniotic mesenchymal stromal cells (hAMSCs) [8,9], human chorionic mesenchymal stromal cells (hCMSCs) [10,11], and human chorionic trophoblastic cells (hCTCs).

In the AF, two main populations of stem cells have been isolated: amniotic fluid mesenchymal stem cells (AFMSCs) and amniotic fluid stem (AFS) cells. Because of the easier accessibility of the AF compared with other extraembryonic tissues, these cells may hold much promise in regenerative medicine.

PLACENTA: FUNCTION, ORIGIN, AND COMPOSITION

During human placental development, a range of cell types is generated, depending on gestation, which can be described as epithelial (because they derive from the amniotic membrane), trophoblastic, and hematopoietic (both derived from the chorionic villi). Placental tissue has contributions from both the fetus (amniotic membrane epithelium, extraembryonic mesoderm, and the two-layered trophoblast) and the mother (decidua basalis). The primitive formation of the placenta occurs from cells of fetal origin, known as trophoblast, that invade the uterine endometrium, form the outer layer of the blastocyst, and produce a network of protrusions, the villi and the lacunae system. On the 7th to 10th day after conception, the chorionic membranes are developed from layers of proliferating placental cells. At day 9 postconception, the inner cell mass induces the formation of the epiblast and hypoblast that subsequently become the amniotic cavity and the yolk sac. The process of gastrulation enables the bilaminar disc to differentiate into the three germ layers (ectoderm, mesoderm, and endoderm), followed by organogenesis [12,13].

During the maturation of the syncytium, the villi establish the maternofetal transport of blood nutrients, oxygen, gases, and waste products, and they differentiate from mesenchymal villi into immature intermediate villi. The placental progenitor stem cells are the cytotrophoblast cells emanating from the trophectodermal layer that result in the villous syncytiotrophoblast, which is a multinucleated aggregate of cytotrophoblast cells, and the extravillous cytotrophoblasts (EVTs) [14]. The trophoblast invasion of the maternal decidualized endometrium is also associated with hormonal secretions, such as human chorionic gonadotrophin, which downregulates maternal cellular immunity and promotes angiogenic activity of the EVTs [15]. By the 12th week of gestation, the placenta has adopted a

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00009-6

hemotrophic nutritional function, in particular causing extensive transformation of the maternal spiral arteries into augmented high-flow, low-resistance vessels that provide sufficient nutrients and oxygen for the developing fetus.

Human fetal placental cells can be divided into the hAECs, hAMSCs, hCMSCs, and hCTCs. Isolation of these latter cells (hCMSCs and hCTCs) can be realized directly from the placenta or through chorionic villus sampling, a form of invasive ultrasound-guided prenatal diagnosis that entails sampling of the placental tissue from 11 weeks of gestation. Isolation of the heterogeneous population of cells (hAECs, hCMSCs, and hCTCs) can be implemented from different placenta regions through enzymatic digestion with dispase or collagenase in synergy with DNase.

AMNIOTIC FLUID: FUNCTION, ORIGIN, AND COMPOSITION

The AF is the clear, watery liquid that surrounds the growing fetus within the amniotic cavity. It allows the fetus to grow freely and move inside the uterus, protects it from outside injuries by cushioning sudden blows or movements and by maintaining consistent pressure and temperature, and acts as a vehicle for the exchange of body chemicals with the mother [16,17].

In humans, the AF starts to appear at the beginning of the second week of gestation as a small film of liquid between the cells of the epiblast. Between days 8 and 10 after fertilization, this fluid gradually expands and separates the epiblast (i.e., the future embryo) from the amnioblasts (i.e., the future amnion), thus forming the amniotic cavity [6]. Thereafter, it progressively increases in volume, completely surrounding the embryo after the fourth week of pregnancy. Over the course of gestation, AF volume markedly changes from 20 mL in the seventh week to 600 mL in the 25th week, 1000 mL in the 34th week, and 800 mL at birth. During the first half of gestation, the AF results from active sodium and chloride transport across the amniotic membrane and the nonkeratinized fetal skin, with concomitant passive movement of water. In the second half of gestation, the AF is composed of fetal urine, gastrointestinal excretions, respiratory secretions, and substances exchanged through the sac membranes [18–21].

The AF is primarily composed of water and electrolytes (98%–99%) but it also contains chemical substances (e.g., glucose, lipids, proteins, hormones, and enzymes), suspended materials (e.g., vernix caseosa, lanugo hair, and meconium), and cells. AF cells are derived both from extraembryonic structures (i.e., placenta and fetal membranes) and from embryonic and fetal tissues [22]. Although AF cells are known to express markers of all three germ layers [23], their exact origin still represents a matter of discussion; the consensus is that they consist mainly of cells shed in the amniotic cavity from the developing skin, respiratory apparatus, and urinary and gastrointestinal tracts [18,24]. AF cells display a broad range of morphologies and behaviors varying with gestational age and fetal development [25]. Under normal conditions, the number of AF cells increases with advancing gestation; if a fetal disease is present, AF cell counts can be either dramatically reduced (e.g., intrauterine death, urogenital atresia) or abnormally elevated (e.g., anencephaly, spina bifida, exomphalos) [26]. Based on their morphological and growth characteristics, viable adherent cells from the AF are classified into three main groups: epithelioid (33.7%), AF (60.8%), and fibroblastic type (5.5%) [25]. In the event of fetal abnormalities, other types of cells can be found in the AF, e.g., neural cells in the presence of neural tube defects and peritoneal cells in case of abdominal wall malformations [26–28].

Most cells present in the AF are terminally differentiated and have limited proliferative capabilities [26,29]. In the 1990s, however, two groups demonstrated the presence in the AF of small subsets of cells harboring a proliferation and differentiation potential. First, Torricelli reported the presence of hematopoietic progenitors in the AF collected before the 12th week of gestation [30]. Then Streubel was able to differentiate AF cells into myocytes, which suggested the presence in the AF of nonhematopoietic precursors [31]. These results initiated new interest in the AF as an alternative source of cells for therapeutic applications.

AMNIOTIC EPITHELIAL CELLS

Human amnion consists of amniotic epithelial cells (AECs) on a basement collagenous membrane, an acellular compact layer filled with reticular fibers, a fibroblast layer with Hofbauer cells/histiocytes, and a highly hygroscopic spongy layer with fibrils between the chorion and the amniotic sac [32].

AECs can be obtained with differential enzymatic digestion from the amnion membrane after it is separated from the underlying chorion [33]. The amnion contains epithelial cells expressing surface markers that include both embryonic-specific markers such as the stage-specific antigens (SSEAs) 3 and 5, Tra-1-60, Tra-1-81, and mesenchymal markers CD105, CD90, CD73, CD44, CD29, human leukocyte antigen (HLA)-A, -B, -C, CD13, CD10, CD166, and

CD117. Their immunological properties have not been completely elucidated; however, AECs also appear to be resistant to rejection after allotransplantation, probably owing to their immunosuppression properties (CD59 and HLA-G [34]), which could also lead to their therapeutic role in a disease model. For example, hAECs have been reported to lower the blood glucose levels of streptozotocin-induced diabetic mice several weeks after implantation, potentially by differentiation into β cells [35].

hAECs are considered multipotent cells because of their capacity to differentiate into different lineages. In particular, they have been able to mature under specific culture conditions into neuronal cells that synthesize acetylcholine, norepinephrine, and dopamine [6,36,37]. In vivo, hAECs have been reported to be neuroprotective and neuroregenerative, probably in relation to growth factor secretion. Indeed, studies showed that hAEC-conditioned media exhibit neurotrophic effects on rat cortical cells [38], and because of the expression of neural markers such as nestin, glial fibrillary acidic protein, and microtubule-associated protein 2, they are inclined toward neuronal lineages. hAECs have also been used to treat peripheral nerve injuries in animal models, in which they have shown to enhance the growth of host neurons and guide regenerative sprouting [68a]. In addition to their neurogenic potential, some relevant work has been done on exploring the hepatic potential of AECs. First, AECs produce albumin and α-fetoprotein, and they show glycogen storage and hepatic differentiation potential in vitro [39,40]. Moreover, in vitro, hAECs had the capacity to metabolize ammonia, testosterone and 17α-hydroxyprogesterone caproate, whereas they expressed hepatocyte markers such as albumin, A1AT, CYP2A4, 3A7, 1A2, 2B6, ASGPR1, and inducible fetal cytochromes. After intrahepatic transplantation into immunodeficient (severe combined immunodeficient [SCID])/beige mice, hAECs demonstrated functional hepatic characteristics [39], and after pretreatment of SCID/beige mice with retrorsine, hAECs expressed mature liver genes, plasma proteins, and hepatic enzymes to a level equal to adult liver tissue. hAECs showed therapeutic efficacy after transplantation in a mouse model of cirrhosis [41]. The transplantation of human amnion−derived epithelial cells to the liver appears to have desired therapeutic properties including the secretion of matrix metalloproteinase that instigate fibrinolysis and increase in interleukin-10 concentration. In a liver disease mouse model, amnion epithelial cell transplantation resulted in hepatic engraftment with decreased inflammation, fibrosis, and hepatocyte apoptosis [42]. Zhang et al. infused amnion-derived cells in a carbon tetrachloride −-treated mouse liver, and they showed minimal fibrosis and apoptosis [43]. Ricci et al. used a piece of human amniotic membrane (hAM) to assess fibrosis in rat liver and demonstrated increased antifibrotic properties of the hAM with a reduction in ductular reaction and extracellular matrix (ECM) deposition [44]. Vaghjiani et al. showed that the differentiation of hAECs into hepatic-like cells can remain viable and functional after encapsulation in barium alginate microspheres in vitro, and they can express CYP3A4, which is thought to break down nearly 50% of all therapeutic drugs [45].

Moreover, the cryopreserved amniotic membrane and its by-products have been recognized as significant tools for the treatment of ulceration and epithelial defects (corneal or conjunctival) [46,47]. Nakamura et al. used autologous serum corneal epithelial cells on an amniotic membrane to transplant nine eyes of nine patients with total limbal stem cell deficiency, and they demonstrated improvement in visual acuity and complete corneal epithelialization within 2−5 days [48]. Wang et al. experimented on allogeneic green fluorescent protein $(GFP)^+$ mice intact amniotic epithelium grafts with syngeneic (EGFP-C57BL/6 to C57BL/6 W/t) and allogeneic (EGFP-C57BL/6 to BALB/c W/t) AE cells that were transplanted into the cornea or conjunctiva or inserted into the anterior chambers. The researchers showed that major histocompatibility complex (MHC) class I beta antigens were minimally expressed after implantation [49]. Finally, other potential clinical applications have been explored and AECs have been considered potentially useful for a broad variety of conditions including ophthalmic diseases, lung fibrosis, liver fibrosis, multiple sclerosis, congenital metabolic disorders such as ornithine transcarbamylase deficiency, familial hypercholesterolemia, spinal cord injuries, and Parkinson disease and for allogeneic cell transplantations [50−52].

AMNIOTIC MESENCHYMAL STEM CELLS

Mesenchymal stem cells (MSCs) represent a population of multipotent stem cells able to differentiate toward mesoderm-derived lineages (i.e., adipogenic, chondrogenic, myogenic, and osteogenic) [53]. Initially identified in adult bone marrow, where they represent 0.001%−0.01% of total nucleated cells [54], MSCs have since been isolated from several adult (e.g., adipose tissue, skeletal muscle, liver, and brain), fetal (i.e., bone marrow, liver, and blood), and extraembryonic tissues (i.e., placenta and amnion) [55].

The presence of a subpopulation of AF cells with mesenchymal features able to proliferate in vitro more rapidly than comparable fetal and adult cells was described for the first time in 2001 [56]. In 2003, In 't Anker demonstrated that the AF can be an abundant source of fetal cells that exhibit a phenotype and a multilineage differentiation

potential similar to that of bone marrow–derived MSCs (BM-MSCs); these cells were named AFMSCs [57]. Soon after that article, other groups independently confirmed similar results.

Isolation and Culture

AFMSCs can easily be obtained: in humans, from small volumes (2–5 mL) of second- and third-trimester AF [57a,61], where their percentage is estimated to be 0.9%–1.5% of the total AF cells [58]; and in rodents, from the AF collected during the second or third week of pregnancy [59,60]. Various protocols have been proposed for their isolation; all are based on the expansion of unselected populations of AF cells in serum-rich conditions without feeder layers, allowing cell selection by culture conditions. The success rate of the isolation of AFMSCs was reported by different authors to be 100% [61]. AFMSCs grow in basic medium containing fetal bovine serum (20%) and fibroblast growth factor (5 ng/mL). It was shown that human AFMSCs can be also cultured in the absence of animal serum without losing their properties [62]; this finding is a fundamental prerequisite for the beginning of clinical trials in humans.

Characterization

The fetal versus maternal origin of AFMSCs has been investigated by different authors. Molecular HLA typing and amplification of the SRY gene in AF samples collected from male fetuses [57,58] demonstrated the exclusive fetal derivation of these cells. However, whether AFMSCs originate from the fetus or from the fetal portion of extraembryonic tissues remains a matter of debate [62].

AFMSCs display a uniform spindle-shaped, fibroblast-like morphology similar to that of other MSCs populations and expand rapidly in culture [63]. Human cells derived from a single 2-mL AF sample can increase to 180×10^6 cells within 4 weeks (three passages), and as demonstrated by growth kinetics assays, they possess a greater proliferative potential (average doubling time, 25–38 h) compared with that of BM-MSCs (average doubling time, 30–90 h) [57,58,60,64]. Moreover, AFMSC clonogenic potential has been proved to exceed that of MSCs isolated from bone marrow (86 ± 4.3 versus 70 ± 5.1 colonies) [60]. Despite their high proliferation rate, AFMSCs retain a normal karyotype and do not display tumorigenic potential even after extensive expansion in culture [58,64].

Analysis of AFMSC transcriptome demonstrated that: (1) the AFMSC gene expression profile, as well as that of other MSC populations, remains stable between passages in culture, enduring cryopreservation and thawing well; (2) AFMSCs share with MSCs derived from other sources a core set of genes involved in ECM remodeling, cytoskeletal organization, chemokine regulation, plasmin activation, transforming growth factor-β, and Wnt signaling pathways; and (3) compared with other MSCs, AFMSCs show a unique gene expression signature that consists of the upregulation of genes involved in signal transduction pathways (e.g., HHAT, F2R, and F2RL) and in uterine maturation and contraction (e.g., OXTR and PLA2G10), which suggests a role of AFMSCs in modulating interactions between the fetus and the uterus during pregnancy [63].

Different investigators determined the cell surface antigenic profile of human AFMSCs through flow cytometry (Table 9.1). Cultured human AFMSCs are positive for mesenchymal markers (i.e., CD90, CD73, CD105, and CD166), for several adhesion molecules (i.e., CD29, CD44, CD49e, and CD54), and for antigens belonging to MHC-I. They are negative for hematopoietic and endothelial markers (e.g., CD45, CD34, CD14, CD133, and CD31).

AFMSCs exhibit a broad differentiation potential toward mesenchymal lineages. Under specific in vitro inducing conditions, they are able to differentiate toward the adipogenic, osteogenic, and chondrogenic lineage [57,60,63].

Despite not being pluripotent, AFMSCs can be efficiently reprogrammed into pluripotent stem cells (iPS) via retroviral transduction of defined transcription factors (Oct4, Sox2, Klf-4, and c-Myc). Strikingly, AFMSC reprogramming capacity is significantly higher (100-fold) and much quicker (6 days versus 16–30 days) compared with that of somatic cells such as skin fibroblasts. Similarly to iPS derived from other sources, iPS derived from AF cells generate embryoid bodies (EBs) and differentiate toward all three germ layers in vitro; in vivo, they form teratomas when injected into SCID mice [65].

Preclinical Studies

After the identification of AFMSCs, various studies investigated their therapeutic potential in different experimental settings. Different groups demonstrated that AFMSCs are able not only to express cardiac and

endothelial-specific markers under specific culture conditions, but also to integrate into normal and ischemic cardiac tissue, where they differentiate into cardiomyocytes and endothelial cells [66−69]. In a rat model of bladder cryoinjury, AFMSCs show the ability to differentiate into smooth muscle and prevent the compensatory hypertrophy of surviving smooth muscle cells [59].

AFMSCs can be a suitable cell source for tissue engineering of congenital malformations. In an ovine model of diaphragmatic hernia, repair of the muscle deficit using grafts engineered with autologous mesenchymal amniocytes leads to better structural and functional results compared with equivalent fetal myoblast-based and acellular implants [62,70]. Engineered cartilaginous grafts have been derived from AFMSCs grown on biodegradable meshes in serum-free chondrogenic conditions for at least 12 weeks; these grafts have been successfully used to repair tracheal defects in fetal lambs when implanted in utero [62]. The surgical implantation of AFMSCs seeded on nanofibrous scaffolds and predifferentiated in vitro toward the osteogenic lineage into a leporine model of sternal defect led to complete bone repair in 2 months [71].

Intriguingly, studies suggested that AFMSCs can harbor trophic and protective effects in the central and peripheral nervous systems. Pan showed that AFMSCs facilitate peripheral nerve regeneration after injury and

hypothesized that this can be determined by cell secretion of neurotrophic factors [72–74]. After transplantation into the striatum, AFMSCs are capable of surviving and integrating in the rat adult brain and of migrating toward areas of ischemic damage [75]. Moreover, the intraventricular administration of AFMSCs in mice with focal cerebral ischemia-reperfusion (IR) injuries significantly reverses neurological deficits in treated animals [76].

Remarkably, it was also observed that AFMSCs present in vitro had an immunosuppressive effect similar to that of BM-MSCs [77]. After stimulation of peripheral blood mononuclear cells with anti-CD3, anti-CD28, or phytohemagglutinin, irradiated AFMSCs demonstrated a significant inhibition of T-cell proliferation with a dose-dependent kinetics [64].

AMNIOTIC FLUID STEM CELLS

The first suggestion that the AF may contain undifferentiated cells was based on the observation that AF-derived cells expressed skeletal muscle proteins when cultured in the supernatant of rhabdomyosarcoma cell lines [31]. Subsequently, AF-derived cells were shown to differentiate into osteocytes, adipocytes, and fibroblasts while having a cell marker profile comparable to MSCs [57]. Brivanlou and colleagues were the first to confirm that a subpopulation of AF-derived cells (approximately 0.5%–1% of total live cells) have stem cell potential, by demonstrating the expression of octamer transcription factor-4 (Oct-4) at the transcriptional and protein levels [78]. Remarkably, Karlmark et al. transfected human AF cells with the GFP gene under either the Oct-4 or the Rex-1 promoter and established that some AF cells were able to activate these promoter [79]. Subsequently, we and others used CD117 (c-Kit; type III tyrosine kinase receptor for stem cell factor with essential roles in gametogenesis, melanogenesis, and hematopoiesis) as a means to select the undifferentiated population from the AF [80,81]. These CD117-expressing cells are a heterogeneous population; they were isolated from small [80–83] and large animals [84] as well as humans [80,85] and are known as AFSC.

Isolation and Culture

The proportion of c-kit$^+$ cells in the AF varies over the course of gestation, roughly describing a Gaussian curve; they appear at very early time points in gestation (i.e., at 7 weeks of amenorrhea in humans and at embryonic day (E)9.5 in mice) and present a peak at midgestation equal to 90×10^4 cells/fetus at 20 weeks of pregnancy in humans and 10,000 cells/fetus at E12.5 in mice [81]. Human AFS cells (AFSC) can be derived either from small volumes (5 mL) of second-trimester AF (14–22 weeks of gestation) or from confluent backup amniocentesis cultures. Murine AFSC are obtainable from the AF collected during the second week of gestation (E11.5–14.5) [80,86–88]. AFSC isolation is based on a two-step protocol consisting of the prior immunological selection of c-kit–positive cells from the AF (approximately 1% of total AF cells) and in the subsequent expansion of these cells in culture [80,87,89–92]. Isolated AFSC can be expanded in feeder layer-free, serum-rich conditions without evidence of spontaneous differentiation in vitro. Cells are cultured in basic medium containing 15% of fetal bovine serum and Chang supplement [80,92].

Characterization

Karyotype analysis of human AFSC deriving from pregnancies in which the fetus was male revealed the fetal origin of these cells [80].

AFSC proliferate well during ex vivo expansion. When cultivated, they display a spectrum of morphologies ranging from a fibroblast-like to an oval-round shape (Fig. 1A). As demonstrated by different authors, AFSC possess great clonogenic potential [80,88]. Clonal AFSC lines expand rapidly in culture (doubling time, 36 h); more interesting, they maintain a constant telomere length (20 kilobase pairs) between early and late passages (Fig. 1B). Almost all clonal AFSC lines express markers of a pluripotent undifferentiated state: Oct4 and NANOG [80,88,89,92,93]. However, they have been proved not to form tumors when injected in SCID mice [80].

Different investigators determined the cell surface antigenic profile of AFSC through flow cytometry (Table 9.2). Cultured human AFSC are positive for embryonic stem (ES) cell (e.g., SSEA-4) and mesenchymal markers (e.g., CD73, CD90, and CD105), for several adhesion molecules (e.g., CD29 and CD44) and for antigens belonging to MHC-I. They are negative for hematopoietic and endothelial markers (e.g., CD14, CD34, CD45, CD133, and CD31), and for antigens belonging to MHC-II.

Because the stability of cell lines is a fundamental prerequisite for basic and translational research, the capacity of AFSC to maintain their baseline characteristics over passages has been evaluated based on multiple parameters. Despite their high proliferation rate, AFSC and derived clonal lines show a homogeneous, diploid DNA content without evidence of chromosomal rearrangement even after expansion to 250 population doublings [80,89] (Fig. 1C). Moreover, AFSC maintain constant morphology, doubling time, apoptosis rate, cell cycle distribution,

and marker expression (e.g., Oct4, CD117, CD29, and CD44) up to 25 passages [89,92]. During in vitro expansion, however, cell volume tends to increase and significant fluctuations of proteins involved in different networks (i.e., signaling, antioxidant, proteasomal, cytoskeleton, connective tissue, and chaperone proteins) can be observed using a gel-based proteomic approach [89]; the significance of these modifications warrants further investigations but needs to be taken in consideration when interpreting experiments over several passages and comparing results from different groups.

AFSC and, more important, derived clonal cell lines are able to differentiate toward tissues representative of all three embryonic germ layers spontaneously, when cultured in suspension to form EBs, and when grown under specific differentiation conditions.

EBs consist of three-dimensional aggregates of ES cells, which recapitulate the first steps of early mammalian embryogenesis [93a–93c]. As ES cells, when cultured in suspension and without antidifferentiation factors, AFSC harbor the potential to form EBs with high efficiency: the incidence of EB formation (i.e., the percentage of EB recovered from 15 hanging drops) is estimated to be around 28% for AFSC lines and around 67% for AFSC clonal lines. Similar to ES cells, EB generation by AFSC is regulated by the mammalian target of rapamycin pathway and is accompanied by a decrease of Oct4 and Nodal expression and by an induction of endodermal (GATA4), mesodermal (Brachyury and HBE1) and ectodermal (Nestin and Pax6) markers [92,94].

Under specific mesenchymal differentiation conditions, AFSC express molecular markers of adipose, bone, muscle, and endothelial differentiated cells (e.g., lipoprotein lipase, desmin, osteocalcin, and vascular cell adhesion protein 1). In the adipogenic, chondrogenic, and osteogenic medium, AFSC respectively develop intracellular lipid droplets, secrete glycosaminoglycans, and produce mineralized calcium [86,88]. Under conditions inducing cell differentiation toward the hepatic lineage, AFSC express hepatocyte-specific transcripts (e.g., albumin, α-fetoprotein, and multidrug-resistant membrane transporter 1) and acquire the liver-specific function of urea secretion (Fig. 2A) [80]. Under neuronal conditions, AFSC are capable of entering the neuroectodermal lineage. After induction, they express neuronal markers (e.g., G protein–coupled inwardly rectifying K^+ potassium channels), exhibit barium-sensitive potassium current, and release glutamate after stimulation (Fig. 2B). Ongoing studies are investigating AFSC capacity to yield mature, functional neurons [95–97].

AFSC can be easily manipulated in vitro. They can be transduced with viral vectors more efficiently than can adult MSCs, and after infection, they maintain their antigenic profile and the ability to differentiate into different lineages [98]. AFSC labeled with superparamagnetic micrometer-sized iron oxide particles retain their potency and can be tracked noninvasively by magnetic resonance imaging (MRI) for at least 4 weeks after injection in vivo [99].

Preclinical Studies

Several reports have investigated the potential applications of AFSC in different settings.

Musculoskeletal System

We investigated the osteogenic potential of AFSC by inducing osteogenic differentiation with culture media containing dexamethasone, β-glycerophosphate, and ascorbic acid-2-phosphate. After seeding in a collagen/alginate scaffold, they were implanted subcutaneously in immunodeficient mice. At 18 weeks, micro−computed tomography revealed highly mineralized tissues and blocks of bone-like material [80]. In a study by Sun et al., osteogenic differentiation of human AFSC was achieved using bone morphogenetic protein-7 and seeding on nanofibrous scaffolds, as evident by alkaline phosphatase activity, calcium content, von Kossa staining, and the expression of osteogenic genes. Implantation into the subcutaneous space led to bone formation in 8 weeks with positive von Kossa staining and a radio-opaque profile upon X-ray [100].

A series of experiments by the Goldberg laboratory investigated the osteogenesis of AFSC after seeding on a poly(ε-caprolactone) (PCL) biodegradable polymer. Cells that were differentiated in a three-dimensional PCL scaffold deposited mineralized matrix and were viable after 15 weeks of culture. It was also shown that predifferentiated cells in vitro produced seven times more mineralized matrix when implanted subcutaneously in vivo [101]. When the authors compared AFSC and BM-MSC for osteogenesis after seeding on scaffolds and long-term in vitro culture, they came across some striking results. Although BM-MSC differentiated more rapidly than AFSC, the growth and production of mineralized matrix halted at 5 weeks. In contrast, AFSC continued to produce matrix for up to 15 weeks, which led to a fivefold increase in overall production compared with BM-MSC seeded scaffolds.

We demonstrated for the first time the functional and stable long-term integration of AFSC into the skeletal muscle of human α-skeletal actin−Cre SmnF7/F7 mutant mice, which closely replicates the clinical features of human muscular dystrophy [102]. AFSC were obtained from E11.5−13.5 GFP^+ mice through direct CD117 selection immediately after AF collection. Approximately 25,000 freshly isolated AFSC were injected into the tail vein of each animal without previous expansion in culture. Transplanted mice displayed enhanced muscle strength, improved survival rate by 75%, and restored muscle phenotype compared with untreated animals. Not only was dystrophin distribution in GFP^+ myofibers similar to that of wild-type animals, GFP^+ cells were found to be engrafted into the muscle stem cell niche (as demonstrated by their sublaminal position and by Pax7 and α7-integrin expression). Functional integration of AFSC in the stem cell niche was confirmed by successful secondary transplants of GFP^+ satellite cells derived from AFSC-treated mice into untreated SmnF7/F7 mutant mice. To progress toward their application for therapy, the therapeutic potential of cultured AFSC was investigated and 25,000 AFSC, expanded under "embryonic-type" conditions, were intravenously injected into SmnF7/F7 mice. Cultured AFSC regenerated approximately 20% of the recipient muscle fibers compared with 50% when freshly isolated AFSC were used; this highlighted the importance of optimizing cell expansion protocols. Available data suggest that AFSC can differentiate toward myogenic lineages, engraft into the muscle stem cell niche, and participate in muscle regeneration in animal models of muscle injury. Hence, AFSC constitute a promising therapeutic option for skeletal muscle degenerative diseases.

Nervous System

We previously investigated human AFSC injection in the brain of Twitcher mice (a model of Krabbe globoid leukodystrophy associated with progressive oligodendrocyte and neuronal loss). Human AFSC engrafted into the lateral cerebral ventricles differentiated to cells that were similar to the surrounding environment and survived for up to 2 months. It was also demonstrated that engraftment was variable; 70% of AFSC survived in the brain of Twitcher mice, in contrast to only 30% of AFSC in the brain of normal mice [80]. A study by Prasongchean et al. indicated that treatment with small molecules, which normally leads to neuronal differentiation and grafting of AFSC into environments such as organotypic rat hippocampal cultures and the embryonic chick nervous system, led to no expression of neural cell markers. However, AFSC reduced hemorrhage and increased survival in a chick embryo model of extensive thoracic crush injury. Survival was not improved by mesenchymal or neural cells, or desmopressin. The authors explained that this effect was associated with the secretion of paracrine factors as evidenced by a transwell coculture model [103].

Heart

We previously looked at the cardiomyogenic potential of AFSC in vitro and in vivo. AFSC cultured in cardiomyocyte induction media or in coculture with cardiomyocytes demonstrated the expression of proteins specific for cardiomyocytes (atrial natriuretic peptide and α-myosin heavy chain), endothelial (CD31 and CD144), and smooth muscle cells (α-smooth muscle actin). In our first experience with xenogenic transplantation, human AFSC were transplanted in a rat model of myocardial infarction (MI). Cells of the immune system were recruited including

T, B, and NK cells and macrophages, and resulted in cell rejection. We speculated that this may be caused by AFSC expression of B7 costimulatory molecules CD80 and CD86 as well as macrophage marker CD68 [104]. In the next step, we attempted allogenic rat AFSC cardiac therapy by intracardiac transplantation in rats with IR injury. Three weeks after transplantation, a portion of the cells acquired an endothelial or smooth muscle phenotype and a smaller number had cardiomyocyte characteristics. Left ventricular ejection fraction was improved in the animals that had the AFSC injection, as quantified using MRI, and which suggested a paracrine therapeutic effect [82]. We then aimed to investigate this paracrine effect further using a rat model of MI and xenogeneic transplantation of human AFSC administered intravascularly immediately after reperfusion. This was dissimilar to our previous attempt with xenogeneic cellular cardiomyoplasty, which involved intramuscular injection of human AFSC within 20 min of coronary artery occlusion without reperfusion. Intravascular injection of human AFSC and their conditioned medium was cardioprotective and improved cell survival, and it decreased the infarct size from 54% to around 40% in both cases. We also showed that AFSC secrete the actin monomer-binding protein thymosin β-4 (Tβ-4), a paracrine factor with cardioprotective properties [105]. Tβ-4 has also been implicated as being cardioprotective in MI models that involved BM-MSC injection [106]. In addition to models of myocardial IR injury, we investigated the salutary effects of AFSC in a rat model of right heart failure resulting from pulmonary hypertension. After intravascular injection, AFSC engrafted in the lung, heart, and skeletal muscle reduced brain natriuretic peptide, a surrogate marker for heart failure, and proinflammatory cytokines. Moreover, AFSC differentiated into endothelial and vascular cells forming microvessels, capillaries, and small arteries. A 35% decrease in pulmonary arteriole thickness accompanied the injection [107]. Of relevance, in a seminal article, Rafii demonstrated that it was possible to convert human midgestation AF-derived cells directly into a stable and expandable population of vascular endothelial cells without using pluripotency factors [108]. Notably, it has been shown that ckit^{+} AFSC prior differentiation express early endothelial transcription factors. Moreover, in vivo, AFSC from both second and third trimesters expanded in hypoxia were able to rescue surface blood flow when locally injected in mice after chronic ischemia damage, and possessed the ability to fix carotid artery electric damage [109].

Hematopoietic System

Ditadi and colleagues were the first to demonstrate the hematopoietic potential of murine and human CD117^{+}/Lin^{-} AFSC [81]. In vitro, the AFSC population in both species displayed multilineage hematopoietic potential, as demonstrated by the generation of erythroid, myeloid, and lymphoid cells. In vivo, cells belonging to all hematopoietic lineages were found after primary and secondary transplantation of murine AFSC into immunocompromised hosts, thus demonstrating the long-term hematopoietic repopulating capacity of these cells. The latter results support the idea that the AF may be a source of stem cells with the potential for therapy of hematological disorders.

One of the most exciting applications of AFSC in this setting is in the field of in utero transplantation (IUT). IUT has been proposed as a novel approach for the treatment of inherited hematological disorders (including thalassemia and sickle cell disease) before birth [110]. Clinical translation has been limited by competitive and immunological barriers associated with IUT of adult bone marrow−derived HSC [111]. The use of AFSC for IUT could address many of these limitations. AFSC are of fetal origin, and as a result should be able to compete better against host cells compared with adult stem cells (potentially overcoming competitive barriers to engraftment). They are nonimmunogenic to the fetus at any gestational age and are also unlikely to result in maternal immunization because of the tolerogenic properties of the placenta. IUT of AFSC would involve harvesting the cells from the AF, employing in vitro gene therapy to correct the genetic defect, and transplanting back to the donor fetus. Such a combined autologous stem cell−gene transfer approach would also address some of the risks associated with administering gene therapy directly to the fetus (in utero gene therapy) [111]. The possibility of performing in vitro gene transfer to harvested ASFC would allow cells to be checked for insertional mutagenesis before transplantation and would obviate the risk of germline transmission of transgenes. In proof of principle studies, Shaw and colleagues showed that IUT of autologous (isolated using ultrasound-guided amniocentesis), expanded, and transduced AFSC resulted in widespread tissue engraftment (including the hematopoietic system) in the ovine fetus [112]. We are investigating the hematopoietic potential of freshly isolated and expanded AFSC after intravenous transplantation in immunocompetent fetal mice, and have obtained stable, multilineage engraftment at near-therapeutic levels using relatively small donor cell numbers. Whether in utero stem cell−gene therapy with AFSC would be therapeutic in models of hematological and other congenital disorders remains to be determined.

Kidney

AFSC have been shown to have plastic regenerative properties in the lung, by differentiating into different lineages according to the type of lung injury taking place in animal models of disease. AFSC injected intravascularly into

nude mice subjected to hyperoxia-induced pulmonary injury migrated to the lung and expressed human pulmonary epithelial differentiation marker thyroid transcription factor 1 and type-II pneumocyte marker surfactant protein C. After naphthalene injury to Clara cells, AFSC expressed the Clara cell−specific 10-kDa protein [113]. Moreover, in an adult rat model of hyperoxic lung injury, treatment with human AFSC has a reparative potential through paracrine involvement in alveolarization and angiogenesis [114]. In an established nitrofen-induced rat model of lung hypoplasia, lung growth, bronchial motility, and innervation were rescued by AFSC both in vitro and in vivo, which was similarly to results observed before with retinoic acid. The beneficial effect of AFSC was probably related to the paracrine action of growth factor secretion [115]. Those results have been validated in fetal rabbit with a surgically created left diaphragmatic hernia at day 23 (term, day 32). In this model, human AFSC exert an additional effect on tracheal occlusion leading to a decrease in mean terminal bronchiole density, a measure of alveolar number surrounding the terminal bronchioles, without signs of toxicity [116].

Lung

The first evidence regarding a nephrogenic potential of AFSC arose from a series of experiments involving the ex vivo growth of murine embryonic kidneys that were injected with labeled AFSC. Whereas AFSC were viable for up to 10 days' growth, they were also shown to contribute to a number of components of the developing kidney, such as the renal vesicle and S- and C-shape bodies. In addition, the ECM and surrounding cells induced renal differentiation, with the AFSC expressing kidney markers (zona occludens-1, glial-derived neurotrophic factor, and claudin) [91].

In a mouse model of acute tubular necrosis (ATN) involving glycerol injection, luciferase-labeled injected AFSC homed to the injured kidney. This decreased creatinine and blood urea nitrogen (BUN) levels and reduced the number of damaged tubules while increasing the proliferation of tubular epithelial cells. Interestingly, AFSC injected during the acute phase of ATN (between 48 and 72 h) had no effect on creatinine and BUN levels, whereas AFSC injected into the kidney on the same day of glycerol injection resulted in no observed peaks in creatinine or BUN. The authors speculated that this may be the result of AFSC accelerating the proliferation of partially damage epithelial tubular cells while preventing apoptosis [117]. Another laboratory confirmed the protective effect of AFSC in the same mouse model of ATN while comparing their effect with MSC. In addition to results regarding the amelioration of the effect of glycerol, it was demonstrated that MSC were more efficient in inducing proliferation and AFSC were more antiapoptotic. Sedrakyan et al. used Col4a5(−/−) mice as a mouse model of Alport syndrome to assess the effect of AFSC in renal fibrosis [83]. Early intracardiac administration of AFSC delayed interstitial fibrosis and the progression of glomerular sclerosis and prolonged animal survival. However, AFSC were not demonstrated to differentiate into podocytes, which suggests that the positive effects to the basement membrane were again mediated, as in other model of disease, by a paracrine mechanism [102,118]. It was reported for the first time that AFSCs mixed with organoids made with murine embryonic kidney contributed to the formation of glomerular structures, differentiated into podocytes with slit diaphragms, and internalized exogenously infused bovine serum albumin, attaining unprecedented (for donor stem cells) degrees of specialization and function in vivo [119].

Intestine

We looked at the effect of AFSC in a rat model of necrotizing enterocolitis (NEC) [120]. After 24 h of life, NEC rats were randomized to treatments of AFSC, BM-MSC, myoblasts (as a committed negative control), or phosphate-buffered saline (PBS) via intraperitoneal administration. NEC rats treated with AFSC showed significantly higher survival at 7 days compared with all the other groups and had an improved NEC clinical status at 96 h. MRI displayed significantly decreased peritoneal fluid accumulation (a surrogate marker for NEC grade) in the AFSC-treated rats. The improved clinical picture of the pups injected with AFSC was also evident by measurement of intestinal permeability, contraction, and motility.

The clinical data were confirmed by histological analysis, demonstrating a decreased amount of villus sloughing, core separation, and venous congestion. The relationship between these therapeutic effects and the presence of AFSC in the intestine was confirmed by tracking AFSC expressing GFP. At 48 h, cells were adherent to the mesentery; at 72 h, they were found in the serosa and muscularis; and at 96 h, they were located in the villi. The low cell numbers in these locations alongside the great clinical differences among treated groups suggested a paracrine effect. Accordingly, when we performed microarray analysis we saw differences in a number of genes involved in inflammation and tissue repair, cell cycle regulation, and enterocyte differentiation. These results were corroborated by immunofluorescence analysis examining cell proliferation and apoptosis.

We then sought to investigate the paracrine mechanism by which AFSC mediate their therapeutic effect and established that the number of cryptal cells expressing cyclo-oxygenase-2 ($COX\text{-}2^{+}$) inversely correlated with the

degree of intestinal damage. COX-2^+ cells were diminished in rats treated with PBS, whereas they were maintained in rats treated with AFSC. Interestingly, although the total number of COX-2^+ cells in villi was similar in AFSC-treated and control animals, cryptal COX-2^+ cells were significantly increased in the AFSC rats compared with both control animals and pups treated with PBS. This dependence on COX-2 was confirmed when the effect of AFSC was abolished both by selective COX-2 and nonselective COX inhibition, but it remained unaffected by a selective COX-1 inhibitor [121].

CONCLUSIONS

Many stem cell populations (e.g., embryonic, adult, and fetal stem cells) as well as methods for generating pluripotent cells (e.g., nuclear reprogramming) have been described. All of them have specific advantages and disadvantages. It has yet to be established which type of stem cell represents the best candidate for cell therapy. However, although it is likely that one cell type may be better than another, depending on the clinical scenario, the discovery of easily accessible cells of fetal derivation, not burdened by ethical concerns, in the AF has the potential of expanding new horizons in regenerative medicine. In fact, amniocentesis is routinely performed for the antenatal diagnosis of genetic diseases and its safety has been established by several studies documenting an extremely low overall fetal loss rate (0.06%−0.83%) related to the procedure [122,123]. Moreover, stem cells can be obtained from AF samples without interfering with diagnostic procedures.

Two stem cell populations have been isolated from the AF (i.e., AFMSCs and AFSC) and both can be used as primary (not transformed or immortalized) cells without further technical manipulations. AFMSCs exhibit typical MSC characteristics: fibroblastic-like morphology, clonogenic capacity, multilineage differentiation potential, immunosuppressive properties, expression of a mesenchymal gene expression profile, and a mesenchymal set of surface antigens. However, ahead of other MSC sources, AFMSCs are easier to isolate and have better proliferation capacities. The harvest of bone marrow remains a highly invasive and painful procedure, and the number, proliferation, and differentiation potential of these cells decline with increasing age [124,125]. Similarly, umbilical cord blood−derived MSCs exist at a low percentage and expand slowly in culture [126].

AFSC, on the other hand, represent a class of broadly stem cells with intermediate characteristics between ES and AS cells [29,127]. They express both embryonic and MSC markers, are able to differentiate into lineages representative of all embryonic germ layers, and do not form tumors after implantation in vivo. However, AFSC have been identified only recently and many questions need to be answered concerning their origin, epigenetic state, immunological reactivity, regeneration, and differentiation potential in vivo. AFSC may not differentiate as promptly as do ES cells and their lack of tumorigenesis can be argued against their pluripotency.

Although further studies are needed to better understand their biological properties and define their therapeutic potential, stem cells present in the AF appear to be promising candidates for cell therapy and tissue engineering. In particular, they represent an attractive source for the treatment of perinatal disorders such as congenital malformations (e.g., congenital diaphragmatic hernia) and acquired neonatal diseases requiring tissue repair/regeneration (e.g., NEC). In a future clinical scenario, AF cells collected during a routinely performed amniocentesis could be banked, and in case of need, subsequently expanded in culture or engineered in acellular grafts [29,62]. In this way, affected children could benefit from having autologous expanded or engineered cells ready for implantation either before birth or in the neonatal period [128].

CHAPTER

10

Cord Blood Stem Cells

Kristin M. Page, Jessica M. Sun, Joanne Kurtzberg

Duke University, Durham, NC, United States

INTRODUCTION

Umbilical cord blood (CB) is firmly established as an unrelated donor source for hematopoietic stem cell transplantation (HSCT) and is a readily available cell source in the evolving fields of regenerative medicine and cellular therapies. Worldwide, there are over 160 public banks with a global inventory of over 700,000 fully characterized, high-quality cord blood units (CBUs) [1], and more than 5 million CBUs have been banked at an estimated 215 family banks. In this chapter, we review the history of CB transplantation (CBT) and banking as well as established and emerging clinical uses of CB in regenerative medicine.

A BRIEF HISTORY

CB was first recognized as rich source of hematopoietic stem and progenitor cells (HSCs) several decades ago. In a pivotal series of experiments, Dr. Ted Boyce, working with Dr. Hal Broxmeyer and colleagues, demonstrated that CB HSCs possessed high proliferative potential, could successfully repopulate hematopoiesis in murine models and tolerated cryopreservation and thawing with efficient HSC recovery [2]. This critical work provided the scientific rationale to investigate CB as a potential source of donor HSCs in humans.

The first patient to undergo a CBT was a 5-year-old boy with Fanconi anemia. Through prenatal testing, it was determined that his mother was pregnant with an unaffected human leukocyte antigen (HLA) matched sibling. Upon the sibling's birth, the CB was collected into a sterile bottle containing preservative-free heparin and transported to Dr. Broxmeyer's laboratory, where it was diluted with tissue culture media and dimethyl sulfoxide (DMSO). The CB was then cryopreserved and stored under liquid nitrogen until it was transported to Paris, France, where the transplant would occur. The clinicians caring for the family elected to wait until the healthy sibling donor was 6 months of age so that she could serve as a backup bone marrow donor if the cord blood transplant failed. In 1988, Dr. Eliane Gluckman performed the first CBT in the world using the sibling's CB as the donor [3]. The child successfully engrafted with his sister's cells and has remained healthy with full donor chimerism ever since. Building on this initial success, additional related donor CBTs were performed in selected centers over the next 5 years [4–7]; the first unrelated donor CB bank was established by Dr. Pablo Rubinstein at the New York Blood Center in 1992. In the following year, Dr. Joanne Kurtzberg performed the first unrelated donor CBT at Duke University in a 4-year-old child with relapsed T-cell leukemia. Early experience with unrelated CBT demonstrated that partially HLA-mismatched, banked unrelated donor CB could successfully restore hematopoiesis with an incidence of graft versus host disease (GvHD) lower than expected and that engraftment was associated with the total nucleated cell (TNC) dose available relative to the recipient's body size [8,9].

With the extension into the unrelated donor setting, the fields of CBT and banking expanded rapidly. In 1995, EUROCORD was established by Dr. Eliane Gluckman; it continues to operate as an international CBT registry on behalf of the European Group for Blood and Marrow Transplantation. In 1996, the Foundation for the Accreditation of Cellular Therapy (FACT) was established by its parent organizations, the International Society for Cellular Therapy and the American Society of Blood and Marrow Transplantation (ASBMT). The following year, the International NetCord Foundation was established to serve as a registry for international public banks. The first

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00010-2

international public CB banking standards were created by NetCord and the first accreditation program resulted from a collaboration between FACT and NetCord in 1999. Although participation is these programs is considered voluntary, many public CB banks are required to received accreditation from FACT/NetCord or the American Association of Blood Banks to participate in registries and receive reimbursement for units distributed for transplantation.

In the United States, the National Marrow Donor Program (NMDP) established the Center for Cord Blood in 1999 and expanded the unrelated donor registry to include publically banked CBUs. In 2006, after passage of the Stem Cell Act of 2005, Congress established the CW Bill Young Cell Transplantation Program. This program awarded contracts to the NMDP to create a single point of access donor registry and coordinating centers for CB and adult donors, to the Center for International Blood and Marrow Transplant Research to develop a stem cell outcomes database, and to the Health Resources and Services Administration of the Department of Health and Human Services to administer these programs and establish the national cord blood inventory (NCBI), a US network of public CB banks. This program was reauthorized in 2010 and 2015. A major goal of the program is to create a large repository of high-quality CBUs from donors of diverse ancestry to enable access to HSCT for as many patients as possible. In the United States, the Food and Drug Administration (FDA) regulates unrelated donor CB as biological product and issued final guidance for public banks to obtain a Biological License Agreement (BLA) in 2011. Seven public banks in the United States have obtained a BLA.

CORD BLOOD BANKING

Historically, after the birth of a baby, the CB and placenta were discarded as medical waste. With the advent of CBT, methods to reliably collect, process, test, cryopreserve, and store CB were developed with the goal of creating banks that could provide ready access to safe CBU products suitable for transplantation. Since the establishment of the first unrelated donor CB bank, the banking industry exploded, with an estimated worldwide inventory of more than 6 million CBUs stored in a combination of public and family CB banks [10]. Although the "shelf life" of banked cord blood is not known, successful transplants have been performed with units stored as long as 25 years. As the field has grown and advanced, accrediting agencies have emerged and developed standards for quality banking practices. In the United States, the FDA regulates unrelated CB as a biological product.

PUBLIC VERSUS FAMILY (OR PRIVATE) BANKS

There are two main types of CB banks. Public banks collect, process, and store donated CBUs intended for unrelated allogeneic transplantation at no expense to the donor or their family. Mothers consent to donate their baby's CB for public use and thereby relinquish all future rights to the unit. In the United States and most other countries, public banks are subject to strict regulatory oversight and use stringent volume, cell count, sterility, donor eligibility, and medical history specifications to determine which collected CBUs are banked. Because cell count is a critical determinant of CBU use, only larger units containing sufficient cells for a single or double CBT of an adult-sized individual are banked. As a result, many donated units do not qualify to be banked and are discarded or used for research, depending on the consent given by the donor family.

Family (or private) banks are generally "for-profit" businesses that charge the parents an initial processing fee and an annual storage fee to store CB exclusively for use by the child or the family. In actuality, the likelihood of using a privately banked CB for transplantation is low [11]. Therefore, the American Academy of Pediatrics, American Congress of Obstetricians and Gynecologists (ACOG), and ASBMT and other similar organizations worldwide do not recommend banking CB for personal use unless there is a family history of a disease (e.g., malignancy or hemoglobinopathy) that is amenable to HSCT [11–13]. To facilitate banking in these instances, many public and family banks offer "directed donor" programs, some of which waive charges associated with the banking process. Family banks are not subjected to the same regulatory oversight as public banks, although this varies among countries. Family banks generally use less stringent criteria for banking, which leads to wide variations in volume and cell content of the private inventory. According to a study of the safety of autologous CB infusions to treat children with acquired brain injury, CBUs from family banks were inferior to those stored in public banks with respect to collection volume, total nucleated cell count (TNCC), and $CD34^+$ count (Fig. 10.1) [14]. Because the use of CB is likely to expand, particularly in the field of regenerative medicine, the

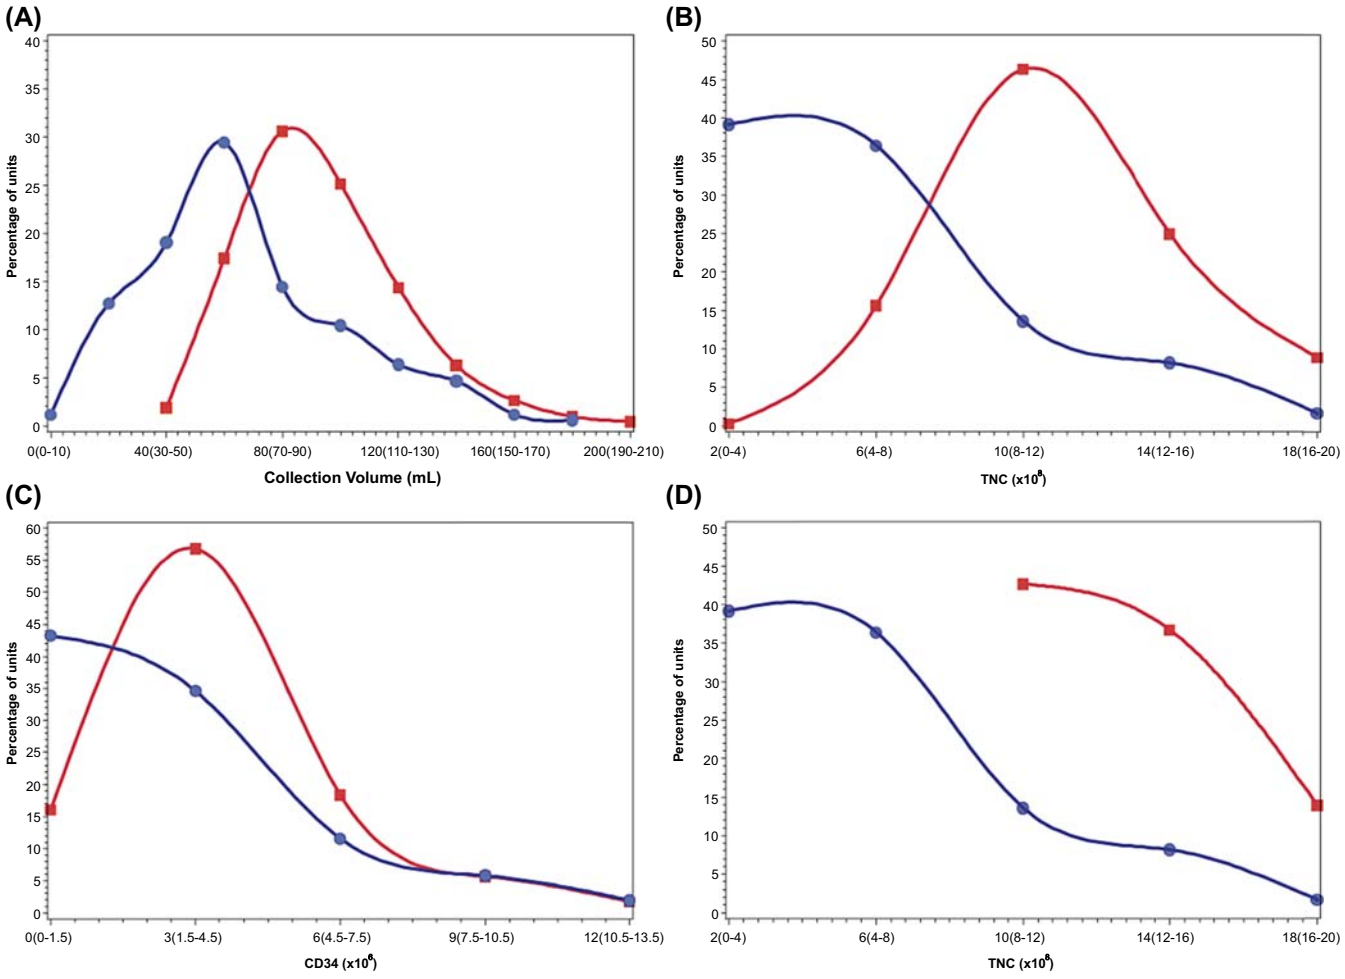

FIGURE 10.1 **Distributions of quality variables.** In (A–C), the distribution of autologous CBUs is compared with the entire Carolinas Cord Blood inventory with respect to collection volume (A), TNC (B), and CD34 content (C). In (D), TNC of autologous CBUs (represented as *red circles*) and National Cord Blood Inventory–eligible Carolinas Cord Blood Bank CBUs (represented as *blue squares*) are compared. *CBUs*, cord blood units; *TNC*, total nucleated cell. *Used with permission from Sun J, Allison J, McLaughlin C, et al. Differences in quality between privately and publicly banked umbilical cord blood units: a pilot study of autologous cord blood infusion in children with acquired neurologic disorders. Transfusion 2010;50(9):1980–7.*

indications and criteria that a CBU must meet for use may change. In response to these changes, the role of regulatory oversight in family CB banking may need to be optimized.

PUBLIC CORD BLOOD BANKING PROCEDURES

Donor Recruitment and Consent

Mothers who are potentially eligible for donation are identified based on clinical characteristics defined by the individual bank. At the Carolinas Cord Blood Bank (CCBB), donations are accepted from healthy mothers (aged ≥18 years) who are carrying healthy singleton pregnancies of at least 34 weeks' gestation and who provide written informed consent for donation before collection. Consent gives permission to collect the CBU. For potentially eligible units, the mother is approached again to give written informed consent for banking the unit for use in transplantation. These mothers provide a medical and family history, a maternal blood specimen to screen for certain communicable diseases, and a review of medical records of the infant and maternal donors. The mother also gives permission for the CB to be used for research if it does not meet specifications for banking.

Collection Techniques

CB can be collected from either vaginal or cesarean births, either before delivery of the placenta (in utero) by obstetrical staff or after delivery of the placenta (ex utero), allowing for dedicated, trained bank staff to perform collections. Although the delivery method is dictated by the clinical status of the mother and infant, the method of collection is determined by staffing and collection site practices. Generally, reports have observed higher collection volumes after cesarean compared with vaginal deliveries [15–17] and when CB is collected in utero compared with ex utero [18], although not all reports have agreed [19]. Both collection methods continue to be used routinely, but in utero collections are more common, likely owing to the additional personnel expenses associated with ex utero collections. Regardless of the collection method, CB is typically collected by cannulating the umbilical vein, allowing the placental blood to drain by gravity into collection containers with anticoagulant, most commonly citrate phosphate dextrose. Closed system collection bags are standard, because they have been shown to reduce bacterial contamination [20].

Volume and Cell Count Considerations

The goal of public CB banks is to provide quality CBUs for allogeneic transplantation for all patients in need. Because successful CBT requires a minimum TNC per kilogram dose, thresholds for banking have been established based on the TNCC. It is well-established that collection volume and TNCC are closely correlated. Therefore, many banks weigh the CBU after collection to estimate the volume and then ship to the processing laboratory only units that surpass a specified volume threshold. Low-volume units are discarded at the collection site because they are unlikely to have sufficient TNCC. Alternatively, some banks measure TNCC at the collection site or use other criteria to determine which units proceed to processing.

Efforts to increase collection volume have focused on two general approaches: identifying donations likely to have higher collection volume and developing techniques to obtain the maximal volume from an individual donation. Increased donor birth weight and older gestational age have been closely associated with higher collection volume and TNCC [21–23], although data suggest that collections from younger infants (aged 34–37 weeks' gestation) are more likely to have higher progenitor cell content, as measured by $CD34^+$ and colony-forming unit (CFU) content (Fig. 10.2) [24]. Also, despite comparable collection volumes among donors of different races or ethnicities, the TNCC, $CD34^+$, and CFU content adjusted for collection volume (counts/mL) are lower in individuals of certain racial backgrounds, particularly African Americans, compared with Caucasian donors, even after adjusting for other

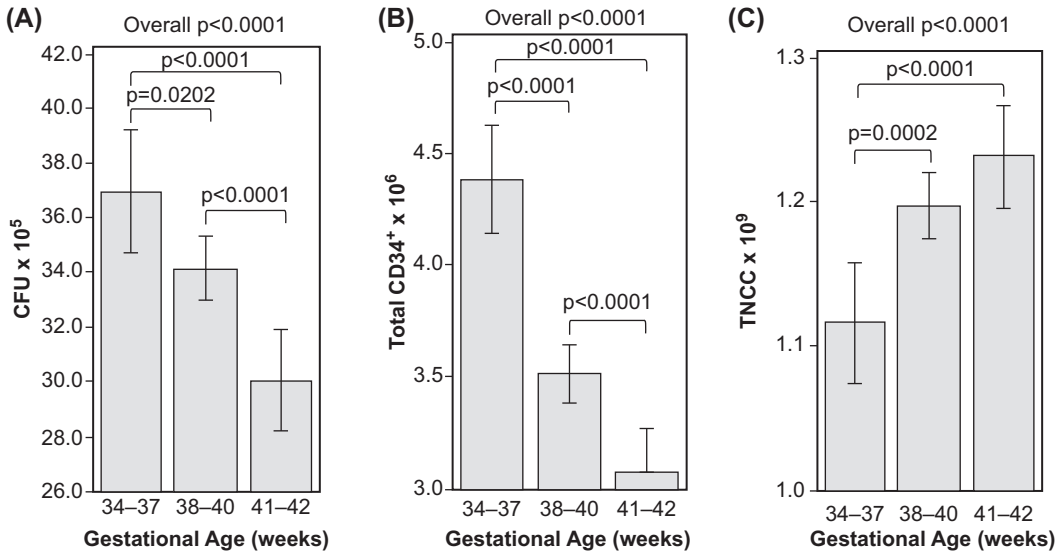

FIGURE 10.2 Impact of infant estimated gestational age on the CFU, $CD34^+$, and post-TNCC content. In (A–C), the adjusted mean CFU (A), $CD34^+$ (B), and post-TNCC (C) is shown in relationship to infant gestational age after adjusting for infant race/ethnicity, birth weight, sex, collection volume, delivery type, and maternal age. Only significant *P* values are shown. Whisker plots represent the 95% confidence intervals. *CFU*, colony-forming unit; *TNCC*, total nucleated cell count. *Used with permission from Page KM, Mendizabal A, Betz-Stablein B, et al. Optimizing donor selection for public cord blood banking: influence of maternal, infant, and collection characteristics on cord blood unit quality. Transfusion 2013;54.*

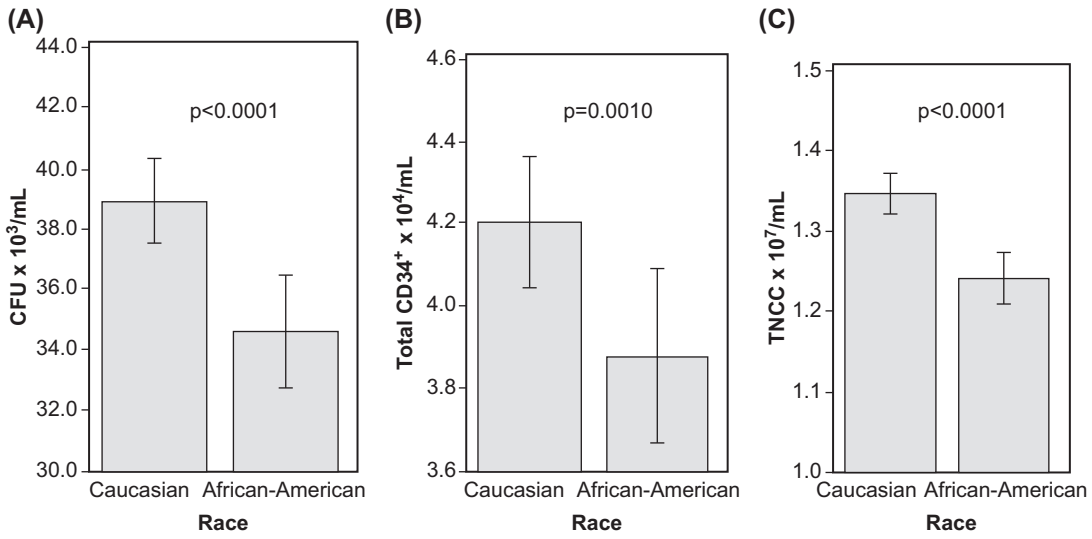

FIGURE 10.3 Comparison of the CFU, CD34$^+$, and post-TNCC concentrations for Caucasian and African American infants. In (A–C), the adjusted mean CFUs/mL (A), CD34$^+$ per mL (B), and post-TNCC/mL (C) are shown in relationship to race for infants of Caucasian and African American race, respectively, after adjusting for infant gestational age, birth weight, sex, collection volume, delivery type, and maternal age. Only significant *P* values are shown. Whisker plots represent the 95% confidence intervals. *CFU*, colony-forming unit; *TNCC*, total nucleated cell count. *Used with permission from Page KM, Mendizabal A, Betz-Stablein B, et al. Optimizing donor selection for public cord blood banking: influence of maternal, infant, and collection characteristics on cord blood unit quality. Transfusion 2013;54.*

clinical factors (Fig. 10.3) [15,24]. Investigations of other clinical factors such as gender and maternal age have been less conclusive [16,24–26]. Although these clinical characteristics are not typically modifiable, understanding their relationship to collection volume and content can inform practical decisions pertaining to unit eligibility, staffing at collection sites, and other banking practices.

Technical approaches to increasing CBU collection volume include increasing perfusion of the placenta to collect additional blood [27,28], but these approaches remain experimental. The timing of cord clamping also affects the volume of blood collected from a placenta. The practice of delayed cord clamping, defined by ACOG as occurring >30 s after delivery [29], is becoming more common. Studies have shown benefits of delayed cord clamping for preterm infants; however, benefits in term infants appear to be marginal [30]. Delays in collection have been associated with smaller volumes and corresponding TNCCs and increase collection failures owing to clotting [16,31,32]. Because blood flow within the umbilical vessels immediately after birth is influenced by multiple physiologic factors [33], the true impact of delayed cord clamping at a specified time point on collection quality is difficult to assess. Early studies demonstrate that delayed clamping beyond 1 min is associated with loss of cord blood available for banking. It is apparent that further studies are needed to better understand the impact of cord clamping on the neonate, but it is also clear that this will be an ongoing discussion with important obstetric, perinatal, and banking implications. With the available data, it is recommended that delayed clamping is not practiced when cord blood is collected as a directed donation within a family for allogeneic transplantation in a sibling.

Processing and Cryopreservation

Many CB banks receive collections from distant sites, which results in potential delays in processing. Although stability of TNCC and CD34$^+$ content at room temperature have been reported to range from 24 to 96 h after collection [15,34–37], we and others have demonstrated small but significant losses of TNCC, CD34$^+$ cells, and CFU content at even earlier time points [24,38,39]. Based on these findings, our standard operating procedures at the CCBB involves triaging CBUs to allow for processing within 24 h of collection. Unrelated donor banking standards require cryopreservation to begin within 48 h of birth.

The general approach to processing CB is similar between banks, although some variations exist. Rubinstein et al. demonstrated that volume reduction achieved through removal of plasma and red blood cells (RBC) allows for more efficient processing and improved cell recovery after thaw [40]. Many banks continue to use the Rubinstein method, or variations of it, to achieve plasma and RBC depletion. Manual CB processing continues to be performed in some

banks, but an increasing number of banks are using automated systems for plasma and RBC reduction. Postprocessing, DMSO, typically in a final concentration of 10% along with 5% dextran or hydroxyethylstarch, is added as a cryoprotectant [41,42]. Cryopreservation occurs via controlled-rate freezing before storage in the liquid or vapor phase of liquid nitrogen for long-term storage at less than −180°C.

Cord Blood Unit Characterization

Banking standards require CB products to be tested and characterized extensively to assess the purity, potency, and sterility of the CBU. Testing in most banks includes assessing postprocessing TNCC, viability, viable $CD34^+$ cells, growth of CFUs, and sterility.

Assessing viability by any of several different methods is included in the banking standards for accreditation and is required for unit licensure. Postprocessed samples should contain at least 85% viable cells. Whereas fresh CB generally has high viability, insults to cells that can decrease viability include temperature changes, longer time to processing, and prolonged exposure to DMSO before cryopreservation [36,39,41], which may affect various cell populations within CB differently [36]. For example, decreases in viability may simply reflect cell death of mature granulocytes and may not reflect loss of HSCs.

$CD34^+$ is a surface marker of HSCs, and higher infused doses (cells per kilogram) have been associated with higher rates of engraftment, less transplant-related mortality, and improved overall survival (OS) [43]. As such, it is common practice to enumerate $CD34^+$ cells before cryopreservation and again after thawing for transplantation. Some transplant centers use the total $CD34^+$ cell dose in CBU selection. However, significant interlaboratory variability exists [44−47]. Efforts to standardize $CD34^+$ measurements led to the development of guidelines by the International Society for Hematotherapy and Graft Engineering [48]. This "dual-platform" method determines the percentage of $CD34^+$ cells by flow cytometry and measures the leukocyte count using an automated cell counter. Subsequently, "single-platform" approaches have been developed that enumerate $CD34^+$ cells using flow cytometry [49,50]. The viable $CD34^+$ content can be measured indirectly by using the percentage of viable cells to adjust the total $CD34^+$ dose. The presence of total $CD34^+$ cells, however, does not assess the viability and overall potency of a given CBU. This led to interest in measuring the viable $CD34^+$ content directly. FDA-cleared kits to enumerate viable $CD34^+$ cells have become more widely available and adopted for use by many CB banks. In fresh CB, total and viable $CD34^+$ content correlates closely [51−53], whereas there is more variability in thawed samples [51]. Use of the viable $CD34^+$ in CBU selection will require further standardization of the methods by the banking community.

The CFU assay, which requires viable cells to multiply and differentiate, is considered by many to be the best measure of CB potency. Studies demonstrated that CFU dose is strongly predictive of neutrophil and platelet engraftment and improved survival [54−58]. Identification and enumeration of colony types (CFU−granulocyte macrophage, CFU−granulocyte/erythrocyte/monocyte/megakaryocyte, and burst forming unit-erythroid) are performed by some banks, but specifications for these parameters are unknown. Despite the ability to assess potency, the CFU is a time-consuming assay that typically provides results 2 weeks later. Similar to measuring $CD34^+$ content, there are also issues with standardization among laboratories [59,60]. These issues have precluded its widespread use. Automated scoring systems and 7-day CFU assays have been developed to address these issues and are becoming more commonly used. There have also been focused efforts to develop alternate measures of potency that would provide results rapidly. Enumeration of CFUs using a thawed contiguous segment has been shown to be representative of the CB product and has been used to assess potency [61].

Aldehyde dehydrogenase (ALDH) is an intracellular enzyme found in high concentration in HSCs and can be measured by a flow cytometry−based assay. Cells scoring positive ($ALDH^{br}$) are viable and likely to correlate with HSC content of a graft [62]. $ALDH^{br}$ activity strongly correlated with CFUs and with speed of engraftment in autologous transplant recipients [63−66]. This suggests that $ALDH^{br}$ content of a CBU may predict potency. In fresh CB, $ALDH^{br}$ correlates well with TNCC, CFU, and $CD34^+$ content [67]. However, potency of a CB graft is best assessed on the thawed product, thereby reflecting any potential injury incurred as a result of cryopreservation and thaw. Therefore, we developed a potency assay for CBU release that can be performed at the time of confirmatory testing using a segment attached to a cryopreserved CBU. The assay enumerates $ALDH^{br}$, $CD34^+$, $CD45^+$, glycophorin A^+, viability (7-AAD^+), and CFUs from the thawed segment (Fig. 10.4). Our study demonstrated a strong correlation between $ALDH^{br}$ and CFUs measured on the segment ($r = 0.78$). However, the correlation between $CD34^+$ (as a percentage of viable CD45 cells) and CFUs was weaker ($r = 0.25$). Comparisons between cryopreserved segments and entire unit demonstrated strong overall correlation ($r = 0.88$). We also observed faster

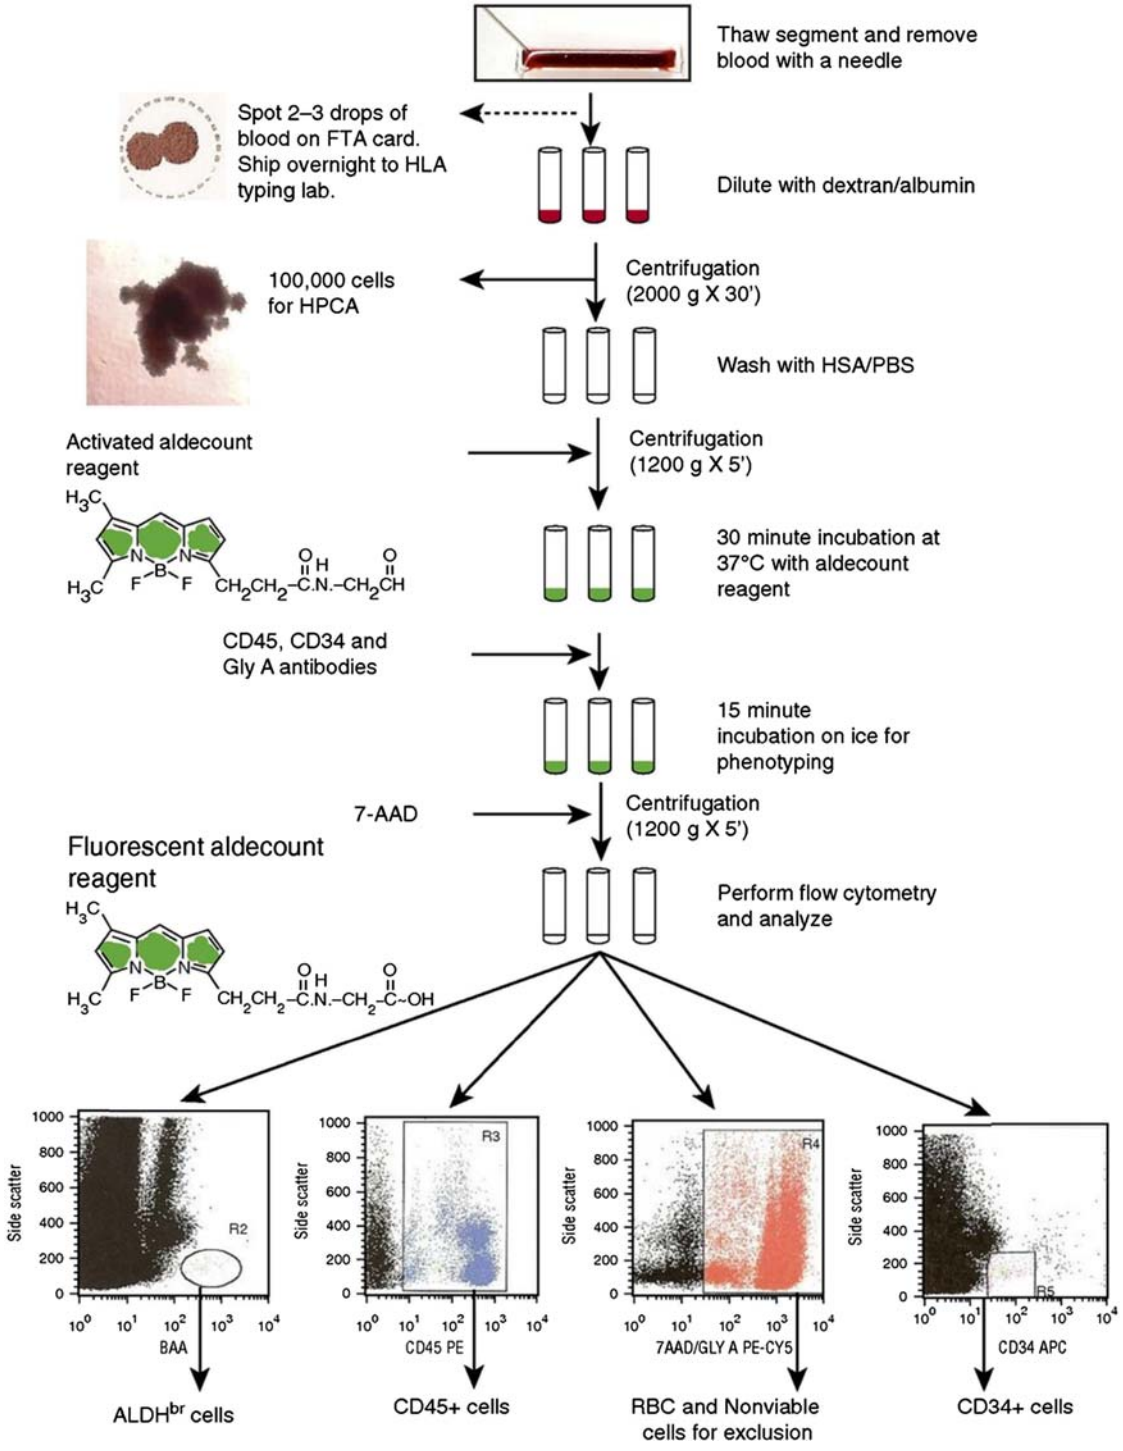

FIGURE 10.4 Flowchart of the ALDH potency assay performed on attached segments of CBUs requested for confirmatory HLA typing for donor selection. *7-AAD*, 7-aminoactinomycin D; *ALDH*, aldehyde dehydrogenase; *FTA*, fast technology analysis; *GlyA*, glycophorin A; *HLA*, human leukocyte antigen; *HPCA*, hematopoietic progenitor cell assay; *HSA/PBS*, human serum albumin/phosphate-buffered saline; *RBC*, red blood cells. *Used with permission from Shoulars KW, Noldner P, Troy JD, et al. engraftment in patients who received CB grafts with higher $ALDH^{br}$ measured on the segment ($P = .03$) [68]. Our findings demonstrated that the assay can serve as a surrogate for postthaw measurements to assess the potency of a potential CBU graft. Based on these findings, we have been using this assay before releasing CBUs from the CCBB to the transplant centers.

Finally, to prevent potential transmission of microbial agents to transplant recipients, all CB banks perform sterility assays on samples of processed CBU before cryopreservation. Screening units for bacterial and fungal contamination is most commonly performed using automated culture systems with high detection capabilities [69,70]. Rates of contamination reported in the literature have been variable, but generally range from 2% to 5% [15,71,72]. CBUs screening positive in sterility assays are excluded from public bank registries. However, directed donor units that are contaminated with bacteria may be stored and used for transplantation after the related recipient is covered with appropriate antibiotics before and after the infusion.

CLINICAL USES OF UMBILICAL CORD BLOOD

Cord Blood Transplantation for Hematological Malignancies

Most of the early clinical experience with CBT was in treating children with hematologic malignancies. The Cord Blood Transplantation Study trial, the first prospective multicenter phase II study of unrelated CBT, enrolled patients with pediatric leukemias, adult leukemias, pediatric immunodeficiencies, and infant leukemia, and pediatric patients with certain inherited metabolic diseases in a series of phase II clinical trials. The cohort of pediatric patients with hematologic malignancies were enrolled from 1998 to 2003 and received myeloablative conditioning (total body irradiation, cyclophosphamide, equine antithymocyte globulin) followed by infusion of an unrelated donor single CBU [12]. The results were encouraging and demonstrated that CB could provide adequate reconstitution of hematopoiesis and immune reconstitution with relatively low rates of GvHD. Relapse-free, 5-year survival was about 50% in this cohort of patients. Results of the adult stratum were less promising, however, likely because of the high number of comorbidities in end-stage patients and also because a typical CBU lacked sufficient cells to engraft reliably in an adult-sized individual. To overcome this obstacle, the team at the University of Minnesota pioneered the use of "double CBT" (i.e., two CBUs for one transplant) and reported improved rates of engraftment and survival in adults [11]. From 2005 to 2012, the Blood and Marrow Transplant Clinical Trials Network, in collaboration with the pediatric cooperative group, Children's Oncology Group, conducted a multicenter, randomized trial comparing one or two CB grafts in children with hematologic malignancies [14]. They found that in adequately dosed children, a single CBU was sufficient for transplant. Of note, chronic GvHD was increased in recipients of double cords compared with recipients of single CBUs. Patients experienced low rates of relapse, about 12%, in both treatment arms, and overall event-free survival was 70%. Milano et al. reported in an analysis of 582 patients that patients with detectable minimal residual disease before transplant had a significantly lower risk of relapse when CB grafts were used, compared with matched and mismatched unrelated adult donor grafts [73]. These results added to growing evidence that CB grafts may be able to provide a more potent antileukemic effect compared with other graft sources.

Cord Blood Transplantation for Nonmalignant Hematological Diseases

CBT has also been used successfully to treat other diseases amenable to HSCT. This heterogeneous group of diseases includes primary immunodeficiencies (PIDs), congenital and acquired bone marrow failure (BMF) syndromes, hemoglobinopathies, and inherited metabolic diseases (discussed separately subsequently). Generally, special considerations for these patients with nonmalignant conditions include decreasing the risk of GvHD and minimizing toxicities caused by the preparative regimen. Although this led to interest in developing reduced intensity conditioning regimens for these patients, rates of graft failure were much higher with this approach and the use of myeloablative conditioning continues to be the standard of care. Exceptions to this include certain diseases that are highly chemosensitive (i.e., Fanconi anemia and dyskeratosis congenita) [74,75] and certain PIDs that require little or no conditioning [76,77]. With several decades of experience in CBT, many lessons have been learned in the care of these primarily pediatric patients with nonmalignant conditions. Importantly, excellent survival (>90%) is noted when related CB grafts are used [75,76,78–82], and GvHD is lower than in related bone marrow recipients [79,81,83]. Therefore, related CBT, when available, is considered the standard of care for patients with nonmalignant diseases [83].

Experience using unrelated donor CB grafts for patients with nonmalignant diseases has generally been successful, depending primarily on the underlying disease. Patients with immunodeficiencies receiving CBT have good outcomes in smaller reports [84–91]. Morio et al. reported a 5-year OS of 69% for 88 patients with PIDs [92] with improved survival noted in patients with Wiskott–Aldrich syndrome (82%). In that series, the most common cause of death was infection. Pai et al. examined outcomes of 240 infants with severe combined immune deficiencies

transplanted using matched related or alternative donors at 25 centers from 2000 to 2009 [76]. They and others observed comparable outcomes for patients receiving unrelated donor transplantation regardless of donor source [76,77]. Younger infants (aged less than 3.5 months) experienced improved outcomes compared with older infants. It is likely, with the wider availability of newborn screening, that children will be transplanted at an earlier age, which will further improve these outcomes. Outcomes after unrelated CBT for inherited and acquired BMF syndromes have not been robust, because of higher rates of primary graft failure. MacMillan et al. described the outcomes of 130 patients with Fanconi anemia [93]. They observed that although outcomes using unrelated CB grafts historically were disappointing, similar neutrophil recovery was seen in patients receiving unrelated bone marrow and CB grafts, a finding attributed to optimizing donor selection and chemotherapy regimens. Unrelated CBT was used to treat other inherited BMF syndromes such as dyskeratosis congenita, congenital amegakaryocytic thrombocytopenia, Diamond-Blackfan anemia, and osteopetrosis [75,94–96], but it has been associated with higher rates of graft failure [75,94]. Similar issues with engraftment were reported in 71 patients undergoing unrelated CBT for acquired severe aplastic anemia [97]. In the report from the European Society for Blood and Marrow Transplantation, the cumulative incidence of neutrophil engraftment was 51% at 60 days and a 3-year OS of 38% [97]. Significantly improved OS was seen in patients who received higher TNC doses ($>3.9 \times 10^7$ cells/kg) from the CB graft. It is important to acknowledge, owing to the rarity of these diseases, that these studies included patients from an earlier transplant era, which probably negatively influenced the results. It is likely that contemporary outcomes would be more robust, because of improvements in supportive care and donor selection. Unrelated CBT remains a viable donor option when matched related donors are unavailable.

Thalassemia major and sickle cell disease (SCD) are the most common hemoglobinopathies worldwide. Allogeneic HSCT is the only curative treatment and best outcomes occur if HSCT is performed early in life, before significant organ dysfunction has occurred. Importantly, patients with hemoglobinopathies are at increased risk for graft rejection owing to several factors such as marrow hyperactivity to compensate for chronic anemia, alloimmunization resulting from multiple transfusions, and lack of prior chemotherapy exposure, which leaves the patient immunocompetent immediately before transplant. Similar to other nonmalignant diseases, the use of related CBT is associated with excellent outcomes [98]. Unrelated CBT for hemoglobinopathies has been more challenging, as highlighted in several studies [99,100]. Ruggeri et al. reported the outcomes of unrelated CBT in 51 children with either thalassemia (N = 35) or SCD (N = 16). Most (76%) received myeloablative conditioning followed by infusion of primarily HLA-mismatched grafts (two to three loci: 50%). High graft failure was seen in this cohort (27 of 51 patients), which was strongly associated with the TNCC cell dose [100]. Given the lower available cell dose in CBUs, it is unsurprising that graft failure has been an issue for these patients in the unrelated donor setting.

Cord Blood Expansion Technologies

Extensive investigations are under way to manipulate or expand CB HSCs ex vivo with the goal of more rapid immune and hematopoietic reconstitution. Expansion techniques that are in clinical trials include a Notch ligand–based platform [101], a nicotinamide-based expansion approach (NiCord) [102], fucosylation [103], coculture with mesenchymal cells [104], Stem-regenin (SR1) [105], and UM171 [106]. Most are being tested in patients with hematologic malignancies, but there is a current phase I trial using NiCord to treat pediatric patients with hemoglobinopathies, with promising early results (ClinicalTrials.gov: NCT01590628) [107]. Likewise, the Notch expanded product is undergoing testing in a multicenter, phase II randomized trial as a bridge to engraftment after a standard CBT after myeloablative conditioning therapy. If successful, these approaches may ultimately be applied to unrelated CBT for patients with hemoglobinopathies, thus broadening the utility of CBT in these diseases.

CORD BLOOD THERAPIES FOR INHERITED AND ACQUIRED BRAIN DISEASES

Cord Blood Transplantation for Inherited Metabolic Disorders

Inherited metabolic disorders (IMD) are a heterogeneous group of genetic diseases. In most of these diseases, a single gene mutation causes an enzyme defect, which leads to the accumulation of substrates that are toxic and/or interfere with normal cellular function. Many affected patients appear normal at birth. During infancy, however, they begin to exhibit disease manifestations, often including progressive neurological deterioration associated with absent or abnormal brain myelination. The ultimate result is death in later infancy or childhood.

In the 1960s, Elizabeth Neufeld demonstrated that coculture of fibroblasts from patients with two different IMDs (Hunter syndrome and Hurler syndrome) cross-corrected each other [108]; this established the basis for enzyme replacement therapy (ERT) and cellular therapy for that purpose. ERT is available for selected IMDs and can be effective in ameliorating certain systemic disease manifestations, although there are limitations. ERT is unable to cross the blood–brain barrier effectively and therefore does not alter the progression of neurologic symptoms [109,110]. Intrathecal ERT [111] and gene therapy [112] are being investigated to attempt to address this shortcoming. However, the only effective therapy to halt neurologic progression of disease is allogeneic HSCT, which serves as a source of permanent cellular ERT [113] providing missing enzyme throughout the body, including the peripheral tissues and the central nervous system [114,115]. Donor microglia cells, which are of myeloid origin, are thought to be the source of ERT after HSCT [116], in addition to acting as normal scavengers in the central nervous system [116–118]. It is also possible that donor cells exert antiinflammatory and proneurogenic effects through paracrine signaling. The timing of migration to, and engraftment of, donor-derived microglia cells in the brain after HSCT is not known. Based on clinical observations, however, it is likely several months after hematologic engraftment.

HSCT is indicated for a subset of IMDs including lysosomal storage diseases, peroxisomal storage diseases, and a few select others. The first HSCT for an IMD was performed in 1980 in a 1-year-old child with Hurler syndrome (mucopolysaccharidosis [MPS], type 1), a lysosomal storage disease, using bone marrow from his parents [119]. Since then, more than 500 transplants have been performed worldwide in patients with Hurler syndrome, which makes it the most transplanted and well-studied IMD. Numerous reports have demonstrated the efficacy of HSCT in Hurler syndrome, including improvements in neurocognitive function, joint integrity, motor development, growth, hydrocephalus, corneal clouding, cardiac function, hepatosplenomegaly, hearing, visual and auditory processing, and OS [120–126]. Despite improvements in both symptoms and life expectancy, survivors experience a variable degree of residual disease burden [127]. Factors associated with superior clinical outcomes include transplantation early in the disease course and the ability to attain full donor chimerism with normal enzyme levels [126,128]. Among patients receiving CBT for Hurler syndrome, a shorter interval between diagnosis and CBT (<4.6 months [82%] versus >4.6 months [57%]) and a conditioning regimen containing busulfan and cyclophosphamide (75% versus 44% using other regimens) are associated with a significantly higher event-free survival [129]. Studies also demonstrate that unrelated, noncarrier CB has advantages in the transplantation of MPS in terms of achieving both full-donor chimerism and normal enzyme levels compared with other donor sources [56,120,128,130–132]. Thus, CB has been identified as an attractive source for HSCT in Hurler syndrome and other MPS types for which HSCT is indicated.

CBT has also been used to treat patients successfully with certain leukodystrophies, a group of disorders caused by genetic defects in the production or maintenance of myelin, including adrenoleukodystrophy [133,134] metachromatic leukodystrophy [135,136], and Krabbe disease (globoid leukodystrophy). Prognosis is strongly affected by the stage of the disease at the time of transplantation; children who undergo HSCT in presymptomatic or early disease stages fare better than those in symptomatic or advanced stages [137]. As such, HSCT is generally reserved for patients with presymptomatic or early disease. This is particularly challenging in the case of early infantile Krabbe disease. Symptoms typically become evident during the first 6 months of life, although there is evidence that damage occurs even prenatally. Krabbe disease is caused by mutations in the lysosomal enzyme galactosylceramidase, which then leads to an accumulation of psychosine followed by apoptosis of myelin-forming cells in the central and peripheral nervous systems. Affected babies develop irritability, spasticity, developmental regression, and seizures. Progression of symptoms is rapid and unrelenting, leading to death typically within 2 years. In 2005, the outcomes of 25 babies with Krabbe disease who received CBT were reported. The cohort included 11 presymptomatic newborns (aged <1 month of life) along with 14 infants transplanted after the onset of symptoms [132]. Survival at 3 years was dramatically improved in the presymptomatic babies (100% versus 42.8%). The presymptomatic babies also exhibited substantial neurodevelopmental gains whereas symptomatic infants stabilized without improvement. Nonetheless, some degree of gross motor function deficit became apparent in all children. An analysis of late outcomes showed that babies transplanted younger than age 30 days had superior outcomes compared with those transplanted at age greater than 30 days [138]. Results from this and other studies [87,132,136] reinforce the importance of early diagnosis and treatment. Given the time-sensitive nature, newborn screening programs for Krabbe disease have been instituted in a portion of US states with further programs in development.

One issue inherent in HSCT is that disease progression can continue in the initial few months after transplantation. While waiting for sufficient numbers of donor cells to engraft in the brain and produce adequate enzyme levels, patients can experience further loss of neurologic function, and most patients are left with some residual and irreversible neurologic impairment. Even when complete donor hematopoietic chimerism and normal serum enzyme levels are obtained and survival is extended for decades, emerging long-term data suggest that eventual neurologic

decline, particularly in motor function, commonly occurs later in life. Additional approaches are necessary to address the multifaceted tissue pathology fully in these diseases and normalize functional outcomes for patients. Augmented cellular therapies, such as CB-derived microglial-like cells (DUOC-01) [139–141] and others [142], gene therapies [112], supplemental enzyme therapy [143], and chaperone therapy, alone or combined with HSCT, are all being investigated in the laboratory and/or clinic for that purpose.

INVESTIGATIONS IN THE TREATMENT OF ACQUIRED BRAIN INJURIES WITH UMBILICAL CORD BLOOD

Aside from acting as cellular enzyme replacement, donor CB cells in patients with IMDs may also have a role in replacing damaged cells, secreting supportive factors, and immunoregulation. These additional possible mechanisms led to the hypothesis that CB might also be beneficial in patients with acquired brain injuries. CB cells have been investigated in preclinical models of stroke, neonatal hypoxic-ischemic encephalopathy (HIE), cerebral palsy, traumatic brain injury, and spinal cord injury. Numerous animal models have demonstrated neuroprotection [144], neovascularization [145], and neuronal regeneration [145] after xenogeneic CB administration, leading to both neurological and survival benefits [144,146–151]. Based on these observations, early-phase clinical trials of CB are under way in human patients with acquired brain injuries, using either autologous or allogeneic CB cells.

Hypoxic Ischemic Encephalopathy

Neonatal HIE results from an acute lack of oxygen to the infant brain, typically attributed to events during labor and delivery. Therapeutic hypothermia is considered the standard of care for babies who meet criteria for moderate to severe HIE. Despite this intervention, moderate to severe HIE is fatal in approximately 25% of patients and causes neurologic sequelae in an additional 25%. In a phase I trial conducted at Duke that enrolled neonates with HIE, fresh autologous CB (volume- and RBC-reduced) was infused within the first 48–72 h of life in one, two, or four doses of $1–5 \times 10^7$ nucleated cells/kg in babies with moderate to severe encephalopathy who qualified for systemic hypothermia [152]. Those babies ($n = 23$) were compared with a concomitant group of babies at Duke who received only therapeutic hypothermia ($n = 83$). Infusions were found to be safe in those critically ill babies. The babies who received cells had increased survival rates to discharge (100% versus 87%; $P = .12$) and improved function at 1 year of age (72% versus 41% with development in the normal range; $P = .05$). Based on these findings, a phase II, randomized, placebo-controlled multicenter study is under way to investigate further the utility of CB infusion in conjunction with therapeutic hypothermia for babies with HIE.

Cerebral Palsy

In most cases, cerebral palsy results from an in utero or perinatal brain injury such as stroke, hypoxic insult, or hemorrhage. Clinical outcomes of patients with cerebral palsy are widely varied, ranging from mild limitations in advanced gross motor skills to severely limited self-mobility despite the use of assistive technology. The use of CB in children with cerebral palsy is being investigated in clinical studies. Romanov et al. reported results of 80 pediatric patients who received multiple intravenous doses of allogeneic, ABO-matched, HLA-unmatched CB. Improvements were noted in children who received at least four doses; however, there was no control group for comparison [153]. Many children with cerebral palsy are expected to make some gains over time, which is an important factor to consider in study design. A double-blind study was conducted in Korea in 93 children who were randomized to receive erythropoietin, erythropoietin plus cyclosporine plus allogeneic CB ($\geq$4/6 HLA matched, $\geq 3 \times 10^7$ TNC/kg), or placebo [154]. They reported greater improvements in cognitive and select motor functions in children who received CB and erythropoietin versus controls; higher cell doses were associated with greater improvement. A CB-only group was not included.

In the United States, investigations of CB in children with cerebral palsy have focused on intravenous infusions of autologous CB that had been banked at the time of the child's birth. An initial safety study of 184 infants and children with cerebral palsy (76%), congenital hydrocephalus (12%), and other brain injuries (12%) identified a temporary hypersensitivity reaction (i.e., hives and/or wheezing) in approximately 1.5% of patients as the only side effect [14]. A randomized, double-blind, placebo-controlled study was subsequently conducted in 63 children aged 1–6 years to evaluate the efficacy of this approach. In that study, there was no difference in motor improvement

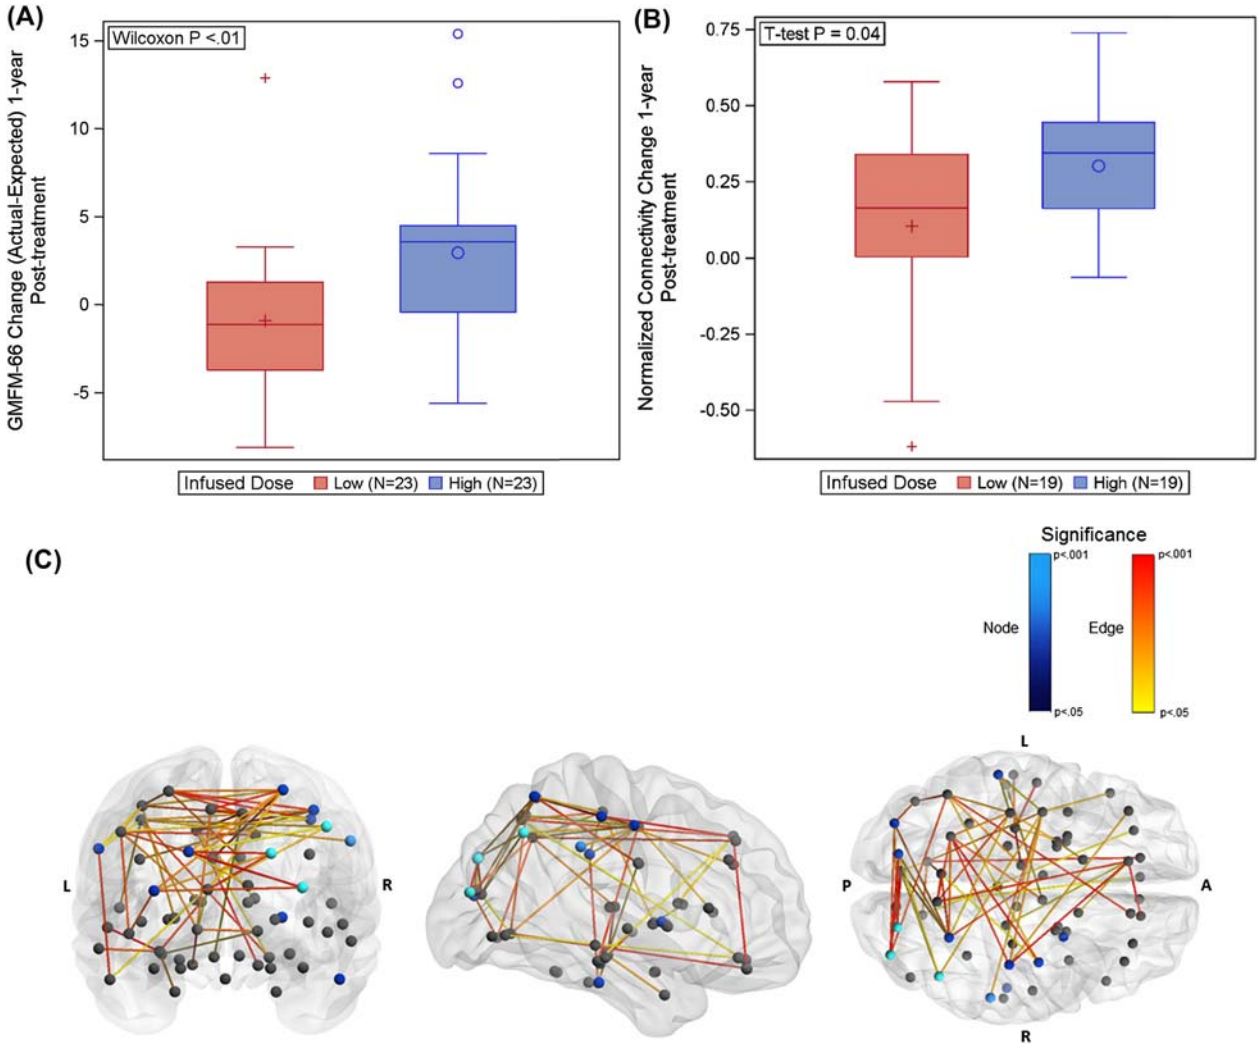

FIGURE 10.5 **Improvements in motor function after appropriately dosed autologous cord blood infusion: correlation with increased whole-brain connectivity.** Gross motor function and brain connectivity 1 year after autologous cord blood treatment by cell dose. (A) Observed−expected GMFM-66 scores 1 year after treatment in patients aged greater than 2 years at the time of autologous cord blood infusion. (B) Change in normalized whole-brain connectivity 1 year after treatment. (C) Connectome representation. Nodes and edges included are those demonstrating significantly increased improvement in children receiving high doses compared with those receiving low doses, as indicated by the *color chart*; insignificant nodes are shown in *gray*. Representative nodes in the sensorimotor network with significant changes correlated with improvement in GMFM-66 scores include the pre- and postcentral gyri, basal ganglia, and brain stem. *GMFM-66*, Gross Motor Function Measure−66.

between study groups as a whole. However, patients receiving a previously cryopreserved nucleated cell dose of $\geq 2.5 \times 10^7$ cells/kg demonstrated greater improvement of motor function and normalized whole brain connectivity than did subjects receiving smaller cell doses, which is consistent with the minimum dose used for allogeneic HSCT (Fig. 10.5) [155].

Stroke

Stroke represents a significant public health concern and is a leading cause of morbidity and mortality among adults. Studies of cell therapy in older patients who have experienced a stroke have focused on autologous bone marrow−derived cells. The only published randomized trial, conducted in 120 patients in India, administered autologous bone marrow mononuclear cells (mean, 280×10^6 cells) as a single intravenous dose 7−30 days after an acute stroke [156]. There was no difference in functional outcomes or infarct volume between groups at 6 months. Additional studies are under way or planned using autologous and allogeneic cells [157]. There are concerns regarding

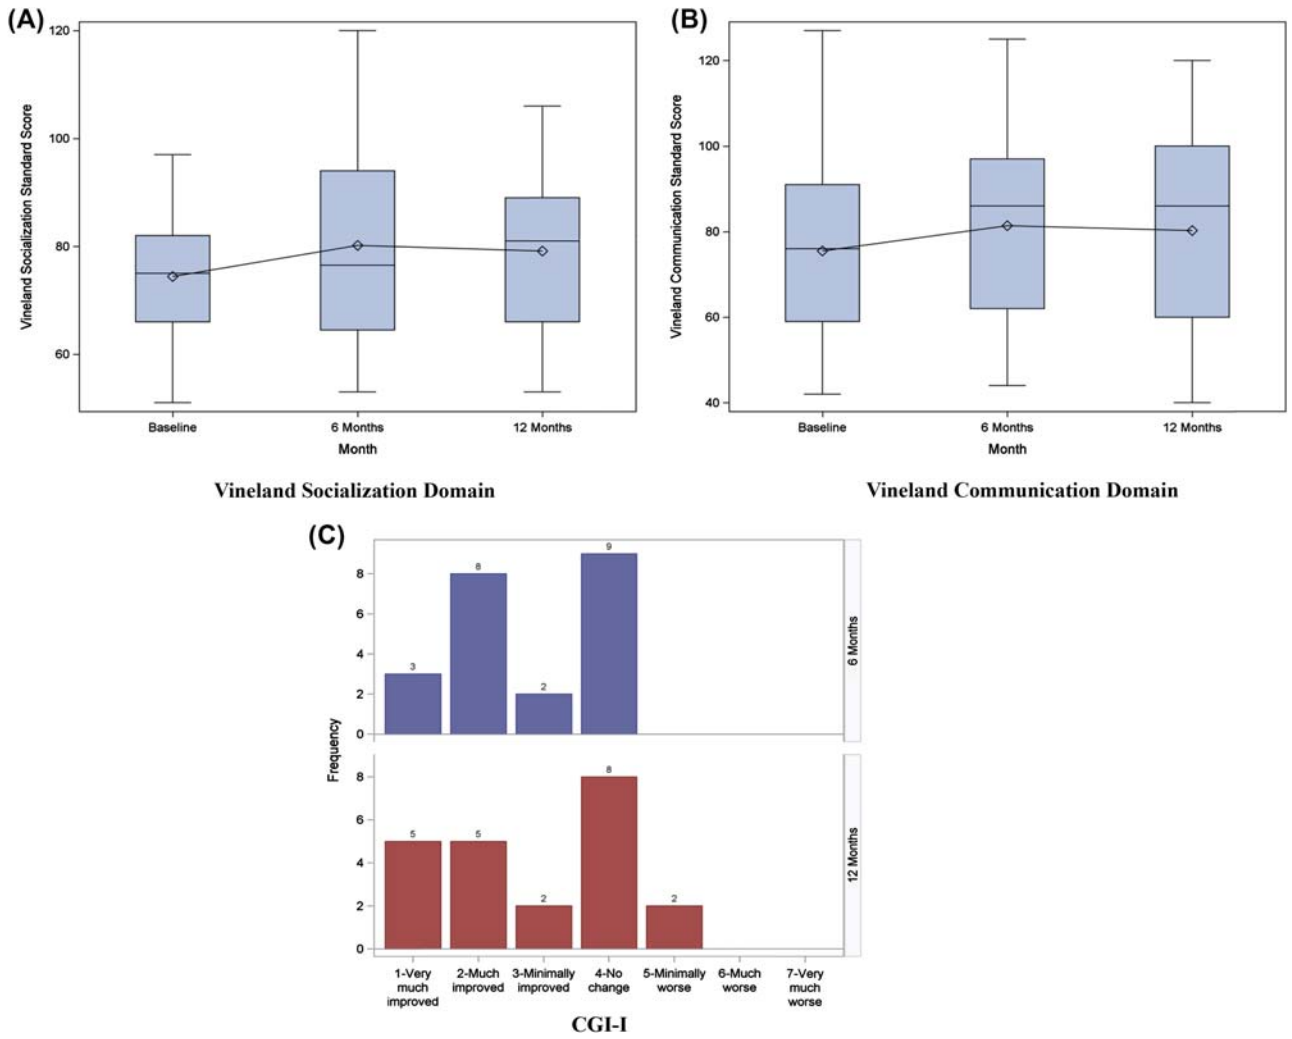

FIGURE 10.6 **Changes in ASD symptoms after autologous CB infusion.** (A) Vineland-II socialization domain standard scores at baseline and 6 months after infusion ($P = .02$ baseline to 6 months). (B) Vineland-II communication domain standard scores at baseline and 6 months after infusion ($P < .01$ baseline to 6 months). (C) Distribution of CGI-I scores at 6 (*blue*) and 12 (*red*) months after infusion. Sample sizes are N = 25 for baseline and 6-month time points and N = 22 at 12 months. *ASD*, autism spectrum disorder; *CB*, cord blood; *CGI-I*, clinician assessment. *Used with permission from Dawson G, Sun JM, Davlantis KS, et al. Autologous cord blood infusions are safe and feasible in young children with autism spectrum disorder: results of a single-center phase I open-label trial. Stem Cells Transl Med 2017;6(5):1332–9.*

the functionality of autologous bone marrow–derived cells, because they must be collected from a typically ill, elderly patient, and the feasibility of early administration may not be possible if the cells must be cultured or processed for any length of time. Therefore, a CB-derived, off-the-shelf therapy is an attractive alternative to autologous bone marrow. A phase I safety study administering ABO-matched, HLA-unmatched allogeneic CB intravenously to adults within 3–10 days of acute ischemic stroke completed accrual and demonstrated no acute safety issues related to the CB infusion [131]. A phase II randomized, placebo-controlled, blinded study to evaluate efficacy has enrolled patients at four centers.

Autism Spectrum Disorder

Intravenous infusion of CB is also being investigated in young children with autism spectrum disorder (ASD), a neurodevelopmental disorder with onset in early childhood. ASD is characterized by impairments in social communication, a restricted range of activities, and repetitive behaviors [158]. Evidence suggests that ASD likely results from a complex interplay between genetic and environmental risk factors, potentially mediated through inflammatory and/or immune processes. One hypothesis regarding the development of ASD is that immune-mediated

changes in fetal brain cytokine profiles may result in abnormal development in the central nervous system, either directly or indirectly via microglial activation. Abnormalities in the number, function, and gene regulation of microglia as well as in localized brain inflammation, pathological astrocyte activation, and synaptic dysfunction have all been described in various models of ASD [159–161]. Cellular therapies are being investigated for their potential to reduce ongoing inflammation via cell-mediated immunomodulation, provide neuroprotection via molecular mechanisms, and/or restore functional synaptic pathways. These potential mechanisms are thought to occur via paracrine effects.

Clinical trials of cell therapy in patients with ASD are still in the early phases; a handful of exploratory studies using various cell sources are under way in several different countries. The open-label phase 1 DukeABCs trial examined the safety and tolerability study of a single intravenous infusion of autologous CB in 25 children aged 2–5 years who had ASD (ClinicalTrials.gov: NCT02176317) [162]. Participants received a single CB infusion (median infused dose, 2.6×10^7/kg; range, $1.0–8.1 \times 10^7$/kg) with no immunosuppression. The infusions were safe, with no serious adverse events and occasional allergic reactions and irritability reported. Improvements in ASD symptoms were observed on caregiver-completed measures (Vineland Adaptive Behavior Scales–Second Edition and Pervasive Developmental Disorder Behavior Inventory), clinician assessment (Clinical Global Impressions scale [CGI-I]), and computerized eye-tracking assessments (Fig. 10.6). Positive changes, including increased social communication skills and receptive/expressive language and decreased repetitive behavior and sensory sensitivities, were observed at 6 months and maintained at 12 months after infusion. A phase 2 double-blind, randomized, controlled study is under way to evaluate the efficacy of autologous or allogeneic CB therapy versus placebo in children with ASD (ClinicalTrials.gov: NCT02847182).

INTRODUCTION

The capacity for unlimited self-renewal and the potential to differentiate into any cell in the body made embryonic stem cells (ESCs) a valuable research tool. However, before the mid-2000s, mouse ESCs, which were first derived in 1981, were more commonly used in research laboratories owing in part to the relative ease with which they could be maintained and expanded compared with the techniques used at the time to culture humans ESCs (hESCs). In 2003, the National Institutes of Health jump-started the field by sponsoring seven hESC laboratory courses across the United States, which trained a cohort that went on to use the technology in their own laboratories. Technological advances in the culture of hESCs such as single-cell passaging [1] and feeder-free media and substrata allowed for more laboratories to culture hESCs successfully. However, there has been no advance more important than the process of reprogramming adult somatic cells into induced pluripotent stem cells (iPSCs). That discovery fundamentally changed the stem cell field.

The production of iPSCs was first reported by Kazutoshi Takahashi and Shinya Yamanaka using adult mouse fibroblasts in 2006 and was immediately hailed as a ground-breaking discovery [2]. The introduction of four transcription factors, *Oct3/4* (*Pou5f1*), *Sox2*, *Klf4*, and *c-Myc* (*Myc*), was sufficient to transform adult fibroblasts into pluripotent stem cells. In 2007, Yamanaka repeated the process using human fibroblasts [3]. The process of reprogramming adult cells into cells functionally equivalent to hESCs has provided an unparalleled tool to study human development and generate cells for regenerative medicine applications. Yamanaka's discovery altered the dogma underlying our knowledge of cell biology and created new fields of study. In 2012, Shinya Yamanaka was awarded the Nobel Prize in Physiology or Medicine, along with John Gurdon, for the discovery that mature cells could be reprogrammed into cells capable of developing into all cells of the body. Gurdon is credited as the first to demonstrate that a cell nucleus could be reprogrammed to a pluripotent state through the process of somatic cell nuclear transfer [4,5].

MECHANISMS OF REPROGRAMMING

Since the first iPSCs study was published, scientists have gained a much better understanding of what was once mostly a black box process, in which the Yamanaka transcription factors were expressed as transgenes in cells and sometime later pluripotent colonies would emerge. Since the advent of iPSC technology, the molecular events underlying reprogramming have intrigued researchers. We now know that the reprogramming process is a positive feedback loop by which core transcription factors regulate the expression of a network of pluripotency-associated genes [6,7]. Early models postulated that reprogramming is a stochastic process in which most transgenic cells can initiate reprogramming but only a few achieve pluripotency [8]. Success in reprogramming may happen only stochastically when the required amount and balance of transgenic expression are achieved in a small subset of cells [9]. Subsequent studies using single-cell approaches at defined time points demonstrated that after the initiation of transgene expression, there is a hierarchical phase with *SOX2* as the upstream factor in the gene expression

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00011-4

hierarchy, meaning that endogenous *SOX2* expression was required before endogenous expression of other key pluripotency-associated genes [10]. Reprogramming itself has been used as a tool to explore the role of various factors systematically in the maintenance of pluripotency. For example, redundancies in the pluripotency network have been identified, such as replacing *SOX2* in the reprogramming process by the closely related *SOX1* and *SOX3* [11]. Krüppel-like factor 2 (*KLF2*) or *KLF5* can be used as substitutes for *KLF4* [12].

EPIGENETIC REMODELING

For reprogramming to occur, major epigenetic barriers must be overcome. Epigenetics refers to modifications of the genome that can affect the ability for genes to be expressed. The addition of a methyl (CH_3) group to the five prime carbon of the cytosine ring is a well-characterized example that typically results in transcriptional inhibition. Throughout the process of differentiation, the methylation pattern in the genome changes and stabilizes different cell states. As such, the methylation state of an adult somatic cell must be remodeled during the reprogramming process to unlock access to the pluripotency-associated gene network. Many of these genes are hypermethylated in donor cell types but are hypomethylated in iPSCs [13]. The reprogramming factors do not affect DNA demethylation directly, so modifications of DNA methylation are likely a secondary effect of transcription factor induction. Achieving pluripotency also requires considerable histone remodeling [14].

Some studies have raised concerns that reprogrammed cells retain an "epigenetic memory" of the somatic tissue from which they were originally derived [15,16]. However, studies have indicated that epigenetic differences account for only a small fraction of the variability among iPSCs and ESCs [13,17]. In addition, like the lead character in the movie *Memento* (https://en.wikipedia.org/wiki/Memento_(film)), the epigenetic memories of iPSCs are short-term and easily lost; it has been shown that time in culture reduces the epigenetic differences among iPSCs [16,18]. This suggests that the global epigenetic patterns of iPSCs stabilize over time, although there are enduring hot spots of variation, such as at imprinted regions [13,19]. Detailed analysis of global gene expression and DNA methylation patterns reveals that variability among ESCs and iPSCs occurs largely because of variations among individual cell lines rather than differences among classes of pluripotent stem cells [13,17,20–22].

REPROGRAMMING TECHNIQUES

The reprogramming process initially was developed using retroviral transduction. Starting from a candidate pool of 24 factors considered to have important roles in pluripotency, Yamanaka reported that the combination of *Pou5f1*, *Klf4*, *Sox2*, and *Myc* was sufficient to produce iPSC colonies from adult mouse fibroblasts. Because the first iPSC lines were created with retroviral vectors that integrated within the host genome, there was concern that uncontrolled integration could disrupt tumor suppressor genes or activate oncogenes through the process of insertional mutagenesis. Of additional concern was that one of the Yamanaka factors, Myc, is an oncogene itself and that reactivation of the transgenes could result in tumor formation. Indeed, 20% of the offspring of chimeric mice derived from iPSCs that were created using retrovirus-developed tumors [23].

Because of the potential tumorigenicity of cells reprogrammed with integrating vectors, there is general consensus that the use of reprogramming methods that integrate transcription factors into the host genome is ill-advised if the cells are planned for clinical use. However, tools available to reprogram cells have rapidly evolved, and now a variety of nonintegrating alternatives exist and are widely practiced [24]. Integration-free methods rely on the fact that transcription factors used to reprogram the cells are necessary only during the early stages of reprogramming, after which awakening of the endogenous pluripotent machinery is sufficient to sustain the pluripotent state. The Sendai virus is a commonly used, nonintegrating method of reprogramming (see Fig. 11.1) [25]. The RNA virus does not translocate to the nucleus and is diluted with each cell division. In addition, episomal vectors can be used to deliver the Yamanaka factors; however, it has been demonstrated that episomal vectors can sometimes integrate into the host genome, so iPSC clones must be subjected to genomic analysis [24]. Another popular method for reprogramming is the introduction of synthetic messenger RNAs (mRNAs) [26]. The challenge with mRNA reprogramming is the need to repeat applications [27].

The efficiency of the first human reprogramming experiments was less than 0.01%, but reprogramming efficiencies of greater than 1% are common. Generally, the methods only need to be efficient enough to produce a few clones of iPSCs; because reprogramming is usually reproducible and much of the effort involved in

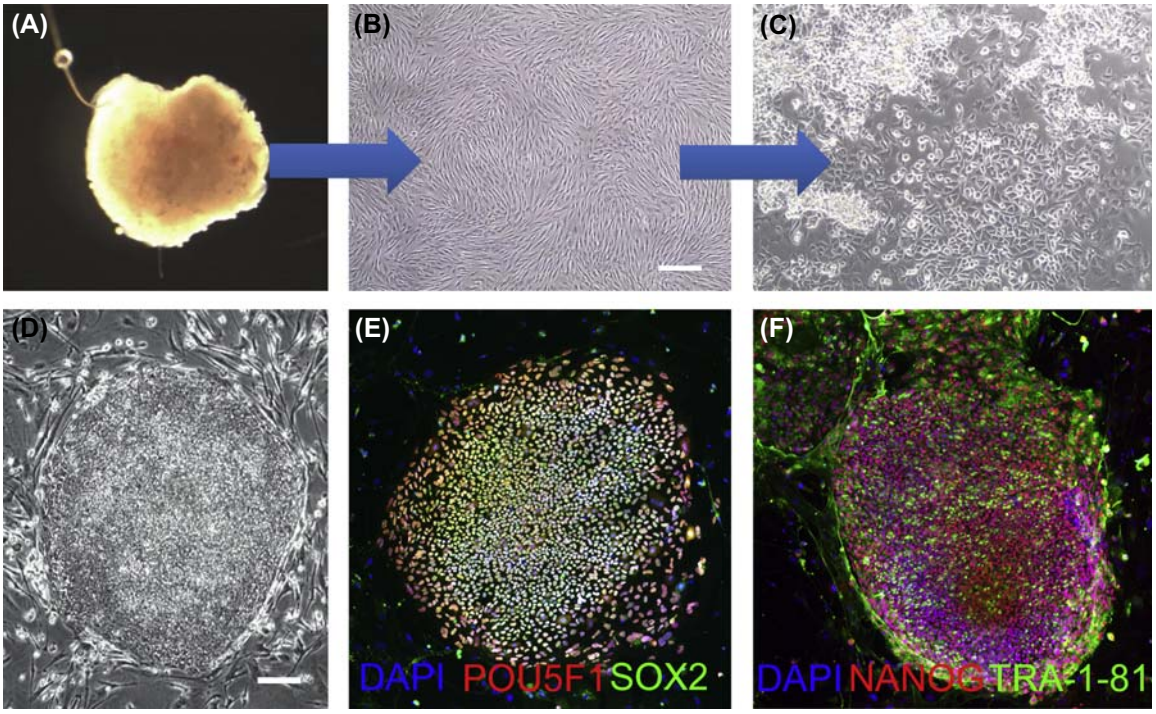

FIGURE 11.1 **Reprogramming human dermal fibroblasts using Sendai virus to deliver the four transcription factors**. A biopsy of dermal tissue (A) is obtained from the patient. The biopsy is then processed and dermal fibroblasts are isolated and cultured (B). After introduction of the Yamanaka factors, the morphology of the fibroblasts changes (C) as the cells undergo the reprogramming process. Finally, after a period of several weeks, colonies emerge (D) that express pluripotency markers, as shown by immunocytochemistry (E, F). Scale bar = 50 μm in (B, C) and 100 μm in (D–F).

reprogramming is in confirming pluripotency and characterization of the iPSCs, analysis of more than a small number of clones is not cost-effective. iPSCs are typically clonally derived, which means that single colonies of reprogrammed cells are picked and subcultured separately from other colonies. Clonal derivation preserves the genetic homogeneity of the iPSC line, a factor that is important in studying genetic disorders that are not present uniformly in the organism's cells. It has been argued that for high-throughput reprogramming, it is necessary to skip the clone-picking step and combine multiple clones [28]. This approach may be appropriate for normal cell lines, although starting populations such as fibroblasts and blood cells are mosaic [29]. Mixture of clones will lead to fluctuations in the subsequent cultures as they proliferate, because some iPSC clones divide slightly faster or are more resistant to stress than others. Many genetic diseases are also mosaic, so a single blood sample or a culture of fibroblasts will yield both normal and mutant iPSC clones. If clones are combined, they would need to be later subcloned and characterized.

INDUCED TRANSDIFFERENTIATION

The same principle of transcription factor–based reprogramming has been applied to direct transformation of one cell type to another. The process of transdifferentiation, also known as lineage reprogramming or direct lineage conversion, can bypass the pluripotent state when converting one cell type to another. Fibroblasts can be transdifferentiated into terminally differentiated cell types such as neurons [30] or cardiomyocytes [31] without using iPSCs. This approach is potentially useful for obtaining mature cell types for which there is currently no robust differentiation scheme. In addition, transdifferentiation is relatively fast compared with iPSC differentiation, which makes it more feasible to screen many individuals in a short period. Bioinformatic analysis can be used to predict what transcription factors are needed to convert one cell type into another [32], although sometimes the same transcription factor is active in more than one cell type, which leads to cells that are hybrids of two or more cell types [33,34]. If the products of transdifferentiation are postmitotic, they might be less likely than iPSC derivatives to contain residual undifferentiated cells that could produce teratomas when used for cell therapy. Several clinical trials are under way using hESC- and iPSC-derived cell preparations, with no report of tumor formation.

There are also drawbacks that should be considered in using direct transdifferentiation of cells such as fibroblasts to mature cell types. Like reprogramming to iPSCs, this process is inefficient, and because mature cell types have a limited capacity to divide (neurons and cardiomyocytes are postmitotic), direct reprogramming requires a large input population and must be repeated each time more cells are required. Transdifferentiated mature populations are not clonally derived, which means that genetic manipulation and characterization of the resulting cell population are difficult or not feasible. These drawbacks may be mitigated by targeting an intermediate progenitor or stem cell that retains a capacity for proliferation but is limited in differentiation capacity; this allows for purification of the cell type desired, and elimination of any abnormally programmed cells [35].

GENOMIC STABILITY

A study examined the potential for genomic damage during reprogramming using whole-genome sequencing and concluded that the reprogramming process itself is not likely to introduce mutations with adverse side effects [36]. Another exome sequencing analysis of fibroblast and iPSC clones concurred and reported that almost all of the genomic variation in iPSCs originates from the cell population used for reprogramming [37]. However, after reprogramming, populations of iPSCs can drift with time in culture like any other cell type, because genetically aberrant subpopulations tend to divide more quickly or are more resistant to apoptosis or other forms of cell death. The types of genetic variations observed range from large-scale karyotypic abnormalities to copy number variations and point mutations. Common karyotypic changes in iPSCs and hESCs include trisomies of chromosomes 12, 17, and X, and duplications of subchromosomal regions on these chromosomes [38–40]. In addition, studies of trinucleotide repeat diseases including Friedreich ataxia and Fragile X syndrome have reported changes in the repeat length after reprogramming [41,42].

Because iPSCs are self-renewing, they never senesce and will continue to divide as long as they are in culture. Because mutations arise when cells replicate, it is inevitable that genomic abnormalities will accumulate if the iPSCs are cultured for long periods of time. Of particular interest are the appearance of deletions of the tumor suppressor TP53 in hESCs after prolonged time in culture [43] and indications that similar deletions occur in iPSCs after long-term culture [44].

APPLICATIONS OF INDUCED PLURIPOTENT STEM CELLS

There has been concern in the field that iPSCs are somehow inferior to hESCs for practical applications. However, a number of reports have demonstrated that hESCs and iPSCs are essentially indistinguishable [13,21,22]. A study on transcriptional and epigenetic comparisons using genetically matched hESC and iPSC lines revealed that hESCs and iPSCs are molecularly and functionally equivalent and cannot be distinguished by their gene expression profiles [45]. This means that all of the applications established for hESCs should be easily transferred to iPSCs (Fig. 11.2).

DISEASE MODELING

Perhaps the most attractive feature of iPSCs is that it allows scientists to study human diseases using human cells. Much progress in modeling human disorders has been made possible by pioneering work to develop robust protocols to generate specific cell types from human iPSCs, including neurons [46–48] and cardiomyocytes [49]. iPSCs have been used routinely to model genetic diseases including monogenic disorders and chromosomal and more complex genetic disorders. Animal model systems have been used to study those disorders for decades, but positive results in animals have not always translated to human studies. This should not be surprising because rodents diverged evolutionarily from humans almost 60 million years ago. For example, in the nervous system, understanding the mechanisms underlying neurological disorders and development of pharmaceutical interventions has lagged far behind disorders affecting other organs. Many highly anticipated drugs, such as those that target Fragile X syndrome [50] and amyotrophic lateral sclerosis (ALS) [51–53], have failed to demonstrate efficacy in human trials after promising preclinical work on animal models. In addition, neurological and psychiatric diseases are complex because they are rarely based on a single gene variant. Notably, many psychiatric diseases arise from mutations in noncoding regions [54,55]. In many cases, these noncoding regions either are not conserved in rodents or they

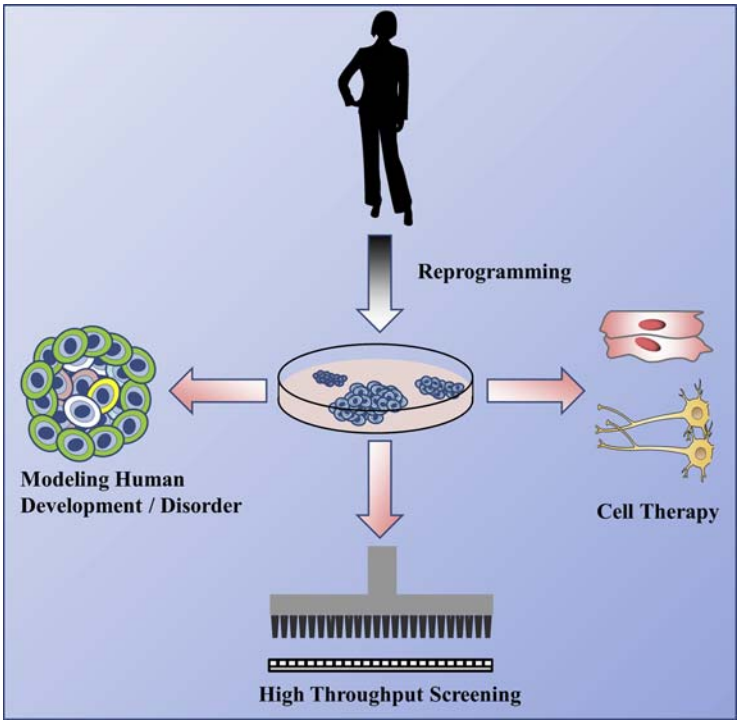

FIGURE 11.2 Applications of induced pluripotent stem cells (iPSCs). Human iPSCs can be used to study and treat human diseases. Aggregates of iPSCs can form organoids that recapitulate aspects of early embryonic development that can be used to model human developmental disorders. Genetically diverse iPSCs and their derivatives can be used in high-throughput screening to improve the preclinical development of pharmaceuticals. In addition, iPSCs can be used to derive therapeutically relevant cell types for autologous transplantation as a cell therapy to treat human diseases.

function differently. In contrast, iPSCs derived from patients with genetic disorders contain all of the complex genetic interactions that underlie the disease.

Timothy syndrome (TS) is a neurodevelopmental disorder that has been successfully investigated using patient-derived iPSCs [56]. TS is a rare monogenic form of autism caused by prolonged activation of the L-type $Ca_v1.2$ calcium channel. The prolonged channel activation results from a gain of function mutation leading to dysregulation of Ca^{2+} signaling in many cell types. One of the striking phenotypes of TS iPSCs is abnormal cortical development; they produce fewer upper-layer neurons and a higher proportion of lower-layer neurons. Interestingly, elevated Ca^{2+} signaling leads to upregulation of tyrosine hydroxylase in cortical neurons. Higher levels of tyrosine hydroxylase, an enzyme that is involved in the biosynthesis of catecholamines, ultimately lead to increased norepinephrine and dopamine production and are associated with aggression in TS patients. Using iPSCs as a model, it was discovered that roscovitine, an L-type channel blocker, can restore tyrosine hydroxylase expression and catecholamine production in TS iPSC-derived neurons. Notably, the transcription regulatory element of human tyrosine hydroxylase locus is not conserved in mice, and the catecholamine phenotype is not observed in a transgenic TS mouse model [57]. In this way, the TS iPSC model provided preclinical validations for future therapeutic development that would otherwise have been missed using only rodent models. Similarly, studies using iPSCs to model other monogenic forms of autism such as Phelan–McDermid syndrome [58], Rett syndrome [59], and Williams syndrome [60] identified human-specific phenotypes and discovered disease-causing pathways.

iPSCs are also useful for studying diseases for which there is evidence of inheritance but no specific mutations identified. For complex diseases such as idiopathic autism and schizophrenia, most cases lack a clear genetic basis. Deriving iPSCs from the patients preserves their genomes, and when differentiated into the relevant cell types, they can be used to study cellular phenotypes and molecular mechanisms without knowing the genetic cause. However, patients who have complex diseases usually present with a wide range of symptoms. Because obtaining information about a disease from patient iPSCs requires multiple patients with the same syndrome, careful consideration should be taken in selecting patients and study controls. For example, to study idiopathic autism, a research group selectively focused on patients who presented with the same clinical phenotype: early brain overgrowth. They observed an increased proliferation rate of the disease-associated iPSC-derived neural progenitor cells and determined that it was likely caused by dysregulation of the β-catenin/BRN2 cascade [61]. Selection of appropriate controls is extremely important to minimize non–disease relevant differences; because humans are genomically diverse, variations in individuals' iPSCs could contribute to differences in cellular behaviors that are not necessarily

disease relevant. For this reason, iPSCs from unaffected family members are usually used to study idiopathic disease to minimize variability owing to genomic diversity [62].

iPSCs are also valuable for validating human-specific disease-causing variants. Advances in sequencing technology have enabled an increase in genome-wide association studies (GWAS) to identify novel disease-causing candidate mutations. For many complex diseases, candidate mutations are found in noncoding regions and most are not evolutionarily conserved in animal models. iPSCs are an ideal platform for validating such candidate mutations identified through GWAS studies. An example is a single nucleotide polymorphism risk variant that appeared to contribute to the pathogenesis of Parkinson disease (PD) [63]. Using genome editing with Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR)/CRISPR-associated protein 9 (Cas9), risk-associated alleles were introduced into wild-type iPSCs; by comparing the otherwise identical cell lines, researchers showed that the risk allele altered cis-regulation of the α-synuclein (SNCA) locus and led to an upregulation of SNCA expression. This variant mimicked a duplication of the coding region for SNCA that was known to be a familial cause of PD [64].

Methods have improved for culturing iPSCs in miniature "organoids" that can resemble the structure of human organs. When iPSCs are aggregated during their differentiation in vitro, they can create their own microenvironment and self-organize into three-dimensional structures. Kidney [65], liver [66], stomach [67], and brain organoids [68] can show remarkable similarities to the corresponding tissues. Researchers have just begun to explore possibilities to model disease using organoids. Multisystem organoids have been developed, including intestinal organoids with components of the enteric nervous system [69]. Organoids may provide a means to produce more fully mature cells in vitro and may be useful for drug screening.

CHALLENGES AND FUTURE POSSIBILITIES IN DISEASE MODELING

It is difficult to mature cells fully in vitro, so it remains challenging to model late-onset diseases. Efforts have been made to age iPSC-derived cells artificially, such as progerin treatment [70] and telomere shortening [71], but it is not clear whether these treatments are realistic mimics of aging. Direct reprogramming from fibroblasts has been reported to preserve age-related characteristics of the donor [72], but direct reprogramming has shortcomings for disease modeling, as discussed earlier. However, in some cases, aspects of late-onset genetic diseases may be detected in iPSC-derived cells. This allows testing of drugs that can correct the cellular phenotype. In one example, ALS patient-derived motor neurons were found to have an abnormal electrophysiological phenotype, which could be corrected with a US Food and Drug Administration–approved anticonvulsant drug, Retigabine [73]. A clinical trial was initiated in 2016 (https://clinicaltrials.gov/ct2/show/NCT02450552) to evaluate the effects of Retigabine on motor neuron activity in people with ALS.

PERSONALIZED MEDICINE

For decades, drug discovery has relied heavily on a reductionist approach in which high-throughput screening is used to identify biologically active molecules based on expression of a recombinant target protein of interest in a single transformed cell line. The transformed lines used in these screening processes tend to be of similar ethnic backgrounds. Decades of experience using this model led to the finding that the genetic background of an individual can determine the success or adverse effects of a particular drug. For this reason, regulatory agencies recommend including a diverse patient population in later-stage clinical trials. A genetically diverse group of iPSC-derived cells would be instrumental in predicting these types of genetically dependent effects in the preclinical stages, making the drug development process more efficient [74].

Proof-of-concept toxicity studies have been performed in stem cell–derived cardiomyocytes [75], hepatocyte-like cells [76], and neurons [77]. However, to draw associations between genotype and drug response, as well as identify associated biomarkers, large collaborative initiatives are needed to generate cell banks that cover diverse ethnic groups, capturing a range of genotypes [74]. Carefully chosen sets of genetically diverse iPSCs could then be used for preclinical development.

In addition to the ethnicity of the patient, multiple disease mechanisms are likely to contribute to one disease phenotype, and one drug is not appropriate or sufficient for all cases. For example, cystic fibrosis is an autosomal recessive disease that is caused by mutations in a gene called cystic fibrosis transmembrane conductance regulator (CFTR), which encodes for a chloride channel. Mutations in this channel result in abnormal regulation of salt and

water, causing severe respiratory and gastrointestinal symptoms. More than 1900 CFTR mutations have been identified (www.genet.sickkids.on.ca). The type of mutation has a direct effect on the efficacy of commonly used medications. For example, for patients who carry a G551D mutation, CFTR channel activity is reduced. Ivacaftor, an oral agent and channel agonist designed to prolong the time in which the chloride channel is open, was effective in treating symptoms in this subgroup of patients [78]. However, this patient subgroup accounts for only 5% of patients with cystic fibrosis. For most patients, a truncation in the protein prohibits proper trafficking to the plasma membrane. In such cases, a channel agonist is ineffective. Another therapeutic, Lumacaftor, which aids in transporting CFTR to the cell surface, is more appropriate for these patients [79]. Identifying the disease mechanism for each CFTR variant could be enhanced by using patient-specific iPSC modeling.

iPSC model systems have been used to predict the clinical outcome of patients with specific mutations. One study examined a selective sodium channel blocker and its effect on inherited erythromelalgia using patient iPSC-derived sensory neurons, and could correlate the in vitro results to patient response and specific mutations [80]. As another example, a retrospective study identified patients who clinically experienced drug-induced QT prolongation upon administration of a nonselective β-blocker, sotalol. Cardiomyocytes derived from these patients' iPSCs recapitulated the patient response in vitro, demonstrating differential arrhythmias after sotalol treatment [81]. These studies demonstrate the exciting potential for using iPSCs to predict patient outcomes and to choose better from clinically available interventions.

CELL THERAPY

Cell therapy is a fast-developing field in modern medicine. Traditionally, cell therapy was limited to bone marrow cells and blood stem cells, but with the ability to generate clinically relevant cell types from stem cells, pluripotent stem cell–based cell therapies are being developed. A potential advantage of using iPSC-based therapies is that the cell line can be chosen to be patient-specific or a close immunological match. Autologous transplantation of iPSCs and their derivatives is expected to be tolerated by the immune system, and patients could benefit from avoiding immunosuppressant treatment required for allogenic transplantation. The creation of banks of iPSCs designed specifically to serve as a close immunological match to a large percentage of the population may also be feasible by deriving cells from individuals homozygous for the major human leukocyte antigen (HLA) markers. Such banks would reduce the time and cost needed to produce cells for therapy. The practicality of these banks depends on the number of cell lines needed to match the population served by the bank. In a country such as Japan, it is estimated that a bank of 50–100 carefully chosen iPSC lines could match 90% of the population [82]. In contrast, the genetic diversity of the populations of Europe and the United States would necessitate banks with orders of magnitude more cell lines, which makes the design more challenging and less feasible. The HLA-matched iPSC banks have not yet been tested in human trials, and there is concern that minor antigens could cause rejection even when there is a perfect major HLA match.

The expectation of immune tolerance of autologous iPSC-derived transplants, however, is brought into question by reports showing that transplantation of mouse iPSCs into syngeneic rodents led to immunogenic teratoma formation [83]. Subsequent studies using rodent models, including a humanized mouse model to reconstitute a human immune system, produced conflicting findings. Whereas some reports [84,85] found that autologous transplants were not immunogenic, others [86] found significant immune response upon autologous transplant of some types of iPSC-derived cells. The autologous immune response may be caused by aberrant antigen expression induced by differentiation in vitro and might be cell type–specific. For example, iPSC-derived smooth muscle cells showed aberrant antigen expression but iPSC-derived retinal pigment cells did not [86]. Therefore, even for autologous transplantation, preclinical studies should include analysis of potential immune response.

Besides the potential immunological advantages of iPSCs, any cell therapy shares the common challenge of properly delivering the cell product [87]. For most cases, delivery of therapeutic cell types must be targeted to a region of interest. Although intravenous injection is simple and easy, it often results in cell capture and the destruction of delivered cells in the lungs or the liver. Consider, for example, the case of myocardial infarction. A myocardial infarct results from the loss of blood flow to a region of the heart, typically resulting from an occluded vessel. The chronic effects of an infarct are physical remodeling of the heart muscle tissue that hypertrophies as the heart struggles to adapt to a loss of function. In this case, restoration of muscle function through cell replacement could stop the remodeling process and provide symptomatic relief to millions of people. Preclinical studies on rodent and nonhuman primate myocardial infarction models reported that transplantation of embryonic stem cell–derived cardiomyocytes can be effective to prevent further deterioration of cardiac function by remuscularization of

myocardial infarcts [88]. However, the heart is not a mechanically hospitable environment for cell delivery. Cells must be physically and electrically integrated in an appropriate manner to provide meaningful improvements and avoid potentially harmful side effects in humans.

In other areas of the body, such as the central nervous system (CNS), transplanted cells are less likely to escape into the bloodstream. The relative ease of delivery is in part why most pluripotent stem cell–based therapies have focused on the CNS. Several groups have developed cell replacement therapies to treat macular degeneration, which is caused by the loss of the retinal pigment epithelium (RPE). The first trial to use iPSCs was led by Dr. Masayo Takahashi in Japan; the first patient was transplanted with autologous iPSC-derived RPE cells, and there are plans to use the HLA-matched Japanese iPSC bank for further trials [89]. PD is another area of intense interest for a pluripotent stem cell–derived cell therapy. PD results from progressive loss of A9 dopaminergic (DA) neurons in the substantia nigra, and by the time the symptoms are diagnosed properly, over 50% of the neurons have already been lost. In 2011, a robust protocol mimicking neuronal development was reported that used activation of the sonic hedgehog and wnt pathways to obtain patterned midbrain progenitor cells [46]. This group further generated DA neurons whose activity could be optogenetically controlled and demonstrated that when transplanted into a rodent PD model, these neurons could integrate into host circuitry, secrete dopamine, and restore movement control [47]. Clinical trials are planned in multiple countries, including Japan, the United States, and Sweden. Some groups plan to use autologous iPSC-derived DA neurons, whereas in Japan, the bank of HLA-matched iPSCs will be used. Other groups using ESCs plan to use immunosuppression for at least 1 year to prevent graft rejection. A unique consortium of researchers (www.gforce-pd.com) who are all arranging to use a similar cell type will provide results that will guide further decisions about whether autologous therapy offers benefits over allogeneic transplants.

CONSERVATION OF ENDANGERED SPECIES

One of the least straightforward and most challenging applications of iPSCs is their potential use in wildlife conservation. One such example is the ongoing effort to save an endangered species, the northern white rhinoceros (NWR), which is on the brink of extinction owing to poaching and civil wars. The three remaining NWRs in the world, including one aging male and two females, all have reproductive issues that prohibit propagation of the species. NWR fibroblasts were first reprogrammed into iPSCs in 2011 [90], and a consortium of researchers met in 2015 to develop a plan to save the NWR, which includes differentiating NWR iPSCs into gametes to use for assisted reproduction [91]. This approach is possible only because of the foresight of researchers who, over the past 3 decades, preserved dermal fibroblasts from 12 genetically diverse NWR individuals (http://institute.sandiegozoo.org/). Since 2011, fibroblasts from several more NWRs have been reprogrammed; the technical hurdles now lie in producing functional gametes and successfully implanting fertilized embryos into surrogate hosts. It was reported that functional oocytes were generated entirely in vitro from mouse iPSCs, which provides further hope that the same can be done with endangered species iPSCs [92].

CONCLUSIONS AND FUTURE DIRECTIONS

For decades, human diseases were modeled in the mouse because of the genetic tools available to alter the mouse genome. hESCs began to be used to generate multiple human cell types that could be used for clinical cell therapy and disease modeling. However, hESCs lacked genomic diversity [93], and although there are hESC lines with genetic mutations, they cannot be linked to the phenotype of a living individual. Reprogramming and derivation of iPSCs have revolutionized the fields of stem cell biology, regenerative medicine, and the study of human disease. iPSCs share all of the benefits of hESCs and also have the advantages of genomic diversity.

The future of reprogramming is difficult to predict because the technology is developing so quickly. For example, one can imagine moving from the culture dish to in vivo reprogramming. Such an approach could be used to augment tissue-specific stem cells to enhance regeneration; however, improvements are necessary in the control over the delivery of the factors in vivo. Interestingly, a study investigated the short-term expression of the Yamanaka factors in genetically engineered rodents and reported a prolonged life span and decreased recovery time after injury [94]. Studies such as this open the door to potential therapies based on iPSC technology.

A complementary technology that is also evolving at a rapid pace is the CRISPR/Cas9 system and other genetic engineering methods that enable targeted genomic editing. Efficient genome editing of iPSCs can be used to correct mutations, allowing autologous cell therapy for genetic disease. Gene editing can also produce better models for disease, allowing the introduction of specific disease-related variants into iPSCs that can be used to better understand phenotypic expression of mutant and wild-type alleles. The applications of iPSCs are a new tool in 21st-century medicine that will improve our understanding of human disease and enable novel approaches to treat currently untreatable diseases.

List of Acronyms and Abbreviations

ALS Amyotrophic lateral sclerosis
CFTR Cystic fibrosis transmembrane conductance regulator
DA Dopaminergic
ESCs Embryonic stem cells
GWAS Genome-wide association study
hESCs Human embryonic stem cells
iPSCs Induced pluripotent stem cells
NWR Northern white rhinoceros
PD Parkinson disease
RPE Retinal pigment epithelium
SNCA α-Synuclein
TS Timothy syndrome

CHAPTER

12

Multipotent Adult Progenitor Cells

Rangarajan Sambathkumar, Manoj Kumar, Catherine M. Verfaillie

University of KU Leuven, Leuven, Belgium

STEM CELLS

Stem cells have the unique capacity to self-renew, either symmetrically or asymmetrically. If stem cell divisions are symmetrical, the two descendant cells become stem cells, expanding the stem cell pool. However, postnatally, most stem cells divide asymmetrically, creating one stem cell and a differentiated cell or progenitor cells, resulting in maintenance of the stem cell pool [1]. Stem cells are unspecialized but can differentiate into multiple or all types of cells, depending on their potency. Totipotent stem cells present in the zygote or in the morula after a few divisions postfertilization can contribute to all of the cell types of embryonic development, including extraembryonic tissues such as, placenta, yolk sac, amnion, trophoblast, and extraembryonic endoderm lineages. Pluripotent stem cells (PSCs) are present in the inner cell mass (ICM) of the 4- to 6-day-old blastocyst. These pluripotent cells can also be derived from the ICM as embryonic stem cells (ESCs) [2–6]. Similar cells, induced PSCs (iPSCs), can be derived from adult somatic cells after overexpression of complements of transcription factors (TFs) such as *Oct4*, *Sox2*, *Klf4*, and *C-myc*. These pluripotent cells can differentiate into cells of three germ layers (ectoderm, mesoderm, and endoderm) in vitro as well as primordial germ cells [7,8] and extraembryonic endoderm [9]. When injected in vivo, they form teratomas, whereas when they are allowed to self-assemble in vitro, they form embryoid bodies.

Mouse ESCs (mESCs) are commonly cultured on feeders with leukemia inhibitory factor (LIF) and express cell surface marker SSEA1 [10,11] as well as *Oct4* [12], *Sox2* [13], *Nanog* [14], and *Rex1* [15]. Morula aggregation or tetraploid complementation studies showed that mESC contributes to chimera formation in the embryo proper or fetus, amnion, placenta, yolk sac mesoderm, trophectoderm, and germline cell types except for extraembryonic endoderm and [16,17]. Culture of mESCs in a so-called "naive" state, resembling cells in the ICM, has been accomplished by culture with inhibitors of glycogen synthase kinase 3β, extracellular signal-regulated kinase 1/2, and LIF [18].

Human ESCs (hESCs) are similar to mouse epiblast stem cells (mEpiSCs) and are established from postimplantation embryos. hESCs express SSEA4, TRA-1-60, and TRA-1-81 as well as the same TFs as are found in mESCs. As such, like mEpiSCs, hESCs do not depend on feeders or LIF, but on basic fibroblast growth factor and activin/nodal signaling to maintain pluripotency [19]. Multiple culture conditions and activation of specific TF gene networks has allowed the conversion of hESCs/iPSCs into a naive-like cell state, the direct derivation of naive PSC from blastocysts, and reprogramming of iPSCs from somatic cells [20–23]. Aside from their possible use in regenerative medicine, PSCs can be used to model cell-fate specification and disease.

ADULT STEM CELLS

Adult stem cells (ASCs), which include multipotent stem cells, can be defined as less or undifferentiated cells that are present with more highly differentiated cells in different organs. The primary role of ASCs is to maintain cell turnover and repair the tissue in which they reside. However, evidence suggests that they may be more versatile than previously thought and may be able to generate cell types different from cells of the tissue of origin. ASCs have been classified by some on the basis of the tissue source of origin. In 1906, Maximov postulated that bone marrow (BM) contains hematopoietic stem cells (HSCs). HSCs can be isolated from BM or mobilized peripheral

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00012-6

blood. HSCs from BM or umbilical cord blood (UCB) can reconstitute all mature blood cell lineages after transplantation into irradiated BM of the animal [24]. Since that discovery, neural stem cells (NSCs) have been isolated from the subventricular zone (SVZ) and dentate gyrus of hippocampus of the adult brain [25,26] and the LGR5-positive stem cells from gastrointestinal tissues [27]. Hair-follicle bulge stem cells [28], limbal stem cells [29,30], epidermal stem cells [31] and MSC, among others, have also been isolated.

In 1974, Friedenstein and colleagues described the presence of fibroblast colony-forming cells in BM as part of the hematopoietic microenvironment or niche [32]. These were characterized by Caplan and Prockop and designated "mesenchymal stem cells" or "mesenchymal stromal cells" (MSCs) [33–36]. MSCs are clonogenic cells that can undergo multiple rounds of self-renewing cell divisions and differentiate into multiple mesodermal cell lineages, including adipocytes, chondrocytes, osteocytes, smooth muscle cells, fibroblast cells, and hematopoietic supportive "stromal" cells [32,33,36]. According to the International Society for Cellular Therapy, human MSCs are plastic-adherent and maintained under standard culture conditions. As much as 95% or more of MSC are positive for CD29, CD105 (SH2), CD106, CD73 (SH3), CD90, CD44, CD49a-f, CD166, Stro-1, CD271, and CD146, but they do not express hematopoietic markers such as CD34, CD45, CD14, CD11b, CD79α, CD19, or human leukocyte antigen (HLA) class II [37,38]. MSCs have proangiogenic, immunomodulatory properties [39] and can be expanded for multiple passages, which makes them highly interesting from a therapeutic perspective. MSCs can be derived from multiple tissues, including BM, adipose tissue [40], UCB [41], and placenta, among others [42].

Many reports have demonstrated that adherent cells from different tissues may display greater differentiation potential than that of MSCs. For instance, in 2002, Jiang et al. described novel culture conditions that allow the isolation of multipotent adult progenitor cells (MAPCs) [43]. Other such cells derived from BM were termed multipotent stem cells [44] and marrow isolated adult lineage inducible cells (MIAMI) [45]. Unrestricted somatic stem cells derived from placental cord blood have also been reported [46]. In addition, cells with apparent greater differentiation potential were derived from amniotic fluid [47], fetal liver (human fetal liver multipotent progenitor cells) [48], BM (very small embryonic-like cells) [49], human UCB [50], and BM, heart, and liver human multipotent adult stem cells [51]. In this chapter, we provide a brief update on the origin, isolation, and characterization and in vitro and in vivo differentiation potential of rodent MAPCs (rMAPCs) and human MAPCs (hMAPCs) and their use in clinical trials.

ISOLATION OF RODENT MULTIPOTENT ADULT PROGENITOR CELL

MAPCs from BM of mice, rats, and humans were first reported in 2001. rMAPCs were expandable in the long term in vitro without senescence. At the single-cell level, MAPC differentiated into mesoderm, endoderm, and ectoderm cell types. Furthermore, we demonstrated that when injected into the blastocyst, Rosa26 mouse-derived MAPC contributed to multiple somatic tissues of the mouse [43]. Murine MAPCs (mMAPCs) were also isolated from muscle and brain [52]. From 2005 to 2006, as described in Subramanian et al. we further optimized culture conditions for the robust isolation of rMAPCs [53]. The most important differences were that cells were maintained under 5% O_2 conditions and were subcloned at very low densities (5 cells/well of 96-well plate) for 6–8 weeks [43,53,54]. In this way, clones could be more easily isolated based on typical MAPC morphology and expression of *Oct4*, a TF, and the cell surface markers SSEA1 and CD31. High *Oct4* clones were more likely to have greater expansion potential in culture.

In 2007, we described the results of a comparative microarray transcriptome analysis of rMAPC isolated using the detailed method described in Subramananian et al. BM MSC, and ESC. This demonstrated that gene expression of the rMAPC differed significantly from MSC and ESC. rMAPCs expressed several ESC-specific genes including *Oct4*, *Rex1*, *Sall4*, *Rex1*, and *Esrrb* and a number of ESC-associated transcripts but did not express *Sox2* or *Nanog*. As noted, rMAPCs express primitive endoderm markers such as *Sox7*, *Sox17*, *Gata4*, *Gata6*, *Foxa2*, *Hnf1b,* and *Hnf4a* [55], similar to the nascent hypoblast of developing blastocysts [56].

In 2008, Debeb et al. described the isolation of rat extraembryonic endodermal precursor (rXENP) from rat blastocyst [57], which like rMAPC, express *Oct4* as well as *Sox7*, *Sox17*, *Gata4*, *Gata6*, *Foxa2*, *Hnf1b*, and *Hnf4a*. To address whether rMAPCs from BM correspond to rXENP derived directly from the rat blastocyst, Lo Nigro et al. assessed whether rat BM MAPC cultured in fibronectin in 2% fetal calf serum (FCS), LIF, platelet-derived growth factor (PDGF), and epidermal growth factor (EGF) could express rXENP characteristics by culturing on rat feeders and LIF. These studies demonstrated that when rMAPCs were cultured in rXENP culture conditions, the rMAPCs were capable of acquiring certain rXENP features, and vice versa. Moreover, the transcriptome and in vitro and

in vivo differentiation potential of rMAPC and rXENP cells were highly similar: They differentiated to mesoderm and endoderm in vitro and created yolk sac–like tumors in vivo.

In addition, these studies suggested that the rMAPC characteristics are affected in vitro during long-term culture conditions [58]. Related findings have been reported for spermatogonial stem cells [59–61] and epiblast stem cells [62], i.e., they can be reprogrammed into an ESC-like state by culturing the cells under ESC conditions. We also demonstrated that rMAPC culture conditions enabled the isolation of extraembryonic endoderm precursor cells from rat blastocyst within 2–10 days after plating blastocyst. Therefore, we demonstrated that the culture conditions favor the growth of rXENP cells. These culture condition characteristics may be important to induce the transdifferentiation of BM cells to this phenotype or allow the rapid expansion of cells that are spontaneously reprogrammed to this phenotype in BM cultures. Which of these two hypotheses is correct is not clear.

ISOLATION OF HUMAN MULTIPOTENT ADULT PROGENITOR CELLS

hMAPCs have also been isolated from human adult BM [63–65]. In 2011 [66], Roobrouck et al. demonstrated that hMAPCs can be expanded more than 70 population doublings, significantly more than hMSCs and human mesoangioblasts. In contrast to rMAPCs, hMAPCs were cultured without LIF; but similar to rMAPCs, the hMAPCs were cultured with FCS, EGF, and PDGF-BB and under hypoxic conditions. Phenotypically, the hMAPCs were positive for CD13, CD73, CD90, and CD105+; expressed low expression levels of HLA class-1 and CD146; and were negative for HLA-DR, CD140a, CD140b, the pericyte marker NG2, alkaline phosphatase, hematopoietic antigens such as CD34, CD45, and CKIT, as well as the endothelial antigens KDR, TIE2, VE-cadherin, intercellular adhesion molecule-1, and CD31 [66]. Comparative transcriptome studies demonstrated that hMAPCs differ from ESCs, monoclonal antibodies, and MSCs. Although quantitative reverse transcriptase–polymerase chain reaction identified *OCT4* transcripts in hMAPC, levels in hMAPCs were significantly lower than in rodent cells or hESCs [66,67]. Roobrouck et al. demonstrated that the expansion potential of the hMAPCs may be partly affected by the culture conditions used to isolate and maintain the cells. Indeed, when human BM MSCs were cultured under MAPC conditions, the expansion potential increased, and when hMAPCs were cultured under MSC conditions, the expansion potential decreased. This was also associated with a partial reversal in the transcriptome characteristics for MSCs and MAPCs, which demonstrated that the phenotype and transcriptome profile are partly imposed by cell culture conditions [66].

DIFFERENTIATION POTENTIAL OF RODENT AND HUMAN MULTIPOTENT ADULT PROGENITOR CELLS IN VITRO

rMAPCs and hMAPCs differentiate into mesodermal lineage cells such as osteogenic [68,69], chondrogenic [70], adipogenic [67,71], and smooth muscle [72,73]. In contrast to MSCs, rMAPCs and hMAPCs also differentiate into endothelial cells [74–76]. Unlike hMAPCs, rMAPCs differentiate into functional hepatocyte [77–79] and glucose-responsive, insulin-producing pancreatic β-like cells in vitro and rescue streptozotocin-induced diabetic mice [80]. For hMAPCs, induction of hepatocyte-specific transcripts and proteins can be induced using differentiation protocols similar to those used for rodent cells; however, this differentiation is less robust [81]. A more robust differentiation to endoderm cells can be obtained by overexpressing endodermal TFs in hMAPCs, which yields a population of so-called induced endodermal progenitor cells (iENDO cells) that can be expanded for at least 40 cell doublings and differentiate into hepatocyte and endocrine pancreatic-like cells in vitro and in vivo. However, iENDO progeny are not fully mature functionally (Article under revision).

REGENERATIVE CAPACITIES OF MULTIPOTENT ADULT PROGENITOR CELLS

Hematopoietic Reconstitution With Multipotent Adult Progenitor Cells

In 2007, Serafini et al. demonstrated that green fluorescent protein (GFP)-labeled transgenic mMAPCs injected into lethally irradiated mice could reconstitute the hematopoietic system in the primary recipients, albeit after a long time, with the creation of HSCs. Thus, although mMAPCs could contribute to hematopoiesis in primary recipients, a thousandfold more mMAPCs were required for efficient engraftment [82]. HSCs harvested from these primary mice could reconstitute the hematopoietic lineages of secondary and tertiary recipients with normal kinetics and protect them from lethal irradiation.

Immunomodulatory Properties of Low-Oct4 Murine Multipotent Adult Progenitor Cells and Human Multipotent Adult Progenitor Cells: In Vitro, Preclinical, and Clinical Studies

In Vitro Effects of Multipotent Adult Progenitor Cells on T Cells, B Cells, and Natural Killer Cells

In 2009, Highfill et al. demonstrated that high-Oct4 ($Oct4^{high}$) mMAPCs can suppress allogenic T-cell activation and proliferation [83]. This suppression occurred through prostaglandin E2 synthesis by MAPCs, which decreased proinflammatory cytokine production [83]. However, Luyckx et al. demonstrated that an $Oct4^{high}$ mMAPC clone had an immunostimulatory effect at a low stimulator to effector (S-E) ratio (100:1 and 10:1) in vitro, whereas a suppressive effect was found at an S:E ratio of 1:1 [84]. On the other hand, when $Oct4^{low}$ mMAPCs, MSCs, or ESCs were tested, the immunostimulatory effect observed with $Oct4^{high}$ mMAPCs was not seen. Furthermore, a local suppressive effect was found after $Oct4^{high}$ mMAPC and mMSC injection in a mouse model of graft versus host disease (GVHD) [85]. Although the exact mechanisms responsible for the differing effects of $Oct4^{high}$ and $Oct4^{low}$ mMAPCs in vitro are not fully understood, these experiments demonstrated that $Oct4^{high}$ and $Oct4^{low}$ mMAPCs have immunosuppressive effects in vivo if delivered locally.

In 2013, Reading et al. demonstrated that hMAPCs suppress T-cell proliferation and type 1 T helper (Th1) and Th17 cytokine production while increasing interleukin (IL)10 production. Furthermore, hMAPCs inhibited the proliferation of autoreactive T cells from patients with type 1 diabetes [86]. In 2015, the same group reported that culturing hMAPCs with CD4 T^+ cells and $CD14^+$ monocytes resulted in the suppression of IL7-dependent T-cell expansion and prevented Th1 (interferon [IFN]-gamma and tumor necrosis factor-4α), Th17 (IL17), and Th22 (IL22) proinflammatory cytokine production. Transwell studies demonstrated that soluble factors, including prostaglandin E, from MAPCs suppressed the T cells [87]. In 2016, Plessers et al. demonstrated that hMAPCs also blocked cytotoxic $CD8^+$ T lymphocytes [88].

Aside from affecting T-cell function, Jacobs et al. reported the effects of hMAPCs on natural killer (NK) cell function. hMAPCs express lower levels of class 1 MHC compared with the MSCs and express inhibitory signals for NK cells, such as poliovirus receptor and unique long−16 binding proteins-2/5/6. When resting NK cells were cocultured with allogeneic hMAPCs at effector−target ratios of 1:1 to 8:1 for 24 h, NK cells did not kill hMAPCs and blocked cytolytic functions of NK cells, because NK-sensitive K562 target cells were not killed. In contrast, IL 2−stimulated NK cells remained capable of killing hMAPCs. hMAPCs dose dependently reduced NK cell proliferation in an indoleamine 2,3-dioxygenase−dependent manner but did not influence the cytotoxic capacity of NK cells induced by IL-2, unless the hMAPCs were also activated using IFN-gamma. Thus, the mutual interaction between NK cells and hMAPCs depends on the activation state of NK cells and the priming of hMAPCs [89].

Finally, Ravanidis et al. demonstrated that rMAPCs can also suppress activated T-cell expansion, and that when challenged with proinflammatory cytokines, the rMAPCs produced chemokines as well as neurotrophic factors, including vascular epithelial growth factor (VEGF) and ciliary neurotropic factor, which could partly protect against hydrogen peroxide−induced death of the oligodendrocyte cell line (OLN93) [90].

In Vivo Immunodulatory Effects

Effect of Multipotent Adult Progenitor Cells on Graft Versus Host Disease

In the 2009 study described earlier, Highfill et al. demonstrated that when $Oct4^{high}$ mMAPCs were injected systemically, the cells did not home to sites for allopriming or suppress GVHD, but when they were injected locally in spleen at BM transplantation, mMAPCs suppressed T-cell proliferation and reduced GVHD via prostaglandin E2 synthesis [83,91]. Similarly, Luckx et al. demonstrated that although $Oct4^{high}$ mMAPCs suppressed local alloreactive T-cell expansion in lymph nodes in vivo, they failed to suppress GVHD when injected systemically [84]. By contrast, Kovacsovics-Bankowski et al. demonstrated that rat MAPCs were immunomodulatory, and when infused intravenously, they could reduce GVHD-related mortality in a rat model of GVHD [91].

In 2014, Maziarz et al. conducted a multicenter phase 1 dose escalation study to access the safety of clinical-grade MAPCs (MultiStem, Athersys, Inc., Cleveland, OH) in allogenic HSC transplantation. This study demonstrated that hMAPC infusions were tolerated without association of any known toxicity, graft failure, incidence, or infection. At the highest single dose (10 million cells/kg body weight) a reduced incidence of grade II to IV GVHD was seen 11.1% (one in nine patients) and no grade III and IV GVHD cases were observed compared with the lower single dose (1.5 million cells/kg body weight) in which 37% grade II to IV (37%) GVHD was observed [92]. Of note, no grade III or IV GVHD cases were observed in the highest single-dose cohort.

Effect of Multipotent Adult Progenitor Cells on Graft Survival When Cotransplanted With Other Cells

Cunha et al. demonstrated that cotransplantation of mouse pancreatic islets and an hMAPC composite pellet under the kidney capsule of alloxan-induced diabetic C57BL/6 mice improved islet function and glycemic control, secretion of c-peptide, and glucose tolerance compared with mice receiving islets alone or separate pellet transplantations of islets and hMAPCs. Moreover, hMAPC production of angiogenic growth factors including VEGF in vitro and in vivo is hypothesized to be responsible for improved graft neovascularization and enhanced islet function [93].

Role of Multipotent Adult Progenitor Cells as Immunomodulation in Solid Organ Transplantation

In 2012, Eggenhofer et al. demonstrated that infusion of third-party MAPCs in an allogenic rat model for heterotopic heart transplantation induced long-term allograft survival with low-dose pharmacological immunosuppression compared with animals treated with immunosuppressive drugs alone. Furthermore, hearts recovered from MAPCs treated animals could be successfully regrafted into naive animals with no immunosuppression [94]. Transcriptome studies demonstrated that the MAPC-induced tolerogenicity was caused by creating tolerogenic macrophages in the heart. Indeed, when monocytes and macrophages were depleted in the first recipient by intravenous administration of clodronate-filled liposomes in organ recipients before MAPC infusion, the tolerogenic effect of MAPCs was diminished and long-term acceptance of graft was reduced [94]. In a more recent study, the effect of clinical-grade hMAPC on the need for immunosuppression in clinical liver transplantation (Mesenchymal Stem Cells in Solid Organ Transplantation) was assessed in a phase I, dose escalation, safety, and feasibility study. Patients received one portal vein and one intravenous injection of third-party hMAPCs. Initial results indicate that no toxicity was found in MAPC-treated patients [95,96]. The clinical effect on liver rejection cannot yet be evaluated.

Multipotent Adult Progenitor Cell Immunodulatory and/or Trophic Effects in Ischemic Disease

Several preclinical and clinical studies in ischemic diseases have demonstrated a role for immunomodulatory and/or trophic effects that affect the degree of ischemic damage in the central nervous system, heart, and limbs.

Ischemic Stroke In 2010, Mays et al. demonstrated the neuroprotection of endogenous tissues at the site of injury and improved locomotor function when hMAPCs were injected directly into the striatum of a rat model of ischemic stroke. It was hypothesized that this was caused in part by the secretion of trophic factors by hMAPCs and reduced neuroinflammation at the site of injury. This resulted in decreased neuronal cell death and increased neoangiogenesis, indirectly contributing to tissue regeneration [97]. Similarly, Mora-Lee et al. in 2012 showed that when hMAPCs or MSCs were transplanted in an immunodeficient mouse model of stroke, animals treated with hMAPCs revealed a decreased loss of brain tissue that was associated with increased angiogenesis, and reduced inflammation and glial scar 28 days after stroke. In addition, increased proliferation of NSCs in the SVZ and survival of new neuroblasts were observed in hMAPC-treated animals [98].

In 2014, Hess et al. outlined the clinical protocol for a phase-1/2 randomized, double-blind, placebo-controlled, multicenter dose escalation trial in patients with ischemic stroke who were treated with MultiStem [99].

Jellema et al. demonstrated in a preclinical animal model for hypoxic-ischemic injury in fetal sheep that systemic administration of MAPCs reduced the duration of seizures, prevented microglial proliferation, and modulated peripheral inflammatory responses [100].

Spinal Cord Injury Multipotent adult progenitor cells and related cell types have been shown to modulate the inflammatory response after spinal cord injury, driving macrophages toward an alternatively activated phenotype and reducing the effects of the inhibitory glial scar [101,102]. DePaul et al. demonstrated that intravenous delivery of hMAPCs in an acute contusive spinal cord injury model reduced macrophage-mediated axonal cell death and decreased inflammation by homing MAPCs into the spleen. Functionally, improved recovery of locomotion and urinary function was documented that correlated with reduced macrophage infiltration and increased tissue sparing at the lesion site. Furthermore, the researchers reported a significant increase in arginase 1, a well-established marker of alternatively activated macrophages, in the acutely injured spinal cord. Biodistribution studies demonstrated that hMAPCs preferentially homed to the spleen. These results demonstrate that hMAPCs exert their primary effects in the periphery and support the hypothesis that hMAPCs alter the dynamics of the inflammatory response to central nervous system injury, ultimately leading to improved outcomes [103].

Traumatic Brain Injury In another study, intravenous injection of rMAPCs after traumatic brain injury (TBI) protected rats from neurovascular damage, also by interaction with resident splenocytes. This resulted in improved

preservation of the blood–brain barrier [104]. Intravenous rMAPC delivery after cortical injury induced T-regulatory cells and increased the M2/M1 macrophage ratio in splenocytes and plasma [105]. In addition, in vitro studies demonstrated that microglia activation was modulated by secreted factors from rMAPC–splenocyte cocultures, and these changes resulted from an increase in M1 macrophage apoptosis. Finally, it was shown that infusion of rMAPCs improved spatial learning in a TBI rodent model [106]. Therefore, it appears that neuroprotection in TBI (and possibly other brain or spinal cord injuries) is at least partly mediated by an interaction between MAPCs and splenocytes, which results in the modulation of activated microglia.

Ischemia–Reperfusion Injury The antiinflammatory properties of hMAPCs were also examined in an ex vivo lung explant model of ischemia–reperfusion injury [107]. The intratracheal administration of hMAPCs was shown to reduce cold-induced ischemia lung injury and inflammation and suggested that hMAPCs could be used ex vivo to reduce the effects of reperfusion after long-term cold storage of donor lungs.

Myocardial Infarct In 2007, Pelacho et al. demonstrated that direction injection of *Oct4*^{low} mMAPCs in the border zone surrounding a heart infarction in mice induced the functional improvement of left ventricular contractile cardiac function. The beneficial effect of MAPCs was mainly trophic, because no conversion of MAPCs to myocardial cells was observed, but improved host angiogenesis and changes in local inflammatory response were observed, which likely explained the improved cardiac function [108]. This study was further confirmed in a rat model in which syngeneic and allogeneic rMAPCs were tested in a rat model of acute myocardial infarction (MI) [109] and in the setting of xenogeneic delivery of hMAPCs in a mouse MI model by Dimomeletis et al. in 2010, even though authors suggest that MAPC conversion to cardiomyocytes was seen, what other teams were less conclusive about [110]. Similar observations were found by Zeng et al. [111], when swine MAPCs were directly injected into the heart of allogeneic swine, without or with immunosuppression. This initial study was followed by a longer-term assessment study in which the same group demonstrated that MAPCs imparted long-term functional and bioenergetic improvement in a swine MI model [112]. These studies formed the basis for a phase I clinical trial in which allogeneic clinical-grade hMAPCs (MultiStem) were administered by adventitial delivery into the coronary artery in acute MI patients with patients with an ejection fraction of 45% or less. The results demonstrated that the cells were well-tolerated and that the ejection fraction 4 months posttherapy was increased by ±10% in groups that received 50 or 100 million MultiStem, which was in the 50 and 100 million group also accompanied by a 25% and 8% increase in left ventricular stroke volume, respectively [113].

Peripheral Hind Limb Ischemia Aranguren et al. in 2008 compared the effect of grafting unselected murine bone marrow cells (mBMCs), *Oct4*-expressing mMAPCs, or *Oct4*-expressing mMAPCs predifferentiated to vascular progenitors (mMAPC-VP) in a mouse model of moderate ischemic limb. They demonstrated that mMAPCs, in contrast to mBMC and mMAPC-VP cells, resulted in a sustained improvement in muscle regeneration and function. In addition, when tested in a much more severe model of limb ischemia, they demonstrated that both undifferentiated *Oct4*^{high} mMAPCs and hMAPCs remedied vascular and muscular deficiencies [114]. In a subsequent study, in which human angiogenic progenitor cells isolated from BM based on the expression of AC133 cells and hMAPC cells were compared, hMAPCs improved angiogenesis and muscle regeneration and function significantly better than AC133 cells. These studies demonstrated that the largest effect of mMAPC/hMAPC was through the production of trophic proangiogenic and regenerative stimuli.

Antitumor Effects of Multipotent Adult Progenitor Cells in Glioma

Oct4^{low} mMAPC syngeneic expressing enhanced GFP and firefly luciferase-herpes simplex virus thymidine kinase and labeled with superparamagnetic iron oxide nanoparticles labeled (1% or 10%) were grafted in glioblastoma (GL261)-bearing animals. Magnetic resonance imaging of the animals demonstrated that mOct4^{-} MAPCs were located near the glioblastoma and upon treatment with ganciclovir, a reduction was seen in tumor volume along with a better survival rate compared with control untreated animals. The antitumor effect was hypothesized to be at least partly mediated by the synergistic effects of the immunomodulatory properties of mMAPCs and suicide gene therapy [115].

Possible Mechanisms of Trophic Effects: Secreted Proteome of Multipotent Adult Progenitor Cells

In 2013, using a proteomics approach, Burrows et al. identified the secretome of hMAPCs over 72 h in vitro under steady-state conditions and in response to different inflammatory signals, specifically IFN-gamma or lipopolysaccharide (LPS), or the tolerogenic CD74 ligand, RTL 1000. These studies revealed that MAPCs secrete multiple

molecules involved in regulating extracellular matrix components, as well as chemokines, cytokines, and multiple molecules that affect angiogenesis, activation of growth factors, and the innate immune system. The secretome was highly differentially affected by incubating MAPCs with IFN-gamma, LPS, or RTL-100 [116]. These findings are in line with the immunomodulatory, protective, and proangiogenic effects of MAPCs in different disease settings; the precise contribution of the secreted factors identified in this proteome study will need further validation.

CONCLUSION AND FUTURE DIRECTIONS

We here describe MAPCs derived from rodents (mice and rats) and humans. Although both cell types initially were named MAPCs, based on the fact that they were isolated from BM of rodents and humans and had differentiation and expansion potential greater than MSCs, more recent studies demonstrated specific and important differences between rMAPCs and hMAPCs. Although rMAPCs express the pluripotency gene *Oct4* at levels near those in ESCs, have the potential to differentiate robustly into endodermal cells, and develop into yolk sac tumors when grafted in vivo, these findings do not hold true for human cells.

hMAPC that do not cause tumor formation have been tested extensively for their possible immunomodulatory and trophic effects in different animal models of transplantation, GVHD, central nervous system injury and ischemia, and cardiac and peripheral limb ischemia. The results from these preclinical studies are being tested in ongoing clinical studies using the clinical-grade MultiStem product.

Conflict of Interest Statement

CHAPTER

13

Hematopoietic Stem Cell Properties, Markers, and Therapeutics

John D. Jackson

Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

INTRODUCTION

The hematopoietic system provides for the regulated production of the complete complement of mature blood cells in the peripheral circulation, which includes neutrophils, eosinophils, basophils, monocytes, lymphocytes megakaryocytes (platelets), and erythrocytes. These mature blood cells have a limited life span, which ranges from hours for granulocytes to weeks for erythrocytes and years for some lymphocytes. To maintain equilibrium in the hematopoietic system, the continual production of mature blood cells is required. The hematopoietic system is a self-renewal system in which hematopoietic stem cells divide and differentiate to produce maturing progeny as well as self-renew to maintain a pool of stem cells for the life of the individual. This chapter will define the properties of the hematopoietic system and review the current therapeutic uses of hematopoietic stem cells.

HEMATOPOIETIC STEM CELL PROPERTIES

Hematopoietic cells appear early in embryonic development. The first observable site of hematopoiesis in the mouse is the formation of blood islands in the yolk sac at 7.25–7.5 days postfertilization [1]. Controversy has surrounded the origin of hematopoietic stem cells during embryological development. In studies using parabiosed chorioamnionic membranes from two chick eggs of different sexes, it was determined that spleen, bone marrow, and bursa of Fabricius contained hematopoietic cells of the opposite sex [2]. The results suggested that the hematopoietic organs were seeded by stem cells circulating in the blood. When 7-day-old yolk sac cells were injected into irradiated chicken embryos, both myeloid and lymphoid tissues of the irradiated embryos were repopulated by the injected yolk sac cells, which suggested that the circulating cells were pluripotent, seeded the different organs, and differentiated [3]. Using a mouse model, similar studies demonstrated that yolk sac contained both stem and progenitor cell populations [1]. Yolk sac cells from 7- to 13-day old mouse embryos were injected into irradiated recipients to measure colony-forming unit–spleen (CFU-s) content. Yolk sac–derived CFU-s were detectable at day 8 of gestation and reached a maximum at day 11. These cells also contained hematopoietic progenitor cells, as measured by an in vitro colony assay. Neither hematopoietic stem nor progenitor cells were detectable by day 13 of gestation. The pluripotent nature of yolk sac cells was demonstrated by repopulation of both lymphoid and myeloid tissues of lethally irradiated recipients. The authors concluded from these studies that hematopoietic tissues in embryos were colonized by circulating stem cells that were derived from the yolk sac and that the yolk sac was the only de novo site of hematopoietic stem cell production [1].

In contrast, studies using chick–quail chimeras, in which 2-day-old quail embryos were grafted onto developmentally compatible chick yolk sacs, demonstrated that yolk sac blood island cells did not contribute to intraembryonic hematopoiesis [4]. Only quail hematopoietic cells were found in the thymus and spleen of the grafted quail embryos. The discrepancy in the data was explained by the gestational age of the embryos at which the yolk sac was examined. Seven-day-old chick embryo yolk sac–derived cells were used to repopulate the irradiated

chick embryos [3]. Vascularization was established before day 7 of gestation in the chicken embryos; therefore, it was speculated that cell migration had resulted in the presence of intraembryonic-derived stem cells in the yolk sac before the gestational age of 7 days [4]. Another study demonstrated that hematopoietic cells that were able to colonize the thymus were present in the blood of 4-day-old chick embryos [5].

Lymphoid progenitor cells were shown to be derived from intraembryonic sites and not from yolk sac in a chick–chick chimera model [6]. Using a chick–quail chimera model, the intraembryonic source of hematopoietic stem cells was confirmed and the colonization of embryonic hematopoietic organs was shown to occur via interstitial migration of stem cells rather than the vascular seeding of the stem cells from the yolk sac [7]. To define the location of the hematopoietic stem cells further, anterior and posterior regions of quail blastoderms were grafted onto chicken blastoderms. The origin of the hematopoietic cells was localized to the posterior section of the grafted quail blastoderm; no hematopoietic stem cells were found in the cephalic or anterior grafted blastoderm [7]. The specific site of the origin of hematopoietic stem cells was not identified. However, it was speculated that colonization of the embryonic hematopoietic organs was from stem cells derived from adjacent tissues [7]. The dorsal aorta region of the chicken embryo was suggested to be the site of origin of hematopoietic stem cells [4].

The use of an amphibian developmental model also demonstrated an intraembryonic origin of hematopoietic stem cells [8]. Using an amphibian model containing cytogenetically unique cells, the study showed that there were two sites of hematopoiesis during early amphibian development: one from the ventral blood island mesoderm, which produced a transient population of erythrocytes, and the other from the lateral plate mesoderm in the region of the dorsal aorta-gonad-mesonephros (AGM) region, which produced definitive hematopoiesis [9]. The migration of hematopoietic precursors in the lateral plate was shown to be from the posterior to the more anterior pronephros and dorsal aorta [10].

The two distinct sites of hematopoiesis described in the amphibians may also apply to avian and mammalian hematopoiesis in embryo development. Erythroid cells derived from chicken yolk sac were able to colonize spleens of grafted quail embryos, but only transiently [11]. Chicken-derived erythroid cells were found in the spleen of grafted quail embryos between days 10 and 12; however, by day 13, only quail erythroid cells were seen in the spleen. In addition, up to day 10, chicken red blood cells were most of the circulating red blood cells; however, by day 13, up to 80% of the circulating red blood cells were derived from quail hematopoietic cells [11]. In a mouse model, 9.5-day-old mouse yolk sac cultured in vitro produced primitive erythropoiesis for only a short time [12]. However, if the yolk sac was cultured in a transmembrane organ culture in the presence of embryonic liver rudiment, the yolk sac developed into definitive erythropoiesis [12]. Definitive erythropoiesis was established whether or not there was direct cell–cell contact between the yolk sac and liver rudiment. This result indicates a role for the microenvironment and short-range factors in the induction of definitive erythropoiesis.

Placental Hematopoiesis

During fetal development, the placenta serves as the tissue responsible for maternofetal exchange as well as a source of cytokines and hormones [13]. Early studies in the mouse suggested that the placenta contains hematopoietic activity [14,15]. Hematopoietic cells are found in the placenta as early as day 9 of gestation, which suggests that the placenta may be a site of hematopoietic stem cell generation in situ [16]. However, the placenta may also be seeded with hematopoietic stem cells from the AGM region [17]. Hematopoietic stem cells are rapidly expanded in the placenta between days 11.5 and 12.5 of gestation and decline after day 13.5 of gestation [18]. The placenta may be a source of hematopoietic stem cells for the fetal liver via the fetal circulation [17].

Fetal Liver Hematopoiesis

The fetal liver is the primary hematopoietic organ for fetal development and is the primary site for expansion and maturation of fetal hematopoietic stem cells. Hematopoiesis in the fetal liver depends on the migration of hematopoietic precursor cells and is not a site for the de novo generation of hematopoietic stem cells. In the mouse, yolk sac erythropoiesis declines rapidly from day 15 of gestation with the switch of hematopoiesis to the fetal liver. By day 9.5–10 of gestation, the fetal liver is colonized by circulating hematopoietic progenitors [19]. During this early time of colonization, the major cell type is definitive erythroid cells probably representing progenitors originating in the yolk sac [20]. Lymphoid and myeloid lineages develop later. The first hematopoietic stem cells appear around day 11.5 of gestation and undergo extensive expansion in the fetal liver [21]. The yolk sac, AGM region, and placenta are the potential sites of origin for the cells seeding the fetal liver. Hematopoietic stem cells found in the fetal liver are

pluripotent, as evidenced by the repopulation of lymphoid and myeloid linages after fetal liver cell transplantation into lethally irradiated mice [22]. Using the CFU-s assay, the number of hematopoietic stem cells in the liver reached a maximum at day 18 of gestation and then fell sharply at birth [23]. No hematopoietic stem cells could be detected in the liver 8 days after birth [23]. Developmental changes in the fetal liver microenvironment may influence the homing, retention, support, and differentiation of hematopoietic cells [24]. In adult animals, under normal physiological conditions, liver extramedullary hematopoiesis does not occur. However, under severe physiological stress, extramedullary hematopoiesis can occur [25].

Bone Marrow Hematopoiesis

In adults, the major site of hematopoiesis is the bone marrow. The structure of bone marrow is not random. There is an ordered arrangement of hematopoietic stem and progenitor cells in relation to the hematopoietic microenvironment. Morphologically, the mouse femoral bone marrow consists of cords of highly vascularized hematopoietic tissue that is composed of structural microenvironmental cells that support the maintenance, proliferation, and differentiation of hematopoietic stem and progenitor cells. Spatial organization is important to the regulation of hematopoietic cells. The stromal component of the bone marrow microenvironment is composed of osteoblasts, fibroblasts, adipocytes, chondrocytes, and vascular cells [26]. Bone marrow stromal cells make up the supportive microenvironment for the maintenance of hematopoiesis through the production of growth factors, chemokines, and extracellular matrix, as well as direct cell—cell interaction.

A concept for a bone marrow niche was first proposed by Schofield [27]. He postulated that primitive hematopoietic stem cells reside in the niche in association with stromal cells. When a hematopoietic stem cell divides, one daughter cells remains in the niche representing self-renewal and the other daughter cells leaves the niche to undergo further proliferation and differentiation.

Two types of bone marrow niches have been identified: osteoblastic and vascular. The osteoblastic niche is located near the endosteal surface of the marrow and was first suggested from homing studies of transplanted hematopoietic stem cells [28]. Osteoblasts and bone marrow stromal cells produce SDF-1, which is a homing chemokine for hematopoietic stem cells [29]. The osteoblastic niche provides an environment that supports stem cell quiescence and the long-term survival of hematopoietic stem cells [30]. The vascular niche is located in the central medullary region of the bone marrow. Stem cells located in the vascular niche have access to circulating factors that may allow mobilization into the peripheral circulation via transendothelial migration [31].

In Vitro Hematopoiesis

An in vitro bone marrow culture system was developed by Dexter and colleagues; it supports the long-term maintenance of hematopoietic stem cells [32]. The adherent layer contains several stromal cell populations and is obligatory for the long-term support and production of stem cells [33]. Upon morphological examination of the adherent layer of long-term bone marrow cultures, primitive hematopoietic cells can be seen in close association with the stromal cells (Fig. 13.1 and 13.2).

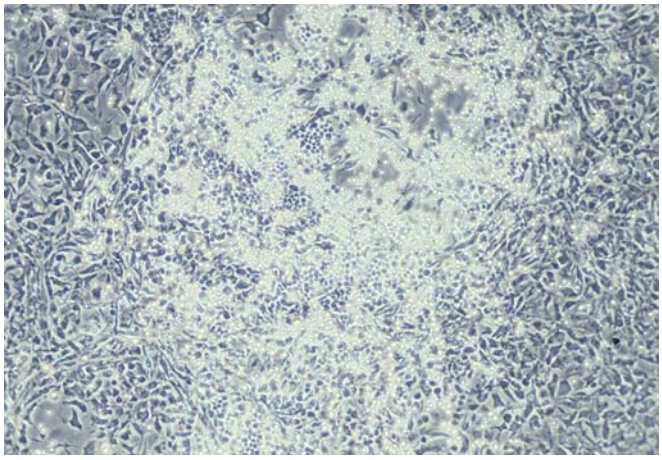

FIGURE 13.1 Photomicrograph of a long-term bone marrow culture showing the adherent stromal layer that contains bone marrow stromal cells and the associated hematopoietic cells (magnification, 20×).

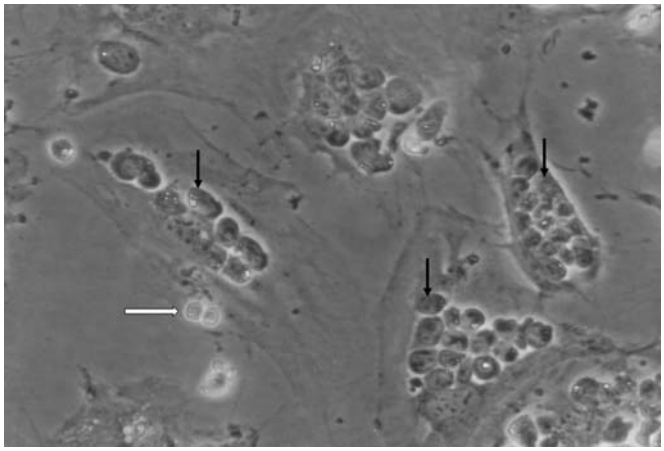

FIGURE 13.2 Photomicrograph showing the interaction of hematopoietic progenitor cells with bone marrow stromal cells. The *black arrows* point out the close association of the hematopoietic progenitor cells with the adherent stromal cells. This interaction is the "cobblestone area." The phase dark cells are hematopoietic progenitor cells that have migrated under the stromal cell (*black arrows*). The phase light hematopoietic progenitor cells are on top of the adherent stromal cell (*white arrow*) (magnification, 100×).

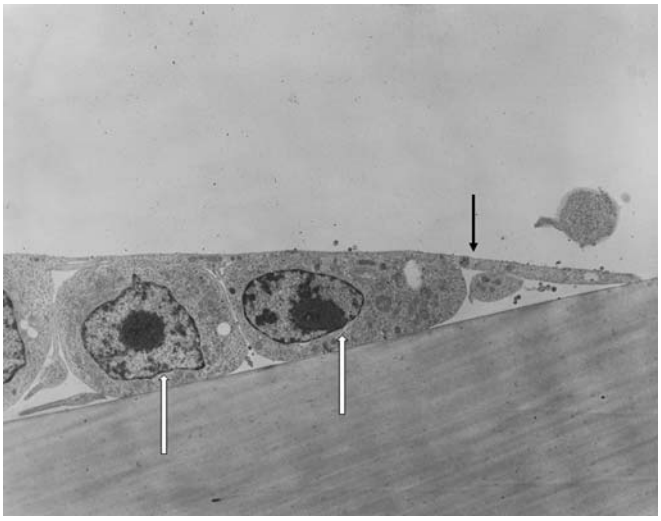

FIGURE 13.3 Transmission electron micrograph of a cobblestone area. Hematopoietic progenitor cells (*white arrows*) have migrated under the stromal cell (*black arrow*) and are in close contact with the stromal cell (magnification, 5550×).

These areas consist of multilayer cellular complexes that are hematopoietically active (Fig. 13.3).

Primitive CFU-s reside in the adherent layer, where they undergo proliferation and differentiation with some of the CFU-s, and many mature cells or their immediate precursors are released into the supernatant [34,35]. The adherent layer contains a larger proportion of more primitive (day 12) CFU-s and the nonadherent or supernatant cells contain a higher number of more mature (day 8) CFU-s [36,37]. Cell-to-cell contact appears to be essential in the in vitro maintenance of these stem cells. The development of in vitro long-term bone marrow cultures has been important in characterizing hematopoietic stem cells and their interaction with stromal cells.

Phenotypic Properties of Hematopoietic Stem Cells

Hematopoietic stem cells represent approximately 0.01% of nucleated cells within adult bone marrow. The identification and isolation of hematopoietic stem cells have been greatly enhanced by technical advancements in flow cytometry and the development of monoclonal antibodies. One of the first comprehensive phenotypic enrichments of mouse hematopoietic stem cells was reported in 1988 by Weissman and colleagues [38]. The procedure was modified over the years, but basically it involved the use of a cocktail of antibodies to deplete mature hematopoietic cells

with the resultant enrichment of hematopoietic stem and progenitor cells. The depletion cocktail included antibodies to B cells (CD45R/B220), granulocytes (Gr-1), macrophages (Mac-1), erythrocytes (Ter-119), and T cells (CD-4 and CD8). The resultant cell population was termed lineage negative (lin^-). Other antibodies were used to subdivide the enriched cell population further, including Sca-1 and c-Kit [39]. The $lin^-/Sca\text{-}1^+/c\text{-}Kit^+$ (LSK) cells represent approximately 0.05% of nucleated bone marrow cells [40]. Thy-1.1 and Thy-1.2 antibodies were also used; however, the expression of Thy-1.1 is mouse strain dependent, and mouse strains expressing Thy-1.2 show variability in expression; therefore, these two markers are not as useful in hematopoietic stem cell purification [41]. CD34 can also be used to subdivide the LSK population. The $CD34^-$ cells contain a more primitive stem cells than do the $CD34^+$. Therefore, long-term repopulating cells fall within the $LSK/CD34^-$ population. Morrison and colleagues used the signaling lymphocyte activation molecule family of cell surface markers to identify a long-term repopulating hematopoietic cell population ($CD150^+/CD244^-/CD48^-$) [31]. CD150 can be added to the LSK scheme to enrich hematopoietic stem cells further.

Another approach to identifying hematopoietic stem cells is the use of fluorescent dye exclusion rather than cell surface markers. This approach uses the stem cell property of the high expression of multidrug resistance (MDR) pumps, which remove drugs and dye from the cells, resulting in low fluorescence. Two different dyes have been used. Rhodamine 123 (Rho123) is a mitochondrial-specific dye. $Rho123^{lo}$-expressing bone marrow cells are enriched in long-term repopulating cells [42,43]. Use of the second dye was describe by Goodell and colleagues [44]. Hoechst 33,342 is a vital dye that binds to DNA; when it is excited by a UV laser, it emits at two wavelengths, 450 nm (Hoechst blue) and 675 nm (Hoechst red). Hematopoietic stem cells efflux the dye owing to their high expression of MDR pumps, resulting in a low concentration of fluorescence. Analysis of the Hoechst red versus Hoechst blue emissions reveals a unique plot with the stem cells present on the side of the fluorescent profile; therefore, it is termed the side population (SP). SP cells are enriched for hematopoietic stem cell activity; most of the hematopoietic repopulating ability is located in the lower portion of the SP fraction [45,46]. Dye exclusion assays can be combined with immunophenotyping methods to provide a more stringent selection of hematopoietic stem cells.

HEMATOPOIETIC STEM CELL THERAPIES

Bone Marrow Transplantation

During the production of nuclear weapons in the 1940s, it was discovered that the hematopoietic system was one of the more sensitive tissues to the effects of irradiation. Many investigators searched for methods to protect the hematopoietic system from the detrimental effects of irradiation. It was found that shielding the spleen would allow irradiated mice to survive [47]. In addition, the infusion of spleen cells also protected mice from lethal irradiation by reconstituting the hematopoietic system [48]. Injection of bone marrow cells also resulted in the recovery of the hematopoietic system and the survival of lethal irradiated animals [49]. During these studies, the dogma was that humoral factors produced by spleen and bone marrow were responsible for the recovery of hematopoiesis in the irradiated animals [50]. However, several studies in the mid-1950s demonstrated that hematopoietic protection after irradiation resulted from infused donor cells that contributed to hematopoietic recovery in the host [51–54]. This discovery of a cellular role in hematopoietic recovery from lethal irradiation initiated the age of hematopoietic stem cell transplantation for malignant diseases.

In 1957, Thomas and colleagues performed the first allogeneic transplantations on six patients who experienced various types of terminal illnesses [55]. The infusion of donor bone marrow cells demonstrated that this procedure could be administered safely; however, no lasting engraftment was noted owing to the modest levels of irradiation and chemotherapy given to the patients. Three years later, Thomas and colleagues transplanted two pediatric patients who had acute leukemia with syngeneic bone marrow after chemotherapy and total body irradiation [56]. Each patient had a twin sibling who provided the donor bone marrow. Although both patients experienced relapse of the disease several months after transplantation, the procedure resulted in hematopoietic reconstitution of the patients. Around the same time, Mathé and colleagues infused allogeneic bone marrow into people who had accidentally been exposed to radiation. Four of the five transplanted patients survived; however, the transplant recipients experienced only transient chimerism. Because the exact dose of irradiation that each victim received was impossible to determine accurately, they probably did not experience a lethal dose of irradiation, and survived owing to short-term hematopoietic support from the infused allogeneic cells and long-term autologous reconstitution of the hematopoietic system [57,58]. These early transplantations established the safety of bone marrow cell infusion, which led to wider use of allogeneic bone marrow transplants in the late 1950s and early 1960s. Unfortunately, no long-term

survivors were noted [59]. Many reasons contributed to this outcome, including the lack of human leukocyte antigen (HLA) matching, insufficient immunosuppression, and the lack of effective supportive care [60–62].

These early transplantation failures reduced enthusiasm for further attempts at clinical transplantation. However, animal studies continued with significant advances in immunosuppression and histocompatibility determination. These addressed issues with graft rejection involving the host immune system attacking infused donor cells, resulting in graft failure and donor-reactive T cells attacking the host tissues and organs such as skin, liver, and intestine and resulting in graft versus host disease (GVHD) [63–66]. Approximately 50% of patients with allogeneic transplantation experience GVHD even though they received major histocompatibility complex–matched donor cells and immunosuppressive drug treatment [67,68]. Other factors determining the development and severity of GVHD are recipient age, the conditioning regimen, and the source of hematopoietic stem cells [69].

Because of the significant morbidity and mortality associated with GVHD and the recognition of the role of donor T cells in GVHD, many clinical investigators examined T-cell depletion to reduce GVHD. Procedures to enrich for hematopoietic stem cells also resulted in donor T-cell depletion and, more important, reduced the number of tumor cells in the graft. However, it was found that patients who received T-depleted or hematopoietic stem cell–enriched grafts experienced an increase in graft failure, tumor relapse, and infection [70,71]. During this time, preclinical and clinical data showed that allogeneic transplantation provided an additional benefit, a graft versus tumor (GVT) effect. In a mouse model, Barnes et al. were the first to demonstrated the GVT effect. T cells within the donor graft were able to recognize and kill the host's tumor cells [72,73]. This effect occurred only in allogeneic, not syngeneic transplantations. Patients who developed GVHD experienced less tumor relapse; therefore, there was a link between GVHD and GVT effects [74–76].

Significant efforts have been reported to enhance GVT effects and suppress GVHD. One approach is to target minor histocompatibility antigens [77,78]. Another approach is to use regulator T cells to modify GVHD and maintain GVT effects [79] as well to use natural killer (NK) cells to augment GVT effects while circumventing GVHD [80,81]. In addition, the infusion of donor leukocytes after allogeneic transplantation was shown to induce remission in patients with chronic myelogenous leukemia [82]. The reduction in relapse in some patients with chronic myeloid leukemia was associated with GVHD; however, other patients achieved remission without GVHD.

Autologous Peripheral Blood Stem Cell Transplantation

During the 1980s and 1990s, clinical transplantation rapidly increased. In earlier times, bone marrow harvested from the posterior iliac crest or the sternum was the primary source of hematopoietic stem cells used in transplantation. However, other sources of hematopoietic stem cells were identified, including peripheral blood and umbilical cord blood.

In 1979, patients with chronic granulocytic leukemia (CGL) were successfully transplanted with autologous peripheral blood stem cells (PBSCs) collected in the chronic phase of the disease [83]. When the patients advanced to the acute phase of CGL, they underwent high-dose therapy and were transplanted with the cryopreserved PBSCs. The patients engrafted and returned to the chronic phase of the disease. This report demonstrated that CGL PBSCs could restore hematopoietic function in the patients with CGL. There were two reports in 1979 and 1980 in which syngeneic PBSC transplants failed [84,85], which reinforced concerns regarding the quality of circulating stem cells and their ability to reestablish bone marrow hematopoiesis [86]. The reason for failure of the PBSC transplants was not clear, but it may have been associated with the method of infusing the cells, which occurred over 1–2 weeks. In 1986, multiple centers reported successful transplantations using nonmobilized (steady-state) PBSC [87–90]. The number of hematopoietic stem cells was significantly lower in the peripheral circulation than in the bone marrow (0.06% and 1.1% $CD34^+$, respectively). Therefore, mobilization procedures were developed to increase the number of circulating hematopoietic stem and progenitor cells. One method was to collect peripheral blood after hematopoietic recovery, after nonmyeloablative chemotherapy. The myelosuppressive effects of chemotherapy induced a hematopoietic rebound, resulting in an increase in circulating hematopoietic stem and progenitor cells in the peripheral blood [91]. The timing of the hematopoietic rebound in the peripheral circulation was difficult to determine; therefore, this technique was not used extensively. After the development of recombinant cytokines, colony-stimulating factors were approved for clinical use. Granulocyte colony-stimulating factor (G-CSF) has become the preferred method of mobilization. PBSCs have since replaced the use of bone marrow stem cells in many transplant centers; approximately 75% of unrelated allogeneic hematopoietic stem cells transplantations and almost 100% autologous transplantations have been performed [92].

Allogeneic Peripheral Blood Stem Cell Transplantation

Initially, there was a reluctance to use allogeneic PBSC for transplantation because of the potential for an increase in GVHD. PBSC collections contain an approximately 10-fold greater number of T cells than a bone marrow harvest. The first reported use of allogeneic peripheral stem cells transplantation was in 1989 [93]. A patient with acute lymphocytic leukemia received a steady-state (nonmobilized) PBSC transplantation from an HLA-matched sibling. The donor preferred peripheral blood collection rather than undergoing a bone marrow harvest. The collections were T-cell depleted; however, the last collection was used unmanipulated to contain the estimated number of T cells in a bone marrow harvest. On day 27 posttransplant, a biopsy showed trilineage engraftment; however, long-term engraftment was not determined because the patient died on day 32 after transplantation. By the mid-1990s, several transplant centers reported successful allogeneic PBSC transplantations [94–96].

The reasons for the switch from bone marrow to PBSC transplantations were numerous. Bone marrow harvest requires general anesthesia with its associated risks and postharvest pain, and patients have reported fatigue [97]. PBSCs are mobilized using a 4- to 5-day course of cytokines (primarily G-CSF) and then isolated using apheresis in 1- to 3-day collection sessions, usually in an outpatient setting. The only requirement is venous access. Therefore, the ease of collection and lower incidences of adverse events may have been the driving force for the switch to PBSCs [98]. In addition, the number of hematopoietic stem cells in cytokine-mobilized PBSC collections was higher than in bone marrow harvests. This higher number of stem cells may be responsible for the more rapid hematopoietic engraftment and immune reconstitution associated with PBSC transplants compared with bone marrow transplantations [99,100]. PBSC transplantations are also associated with a decreased rate of relapse, which may be related to the higher number of T cells present in the PBSC collections and the subsequent increase in GVT effects compared with bone marrow harvests. However, there are some risks associated with PBSC transplantations. A small number of PBSC donors undergoing cytokine mobilization experience bone pain. Of more concern is spleen rupture [101]. With the increase in the number of T cells in the PBSC, an increase in the incidence of chronic GVHD has been noted with no increase in acute GVHD [102,103]. However, the higher chronic GVHD seen in PBSC transplant recipients compared with bone marrow recipients did not lead to an increase in mortality for the PBSC graft recipients [103]. Overall, the risk for disease relapse is lower in PBSC transplantation patients; however, the progression-free survival appears to be similar between PBSC and bone marrow transplant recipients [99,104,105].

Cord Blood Transplantation

The first report of the potential of cord blood as a source for hematopoietic transplantation occurred in 1972 [106]. However, it was the critical work by Broxmeyer that advanced cord blood from the bench to the bedside [107,108]. The first cord blood transplant was performed in 1988 for a 5-year-old patient with Fanconi anemia [109]. The donor cord blood cells were collected from a sibling and cryopreserved. After transplantation, the patient engrafted by day 22 and expressed donor chimerism. This success led to an expansion of the use of cord blood for allogeneic transplantation. Cord blood has also been used for unrelated transplantation in pediatric and adult patients who did not have a related donor [110,111].

Cord blood is a readily available source of allogenic hematopoietic stem cells that can be collected at the time of birth. Both public and private cord blood donor sites are available [112,113].

Challenges in using cord blood for transplantation include delayed engraftment, which may increase the risk for infection [114], and small volumes of cord blood collections, which limit the number of hematopoietic stem cells for engraftment of adults or large pediatric patients [115]. To overcome these challenges, two cord blood collections have been used. Double cord blood transplantations increase the cost and have been associated with an increased incidence of GVHD [116]. Another method for increasing stem cell numbers in cord blood collections is to use ex vivo expansion [117]. No significant improvement was seen in survival or transplantation outcomes with expansion; however, neutrophil engraftment was augmented.

Cord blood transplantation is a valid treatment for both pediatric and adult patients who do not have a matched sibling or unrelated donor. In the future, cord blood needs to be compared with other allogeneic donor sources to define more clearly the advantages of cord blood transplantations.

Hematopoietic Stem Cell Transplantation for Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) describes an immunological syndrome that arises from numerous genetic defects leading to the absence of humoral and cellular immunity in infants [118]. If left untreated, SCID

results in a fatal outcome from multiple and severe infections within the first few years of life. The incidence of SCID in the United States is approximately 1 in 58,000 infants [119].

The most prevalent type of SCID (approximately 45%–50%) is X-linked (X-SCID), in which there is a defect in the common gamma chain of the receptors for interleukin-2, -4, -7, -9, -15, and -21 that affects the development of T and NK cells [120]. It has an X-linked inheritance that results in phenotype expression predominantly in males. The second most prevalent SCID is genetic defects in the recombinase-activating genes [119]. These genes are responsible for the formation of T- and B-cell antigen receptors, which lead to nonfunctional T and B cells. NK cells are not affected. The next most prevalent SCID is the defect in adenosine deaminase (ADA)-SCID. ADA is an enzyme involved in purine metabolism [120]. ADA-SCID results in the accumulation of deoxyadenosine and deoxyadenosine triphosphate, which is toxic to lymphocytes [121]. As a frontline treatment, patients with ADA-SCID receive enzyme replacement therapy (ERT) using polyethylene glycol-conjugated adenosine deaminase (PEG-ADA). There are significant side effects including lymphoproliferative disorders, anemia, and pulmonary insufficiency [121] as well as a decreased thymus T-cell output, reduced T-cell function, and B-cell deficiencies over time [122–124].

Allogeneic hematopoietic stem cell transplantation is the best option for treatment for SCID. Bone marrow mobilized PBSCs from related, unrelated, or cord blood grafts are options for transplantation in patients with SCID. The first transplantation for SCID occurred in 1968 [125]. In 1968–2005 in Europe, patients who received a related genoidentical donor had a long-term survival of 90%, which was higher than for patients who had a related phenoidentical, mismatched related, or unrelated donor [126]. Patients who received a transplantation between 1995 and 2005 did better potentially as a result of improvement in transplantation care. Patients transplanted before age 6 months did better than did patients transplanted at age 1 year or older. In addition, outcomes were improved when patients did not have respiratory damage or viral infection before transplantation.

The Primary Immune Deficiency Treatment Consortium of 41 North American centers reported on 240 patients with SCID who received transplantations from 2000 to 2009 [127]. Grafts were either unmodified or T-cell depleted. Most patients transplanted with grafts from matched sibling donors or mismatched related donors did not receive conditioning; however, patients receiving grafts from unrelated donors or cord blood grafts received myeloablative conditioning, reduced intensity conditioning, or immunosuppression. The overall survival rate at 5 years was 74%. Patients receiving a matched sibling donor had a survival rate of 97%, whereas patients receiving an unrelated cord blood graft had the lowest survival rate of 58%. Similar to the finding from the European group, patients who were younger ($\leq$3.5 months) fared better. Patients older than 3.5 months at the time of transplant and with active infections did poorly.

Although allogeneic transplantation is the treatment of choice, the overall success depends on finding an appropriate donor. Gene therapy offers an alternative treatment in which autologous hematopoietic stem cells are used in association with gene therapy to correct the genetic defect. Gene therapy has been used for X-SCID and ADA-SCID. ADA-SCID was the first to be molecularly identified, and patients with ADA-SCID were the first to be treated with gene therapy in the early 1990s. No significant clinical improvement was seen; however, the trial demonstrated that gene therapy could be delivered safely. The patients with ADA-SCID continued to be treated with PEG-ADA, which may have accounted for the inability to determine the efficacy of the gene therapy. Subsequently, other trials using improved viral vectors and conditioning regimens were conducted to treat patients with ADA-SCID [128–131]. Approximately 40 patients with ADA-SCID have been treated, with significant improvement in immunity without ERT or allogeneic transplantation. These studies confirmed the safety of gene therapy for patients with ADA-SCID and demonstrate their significant clinical improvement.

Twenty patients with X-SCID were treated with autologous hematopoietic stem cells that were modified using gene therapy [132,133]. Significant clinical improvements were seen with T-cell reconstitution and improved B-cell function. However, 5 of the 20 patients developed leukemia [134,135]. The viral insertion site was the cause of the leukemia owing to insertional oncogenesis. This result led to the development of new retroviral and lentiviral vectors that appear to have no genotoxicity [136].

Hematopoietic Stem Cell Transplantation for Tolerance Induction

Immune tolerance is a state in which the immune system accepts donor tissues or organs but retains the ability to respond to foreign antigens such as bacteria or viruses. The induction of donor-specific tolerance is the ultimate goal for solid organ and composite tissue transplantation. This type of tolerance would eliminate the need of life-long immunosuppression with all of the associated side effects and prevent chronic rejection. Mixed chimerism is a state in which the hematopoietic and immune systems of an allogeneic hematopoietic stem cell transplant recipient

contain both donor and recipient cells. Mixed hematopoietic chimerism was first demonstrated to be associated with tolerance in fraternal twin cattle in 1945 [137]. Animal studies, including rodent, pig, dog and nonhuman primate, demonstrated hematopoietic mixed chimerism and tolerance induction for tissue and organ transplantation [138–142]. Because of these preclinical studies, several clinical trials for tolerance induction for kidney transplantation were performed [143–145]. Data from the three centers showed that donor hematopoietic stem cell infusion is feasible to induce tolerance for kidney organ graft. Durable to transient chimerism was established in some of the recipients with withdrawal of immunosuppressants. These results are promising; however, they represent only short-term success. Additional improvements in preconditioning to reduce toxicity and methods to maintain chimerism are needed. In addition, hematopoietic stem cell infusion to induce tolerance needs to be expanded beyond kidney transplants to other tissues and organs.

Hematopoietic Stem Cell Transplantation for Autoimmune Diseases

Autoimmune diseases are clinical conditions that result from the loss of self-tolerance. This includes the failure of both peripheral and central tolerance, which results in the generation of autoreactive T and B cells that damage tissues and organs. Approximately 5% of the population is affected by autoimmune diseases. Autoimmune symptoms can be managed but not cured by conventional treatment, which include antiinflammatory and immunosuppressive drugs. There is a group of autoimmune patients who express severe disease and are resistant to standard treatment. Morbidity and mortality are high for these patients; therefore, an alternative therapy is needed to improve their quality of life. Autologous hematopoietic stem cell transplantation has been evaluated for severe forms of autoimmune diseases. The most promising results have been seen for multiple sclerosis and systemic sclerosis [146]. There has been limited success for Crohn disease and type 1 diabetes [146]. However, significant adverse events, including relapse and mortality, were noted for autologous hematopoietic stem cell transplantations for systemic lupus erythematosus, rheumatoid arthritis, and juvenile idiopathic arthritis [147–149].

The rationale for autologous hematopoietic stem cell transplantation for autoimmune diseases is that it eliminates autoreactive immune cells by conditioning regimens and resets the immune system with the transplantation of hematopoietic stem cells.

Although autologous hematopoietic stem cell transplantation has been shown to reestablish self-tolerance, there are relapses that may be associated with the original genetic risk for autoimmune disease. Allogeneic hematopoietic stem cell transplantations establish a donor immune system in the recipient, potentially offering a more definitive cure. However, the risk for GVHD and the use of ablative conditioning treatments with their associated morbidity and mortality limit the widespread use of allogeneic stem cell transplants [150]. The current data suggest that the earlier that hematopoietic stem cell transplantation is performed, the more benefit is seen for the patient with autoimmune disease. A better understanding is needed of the mechanisms involved with hematopoietic stem cell transplantation in autoimmune diseases.

CONCLUSION

The hematopoietic stem cell is the most highly studied and probably best understood of all stem cell populations. Since the initial identification of the hematopoietic stem cell, its physical and functional properties have been extensively studied in multiple animal models. All of this knowledge has been translated into the clinic for use in treating bone marrow failure, malignancies, immune tolerance, and autoimmune diseases. Hematopoietic stem cells can be isolated from multiple sources including bone marrow, peripheral blood, and cord blood. This makes stem cells easily available in sufficient numbers for clinical use. These properties make hematopoietic stem cells a valuable therapy that can have widespread use in regenerative medicine.

List of Acronyms and Abbreviations

ADA Adenosine deaminase
ADA-SCID Adenosine deaminase-severe combined immunodeficiency
AGM Aorta-gonad-mesonephros
CFU-s Colony forming cell-spleen
CGL Chronic granulocytic leukemia
CML Chronic myeloid leukemia
DNA Deoxyribonucleic acid

GVHD Graft versus host disease
GVT Graft versus tumor
HLA Human leukocyte antigen
JIA Juvenile idiopathic arthritis
Lin− Lineage negative
LSK $lin^{-}/Sca\text{-}1^{+}/c\text{-}Kit^{+}$
MDR Multi drug resistance
NK Natural killer
PBSCs Peripheral blood stem cells
PEG-ADA Poly ethylene glycol conjugated adenosine deaminase
RA Rheumatoid arthritis
RAG Recombinase-activating genes
$Rho123^{lo}$ Rhodamine 123 low
SCID Severe combined immunodeficiency
SLAM Signaling lymphocyte activation molecule
SLE Systemic lupus erythematosus
SP Side population
X-SCID X linked severe combined immunodeficiency

INTRODUCTORY OVERVIEW

In the development of stem cell–based therapeutic platforms for tissue regeneration, the selection of which type of stem cell to use will be enormously important. Adult mesenchymal stem cells (MSCs) are considered one of the most promising tools for cell and cell-based gene therapy in bone repair [1]. The best-known source of MSCs in adult humans is the bone marrow (BM) compartment. Other sources of MSCs have been identified, including adipose tissue, dermal tissue, intervertebral disc, various dental tissues, human placenta, cord blood, and peripheral blood, although the latter finding is still debated [2].

In cell-based therapies, the culture expansion stage is extremely costly and time consuming; in addition, in many cases cells may lose their multipotentiality in vivo and fail to meet the desired goal. It was reported that cultured human MSCs (hMSCs) can undergo spontaneous transformation as a consequence of in vitro expansion [3]. Moreover, culture expansion attenuated the homing ability of MSCs after systemic infusion in irradiated mice [4], which implies that MSCs may lose some of their natural stem cell characteristics after expansion in vitro. Other investigators proposed that all known characteristics of MSCs may be an outcome of the culture stage and do not truly represent the actual characteristics of MSCs residing in vivo at the BM niche [5].

The isolation of an hMSC-enriched population requires an efficient and reproducible method. We reported that we used the CD105-based immunoisolation method to obtain a fresh noncultured population of hMSCs, and we showed these cells' osteogenic potential both in vitro and in vivo [6]. In additional studies, a positive selection method was implemented as well: immunoisolation of MSCs with antibodies directed against the Stro-1 [7,8] and CD146 [9] markers.

One striking feature of MSC therapy is cumulative data on the tolerance shown by the host to allogeneic MSCs. The mechanisms by which this immunotolerance exist are complex and have not yet been thoroughly identified. It has been shown that there is a low expression of alloantigens by MSCs; this may involve pathways (dependent on or independent of cell contact) that are modulated by the secretion of soluble factors such as interleukin (IL)-2, IL-10, transforming growth factor-β1 (TGFβ1), prostaglandin E_2 (PGE2), hepatocyte growth factor (HGF), and others. Immune system cells such as dendritic cells (DCs) and T cells, have also been shown to be affected by the presence of MSCs in mixed lymphocyte cultures [10]. The inhibitory role of MSCs and the value of MSC cotransplantation in allogeneic hematopoietic stem cell (HSC) transplantation were thoroughly examined by Troeger et al. [11].

Several protocols have been established to enable the regeneration of large bone defects using hMSCs that have been expanded in culture. These cells differentiate into osteogenic cells; as vehicles, they deliver a therapeutic gene product such as one of the bone morphogenetic proteins (BMPs). This approach requires the genetic modification of MSCs to overexpress a transgene encoding for an osteogenic gene. BMP-2 has been widely used for this purpose [12–14], as have other members of the BMP family such as BMP-4, BMP-6, and BMP-9 [15–20]. In addition, MSCs have been implemented in regeneration of the heart (cardiac muscle and vascular system), skeletal muscle, nerve, liver, and pancreas; regeneration of cardiac tissue is foremost [21–29].

Resembling the MSCs, exosomes secreted from those cells support tissue homeostasis and correct cell functioning and regeneration, perhaps providing validation for the therapeutic ability of MSCs in a broad variety of diseases. A

Principles of Regenerative Medicine, Third Edition

growing amount of MSC research has been dedicated to deciphering the MSC secretome, if the soluble factors or the factors released in extracellular vesicles (EVs), such as exosomes and microvesicles (MVs) are the active factors [30].

Although the embryonic origin of MSCs remains unclear, multiple methods have been developed to differentiate MSCs derived from induced pluripotent stem cells (iMSCs). These include treatment with specific factors [31] using cell isolation based on specific surface markers [32] or biomaterials-directed differentiation [33,34]. iMSCs were shown to be functional and expandable; however, to advance the application of these cells in clinic, major studies have to be performed to make the differentiation process more efficient and address safety concerns. Although there are several indications that iMSCs are actually less tumorigenic than the reference standard, BM-derived mesenchymal stem cells (BM-MSCs) [31,35], iMSCs must be further explored.

DEFINITION OF MESENCHYMAL STEM CELLS

BM was the first tissue identified to be a source of plastic-adherent fibroblast-like cells that develop colony-forming unit—fibroblasts (CFU-Fs) when seeded into tissue culture plates [36]. These cells, which were originally designated stromal cells, elicited much attention and were the focus of thousands of studies aimed at finding a pure cell population that could eventually be used for regenerative purposes. In these studies, cells were isolated using a variety of methods (discussed later in this chapter) and given names such as MSCs, mesenchymal progenitors, and stromal stem cells. A committee of the International Society for Cytotherapy suggested the name "multipotent mesenchymal stromal cells" [37]; however, most scientists simply refer to these cells as "MSCs."

The precise characterization of MSCs remains a matter of debate. Nevertheless, MSCs are widely defined as a plastic-adherent cell population that can be directed to differentiate in vitro into cells of osteogenic, chondrogenic, adipogenic, myogenic, and other lineages [5,38,39]. As part of their stem cell nature, MSCs proliferate and develop into daughter cells with the same phenotype and pattern of gene expression, thereby maintaining the "stemness" of the original cells. Self-renewal and differentiation potential are two criteria that define MSCs as real stem cells; however, these characteristics have mainly been demonstrated, both in bulk and at the single-cell level, after in vitro manipulation, and there is no clear description of the characteristics displayed by nonmanipulated MSCs in vivo [40]. So far, only one study has claimed to demonstrate the in vivo self-renewal property of MSCs identified by melanoma cell adhesion molecule (MCAM)/CD146 surface markers [41].

In contrast to other stem cells such as HSCs, which are identified by the expression of the CD34 surface marker, MSCs appear to lack one unique marker. The CD105 surface antigen (endoglin) has been used to isolate hMSCs from BM, enabling the characterization of freshly isolated hMSCs before culture. Distinct expression profiles of certain surface antigens, such as CD45 and CD31, have also been demonstrated in freshly isolated hMSCs, whereas expression of these molecules is lower in culture-expanded hMSCs [6]. From these data, one can infer alterations that hMSCs may undergo during the culture process [42]. Findings of other studies, however, indicated that CD146 or STRO1 could serve as unique markers for MSCs [7,8].

In several studies, cultured MSCs have been characterized either by using cell surface antigens or by examining the cells' differentiation potential. In 2006, the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy proposed minimal criteria by which one can define human multipotent mesenchymal stromal cells (also known by the abbreviation "MSCs"): (1) these multipotent mesenchymal stromal cells must be plastic-adherent when maintained in standard culture conditions and form CFU-Fs; (2) these cells must express CD105, CD73, and CD90, and lack expression of CD45, CD34, CD14, CD11b, CD79α, or CD19, and human leukocyte antigen—antigen D-related surface molecules; and (3) these cells must differentiate into osteoblasts, adipocytes, and chondroblasts in vitro [37]. The term "multipotent mesenchymal stromal cells" refers to cultured cells, whereas the term "mesenchymal stem cells" is designated for stem cells yet to be identified in vivo.

THE STEM CELL NATURE OF MESENCHYMAL STEM CELLS

Stem cells are defined by their ability to self-renew and by their potential to undergo differentiation into functional cells under certain conditions. There is minimal evidence showing that such features exist in uncultured MSCs. The consensus is that cultured MSCs can self-renew and differentiate into osteoblasts, adipocytes, and chondroblasts in vitro. Whether these cells can also differentiate into tenogenic, myogenic, and numerous other cells types, as has been claimed in many studies, remains controversial. The debate on this subject originated from

evidence obtained during research into embryonic development. It is known that there is no common progenitor for bone and muscle tissues after sclerotome-myotome specification in somites [43], and hence it is unlikely that such a cell exists in the adult. Supporters of this view claim that MSCs reside in BM and can only develop into bone, cartilage, and adipose cells.

Other researchers claim that MSCs can be isolated from BM as well as other adult tissues and can be differentiated into epithelial, endothelial, hepatic, and neural cells [44–47]. However, studies have shown that MSCs isolated by plastic adherence from various tissues differ considerably in morphology, proliferative capacity, differentiation capability, and the ability to form bone in vivo [48]. Therefore, MSCs from different tissue sources may not be the same cell or they may contain a heterogeneous population of progenitors that can explain the variability in their characteristics. Efforts to find a "pure" or primitive multipotential stem cell across tissues has not been well-supported [49].

Findings of some studies suggest that the multipotentiality of MSCs can be demonstrated by direct injection into extraskeletal tissues such as the brain. It was claimed that an injection of hMSCs into the brain tissue of rats resulted in the cells' long-term engraftment and subsequent migration along pathways similar to those used by neural stem cells [50]. Other studies, however, showed that injected MSCs were rejected or fused to existing differentiated cells within the tissue [51,52]. The results of these studies further strengthened the illusiveness of finding a multipotential stem cell that may reside in all or most tissues. Nevertheless, this does not hinder the therapeutic potential of MSCs from BM or other tissues. It may well be that MSCs, as they are currently used, are a heterogeneous population of cells including both multipotent and progenitor cells with unique capabilities of tissue regeneration and immune response modulation. These capabilities could be exerted via paracrine effects [53], autocrine involvement in tissue repair [54], or both.

WHICH TISSUES CONTAIN MESENCHYMAL STEM CELLS?

The embryonic origin of MSCs is unclear; however, some findings indicate a possible origin of MSCs in a supporting layer of the dorsal aorta in the aorta-gonad–mesonephros region [55]. Consistent with these findings, MSCs or MSC-like cells were found circulating within human fetal blood [56].

MSCs that comprise the stroma-supportive system of BM along with endothelial cells and adipocytes are the most well-studied [57]. An MSC population has also been identified in the BM of the craniofacial complex [58]. In adults, MSCs appear to be "resident" stem cells in many tissues, and they function in the normal turnover of these tissues. Numerous studies have demonstrated the presence of MSCs or MSC-like cells within other tissues such as adipose tissue (adipose tissue–derived stem cells [ASCs]) [59], dermal tissue [60], the intervertebral disc [61], amniotic fluid [62], various dental tissues [63], human placenta [64], cord blood [65], the temporomandibular disc [66], and peripheral blood [67].

ASCs are similar to BM-derived MSCs both morphologically and immunophenotypically; however, ASCs form more CFU-Fs when plated in culture [68]. Adipose tissue is an attractive source of MSCs for regenerative medical purposes; it is relatively easy to obtain, can be collected with the use of local anesthesia, and is associated with minimal discomfort and risks [69].

There has been considerable interest in investigating the hypothesis that MSCs are in fact pericytes that abut the basement membrane and engulf endothelial cells in the microvasculature. Several studies have supported this hypothesis [70], yet there is no agreement among scientists as to whether all BM pericytes are MSCs or whether pericytes found in other tissues are also MSCs. Caplan speculated that all MSCs are pericytes [71], and indeed da Silva Meirelles et al. showed that pericytes from adipose tissue are similar to adipose-derived MSCs in gene expression profiles [72]. However, Blocki et al. showed that only a subset of BM pericytes can be considered MSCs [73]. Sacchetti et al. were the first to determine that $CD146^{+}$ perivascular cells in BM are MSCs [41]. They compared MCAM/CD146-expressing cells from different human tissues and analyzed their differentiation potentials and transcriptomes [74]. The results indicated that although the various cells were associated with microvessels, i.e., pericytes, they differed significantly in their skeletogenic differentiation pattern and their transcriptomic profile. Moreover, Guimarães-Camboa et al. analyzed pericytes from multiple tissues in a mouse model and found that these cells (identified by T-Box 18 expression) did not behave like stem cells in vivo and did not differentiate to other cell types. However, these cells did behave like MSCs in vitro [75].

Based on current knowledge, it is safe to state that MSCs are associated with the microvasculature and that different tissues contain MSC-like cells that have some characteristics in common and others that differ.

MESENCHYMAL STEM CELL ISOLATION TECHNIQUES

Application of MSCs requires isolation of these cells and directing cell differentiation into the appropriate lineage. Since the 1980s [36], Ficoll−Paque density-gradient media have been used to separate mononuclear cells (MNCs) from red blood cells in BM. The MNCs are then collected and seeded in medium containing 10% fetal bovine serum (FBS) at a density of $10-15 \times 10^5$ cells/cm^2 growth area [38]. Adherent spindle-shaped cells appear within 48 h after the initial seeding, and the estimated percentage of MNCs ranges from 0.001% to 0.01%.

Since then, many approaches have been proposed to isolate MSCs. Ficoll Paque−based isolation may be used to isolate MSCs from BM as well as from peripheral blood; this approach has been used in most clinical trials performed to date [76]. Enzymatic treatment of adipose tissue with collagenase is performed to produce ASCs shown to have the high potential for in vitro expansion and in vivo differentiation [59,77,78]. A method based on the biophysical properties of MSCs in suspension under fluidic conditions has been proposed as well [79].

Major disadvantages of these methods are the impurity of the resulting cell population and the need to culture cells before application. The solution to these downsides will include isolation of cells based on the intrinsic properties of MSCs, avoiding culturing, and the generation of immortalized cell lines. Immunoisolation is a method to isolate noncultured MSCs based on cell surface markers. Several studies have employed the "positive selection" technique of immunoisolating MSCs by using antibodies directed against endoglin (CD105) [6], Stro-1 [7,8], CD146 [9], and other MSC markers. Immunodepletion, the "negative selection" of unneeded cell populations, including residual hematopoietic cells, may be used to enrich the MSC population further, especially in combination of the based on different surface markers [80]. Busser et al. compared the use of different cell markers to immunoisolate MSCs from BM and adipose tissue; they found that different antibodies yielded MSC populations that differed in immunophenotype and in differentiation and immunoregulatory capabilities [81].

A major challenge is the development of the large-scale production of good clinical practice−quality MSCs. Clinical-grade cells have to be safe for use; hence, there is a need for microbe-free closed-circuit systems [82]. An additional concern would be the use of xenogenic reagents such as FBS. Several human reagents have been used, including fibroblast growth factor [83] and platelet lysate, which has been shown to produce MSCs with various immunocapabilities [84]. Fekete et al. proposed five large-scale, two-step MSC isolation protocols, which yield as much as 6×10^9 MSCs per BM aspirate [85].

MESENCHYMAL STEM CELL EXOSOMES

In several cases, a positive regenerative and healing effect was evident after systemic or local treatment with MSCs. Verifying the actual presence of these cells at the site of injury, however, is sometimes difficult or insurmountable. In fact, a correlation between administration of cells and observed improvement cannot always be recognized. Based on this difficulty of obtaining proof of the cells' presence, it has been speculated that it is not MSCs that differentiate into tissue-specific mature cells, but instead secreted factors, more precisely exosomes. Resembling their cell source, the MSC, these secreted exosomes support tissue homeostasis and correct the courses of cell function and regeneration, as required. These activities may validate the therapeutic ability of MSCs in a broad variety of diseases. Increasing numbers of MSC research studies have focused on deciphering the MSC secretome, the soluble factors, or the factors released in EVs, such as exosomes and MVs.

EVs consist of subgroups (all secreted membrane-enclosed vesicles) that include exosomes, ectosomes, MVs, microparticles, apoptotic bodies, and other EV subsets. In a position statement, the International Society for Extracellular Vesicles [86] declared that there are no specific markers of EVs with which we can establish basic standards for identification; the organization speculated that this is because EV secretion probably varies greatly depending on the environment. Thus far, there is no solid evidence to affirm that different classes of EVs represent distinct biological entities. Morphology and size guide us to discriminate among various exosomes; specifically, nanospheres are composed of a lipid bilayer similar to a liposome (40−100 nm), MVs or ectosomes are derived from the shedding of the plasma membrane (100−1000 nm), and apoptotic bodies (1−5 μm) are released from the cell membrane as blebs during apoptosis.

Similar to exosomes in general, MSC exosomes transport a composite load that contains nucleic acids, proteins, and lipids. Unique gene products number 857 and more than 150 microRNAs (miRNAs) have been identified, although whether this diverse content is carried by one exclusive type of exosome or is split within different types of exosomes has yet to be determined [87].

The exosomal proteins, RNAs, and lipids mentioned in several published and unpublished studies have been cataloged in ExoCarta, a database that aims to identify specific molecular signatures of tissue/cell type−derived exosomes [88]. ExoCarta contains a list of 100 gene-encoding proteins most often identified in exosomes. The top five protein-encoding genes (index >90) include the following:

1. CD9, which encodes a protein (a member of the tetraspanins) that functions in many cellular processes including differentiation, adhesion, and signal transduction. Expression of the gene has a critical role in suppressing cancer cell motility and metastasis [RefSeq, Jan 2011].
2. HSPA8, which encodes a constitutively expressed member of the heat shock protein 70 family. This protein functions as a chaperone and binds to nascent polypeptides to facilitate correct folding. It also functions as an adenosine triphosphatase in the disassembly of clathrin-coated vesicles during transport of membrane components through the cell [RefSeq, Aug 2011].
3. PDCD6IP (or ALIX), which encodes a protein that functions within cytosolic protein complexes and endosomal sorting complexes required for transport in the abscission stage of cytokinesis, in endosomal vesicle formation, and also in enveloped virus budding. PDCD6IP is also involved in the membrane-shaping phase of endocytosis, binding to endophilins [RefSeq, Jan 2012].
4. Glyceraldehyde 3-phosphate dehydrogenase (GAPDH) encodes a protein of the GADPH family, which has been acknowledged to be a moonlighting protein based on its ability to perform multiple functions. The GAPDH product catalyzes a critical step in carbohydrate metabolism: the reversible oxidative phosphorylation of glyceraldehyde-3-phosphate in the presence of inorganic phosphate and nicotinamide adenine dinucleotide. In addition, in the cell nucleus, the encoded protein has been identified to have uracil DNA glycosylase activity [RefSeq, Nov 2014].
5. Actin β is a major constituent of the contractile apparatus and one of the two nonmuscle cytoskeletal actins. This gene encodes one of six different highly conserved actin proteins involved in cell motility, structure, and integrity [RefSeq, Jul 2008].

Having a number of common protein markers for exosome identification is a step forward in the future implementation of exosomes for therapeutic applications, even though the isolation method is not yet well-confirmed. Established procedures for separating exosomes include ultracentrifugation, density gradient separation, chromatography, immune-affinity capture (IAC), and polymer-based precipitation. With the use of all of these techniques, it is possible to isolate vesicles according to their diameters and markers. IAC appears to be the most effective process based on the number of exosome-related proteins identified on the purified fraction. Nevertheless, there may be situations in which there are no suitable antibodies to determine exosomal markers; in such cases, the use of density-based separation will be advantageous for exosome isolation [89].

The notion that growth factors, chemokines, and cytokines would be the molecules responsible for the systemic and local effects of MSCs, such as immunomodulation, was discarded after several published reports showed that the absence of those molecules did not affect the immunomodulatory activity of MSCs. EVs have been reported since 2010 to be effective therapeutic mediators in MSCs, when Lai et al. revealed that MSCs secrete a specific class of EVs known as exosomes, with diameters ranging from 40 to 100 nm and bearing exosome-associated proteins such as ALG-2-interacting protein X, tumor susceptibility gene 101, and the tetraspanin proteins. After succeeding in deriving and characterizing fetal hMSCs, this group also showed that these cells' secretion was cardioprotective in a mouse model of myocardial ischemia/reperfusion injury. Analysis of the secretion by high-performance liquid chromatography revealed the presence of microparticles with radii ranging from approximately 50 to 65 nm. This population of microparticles was cardioprotective at about one-tenth the dosage of crude secretion [90].

The exosomes contain, carry, and dispense a range of small molecules released from stem cells to nearby cells, thus enabling the uptake of enzymes and nucleic acids through the endocytosis of circulating exosomes, especially by cells in injured tissue, which often has a lower pH than normal tissue; this is a favorable condition for exosome uptake. MSC exosomes not only interact with nearby cells; via blood and other biological fluids, these exosomes can migrate to distant targets. The recipient cell response may differ according to what molecules enclosed in the exosomes reached the objective [91].

Evidence continues to grow showing that MSC-derived EVs produce beneficial effects in several disease models, such as heart conditions and kidney, brain, and skeletal injuries, and in areas of intervention, including aspects of regenerative medicine.

Exosomes released from MSCs and enriched with miRNAs have a definitive role in the heart and blood vessels, exerting antiapoptosis and antiinflammatory effects, cardiac regeneration, and neovascularization, which are considered components of whole molecular mechanisms lying behind the therapeutic potential of MSC

transplantation, according to a thorough review by Huang et al. [92]. Results of preclinical studies suggested that exosomes can be used to treat cardiovascular diseases (CVDs) such as acute myocardial infarction (AMI) and stroke when derived from human, mouse, or rat MSCs. Different experimental models have been used, and cardiac progenitor cell (CPC)-derived exosomes, embryonic stem cell (ESC)-derived exosomes, and $CD34^+$ stem cell—derived exosomes significantly reduced infarct size, restored cardiac function, and stimulated angiogenesis in ischemic zones. CPCs significantly suppressed apoptosis, stimulated angiogenesis, and improved cardiac function in a rat model of AMI. In vitro experiments demonstrated that MSC-derived exosomes augmented the survival and proliferation of CPCs obtained from the infarcted area. Altogether, these studies provide compelling evidence that exosomes derived from a variety of stem cells exert beneficial effects on animal models of CVD [93].

Growth factors known for their proangiogenic activity, such as vascular endothelial growth factor (VEGF), TGFβ1, and IL-8, were identified in exosomes derived from MSCs by proteomic analysis. In addition, it was reported that MSC-derived EVs are also rich in HGF, a transcription factor that stimulates the proliferation and migration of endothelial and vascular smooth muscle cells involved in proangiogenic pathways. Human T-cell factor 4 (TCF4) is a key downstream effector of Wnt signaling, a canonical pathway that has a central role in vascular development and in determining and maintaining the phenotype and functional properties of human stem cells. Therefore, intercellular transmission of EVs containing VEGF, TGFβ1, IL-8, HGF, and TCF4 may have both proangiogenic and prosurvival effects [94].

A metaanalysis performed by Zhang et al. confirmed the clinical effectiveness of using exosomes in ischemia/reperfusion injury, based on reports published between January, 2000 and September, 2015, and indexed in the PubMed and Web of Science databases. The authors' analysis of the data they gathered validated the therapeutic potential of MSC-secreted exosomes in improving heart function. Still, more steps are required to understand these exosomes' mechanism of action fully and ensure their therapeutic safety; in addition, clinical trials are required to optimize this cardiac regeneration approach after ischemic events [95].

Mesenchymal stromal cells promote recovery after acute kidney injury (AKI), and phenotypic changes have been associated with the EVs implicated in the process. Knowing that miRNAs are potential candidates for cell reprogramming toward a regenerative phenotype, Collino et al. conducted a study to evaluate whether miRNA deregulation inhibits the regenerative potential of mesenchymal stromal cells and derived EVs in a model of glycerol-induced AKI in severe combined immunodeficient mice. The results showed that miRNA depletion in mesenchymal stromal cells and in EVs significantly reduced their intrinsic regenerative potential in AKI [96]. Furthermore, when AKI occurs, dedifferentiation of the tubular cells initiates cell regeneration, involving HGF by modulating cell dedifferentiation. MSC—derived MVs deliver RNA into injured tubular cells and alter their gene expression, thus regenerating these cells. It was reported that in damaged tubular cells, HGF synthesis induced by MVs via RNA transfer facilitates cell dedifferentiation and growth, which are important regenerative mechanisms [97].

A study of the growth-promoting effect of EVs derived from different MSC sources on neurons was undertaken by the Khoury group. The researchers compared the effect of human menstrual MSCs (MenSCs), which were mediated via cell-to-cell contact by their total secretomes or by secretome-derived EVs, on neuritic outgrowth in primary neuronal cultures. The researchers showed that MSCs purified from menstrual fluid released MVs and exosomes, and that exosomes present in conditioned medium (CM) exerted a beneficial effect on neuron outgrowth, an action that could not be fully reproduced by exosomes derived from other MSC sources, such as BM-, chorion-, and umbilical cord—derived MSCs, or by other MenSC culture components [98].

Having demonstrated the neuroprotective potential of systemically administered MSCs in a preclinical animal model of hypoxic-ischemic brain injury in ovine fetuses, another research group investigated whether these protective effects can be exerted by MSC-derived extracellular vesicles (MSC-EVs) in a preclinical model of preterm hypoxic-ischemic brain injury. Ovine fetuses were subjected to global hypoxia-ischemia, followed by in utero intravenous administration of MSC-EVs. The systemic administration of MSC-EVs improved brain function by reducing the total number and duration of seizures and by preserving baroreceptor reflex sensitivity. These protective effects were accompanied by a tendency to prevent hypomyelination [99]. These results are relevant because they show that a cell-free preparation composed of neuroprotective MSC-EVs could eventually become a substitute for MSCs, avoiding the potential risks involved in the systemic administration of living cells.

With respect to bone regeneration, Nakamura et al. [100] suggested that MSC-derived exosomes can promote skeletal muscle regeneration by enhancing myogenesis and angiogenesis; these researchers considered exosome-enclosed miR-494 to be an important mediator of this response. In addition, Narayanan et al. [101] demonstrated the potential of exosomes released by MSCs cultured under osteogenic conditions: In both two- and three-dimensional (type I collagen hydrogels) cultures, these exosomes induced lineage-specific differentiation of undifferentiated hMSCs both in vitro and in vivo. Results of the study also showed that exosomes can bind to extracellular

matrix (ECM) proteins such as type I collagen and fibronectin [102]. Work published by Furuta et al. focused on exosomes as a valuable addition to cell-to-cell communication. This study evaluated the role of exosomes isolated from MSC-CM in the fracture healing process of $CD9^{-/-}$ mice, a strain known to produce reduced levels of exosomes. Injection of MSC-EVs accelerated fracture healing in $CD9^{-/-}$ mice, which would otherwise be naturally delayed, whereas injection of exosome-free CM had no rescue effect [103].

Human embryonic MSC-derived exosomes were tested in an animal model of cartilage repair. Osteochondral defects were created on both distal femurs in adult rats, and treatment consisted of intraarticular injections of exosomes or phosphate-buffered saline (PBS), administered after surgery and thereafter weekly for 12 weeks. Overall, the exosome-treated defects displayed an enhanced gross appearance and improved histological scores compared with the contralateral PBS-treated defects. In the exosome-treated defects, cartilage and subchondral bone exhibited complete restoration and complete bonding to adjacent cartilage, as well as an ECM deposition that closely resembled that of an age-matched healthy control [104].

Designating a major role to exosomes in mediating the therapeutic and paracrine effects of MSCs offers additional advantages. There is less immunogenicity than that found with parental cells bearing a low content of membrane-bound proteins, and exosomes can be stored at −20°C for 6 months with no loss of biochemical activity. The cytokines, growth factors, transcription factors, and RNAs contained inside the exosomes are protected from degradation in vivo, thereby potentially preventing some of the problems associated with small soluble molecules, which degrade rapidly [105].

IMMUNOMODULATORY EFFECTS OF MESENCHYMAL STEM CELLS

Several studies have shown that MSCs escape recognition by the immune system and inhibit immune responses [106]. Modulation of the immune system has been detected in both BM-MSCs and ASCs. This property of MSCs facilitates the clinical use of MSCs in an allogeneic manner in both immune disease and regenerative medicine approaches. Numerous clinical trials involving the use of MSCs have been initiated: 38 to study the effect of MSCs on graft-versus-host disease (GVHD), 22 to treat multiple sclerosis, 14 to treat different forms of anemia, 21 to achieve bone regeneration, and 47 to treat patients with cirrhosis or facilitate liver transplantation [107].

Various mechanisms have been suggested to explicate how MSCs prevent allogeneic rejection among different species [108]: weak immunogenicity; interference in the maturation and function of DCs [10]; abolishment of T-cell proliferation by various pathways including Fas/Fas ligand−induced T-cell apoptosis [109]; and interaction with natural killer (NK) cells in cell-to-cell contact or by releasing soluble secreted factors [110]. Although there have been discrepancies, probably owing to differences in implementing experimental systems, most reports have indicated no or low expression of major histocompatibility complex class II proteins [111]. At the molecular level, many researchers believe that MSCs migrate to sites of injury where they secrete various modulator molecules including immunoregulatory and trophic signals [53]. Najar et al. [112] proposed a description of a regulatory network in which each immune mediator affects and is affected by others; accepted major modulators include HGF, TGF-β [113], nitric oxide [114], PGE2 [115], and IL-10 (the central player in the network). IL-10 is not secreted by MSCs, but by lymphocytes [116] in response to MSC secretion of HGF, PGE2, and other factors [81]. IL-10 has a pleotropic effect that includes diversion of the type 1 T helper/type 2 T helper balance and induction of regulatory T-cell differentiation while regulating antigen-presenting cell activity [117]. iMSCs retain some of the characteristic MSC immunomodulatory capabilities [118], including NK cell downregulation [119].

Exosomal signaling has been shown to participate in MSC immunomodulation [120,121]. Blazquez et al. reported that exosomes secreted by ASCs are able to inhibit the proliferation of stimulated T cells harvested from peripheral blood [120]. The contribution of miRNA molecules has been documented as well: for instance, in an MSC-modulated hepatitis C model [122] and an AKI model [96].

The timing of MSC therapy favoring immunomodulation is highly important. Wang et al. [123] described the plasticity of MSCs in response to the three phases of inflammation: inflammatory, reparative, and remodeling. Because the response of MSCs is affected by the stimulation of immune cells, there is an optimal window during which therapy should be applied. For instance, MSC infusion will not affect GVHD if it is performed during BM transfusion, before inflammation has developed [124], although MSCs can modulate GVHD if administrated 2 days later [125]. We observed a similar effect when we used systemic MSC administration to model vertebral compression fracture (VCF) repair; repair worked only when the MSCs were administered 3 days after the creation of the VCF [54]. Ankrum et al. [126] suggested strategies to prolong the persistence of allogeneic MSCs, including low-dose immunosuppression, polymer capsulation, and even genetic modification of exogenously administrated MSCs.

Overall, the way in which MSCs avoid detection by the immune system has not been thoroughly elucidated. Additional soluble factors or cells may be found to exert a significant impact, and novel mechanisms may be revealed.

INDUCED PLURIPOTENT STEM CELL–DERIVED MESENCHYMAL STEM CELLS

The prevalence of musculoskeletal disorders in older persons, taken together with challenges associated with the aging of the world population, has motivated researchers to investigate the impact of aging on the regenerative properties of MSCs, because of these cells' potential as an autologous treatment [127]. Although conflicting results have been published, in a variety of organs the regenerative potential of MSCs appears to decline with advancing age [128]. Human ESCs, the first pluripotent stem cells to be discovered, were found to be capable of inducing mesenchymal tissue formation in vivo [129]. Although ESCs are believed to be immunoprivileged, they have been shown to possess immunogenicity after differentiation [130].

Many ethical questions and debates have arisen from the use of ESCs [131]. As a consequence, there is need for an alternative inexhaustible source of MSCs to treat various skeletal disorders. It has been awhile since induced pluripotent stem cells (iPSCs) were discovered [132], and they provide a feasible solution. The emergence of iPSC technology was saluted with enthusiasm because it provides a reliable technological tool for generating pluripotent cells from practically any somatic cell and, theoretically, for obtaining any differentiated cell type. Use of iPSCs provides relief from a heated ethics controversy over the use of the only other pluripotent stem cells available: ESCs. Also, the notion that less than a handful of genes could reprogram an adult cell into pluripotency was astonishing to the stem cell research community. This discovery provides an opportunity to generate and develop either autologous MSCs or an allogeneic off-the-shelf MSC product. The embryonic origin of MSCs remains unclear, although some studies indicate a possible origin for MSCs in a supporting layer of the dorsal aorta in the aorta-gonad-mesonephros region [55]. Consistent with these findings, MSC-like cells have been found to circulate in fetal human blood [56]. By overcoming the immunological and ethical problems associated with ESCs, use of iPSCs opens a new avenue for cell transplantation–based regenerative medicine [133]. Thus, iPSCs, which are aged cells that possess the properties of young/embryonic cells, could solve one of the bottlenecks for clinical cell therapy, which is the shortage of functional autologous MSCs [134].

Since 2005, several methods have been developed to differentiate pluripotent stem cells (including both ESCs and iPSCs) into MSCs with various efficiencies of differentiation [129]. Initially these methods were developed for ESCs and included OP9 coculture [135], embryoid body formation [129], and direct plating of human ESCs in MSC media [136] with cell sorting [137], scraping [138], or manual colony picking and expansion of spontaneously differentiated human ESCs based on morphology [139]. Some of these methods were applied to iPSCs, as well; specifically, embryoid body formation was used as a first step toward MSC differentiation [31,140]. In other studies, Dulbecco's Modified Eagle Medium or a similar medium was used to culture iPSCs for prolonged periods to initiate spontaneous differentiation toward the mesenchymal lineage [119]. New methods were also developed to induce well-controlled and efficient reprogramming of iPSCs to iMSCs, including treatment with specific factors [31], using cell isolation based on specific surface markers [32], or biomaterials-directed differentiation [34]. Unfortunately, there is no consensus method to differentiate iMSCs, and differences in protocols, however small, can result in variable differentiation potentials, expandability, and properties of the end point tissue that is formed using those cells [31]. Therefore, these is a need to unify the differentiation methods and elaborate multiple tests to evaluate each batch of differentiated cells, to develop these cells into a potential therapeutic agent and move them forward to clinical applications.

Shortly after their discovery, the value of iPSCs as tools for modeling diseases became widely appreciated in the general stem cell scientific community. One of the main advantages of iPSCs lies in the ability to derive these cells from the individual patient, expand the cells, differentiate them into the desired cell type, and recreate the patient's disease in a dish. This method is mostly relevant in cases of genetic diseases, in which a mutation is transferred from the patient's somatic cells to the iPSCs and then to the differentiated cells, allowing researchers to investigate the phenotype of target cells without the need to procure target tissue or cells from the patient. There are no known diseases that specifically originate in mutated or compromised MSCs. Multiple disorders of mesenchymal tissues, such as Marfan syndrome [141] and fibrodysplasia ossificans progressiva [142], have been studied using iPSC-mediated disease modeling; however, most of these models used direct reprogramming of iPSCs to the cell of interest without passing through the intermediate MSC stage [143].

Levi and colleagues showed that iPSCs can be directed toward osteogenic differentiation in the presence of BMP-2 protein [144]. In that study, no teratoma formation was observed, even though no differentiation of iPSCs was induced before implantation. Still, the question of the tumorigenicity of pluripotent stem cells remains unanswered [145], and it is less likely that iPSCs will be used in the clinical setting unless a well-controlled differentiation procedure is developed that rules out any chance of tumor formation. Nevertheless, when tumorigenicity was specifically studied and iMSCs were compared with BM-MSCs, iMSCs were found to be less tumorigenic than BM-MSCs [31]. These iMSCs homed to tumors with efficiencies similar to BM-MSCs but were much less prone than BM-MSCs to promote an epithelial–mesenchymal transition, invasion, stemness, and growth of cancer cells [35]. These observations might be explained by the much lower expression of receptors for IL-1 and TGFβ, downstream protumor factors, and hyaluronan and its cofactor TSG6, all of which contribute to the protumor effects of BM-MSCs [35]. All of these findings suggest that once standardized, iMSCs will have the potential to become a safer alternative to the traditional and well-established BM-MSCs for therapeutic applications, especially in patients with cancer.

List of Acronyms and Abbreviations

AKI Acute kidney injury
AMI Acute myocardial infarction
ASC Adipose tissue–derived stem cell
ATPase Adenosine triphosphatase
BM Bone marrow
BM-MSC Bone marrow-derived mesenchymal stem cell
BMP Bone morphogenetic protein
CFU-F Colony-forming unit–fibroblast
CPC Cardiac progenitor cell
CVD Cardiovascular disease
DMEM Dulbecco's modified eagle medium
ECM Extracellular matrix
ESC Embryonic stem cell
ESCRT Endosomal sorting complexes required for transport
EV Extracellular vesicle
GCP Good clinical practice
GVHD Graft-versus-host disease
HGF Hepatocyte growth factor
hMSC Human mesenchymal stem cell
IAC Immune-affinity capture
IL Interleukin
iMSC Induced-pluripotent stem cell–derived MSCs
iPSC Induced pluripotent stem cell
MenSC Menstrual mesenchymal stem cell
MHC Major histocompatibility complex
miRNA microRNA
MLC Mixed lymphocyte culture
MNC Mononuclear cell
MSC Mesenchymal stem cell
MSC-EV MSC-derived extracellular vesicle
MV Microvesicle
NAD Nicotinamide adenine dinucleotide
NK Natural killer
PBS Phosphate buffered saline
PGE2 Prostaglandin E_2
TCF4 T-cell factor 4
$TGF\beta_1$ Transforming growth factor-beta1
VCF Vertebral compression fracture
VEGF Vascular endothelial growth factor

Mesenchymal Stem Cells in Regenerative Medicine

Arnold I. Caplan

Case Western Reserve University, Cleveland, OH, United States

INTRODUCTION AND HISTORY

The body continuously changes, and this is controlled primarily by genetic factors. The same genomic program that brings the fertilized egg through a series of multiplication and differentiation changes to bring about the birth of a complete multitissued organism controls the continuous changes through neonatal, juvenile, and teen stages and all of adulthood. Individuals aged 10, 30, 50, 70, and 90 years exemplify this continuous genetic and distinctive process of change. Importantly, the later stage of this process, referred to as aging, is not a disease state but rather part of this genomically controlled continuum. The central feature of change is that tissue-specific progenitor cells divide and their progeny differentiate in a sequence of site-specific changes to both expand the dimensions of tissues and *replace* cells that naturally expire. Every cell in the body has a life span measured in minutes, weeks, or in some rare cases, years. With only a few exceptions, end-stage differentiated cells die within a fixed time frame. The progenitor cells for that expired cell must replace the expired cells; the rate of replacement controls whether the tissue will increase in size, be maintained, or experience atrophy as seen in old age.

Within this view, I proposed the scheme pictured in Fig. 15.1, recognizing that bone marrow contained osteochondral progenitors, which had been used for decades to repair bones [1–3]. Fig. 15.1 was established in schematic form to mimic what was known about the lineages of hematopoiesis [4], except that in 1988 we knew the most about the lineage progression on the left of Fig. 15.1 [5] and nothing about the lineages on the right. In addition, in reviewing prior experiments from Dr. A. Friedenstein's lab in Moscow and her own findings, Professor Maureen Owen also proposed the existence of osteochondral progenitors in a logic mirroring hematopoiesis [6]. The dogma of that era (the 1980s and early 1990s) was that there was only one progenitor or stem cell, the hematopoietic stem cell (HSC), in adult organisms. The full scope of Fig. 15.1 was clearly not envisioned in 1988 and the term mesenchymal stem cell (MSC) was considered by some to be provocative at best and by others to be outlandish. Because the focus of Fig. 15.1 was on the differentiation lineages, all of the research of that era focused on tissue engineering strategies to rebuild damaged tissues; most experiments and transplantations were formulated in the orthopedic sector with bone [7,8], cartilage [9,10], muscle [11,12], and tendon [13] being prominent.

Because the MSCs were isolated from marrow, it was hypothesized that these cells were the progenitors for the bone marrow stroma (the highly differentiated tissue that supports all of hematopoiesis) [14]. Although most preclinical models using MSCs were in the orthopedic sector (bone, cartilage, and tendon) in the early 1990s, the first clinical trial using human MSCs (hMSCs) conducted by my colleagues in hematology-oncology was to supplement bone marrow transplantations with culture-expanded hMSCs for patients with cancer and eventually for patients with gene defects in mesenchymal-linked processes or tissues [15–17]. The logic of that era was that the MSCs, like the HSCs, would "home" back to the marrow when infused into the bloodstream; once home, the MSCs would rebuild or enhance the marrow scaffold to accelerate the engraftment of the HSCs and stimulate the recovery of the blood cell–forming capacity of the marrow by directly fabricating microenvironments for each distinct lineage pathway for hematopoiesis. Indeed, the early clinical evidence showed that the added MSCs improved both the kinetics and outcomes of hematopoietic recovery in bone marrow–transplanted patients with cancer [18].

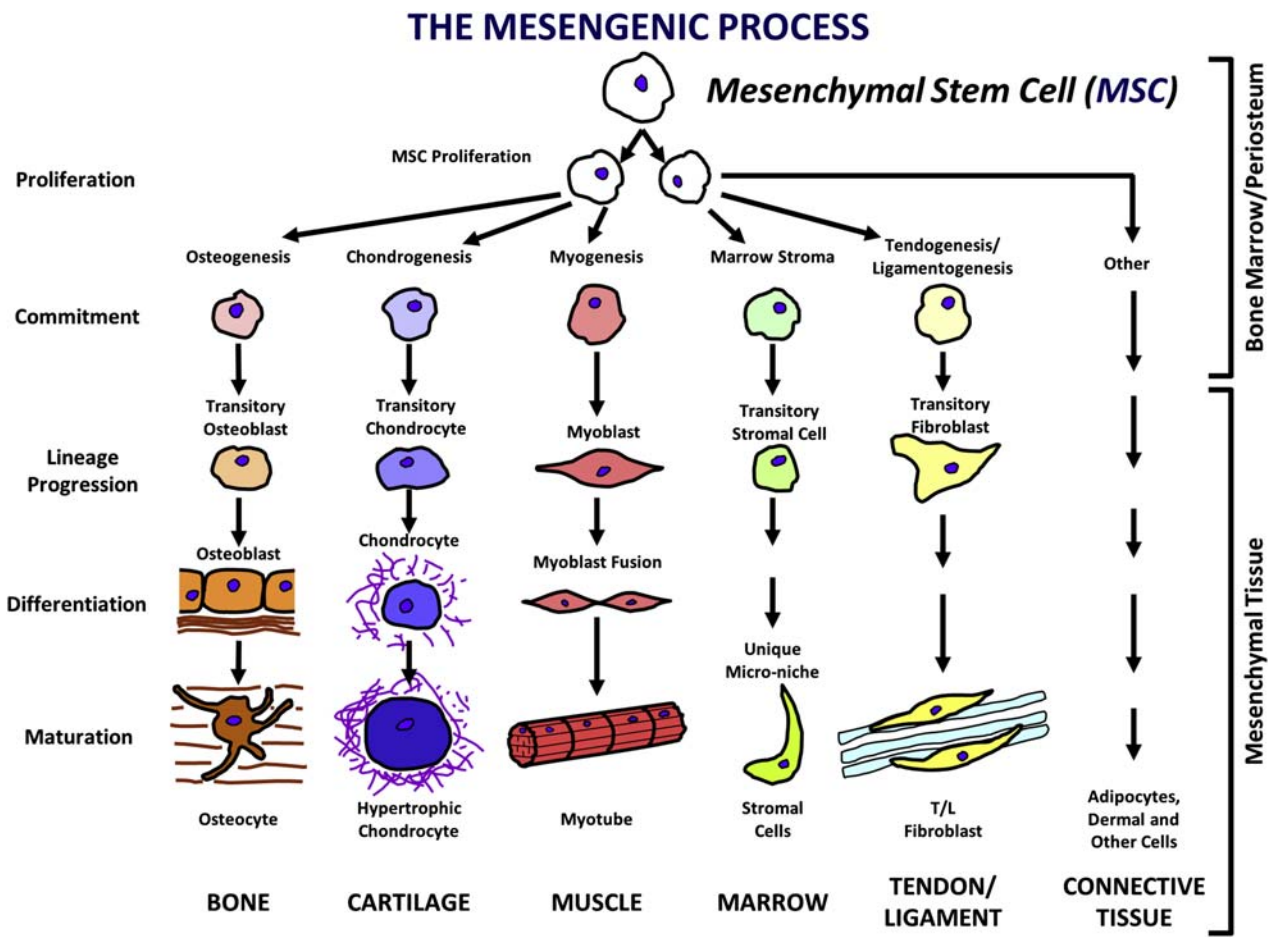

FIGURE 15.1 **The mesengenic process.** This figure was generated in the late 1980s and proposed that a mesenchymal stem cell (MSC) existed in bone marrow and that its progeny could be induced to enter one of several mesenchymal lineage pathways [5–14]. The left side of the diagram was already experimentally established [5] whereas little was known about the lineages on the right. The lineage format was constructed from what was known about the hematopoietic lineage pathway [4].

This involvement of the hematologists-oncologists led to the realization that hMSCs were immunomodulators and, thus allogeneic MSCs were not immediately interrogated by the host's immune system [17,19,20]. This allows allogeneic hMSCs to be infused into the bloodstream as a delivery modality with the cells functioning in tissue areas of inflammation or vascular damage. As discussed subsequently, this also allows hMSCs to be used in rodent models of multiple sclerosis (MS) [21,22], asthma [23,24], inflammatory bowel disease [25], graft versus host disease (GvHD) [26], etc., without rapid and intense immunorejection.

NEW INSIGHT

When Steven Haynesworth and I first started working with hMSCs, we developed monoclonal antibodies to cell-surface antigens on these cells called SH2, SH3, and SH4 [27]. Subsequently, we showed that SH2 was a unique antigen on endoglin (also known as CD105) [28] and SH3=SH4=CD73 [29]. The initial screens for these monoclonal antibodies were to their binding to hMSCs in culture and then to frozen sections of marrow plugs. It was not until years later that we realized that SH2-positive cells colocalized with the external aspects of small blood vessels in those marrow sections. Through the detailed research from the laboratories of B. Peault [30], I. Bianco [31], and others [32], we now understand that MSCs are identical to perivascular cells, referred to here as pericytes. Indeed, I have hypothesized [33] that *all* MSCs are derived from pericytes (the reverse is not correct in that some pericytes are so highly differentiated that they cannot form MSCs). In this context, we published an article on human skin showing SH2-positive cells sitting on blood vessels [34]. For reasons still not clear, only a small proportion of

such cells stained positive in sections of skin, with the most numerous positive images in specimens from young donors. Perhaps the antibody SH-2 stains differently from CD105 [28].

The current literature documents that MSCs can be isolated from marrow [35], fat [36,37], muscle [38], skin [39], periosteum [40], tendon [41], neural tissues [42], etc. These tissues all have blood vessels in common and such vessels have perivascular cells on the adlumenal surface. The positioning of such pericytes is controlled by a number of factors, but the prominent component is the platelet-derived growth factor (PDGF) receptor [43]. Thus, PDGF not only acts as a powerful chemoattractant and mitogen for mesenchymal cells, its receptors function to stabilize interactions between perivascular cells and vascular endothelial cells. I would suggest that in tissue domains of inflammation or blood vessel damage, the pericytes are liberated from their adlumenal locations and apparently function as activated MSCs.

Based on the clinically relevant effects of activated MSCs, we have suggested that the therapeutic capabilities of MSCs (i.e., liberated pericytes) reflect their biologic functionality at sites of tissue injury or inflammation. These therapeutic activities involve the modulation of the local immune cells to inhibit their surveillance of the damaged tissue, thus inhibiting the initiation of autoimmune activities [44]. Furthermore, the activated MSCs produce trophic effects by secreting a spectrum of bioactive molecules that inhibit apoptosis (especially in areas of ischemia), prevent scar formation, and stimulate angiogenesis by secreting vascular endothelial growth factor to attract endothelial cells to form new blood vessels, forming perivascular contacts stabilizing such newly formed vessels [45], and secreting mitogens that directly affect tissue intrinsic progenitors [46] (Fig. 15.2). These effects have resulted in clinically relevant therapies, as discussed subsequently and outlined in Table 15.1.

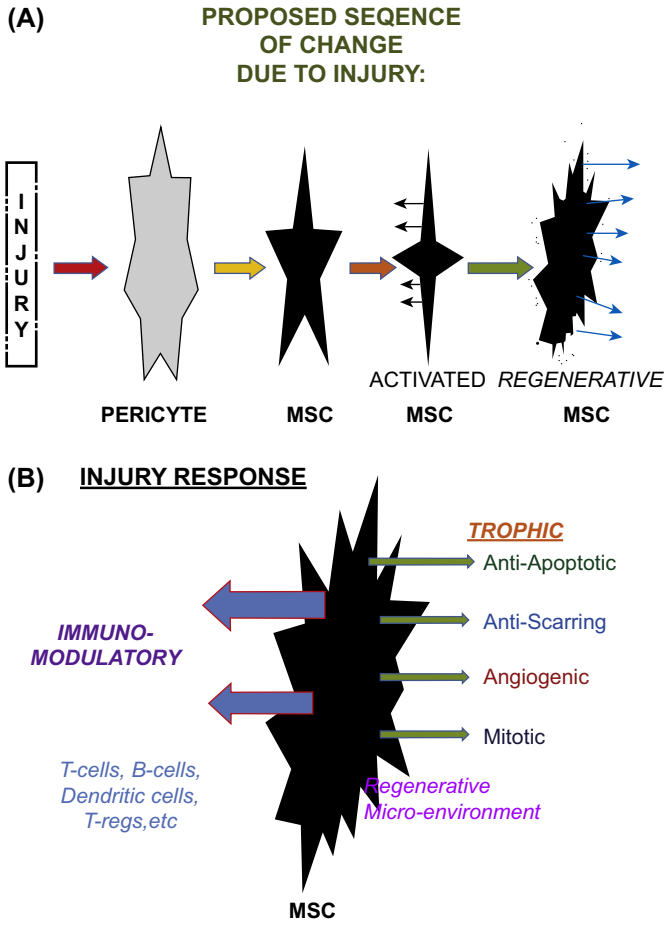

FIGURE 15.2 **Mesenchymal stem cells (MSCs) are immunomodulatory and trophic.** (A) The sequential activation as a response to injury affects pericytes and liberates them from functional contact with blood vessels to become functional MSCs. These MSCs become immuno-activated and secrete factors that organize a regenerative microenvironment. (B) The bioactive molecules secreted by activated MSCs are immunomodulatory and affect a variety of immuno-related cells [17,19,32,33]. Other secreted molecules establish a regenerative microenvironment by establishing a powerful trophic field [44,46].

TABLE 15.1 Therapeutic Effects of Mesenchymal Stem Cells

Tissue	Injury/Disease	References
Bone marrow	Graft versus host disease	[26,71]
Brain	Stroke/multiple sclerosis/ amyotrophic lateral sclerosis	[21,22,53,58,72]
Spinal cord	Cut/contusion	[73,74]
Bowel	Inflammatory bowel disease	[25,48]
Tendon	Tendonitis	[75,76]
Muscle	Defect/muscular dystrophy	[38,47]
Pancreas	Diabetes	[61]
Lung	Asthma/cystic fibrosis	[23,24]
Heart	Acute myocardial infarct, chronic	[64,65]

Given the proposed pericyte—MSC relationship, it is easy to understand why large numbers of MSCs can be isolated from adipose or muscle tissue. Indeed, although marrow MSCs are the most widely studied ones, data from fat and muscle appear to be complementary [47,48]. The fact that fat contains a 300- to 500-fold greater number of MSCs per milliliter of material accounts for the assertion that adipose-derived MSCs can be obtained in sufficient numbers without in vitro expansion [49]. Simply, liposuctioned fat is dispersed in a homogeneous slurry and incubated with digestive enzymes such as collagenase to free the pericytes from their capillary endothelial cell attachments, and the liberated cells are centrifuged after saline washes [50]. The adipocytes float and the pelleted cells, called the stromal vascular fraction (SVF), contain MSCs with some contaminating endothelial cells and monocytes [51]. For autologous cell-based MSC therapy, the SVF has been used directly with clear therapeutic effects [52,53]. Likewise, the SVF represents a relatively pure starting suspension for the culture attachment of MSCs and their further expansion.

Again, for emphasis, relatively large numbers of MSCs can be obtained from muscle [38], placenta [52] and other highly vascularized tissues [54]. From unpublished studies in my laboratory (Sung, Lennon, and Caplan), I suggest that MSCs are absent in cord blood but plentiful in the perivascular fraction of the cord. I further assert that if MSCs have been identified in cord blood, they have been found as an artifact of collection and are dislodged from their natural habitat (by needle insertion) during cord blood retrieval.

ALL MESENCHYMAL STEM CELLS ARE NOT CREATED EQUAL

Because I have asserted that *all* MSCs are derived from pericytes, it also follows that MSCs from different tissue sources must be different, because they reside in different tissue microenvironments. We have published various assays to test for the capacity of MSCs (primarily from marrow) to differentiate into bone [8], cartilage [10], muscle [12], and marrow stroma [55]. In many cases, these assays have been optimized for marrow MSCs [56], but not for MSCs from other tissues. For example, dexamethasone stimulates hMSCs to differentiate into osteoblasts but it induces mouse MSCs to become adipocytes [57]. For cartilage induction, hMSCs from marrow require transforming growth factor-β (TGF-β) in defined medium [10]. Fat-derived hMSCs do not respond to TGB-β alone but require the addition of bone morphogenetic protein-6 with TGF-β for optimal chondrogenic differentiation [58]. The relationship between the capacity of MSCs to be induced into specific and multiple phenotypic pathways and their intrinsic secretory profile remains unknown. It is clear that MSCs from a variety of tissues are multipotent, but their capacity to respond to certain signaling molecules and their ability to differentiate are apparently independent of their source or their therapeutic or secretory potential. MSCs are presumably conditioned by the tissue microenvironment from which they were purified, and thus all MSCs are not equivalent.

Clinically Relevant Therapies Using Mesenchymal Stem Cells

Often the US Food and Drug Administration requires animal trials as preclinical proof of concept for the use of a drug or device. No animal models match the human disease condition exactly. Indeed, in most cases of animal models of cell-based therapies, autologous animal cells have been preferentially used [9,13,38,41]. The reason for

including this section on preclinical studies is to set forth the unique example that hMSCs are being used in animal models to cure their disease states (see, for example, Bonfield et al. [23,24] and Bai et al. [22]). This in itself is a remarkable property of hMSCs, in that the animals' immune systems do not overtly reject the human cells whereas the (usually, second passage) hMSCs orchestrate the cures.

Multiple Sclerosis

Experimental Autoimmune Encephalitis Model

A mouse model for MS involves exposing immunocompetent animals to molecules from myelin in the presence of adjuvant that causes the animals to mount an immune reaction to these molecules, which in turn causes a series of demyelinating events mimicking human MS. Two models have been used by us: severe, monophasic MS and recurring-remitting MS. In both cases, hMSCs cure the animal after a single tail vein injection of 10^6 hMSCs [22]. We have separately shown that molecules secreted by hMSCs preferentially cause central nervous system neural stem cells to differentiate into oligodendrocytes, the cells that wrap nerve axons with myelin [21]. The end result is a cured animal that exhibits no signs of MS.

Asthma

Ovalbumin Model

Mice were injected with the chicken protein ovalbumin in adjuvant to immune-sensitize the animal. After 2 weeks, ovalbumin was atomized daily or every other day into the lungs of these sensitized mice, causing an intense inflammatory response. At 3 or 7 days or 11 weeks after the initial exposure of the lungs to ovalbumin followed by exposure to ovalbumin daily or every other day, 5–10 mice were injected in the tail vein with 10^6 hMSCs [23,24]. Ovalbumin treatment was continued for 4 days or 1 week after the injection of hMSCs; the animals were killed at 1, 4, 8, or 12 weeks after the initial ovalbumin exposure to the lungs was begun. The hMSCs were compared with saline-injected animals. In the saline-injected, ovalbumin-sensitized mice, the lung tissue was hugely inflamed; at the longer time points, scar tissue was apparent. In the hMSC-injected mice, the lungs looked normal with the reestablishment of intact endothelial lining and the absence of inflammation [23,24]. Experiments document that scar tissue from chronically inflamed lungs is replaced by normal tissue after multiple hMSC exposures [24]. Again, hMSCs facilitate the cure of this asthma-like condition in mouse models.

Inflammatory Bowel Disease

Mice can be exposed to dopamine dysregulation syndrome, which causes severe inflammatory bowel disease that is lethal. When hMSCs are targeted to the sites of inflammation using a proprietary cell-docking system, 80%–90% of the animals are cured [25]. No other single treatment can accomplish this cure. Whether the enhanced targeting is required for human subjects is not known, although phase I and II clinical trial data appear to indicate that substantial improvement in patients with Crohn disease can be experienced with infusion of hMSCs alone, with high doses required (Osiris Therapeutics, Inc., www.osiristx.com; now owned by Mesoblast, Ltd.).

Stroke and Acute Myocardial Infarct

By occluding a major artery leading to the brain [59] or suturing the heart [60], mouse models of stroke or acute myocardial infarct (AMI) have been created. Two to 7 days after these models of severe ischemia were created, hMSCs were injected via the tail vein [59,60]. The animals were monitored for 5–10 weeks and those that received hMSC therapy returned to full and normal function. The therapeutic effects resulted from the trophic activity of hMSCs that homed to sites of vascular injury and inflammation.

Diabetes

In both mice and rats, the immune destruction of pancreatic islet cells was initiated by exposing the animal to streptozotocin. By monitoring systemic secretion of insulin, a continuous, autoimmune-mediated elimination of islets, and thus the diminution of insulin secretion, was observed. Using a single intravenous injection of hMSCs, the decline of insulin secretion was halted and the eventual regeneration of islet cells was observed [61].

CLINICAL TRIALS

Worldwide, over 830 separate clinical trials are being conducted using MSCs for various clinical maladies; the most are conducted outside the United States. Such clinical trial listings do not include infusions of MSCs occurring in clinics and hospitals operating within the medical tourism industry. Indeed, the use of MSCs, both autologous (SVF and culture-expanded MSCs) and allogeneic, from marrow and other sources, form an expanding sector of the medical tourism markets in the Caribbean, Central and South America, Europe, and Asia. Most, if not all, of these MSC uses are in open-label, nonrandomized, nonplacebo controlled studies. Although one can find fault with such studies, they provide patients with access to potential therapeutics long before MSCs will be officially approved for use by regulatory agencies. Because many drugs are used "off-label" by medical practitioners, it is tempting to be enthusiastic about such treatments, especially using autologous SVF. In this regard, somewhere between 10,000 and 50,000 individuals have been infused with various preparations of MSCs with no reported adverse reactions. Certainly, if one million patients are infused with MSCs, we should expect some adverse events. In this regard, whether in sanctioned clinical trials or in other situations, the medical community must be informed quickly and completely about any and all adverse events so that we can understand the problems and limitations of these new therapies.

THE NEW MESENCHYMAL STEM CELLS

Long ago, when we developed the isolation and culturing technology and assays for hMSCs [62,63], we envisioned using these cells in tissue-engineering applications in orthopedics. We started Osiris Therapeutics, Inc. as a "bioorthopedic" company, which interestingly, followed our academic lead by furthering our initial investigator-initiated clinical trials in the augmentation of bone marrow transplantations for patients with cancer [15–19]. Within the first 10 years of Osiris, it became clear that the MSCs had a unique immunomodulatory capacity [17,19]. This led to the use of MSCs in GvHD, and the new management of Osiris brought us into the current wide range of use of MSCs as briefly outlined previously (now owned by Mesoblast, Ltd.) For the record, we set up the correct animal models for the wrong reasons. For example, the AMI model was established because it was hypothesized that MSCs would differentiate into cardiac myocytes and thus fix the damaged heart [64]. Early reports documented such differentiation by showing the labeled MSCs docked in ischemic heart tissue and the label was seen in and on cells with markers for cardiac myocytes [65]. This most probably resulted from the low frequency of fusion between the labeled MSCs and resident cardiac myocytes. We now understand more clearly that the MSCs have a complex, multicomponent trophic effect that establishes a protective and regenerative microenvironment that allows the heart to minimize the damage caused by blood vessel blockage, as shown schematically in Fig. 15.2.

The "new hypothesis" regarding MSCs is that they are site-regulated pumps for bioactive molecules that are both immunomodulatory and trophic. As outlined in review articles [44,66,67], tens to hundreds of molecules are provided and modulated at each site of injury or inflammation. Such modulation is probably site-specific and also controlled by the genetic markup of both the host and donor. The corollary is that it patients who exhibit autoimmune diseases may have defects in their MSCs with regard to specific site-regulated responses. Such defects may not be manifested by the absences of key components, but rather may be a consequence of low levels of key components. Such low levels may not be detrimental until a specific age or stress condition is experienced. Likewise, the reported decreases in MSCs with age may be controlled by the age-related decrease in tissue vascular density that is seen with age or disease state, such as diabetes. Given the relationship between pericytes and MSCs [30–33], the central issue is to determine the cause of vascular density decreases: is this controlled by the MSC/pericytes, the endothelial cells, or the tissues hosting the vasculature?

The "new" MSC, the pericyte, allows a better understanding of both a variety of diseases and the development and maintenance capacities of a variety of tissues. As a compositum of this newer information, we have constructed a poster that summarizes all of the newest information on the pericyte MSCs [68]. The new MSC treatment protocols using both culture-expanded and freshly isolated uncultured MSCs (i.e., SVF) open the door to new therapies and new medical horizons. The "old" MSCs can still be used for a variety of orthopedic indications, but they will now be used with new insights and new hypotheses. The third decade of this century will usher in "new medicine" and new treatment protocols using MSCs. The next technical hurdle will be to learn how to orchestrate the docking or targeting [25,69,70] of systemically introduced MSCs more efficiently to effect efficient therapeutic outcomes.

Cell Therapy of Liver Disease: From Hepatocytes to Stem Cells

Stephen C. Strom[1], *Carl Jorns*[2]

[1]Department of Laboratory Medicine, Karolinska Institute and Division of Pathology, Karolinska University Hospital, Stockholm, Sweden; [2]Department of Transplantation Surgery, Karolinska University Hospital, Karolinska Institute, Stockholm, Sweden

INTRODUCTION

The concept of regenerative medicine implies that the clinician works with the innate healing and regenerative process of the body to effect an improvement in a patient's health. Perhaps more than with any other organ, the liver offers the greatest opportunity for regenerative medicine. This is because, unlike most other tissues, the liver has the capacity to regenerate after massive chemical or physical insult and tissue loss [1]. Our very existence may well rely on the ability to regenerate liver mass. The liver is an incredibly complex organ that performs diverse biological functions from glycogen storage and catabolism to maintain blood sugar levels to the production and secretion of critical plasma proteins including albumin, clotting factors, and protease inhibitors. In addition, the liver is the major site in the body for the metabolism and excretion of hormones, metabolic waste products such as ammonia, as well as exogenous compounds such as toxins, drugs, and a variety of other compounds to which we are exposed through diet and environment. These processes are so critical to survival that the loss of any of these functions has serious and often lethal consequences for the individual.

Until recently, the only option for treating chronic liver disease or metabolic defects in liver function has been whole-organ transplantation. Hepatocyte transplantation has been performed as the standard. Although still an experimental therapy, there are some potential advantages for a cell therapy approach to treat liver disease. Some advantages to and problems with current treatments for liver disease are listed in Table 16.1.

Despite the unquestioned success of this technique, orthotopic liver transplantation (OLT) requires major surgery and has a significantly long recovery period. Financial costs associated with OLT and lifelong immunosuppression are considerable. There is a high incidence of complications from the surgical procedure and the concomitant immunosuppression that is required after the organ transplant. Complications can range from simple infections to renal failure, hyperlipidemia, and an increased incidence of skin and other types of cancers after long-term immunosuppression. As with all other organs, the number of liver donors does not nearly equal the number of patients on the waiting list. Patients may wait 2 or more years for a liver transplant, and there is a death rate of greater than 10% per year for patients on the waiting list. Timing is critical for whole-organ transplant. An ABO-compatible liver donor must be available when a patient requires the transplant. Some limitations associated with whole-organ transplants are addressed with hepatocyte transplants (Table 16.1). Hepatocyte transplants do not require major surgical procedures because they are performed by infusing cells into the blood supply to an organ such as the liver or spleen. Thus, hepatocyte transplants are less invasive and less costly procedures. Because major surgery is not required, fewer complications are associated with the procedure. Cell infusions are minor procedures, and thus essentially no recovery period is needed. If patients were healthy before the procedures, such as stable metabolic disease patients, they would likely feel no adverse effects from the procedure other than from the placement of a catheter. Hepatocytes can be banked and cryopreserved, so theoretically, cells could be available at any time for a patient transplant. The timing of a hepatocyte transplant depends on the status of the patient rather than on the availability of a suitable

Less invasive and less costly procedure
Complications, fewer, and less severe
Timing of procedure is easier
Alternative cell sources
Patient retains native liver
Graft loss is not necessarily lethal
Option remains for whole-organ transplant

organ. Currently, the source of hepatocytes for hepatocyte transplants is mainly discarded organs not suitable for whole-organ transplant [2]. There are not enough hepatocytes to transplant all recipients who would likely benefit from the procedure. However, some inventive new ideas have been proposed, such as to use segment IV, which can be made available from a split-liver procedure [3] to make more hepatocytes available for transplants. Another novel source of good-quality hepatocytes is neonatal donors. Because of their small size and potential immaturity, these livers are usually not used for whole-organ transplantation. However, experience shows that these neonatal donor livers can give high-yield, good-quality hepatocytes that are resistant to cryopreservation damage. Alternative sources of hepatocytes could also be available in the future. Among the many options discussed are xenotransplants from pigs or other species, immortalized hepatocytes, and stem cell–derived hepatocytes. Future developments in these areas may make the number of cells available for hepatocyte transplants virtually unlimited.

A significant benefit of hepatocyte transplantation is that patients retain their native liver. In cases of cell transplants for metabolic disease, the patient's native liver still performs all of the liver functions with the exception of the function that initiates the disease. Patients with ornithine transcarbamylase deficiency (OTC) have a mutation in an enzyme involved in the urea cycle that prevents the metabolism and elimination of ammonia. Although the native liver is not proficient in ammonia metabolism, it is still capable of performing other liver functions including the secretion of clotting factors and albumin, drug metabolism, and all other metabolic and synthetic processes. A cell transplant only needs to support the ammonia metabolism for the patient and will not be required to provide complete liver support. Because all liver functions do not depend on donor cells, loss of the cell graft or failure of the cells to function properly will not necessarily be life-threatening, especially for a patient with stable metabolic disease. Finally, a whole-organ transplant always remains an option for the patient with a cell transplant. Even if the cell transplant fails to function or is rejected, nothing performed as part of the cell transplant procedure would likely interfere with a subsequent whole-organ transplant. Fisher et al. [4] reported that prior hepatocyte transplantation did not sensitize the cell transplant recipient to either the donor cells or to an eventual liver graft. Thus, despite sometimes transplanting hepatocytes directly into an immunological response organ (the spleen), no immunological reactions were initiated that are deleterious to the cell transplant or an eventual whole-organ transplant. However, more data must be obtained to validate these initial observations.

There are potential disadvantages of hepatocyte transplants as well. First, there are no reports of long-term complete corrections of metabolic liver disease in patients after cell transplantation alone. Because it is a new field, much additional experimentation will be required to determine the full efficacy of cell therapy of liver disease and the length of time the cell graft will function. Also, like whole-organ transplants, it is believed that cell transplant recipients will require the administration of immunosuppressive drugs. The most relevant reviews on this subject are from Jorns et al. [5], Gramignoli et al. [6], and Khan et al. [7].

BACKGROUND STUDIES

Choice of Sites for Hepatocyte Transplantation

Hepatocyte transplants have been conducted for over 20 years. A number of good reviews are available for details of the experiments and the original references that may be omitted in this review [8–13]. The large numbers of preclinical studies conducted on hepatocyte transplants firmly establish that the transplants are safe and effective. The most common sites for the transplantation of hepatocytes are the spleen and the liver; however, transplants to the peritoneal cavity, stomach, or omentum have been reported. Long-term survival of the cells is readily measured after transplants into the spleen or liver. Most cells transplanted into the peritoneal cavity intellectual property (IP) are rapidly lost. After IP transplants, only cells that nidate near blood vessels and can attract sufficient nutrition survive in the long term. Despite the ease of the procedure, IP transplants of hepatocytes have only limited efficacy. Transplants of hepatocytes to the spleen or the liver have been shown to function for the lifetime of the recipient [14–17]. Studies by Mito and coworkers clearly showed long-term survival of hepatocytes and that over time, the spleen of an animal can be "hepatized" to the point at which 80% of the mass of the organ can replaced with hepatocytes [16,18–21].

The concept of establishing ectopic liver function in the spleen is similar in theory to the bioartificial liver (BAL). In BAL, the hepatocytes are seeded into and maintained in some form of an extracorporal device. The patient's blood or plasma is pumped to the device where it interacts with the hepatocytes across membrane barriers and is then returned to the patient by a second series of pumps. There are reports that BAL can provide short-term synthetic and metabolic support [22,23]. The ease of transplant of hepatocytes and the abundance of the patient's own natural basement membrane components coupled with the naturally high blood flow make the spleen a useful site for establishing short- or long-term ectopic liver function. It is likely that hepatocyte transplants will be easier, cheaper, and more efficient, and will provide the same or better level of support as extracorporal devices.

For transplants into the liver, the preferred route for administering cells is via the portal vein. Cells are infused into the blood supply that feeds the liver and the hepatocytes are distributed to the different lobes in proportion to the blood flow they receive from the portal vein. Portal vein injections are difficult in small animals, so an alternative method is used in these studies. Hepatocytes are injected directly into the splenic pulp. The proportion of the cells that remain in the spleen is determined by the extent to which the outflow through splenic veins is impeded. In the studies of Mito et al. [16], in which the spleen was "hepatized," the authors briefly occluded the splenic outflow, which retained the cells in the spleen. Alternatively, when the spleen is used as a method to affect a portal vein injection, the splenic veins are left open. It was reported that up to 52% of cells injected into the spleen traverse to the liver via the splenic and portal veins within a few minutes [14,17].

Integration of Hepatocytes After Transplantation

Integration of hepatocytes into a recipient liver is a complex process that requires the interaction of donor and native hepatocytes to form an integrated tissue. The process may be considered to take place in four steps (Table 16.2) [24–27]. Although they are presented as separate, there is considerable overlap of the steps in both time and space. Some of the most spectacular photographs of the entire process are provided by Koenig et al. [27]. After infusion into the portal vein, hepatocytes must traverse the endothelium to escape the vascular system. Although the liver has fenestrated endothelium, under normal conditions the pores, which are in the range of 150 nm, are far too small to provide a simple transit of parenchymal hepatocytes, which are 20–50 μm in size. Infusions of hepatocytes quickly fill the portal veins and embolize secondary and tertiary portal radicals [28]. Portal pressures increase as flow is restricted by hepatocyte plugs in the portal veins. Venograms that were normal before cell transplantation

TABLE 16.2 Integration of Donor Hepatocytes Into Native Liver After Transplantation

Remodeling of liver via modulation of extracellular matrix

become markedly attenuated and show greater filling of vessels proximal to the portal vein, including the mesenteric and splenic vein. If the number of hepatocytes transplanted is in the range of 5% of the total number of hepatocytes in the native liver, the portal hypertension is transient and resolves within minutes to hours.

A proportion of transplanted cells begin to fill sinusoidal spaces and the space of Disse as the endothelium in the region of the transplanted cells begins to degenerate. It is likely that both physical and humoral (growth factors and cytokines) factors are involved in this process. Microscopic analysis of tissue sections reveals that endothelium is breached in many places and donor hepatocytes leave the portal veins in regions where endothelium is incomplete and broken. Reports suggest that most hepatocytes that eventually integrate into recipient liver will have traversed the endothelial barrier by 24 h posttransplant. Cells that remain in the portal vessels are eventually removed by macrophages between 16 and 24 h posttransplant. Other reports suggest that cells may continue to integrate into parenchyma for 2–3 days after transplantation [29]. Transient hypoxia in the region of the occluded vessels leads to changes in the endothelium as well as both recipient and donor hepatocytes. Endothelium and donor and native hepatocytes all express vascular endothelial growth factor (VEGF) in the areas of hepatocyte integration [25,29], a factor known to be induced by hypoxia. It is interesting that VEGF was previously known as vascular permeability factor (VPF). Expression and secretion of VEGF/VPF, a potent angiogenesis factor, are thought to contribute to the reformation of new sinusoids and restoration of the endothelial barrier after cell transplantation.

Passage through the endothelial barrier allows donor hepatocytes to become integrated into recipient parenchyma. Full integration of donor hepatocytes and restoration of full hepatic function are difficult to ascertain. However, careful studies of the expression of antigens and activities localized to specific membrane fractions clearly demonstrate that donor hepatocytes fully integrate into the hepatic plate of native liver and for hybrid structures between native and donor cells within 3–5 days after transplantation. The antibody to CD26 recognizes the dipeptidyl peptidase IV (DPPIV) antigen, which is localized to the basolateral membrane of hepatocytes. Antibodies to connexin 32 can be used to visualize gap junctions between adjacent hepatocytes. Likewise, canicular adenosine triphosphatase (ATPase) activity can be used to identify bile canicular regions between adjacent hepatocytes. Proper localization of these different antigens and activities requires that the hepatocyte be fully integrated into the hepatic plate and polarized. By 3–7 days posttransplant, hybrid structures could be visualized in recipient liver containing both donor (DPPIV) hepatocytes and recipient ATPase activity [24] or donor DPPIV colocalized with connexin 32 [27]. Both studies clearly demonstrate proper integration of donor hepatocytes as well as the reestablishment of intracellular communication (connexin 32) between donor and recipient hepatocytes. Hybrid structures between donor and recipient hepatocytes were shown to be functional, as demonstrated by the transport and excretion of a fluorescent conjugated bile acid [24]. Hepatic transport of indocyanine and sulfobromophthalein into the bile after hepatocyte transplantation was also reported by Hamaguchi et al. [30]. Hepatocyte transplants were conducted on Eisai-hyperbilirubinemic rats. These animals have a defect in multidrug resistance protein-2, which prevents the normal transport of bile acid conjugates and their excretion into bile. This is a relevant animal model of metabolic disease because the condition is similar to Dubin–Johnson syndrome in humans. Correction of this transport defect by hepatocyte transplantation is definitive proof of the complete functional integration of donor hepatocytes into recipient liver.

As part of the integration process, there is significant remodeling of the hepatic parenchyma. Koenig et al. [27] reported the activation and release of matrix metalloprotease-2 (MMP-2) in the immediate area of donor cells. It is not clear whether the proteases are produced by the donor or recipient's cells, or even which cell type is the source of the protease, but the degradation of extracellular matrix components creates space for the donor cells and allows them to migrate from the circulation. Expression of MMP-2 was detected in and surrounding foci of proliferating donor hepatocytes 2 months after cell transplantation. Increased production and release of MMP-2 were also observed at the growth edge of nodules of fetal rat hepatocytes proliferating in adult liver after transplantation [31]. Whereas all of the components of the process are not completely understood, it is clear that hepatocytes can be transplanted into the vascular supply of the liver, breach the endothelial barrier, remodel and integrate into hepatic parenchyma, and establish communication with adjacent cells and the biliary tree, all within 3–5 days in a process of remodeling that completely retains normal host hepatic architecture.

CLINICAL HEPATOCYTE TRANSPLANTATION

Hepatocyte transplantation has been employed in clinics using three types of procedures (Table 16.3). Cell transplants were used to provide short-term liver support to patients who are dying of the disease before a suitable organ could be found. Because these patients were already listed for a whole-organ transplant, hepatocyte infusion was used, sometimes referred to as a "bridge" to transplant. A second use for hepatocyte transplants came from attempts

TABLE 16.3 Opportunities for Hepatocyte Transplantation

"Bridge" for patients to whole-organ transplantation
Cell support for acute liver failure
Cell therapy for metabolic disease

to bridge people to OLT. It was discovered that some patients receiving hepatocyte transplants recovered completely after the hepatocyte transplants and no longer required whole-organ transplant. The third general use for hepatocyte transplants is to correct metabolic liver disease. Each technique will be discussed separately.

Hepatocyte Bridge

With the bridge technique, hepatocytes are provided to a patient in acute liver failure or those experiencing acute decompensation after chronic liver disease. Most of these patients are already listed for OLT and are in danger of dying before a suitable organ can be found. Hepatocyte transplants have been conducted on these patients in an effort to keep them alive long enough to receive OLT. The primary goal of the bridge transplant is not to prevent whole-organ transplant, but rather to support and sustain the patient until an organ becomes available. Preclinical studies with several different models of acute or chronic liver failure have demonstrated that hepatocyte transplantation can support liver function and improve survival [32–41]. The results with human hepatocyte transplantation in the clinic also show an increase in the survival of patients after hepatocyte transplantation. Several reports and review articles provide details regarding patients and transplant procedures [9,11–13,42–47]. The results indicate that there is a 65% survival rate for patients receiving hepatocyte transplants. Although randomized control studies could not be conducted, preliminary results with approximately 25 patients indicate a survival advantage for patients receiving cell transplants. In addition to increased survival, there are consistent reports that clinical parameters such as ammonia levels, intracranial pressure, and cerebral blood flow improved after hepatocyte transplantation [12,42,43,46–49]. These results indicate that desperately ill patients who receive hepatocyte transplants are more likely to survive long enough to receive OLT than are the nontransplant controls.

Most patients who would be candidates for the hepatocyte bridge technique have chronic liver disease and advanced cirrhosis. Because of cirrhotic changes in the liver and accompanying portal hypertension, hepatocytes were not transplanted into the liver (portal vein) in most clinical studies. Preclinical studies were conducted where cirrhosis was induced in rats by administering phenobarbital and carbon tetrachloride [50]. When hepatocytes were subsequently transplanted into animals with increased portal pressures and cirrhosis, there was significantly greater intrapulmonary translocation of donor cells, presumably because of portosystemic shunting. These results suggest that serious complications could arise if portal infusion of hepatocytes were conducted on patients who had cirrhosis and portal hypertension. Indeed, shunting of transplanted hepatocytes to pulmonary vascular beds was reported in one clinical study [42]. To avoid this possible complication, Fisher et al. recommended that hepatocytes be transplanted into the spleen in cirrhotic patients via the splenic artery [43,47]. Despite the obvious success of the splenic artery route for hepatocyte transplantation, a report suggested that transplantation of hepatocytes by direct splenic puncture resulted in superior engraftment and fewer serious complications, although long-term engraftment was not studied [51]. Although the method for splenic delivery of cells may not be resolved, it is clear that in cases where physical and/or anatomic abnormalities are present in the native liver, the preferred route for hepatocyte transplantation is to an ectopic site, the spleen.

Promising results that have been reported suggest that hepatocyte transplantation is beneficial to patients experiencing severe hepatic insufficiency while awaiting OLT. A logical extension of these results might be to use hepatocyte transplants earlier in the process. Rather than wait until the patient is near death and with no immediate prospect for a whole-organ transplant, a more preemptive approach might be warranted. Hepatocyte transplants could be performed when patients awaiting OLT become unstable. This would presumably stabilize the patient and avoid or at least delay more serious complications of liver failure. Early intervention might avoid more costly hospitalization and other treatments.

Hepatocyte Transplantation in Acute Liver Failure

As described earlier, hepatocyte transplants have been used as a bridge to OLT. Most patients who have been referred for bridge transplants have already had chronic liver disease and cirrhotic changes in liver architecture.

There is a subgroup of patients referred for OLT who experience acute liver failure. In these patients there is massive loss of hepatocytes over a short time leading to hepatic insufficiency. Except for the dramatic loss of hepatocytes, there is no long-standing pathological change in liver architecture. Because the liver has the capacity for robust regeneration after loss of liver mass [1], there is considerable interest in trying to correct acute liver failure with hepatocyte transplantation. The hypothesis is similar to the bridge technique, in which hepatocyte transplantation is used to provide support at a time of critical and otherwise lethal liver failure. The expectation is that if the patient survives the acute loss of tissue mass, their native liver will regenerate. If the native liver regenerates, there will no longer be a need for OLT. An exogenous source of hepatocytes by transplantation would provide support of liver function to prevent lethal hepatic failure. Both donor and native hepatocytes would be expected to participate in the regeneration response. Once the native liver has been fully restored, there might not be a need for donor-derived hepatocytes. If the chimeric liver generated after the transplant is composed predominantly of native hepatocytes, the patient could safely be removed from immunosuppressive therapy. In this manner, the patient receives what amounts to a temporary liver cell transplant. If cell therapy is sufficient, the patient will be spared whole-organ transplantation and lifelong immunosuppression. Several preclinical studies support the hypothesis that hepatocyte transplantation can provide sufficient liver function to maintain an animal experiencing acute liver failure. Studies have shown that hepatocyte transplants dramatically improve the survival of animals with acute liver failure induced by D-galactosamine [37,39,40,52], 90% hepatectomy [35,36,38,53], or ischemic liver injury [41,54].

There are reports of the reversal of acute liver failure in four patients after hepatocyte transplantation [43,45,55,56]. The causes of acute liver failure ranged from hepatitis B—induced liver failure to acetaminophen intoxication, liver toxicity after eating poisonous mushrooms, and liver failure of unknown etiology in a pediatric patient. In each case, patients presented with classic symptoms of acute liver failure, and most were immediately listed for OLT. The number of cells transplanted varied for different procedures but ranged from approximately one to five billion total viable cells. In all cases, cells were transplanted into the portal vein to achieve a direct transplant into the liver. In general, patients were given fresh-frozen plasma before placement of the catheter to prevent bleeding. The results presented by Fisher et al. [55] are typical of the response to hepatocyte transplantation. There is usually a rapid fall in ammonia levels after the transplant. Circulating levels of clotting factors stabilize after the transplant and then slowly increase over the next 2 weeks. Fisher et al. reported that Factor VII levels were 1% of normal before the transplant and increased to 25% by 7 days and 64% of normal by week 2 after the cell transplant. Recovery of the clotting factors is usually rapid enough that after the cell transplant, no additional fresh-frozen plasma is required.

Patients are generally discharged within 2—4 weeks and are judged to experience a complete recovery. Cell transplant recipients ranged in age from 3 to 64 years, indicating that even older patients have sufficient regenerative capacity to be supported by hepatocyte transplantation.

As is observed with donor tissue allografts, hepatocyte allografts produce and secrete soluble human leukocyte antigen-I (sHLA-I) immediately upon implantation. If there is a mismatch between the donor and recipient, the donor-specific sHLA-I can be detected in the circulation and quantified by enzyme-linked immunosorbent assay. Donor-specific HLA class I alleles can be identified and quantified by polymerase chain reaction analysis of tissue samples taken at biopsy. When it is determined that the preponderance of cells in the patient's liver are native, the patient can slowly be removed from immunosuppressive therapy, as described by Fisher et al. [55]. In the cases that were described, patients recovered completely from liver failure after hepatocyte transplantation without serious adverse consequences and without whole-organ transplant and lifelong immunosuppression. Although the numbers of patients are small, treatment of acute liver failure by hepatocyte transplant has some significant advantages that make further investigation of this novel therapy appropriate (Table 16.3).

Hepatocyte Transplantation for Metabolic Liver Disease

A common indication for whole-organ transplantation in pediatric patients is metabolic liver disease. In these cases, there is usually a genetic defect in an enzyme or protein that is produced in the liver that inactivates a critical liver function. Although all other liver functions are generally normal, the liver is removed and replaced with a liver that can perform the missing function. Because usually only one genetic defect is associated with each metabolic liver disease, a gene therapy approach to correct the defect would seem appropriate. Unfortunately, gene therapy has met with considerable problems that have prevented successful use of this experimental technique. Hepatocyte transplantation has been used in attempts to correct metabolic defects associated with several types of metabolic liver disease (Table 16.4).

TABLE 16.4 Clinical Transplants for Metabolic Liver Disease

α1-Antitrypsin deficiency
Hereditary tyrosinemia type 1

In an approach similar to gene therapy, with hepatocyte transplants one tries to seed the patient's liver with cells that are proficient in the enzyme or function missing in the native liver. The goal is to repopulate the liver of the transplant recipient with sufficient numbers of hepatocytes to provide the missing liver function by donor cells.

Large numbers of hepatocytes cannot be infused into the portal system because of problems with embolism of the portal veins and portal hypertension. We have used as a general rule to infuse approximately 2–3 10^8 cells/kg body weight of the recipient [57,58]. Infusions of these cell numbers resulted in no long-term complications. There is always a transient increase in portal pressures that resolves within hours [45,46,57–61]. Although it is experimental, this number was arrived at by extrapolation from preclinical studies with nonhuman primates. Grossman et al. [62] reported that the infusion of 1–3 10^8 cells/kg into baboons that had previously received a left or right lobectomy was accomplished without serious complications and with only transient increases in portal pressures. Because only a few percentages of liver mass can be transplanted at any time, single hepatocyte transplants cannot be expected to replace a large percentage of liver with donor cells. For this reason, the metabolic diseases that are candidates for cell transplants are those in which the restoration of 10% of total liver function or activity is likely to correct the disease. The liver has highly redundant functions. Thus, it is recognized that 10% of a normal amount of gene product or enzyme activity would likely correct the symptoms of most metabolic liver diseases. For most metabolic liver disease and all of those listed in Table 16.4, it is believed that replacing the liver with 10% donor hepatocytes would either be completely corrective or at least ameliorate most of the symptoms of the disease.

In general, hepatocyte transplants work best when the donor cells have a selective growth advantage. There are a number of animal models of liver disease in which the native hepatocytes show an increased death rate compared with normal liver [63–66]. In these situations, when cells without the defect are transplanted into the diseased liver, the donor cells have a strong and selective growth advantage compared with the native hepatocytes. Over time the liver may become nearly completely replaced with donor cells. In certain human diseases, there might be sufficient selective pressure to favor the replacement of large parts of the liver strongly with donor cells. Such diseases include tyrosinemia type 1, Wilson disease [67], progressive familial intrahepatic cholestasis (PFIC) [63], and α1-antitrypsin deficiency [68]. In these diseases, integration of only a small proportion of liver mass by hepatocyte transplantation would likely be necessary because the donor cells would be expected to continue to proliferate in the host liver and over time replace the diseased cells. Although there are clear examples of this in studies of transplants of laboratory animals, no studies with human patients show comparable results.

Most metabolic diseases such as Crigler–Najjar syndrome (CN), OTC deficiency, and all of the diseases listed in Table 16.4 would not be expected to show such selective growth pressure for donor cells. For diseases such as these, multiple transplants over time will be required to populate the liver with 10% donor cells [69].

A large number of studies with different animal models have shown the efficacy of hepatocyte transplantation to correct metabolic liver disease (reviewed in Malhi and Gupta [10] and Strom et al. [13]. Metabolic defects in bilirubin metabolism [15,30,35,70–73], albumin secretion [16,18,69,74–76], ascorbic acid production [77,78], tyrosinemia type 1 [64], copper excretion [67,79,80], and PFIC [63], as well as other defects in biliary transport similar to Dubin–Johnson

syndrome in humans [30] have been shown to be amenable to correction by hepatocyte transplantation. These encouraging results suggested that similar defects in human patients could be corrected by hepatocyte transplantation. The diseases listed in Table 16.4 have been the focus of human trials of hepatocyte transplants.

Hepatocyte transplants were previously shown to result in the rapid correction of ammonia levels [12,42,45,47]. For this reason, urea cycle defects that result in life-threatening hyperammonemia were the first metabolic disease target for hepatocyte transplants [47,59]. In the initial study, one billion viable cells were transplanted into the portal vein of a 5-year-old recipient. Portal pressures increased from 11 cm of water before cell transplant to 19 cm immediately after the cell infusion but recovered rapidly. The patient's ammonia levels normalized without medical intervention within 48 h of cell infusion and glutamine levels returned to normal. Although OTC activity was undetectable before cell transplant, measurable OTC activity was detected in a biopsy performed at 28 days. In these studies, 10% of cells were labeled with indium^{111} before infusion into the patient to monitor distribution of the cells. Quantitative analysis of the scintigraphic images showed an average distribution ratio of liver to spleen of 9.5:1. Measurements made before cell infusion indicated that free indium was released from hepatocytes at a rate of 10% per hour, and free indium is rapidly cleared from the circulation by reticuloendothelial systems such as the spleen. Thus, most of the tracer in the spleen after cell infusion was thought to be free indium, not hepatocytes. Pulmonary radiotracer uptake was consistent with background counts, indicating the absence of portosystemic shunting despite the modest increase in portal pressures observed at the time of transplant. This first transplant for metabolic liver disease indicated that hepatocyte transplantation into the portal vein could be conducted safely in patients with no significant liver pathology with only a moderate and reversible increase in portal pressures. From the rapid normalization of ammonia levels after hepatocyte transplant, it was concluded that cell transplantation can partially correct the hyperammonemia associated with the disease. Subsequent studies verified that partial corrections of ammonia levels are possible by cell transplants alone [58,81–84]. Although complete corrections of OTC deficiency have not been accomplished, these studies indicate that cell transplants provide much-needed metabolic control of ammonia levels. Even in the absence of complete correction, liver cell transplantation should be considered a bridge to whole-organ transplantation for patients with OTC to prevent neurological problems associated with uncontrolled hyperammonemia [59,82–84].

A number of groups have attempted to correct CN syndrome type 1 with hepatocyte transplants. The first case was in typical many ways of results obtained by other groups and will be discussed in greater detail [57]. This disease is caused by a defect in the enzyme that is responsible for the conjugation and eventual excretion of bilirubin. Absence of the enzyme results in severe hyperbilirubinemia, which can lead to central nervous system toxicity including kernicterus. After the transplantation of approximately 7.5 billion cells into the liver of a 10-year-old girl, there was a slow and continuous decrease in circulating bilirubin levels over the first 30–40 days, and bilirubin conjugates were readily detected in the bile. Overall, there was approximately a 60%–65% decrease in bilirubin levels compared with pretransplant levels. Because the bilirubin conjugates could be produced only by the donor cells, their detection in the bile demonstrated the robust biochemical function of the transplanted cells and established that donor hepatocytes integrated into the hepatic parenchyma and quickly established connections with the recipient's biliary tree.

Several important findings were gained from this transplant. First, large numbers of hepatocytes could be safely transplanted into the portal vein without complication. Although the total numbers of hepatocytes in liver are difficult to assess, a transplant of 7.5 billion cells represents an estimated 3.5%–7.5% of the liver mass, which was transplanted without complication over approximately 15 h. Second, the apparent engraftment and function of hepatocytes in the clinical trials seemed to exceed that found in previous animal studies. The transplantation of 3.5%–7.5% of liver mass resulted in the restoration of approximately 5% of a normal amount of bilirubin conjugation capacity in the liver. Third, a long-term correction in bilirubin levels was observed. This patient was observed for more than 1.5 years. Fourth, single transplants of hepatocytes are effective in creating partial corrections of the disease but given the limitation of transplanting $2–3 \times 10^8$ cells/kg body weight, one cannot transplant sufficient numbers of hepatocytes to achieve complete correction of metabolic liver disease with one transplant. It is estimated that complete corrections would require two to four transplants if each were as successful and efficient as the first. Finally, this was the first unequivocal demonstration of the long-term success of hepatocyte transplantation. Although patients were bridged to transplant and clinical parameters such as ammonia levels rapidly changed after transplantation, for many of the previous patients who underwent subsequent OLT it was difficult to assess the long-term metabolic function of the transplanted cells. These studies firmly established that hepatocyte transplants were an effective means to correct metabolic liver disease. The results of hepatocyte transplants of other patients with CN largely confirm those seen with the first patient [81,85,86].

Muraca et al. [87] and Lee et al. [87a] reported partial correction of glycogen storage disease type 1 after hepatocyte transplantation. Improvement was documented by the patient's ability to maintain blood glucose between meals as well as sustained and higher glucose levels with meals. Sokal et al. [61] employed hepatocyte transplants to achieve a partial correction of infantile Refsum disease, an autosomal recessive inborn error in peroxisome metabolism of very long chain fatty acid metabolism, bile acid, and pipecolic acid. The authors reported improvement in fatty acid metabolism and a reduction in circulating pipecolic acid and bile salt levels. An overall improvement in the health of the patient was evident by the report of a significant increase in muscle strength and weight gain. Dhawan et al. [81] reported that hepatocyte transplantation partially corrected a severe deficiency in the production and secretion of coagulation Factor VII. After cell transplant, the Factor VII requirement decreased nearly 80% of that administered before heart transplantation. Stephenne et al. [88] reported the complete correction of a 3.5-year-old female patient with neonatal onset argininosuccinic lyase (ASL) deficiency. Like OTC deficiency, patients with ASL deficiency are at risk for brain damage from hyperammonemia. The patient received three sequential hepatocyte transplants over 5 months. Both freshly isolated and previously cryopreserved hepatocytes were used. At 1 year after transplant, the patient displayed 3% of normal ASL activity in hepatic biopsy samples. Engraftment of donor cells could be demonstrated by fluorescence in situ hybridization for Y chromosomes. These results confirm that hepatocyte transplantation can achieve sustained engraftment of donor cells and sustained metabolic and clinical control.

HEPATOCYTE TRANSPLANTATION NOVEL USES, CHALLENGES, AND FUTURE DIRECTIONS

Hepatocyte Transplants for Non–Organ Transplant Candidates

Most patients who have received a hepatocyte transplant were already listed for a whole-organ transplant. The need for liver support is not limited to this group. There are large numbers of patients for whom OLT is not an option. Patients in this group could include alcoholic cirrhotic patients who have not met the required abstinence period, acute liver failure patients resulting from suicide attempts, and patients with cancer. Early case reports suggested that hepatocyte transplants into the spleen could be useful to restore liver function to end-stage cirrhotic patients [12]. Although both of the patients in the reported study eventually died of concomitant renal failure that was left untreated, the patients sufficiently improved after the cell transplants to the point where they were able to be discharged from the hospital. Fox and coworkers created an animal model to study the efficacy of hepatocyte transplants to support liver function in cirrhosis in a more controlled setting. Their studies clearly demonstrated that hepatocyte transplants significantly improve liver function and survival of rats experiencing chronic liver failure after repeated injections of carbon tetrachloride [32,89,90]. Because millions of patients are currently infected with hepatitis viruses, there is clearly a need for additional means to support liver function in these patients. Notwithstanding the difficulties of such clinical studies in cirrhotic patients, cell transplantation should be thoroughly evaluated as a possible support therapy.

In addition to cirrhotic patients who may not be candidates for OLT, there are metabolic liver diseases such as phenylketonuria (PKU) that are not currently referred for OLT. Although some still believe that diseases such as PKU can be adequately controlled by diet, there is evidence of continued and progressive mental deterioration in most patients treated with diet alone. It is likely that cell therapy with hepatocytes would improve the control of phenylalanine levels in these patients. Severely affected patients with PKU and those not controlled well by diet alone should be given serious consideration for inclusion in hepatocyte transplant protocols, because it seems that the benefits would likely outweigh the risks for these individuals [91]. Reports confirm that serum phenylalanine levels were significantly reduced after hepatocyte transplants [92,93].

An important factor preventing the use of hepatocyte transplants in additional medical centers is the limited availability of hepatocytes. The normal source of cells for hepatocyte transplants are livers with greater than 50% steatosis, vascular plaques, or other factors that render the tissue unsuitable for whole-organ transplantation [2,42,45–47,55,57,58,87,94–96]. Better use of existing liver tissue could increase the numbers of hepatocytes available immediately. In the United States, no regulations require donor organs to be allocated to transplantation research centers for hepatocyte isolation, and relatively few organs go to centers where hepatocyte transplant is a possibility. Most organs that are not used for whole-organ transplant are provided to commercial firms where hepatocytes are isolated for resale or for in-house metabolism and toxicology studies. Although most uses of donor liver tissue have merit, simple allocation procedures could be instituted to route the organs to transplant centers for initial review and

selection of the most suitable cases for cell isolation. Split-liver procedures have made it possible to use caudate lobe and segment IV for hepatocyte isolation. Depending on the surgical procedure, these portions of liver tissue may remain untransplanted and have been shown to be useful for hepatocyte isolation [3]. Although currently not widely applied, most livers that are currently transplanted could be split. A portion such as the left lateral segment could be made available for cell isolation while the remaining liver tissue is used as a tissue graft. Because hepatocyte transplantation is not currently the standard of care, such proposals are not currently feasible. However, if the efficacy of hepatocyte transplants were firmly established, the risk and extra time needed for the split procedure would be outweighed by the benefit of the cell transplants. Cell transplants rather than OLT could free up the organs that are now used for acute liver failure and metabolic disease patients.

Methods to Improve Engraftment and Repopulation

Hepatocyte transplants will not be able to progress past the small numbers of patients who are being transplanted until sufficient numbers of hepatocytes become available or engraftment and repopulation are significantly improved [96]. It has become evident that pretreatment of the native liver of the transplant recipient to induce regeneration and proliferation of donor hepatocytes may be needed before hepatocyte transplantation. Most pretreatment conditioning regiments used in studies with experimental animals are too hazardous to be applied in a clinical setting. The two most common approaches that have been suggested are portal embolization and hepatic irradiation [97–99,99a]. The theories and literature on these techniques are widely available and will not be presented here. There is another technique, partial hepatic resection, more commonly called partial hepatectomy, that is commonly used in experimental animals and that has been introduced in clinical hepatocyte transplantation [86]. Because of improved techniques and instruments and increased activities at experienced centers, liver resection and living donor liver transplantation are now common procedures. With today's advanced surgical techniques and in the hands of surgeons with considerable experience with reduced grafts and split livers, partial liver resection would likely be as safe as portal embolization and hepatic irradiation and should also be considered a possible pretreatment for hepatocyte transplantation. A partial resection for tissue collection for cell isolation is a much simpler and safer surgical procedure than those routinely performed in the clinic today. Partial liver resections are most commonly performed to remove malignancies or during living donor transplant procedures. When performing a surgical procedure for tumor removal, the amount of tissue and the location of the procedure are dictated by the location of the tumor(s). Likewise, in the case of living donor liver graft removal, the surgeons need to consider preserving vessels as well as minimizing ischemia injury to the graft during surgery.

Removal of liver tissue for cell isolation will be much safer because the only concern for the surgeon will be the safety of the patient. Because the resected liver tissue will not be used as a tissue graft, the surgeon will not be concerned about the vessels in the resected tissue. Cell isolation on resected tissue can be conducted through a number of portal or hepatic vessels; thus, concern regarding maintaining appropriate hepatic artery, portal vein, and biliary flow patterns in the resected tissue is removed. The amount and exact location of the tissue to be removed can be dictated by the surgeon and performed in the safest, fastest, and easiest way. Although there are risks associated with both the surgery and anesthesia, risks associated with liver resection as a tissue source for cell isolation would likely be much lower than for living donor liver transplantation. As example, in a report of 100 donor resections from one center, no life-threatening complications occurred [100]. Hepatectomy before hepatocyte transplantation was already performed in a series of patients transplanted for familial hypercholesterolemia in 1992–1994. Those patients underwent left lateral hepatectomy to harvest tissue for hepatocyte isolation and subsequent retroviral transduction of the low-density lipoprotein receptor [101]. Transplantation of transduced autologous hepatocytes was performed on day 3 after the operation. The surgical safety of this procedure was thoroughly studied and reported to have no major complications [102].

A point that remains unanswered is to what extent hepatectomy will generate a sufficient signal to improve the engraftment or proliferation of transplanted hepatocytes. The timing of the transplantation after hepatectomy might also be important. Efimova et al. measured serum growth factors in healthy individuals after living related liver donation and showed that hepatocyte growth factor (HGF) increased 12-fold at 2 h postoperation and thereafter stabilized at a threefold higher level compared with preoperation for an additional 5 days [103]. Other growth factors such as VEGF and epidermal growth factor (EGF) did not change significantly and transforming growth factor-α (TNF-α) was not detected at all. These results were confirmed in two clinical cases of hepatocyte transplantation for CN type I. Partial hepatectomy of the left lateral section was performed immediately before hepatocyte infusion. Partial hepatectomy and hepatocyte transplantation was associated with a strong increase in serum HGF and EGF whereas TNF-α remained unchanged. These data suggest that partial hepatic resection could provide a significant

stimulus to donor hepatocytes and that the effect would last at least 5 days. Taken together, these data suggest that partial hepatic resection could be a safe and effective pretreatment to hepatocyte transplantation.

Cell Transplantation Immunology

The liver has tolerogenic properties and initially it was believed that only minimal immunosuppressive therapy was necessary in clinical hepatocyte transplantation. However, clinical experience has shown that immunosuppressive treatment is essential to avoid allograft rejection. However, there is no consensus or convincing evidence regarding the optimal immunosuppressive protocol. Most centers have adopted the same immunosuppressive protocol used for liver transplantation, including induction treatment with corticosteroids and maintenance therapy with calcineurin inhibitors, tacrolimus or cyclosporine, mycophenolate mofetil, and corticosteroids. Corticosteroids have to be used cautiously in patients with urea cycle disorders owing to their catabolic effect with a risk to induce crisis. Some centers have also added induction therapy with basiliximab or antithymocyte globulin.

Tailoring an optimal immunosuppressive treatment in clinical hepatocyte transplantation is challenging for the following reasons. No universal and reliable marker of graft function exists. In clinical liver transplantation, several simple liver function tests easily analyzed from a blood sample can exactly define liver allograft function. However, these tests are not useful in clinical hepatocyte transplantation because the hepatocyte graft usually comprises only 2%–10% of the liver mass. Furthermore, no good markers exist for allograft rejection. In clinical liver transplantation, these liver function tests are good markers of allograft rejection and histological analysis of a liver biopsy confirms the diagnosis. However, liver biopsy is not useful in hepatocyte transplantation because the procedure is invasive and has a high sampling error. Finally, knowledge is limited about the mechanism of hepatocyte allograft rejection.

Immunological studies in mouse models of hepatocyte transplantation have shown that allograft rejection is a T cell–mediated process and that humoral immunity is only minimally stimulated [104,105]. In contrast to liver allografts, which are mildly immunogenic or even tolerogenic, the allogenic hepatocytes are strongly antigenic and probably also resistant to the mechanism of allograft tolerance.

Clinical experience has confirmed that hepatocyte allograft rejection is associated with a T cell–dependent mechanism. Allen et al. [106] showed that hepatocyte allograft loss in a patient with CN type I was associated with a cellular alloresponse directed against donor class I HLA without detection of HLA antibodies. In contrast, Jorns et al. [106a] reported the appearance of de novo donor-specific HLA antibodies associated with hepatocyte allograft loss in two patients with CN. Soltys et al. [92] reported a potential noninvasive marker of hepatocyte allograft rejection. Blood analysis of allospecific CD154-positive T-cytotoxic memory cells was studied as an early marker to predict acute rejection in pediatric patients after liver, kidney, and multivisceral transplantation. In clinical hepatocyte transplantation, this assay was able to predict allograft rejection in two patients with urea cycle disorders.

Besides these mechanisms of adaptive immunity, a large proportion of transplanted hepatocytes may be destroyed by an immediate innate immune reaction. An innate immune reaction, the instant blood-mediated immune reaction, has been described in clinical hepatocyte transplantation. When in contact with blood, the expression of tissue factor on the surface of hepatocytes activates the coagulation cascade and complement system, resulting in clot formation and infiltration of leukocytes, finally destroying a major proportion of transfused hepatocytes [107,108]. Current immunosuppressive treatment protocols only partially prevent this immediate destruction. However, the addition of *N*-acetylcysteine, heparin, or low–molecular weight dextran sulfate has the possibility of ameliorating this reaction [109].

Stem Cells and Alternative Cell Sources for Liver Therapy

In addition to attempts to improve engraftment and repopulation of the liver, alternative cell sources for hepatocytes have been proposed. Xenotransplants [90], immortalized human hepatocytes [36,89,110,111], and stem cell–derived hepatocytes [112–116] and fetal hepatocytes have been proposed as alternative sources of cells for clinical transplants. To date, no alternative cell source has been found that meets all of the requirements for safety and efficacy. There is great interest in stem cell–derived hepatocytes and the possibility that they might become a future source of cells for clinical transplantation.

Proponents for the use of stem cells suggest that because of their wide availability and small size, stem cells could be a feasible and efficient alternative to hepatocytes for cellular therapy [117]. Although it is true that once generated, stem cells should be available in sufficient numbers for transplant protocols, it is not clear whether the small size of the stem cells would actually favor engraftment and repopulation of target organs. It is pleasing to speculate that the relatively low levels of engraftment of mature hepatocytes after transplant result from their large diameter, and that

the 50%–90% of transplanted hepatocytes do not engraft because they temporarily obstruct and become trapped in portal veins or hepatic sinusoids. However, obstruction of the portal vessels and hepatic sinusoids and transient increases in portal pressure may actually be necessary steps in engraftment into the liver parenchyma. Smaller, stem cell–derived, hepatocyte-like cells may actually engraft less effectively than mature hepatocytes. When examined in transplant models, smaller hepatocytes or hepatocyte-like cells were usually less effective than larger or more mature hepatocytes [13,118–120]. Sharma et al. [121] directly examined and compared the engraftment and proliferation of mouse embryonic stem cell (ES)-derived, hepatocyte-like cells and mature hepatocytes in the $FAH^{-/-}$ mouse. The $FAH^{-/-}$ is a robust model of metabolic liver disease in which transplanted donor ($FAH^{+/+}$) hepatocytes are under strong positive growth selection leading to rapid and effective repopulation of the disease mouse liver. Mouse ES-derived cells with hepatic features were found to engraft less efficiently compared with mature hepatocytes and showed limited capacity for repopulation and tissue formation.

Of the cell types most often suggested to become a source of cells for clinical transplants, ES and induced pluripotent stem cells (iPS) may hold the greatest promise for future therapy. However, to move this potential therapy to the clinics, two significant roadblocks have to be overcome: efficient and effective hepatic differentiation of the stem cells and removal of the tumorigenic potential of the transplanted cells. To date, neither condition has been met. No published protocols are efficient or effective enough to produce large numbers of mature human hepatocytes that could be used immediately for transplants. The problem of tumor formation from cells in the population that did not undergo hepatic differentiation and the possibility that differentiated hepatocyte-like cells could regress back to undifferentiated stem cells after transplantation will have to be overcome before either ES or iPS cells could be considered for clinical protocols. Also, as stated earlier, ES-derived, hepatocyte-like cells demonstrated limited capacity for liver tissue formation after transplantation compared with mature hepatocytes. Thus, much more basic research will be required before ES or iPS-derived hepatocytes are ready for the clinics.

Cell types that are currently in clinical practice and could potentially be available for cellular therapy are those from bone marrow and mesenchymal stromal cells (MSC). After the initial publication of Petersen et al., there was great excitement about the possibility that bone marrow cells might serve as a source of hepatocytes to correct liver disease [122]. Subsequent detailed work suggested that cell fusion is the principal source of bone marrow–derived hepatocytes observed in the experimental model [123]. Although there is still controversy regarding this issue, the bulk of data suggests that bone marrow is not the source of progenitor cells in the liver [124,125] and there is little evidence for the conversion of hematopoietic cells to hepatocytes in vivo in experiments with animals [126,139] or in a clinical setting [127]. When the presence of X and Y chromosomes was analyzed in liver biopsies taken from sex-mismatched liver transplant recipients (eight female to male and five male to female), the recipient-specific sex chromosome pattern was detected only in the inflammatory cells but not hepatocytes [127]. This study had a transplant to biopsy interval of 4.5 years (range, 1.2–12 years) and the authors concluded that recipient engraftment of stem hematopoietic cells is an infrequent feature in long-term grafts. Thus, bone marrow cells may not be a relevant source of hepatocytes for the treatment of liver disease.

The same cannot be said for human amnion epithelial stem cells (hAE). Whereas hAE have many of the properties that are thought to be useful in MSC, such as the ability to modulate the immune system, enhance tissue regeneration, and a lack of tumorigenicity, hAE have additional properties that make them more useful than MSC for the treatment of liver disease. Because hAE are an epithelial tissue like the liver, they do not have to cross a germ layer boundary to become hepatocyte-like cells. There is little evidence of mature liver gene expression in MSC even when transplanted into the liver, but there is good evidence that hAE cells differentiate to cells that express mature liver genes at levels that are observed in normal human liver [116], and hAE transplants have shown substantial efficacy in correcting animal models of metabolic liver disease such maple syrup urine disease and PKU [128,129]. In addition to correcting metabolic liver disease effectively, hAE reversed otherwise lethal acute liver failure in mice; and because of their immunomodulatory properties and production of HLA-G, it may be possible to transplant hAE cells into patients without using immunosuppressive drugs [129,130].

MSC isolated from a variety of tissues including cord blood, skin, and human liver have been proposed as a source of hepatocytes for transplantation. There are numerous reports of mesenchymal cells adopting hepatic features when cultured under specific conditions or upon transplantation in vivo. Several groups have reported the expression of hepatic genes and proteins normally expressed in the liver such as albumin, α1-antitrypsin, α-fetoprotein, fibrinogen, glycogen, and even some more mature hepatic markers such as drug-metabolizing genes including CYP3A4 [131–134]. In all cases, when the level of expression of hepatic genes and their functions was measured it was low compared with authentic human hepatocytes. The use of MSC as a source of hepatocytes may depend on their ability to differentiate to cells with a mature hepatic phenotype upon transplantation. When examined

carefully, after transplantation into the mouse liver human cord blood mononuclear cells resulted in small clusters of hepatocyte-like cells that expressed human albumin and Hep Par, a marker protein found in hepatocytes; however, the cells also expressed mouse cytokeratin 18, which suggested that the clusters of hepatocyte-like cells were the result of cell fusion with endogenous mouse hepatocytes [135]. There is not yet convincing evidence that MSC can differentiate to cells with a broad range of mature hepatic functions.

Although there is little substantial evidence that bone marrow or MSC from different sources form mature hepatocytes in vitro or in vivo, there is growing evidence that these cells may improve liver function when they are infused into patients with cirrhosis. A remarkable article by Sakaida et al. reported that the intravenous transplantation of bone marrow cells reduced liver fibrosis in a model of cirrhosis induced by treating mice with chemokine ligand 4 [136], which eventually led to the proposal to use autologous bone marrow therapy for liver cirrhosis [137]. Several groups soon began phase I safety and feasibility studies with bone marrow cell infusions in cirrhotic patients. Most studies have been uncontrolled investigations of the infusion of bone marrow−derived mononuclear cells [138,139] or CD34-selected cells [140−144]. In most of the studies, granulocyte−colony-stimulating factor (G-CSF) was used to mobilize CD34-positive cells. Cells were delivered through a peripheral vein or infused directly through a hepatic artery. The most common findings were a slight improvement in liver function as measured by a small decrease in bilirubin levels, which was usually accompanied by a small increase in serum albumin levels. Improvements in the Child−Pugh and/or the Model for End-Stage Liver Disease (MELD) scores were also frequently reported [140,142−144]. In one study, bone marrow−derived MSC rather than CD34-positive or unfractionated bone marrow mononuclear cells were infused via a peripheral vein, with similar results [145]. The authors observed an increase in mortality and other complications when the MSC were infused into the hepatic artery of patients with decompensated cirrhosis rather than via a peripheral vein.

In a controlled trial, a minimum of 1×10^8 mononuclear cells from bone marrow aspirates (without G-CSF pretreatment) were infused through the hepatic artery of patients with cirrhosis [146]. Fifteen patients were randomized to each arm of the study. The results indicated that the Child−Pugh score improved in the cell therapy group relative to the controls. The MELD score remained stable in patients receiving the cell therapy, whereas in the control group, the MELD score increased. Serum bilirubin levels were also improved in the treated group. The improvements noted in the different end points were significant for only 90 days. The clinical findings suggested that slight improvements in hepatic function as measured by bilirubin and albumin levels, MELD, or Child−Pugh scores were obtained after the transplantation of bone marrow mononuclear cells or partially purified CD34-positive cells. It is comforting that similar findings were obtained with different protocols and by different groups. What is not clear from these initial studies is the most useful cell type to transplant and the best route of delivery. Perhaps sustained improvements in liver function could be obtained if these parameters were optimized.

With the exception of bone marrow or bone marrow−derived stem cells, other stem cell sources have not been employed to treat liver disease. Much more research will have to be conducted before cell types such as ES or iPS could be approved for clinical trials. Adult stem cells do not seem to show sufficient engraftment, proliferation, and differentiation to hepatocytes to warrant clinical trials with any of the cell types. Human amnion epithelial cells have shown a substantial ability to differentiate to hepatocyte-like cells and correct metabolic liver disease and acute liver failure and are being translated to the clinic to treat patients. However, until hAE are approved for transplant, authentic hepatocytes remain the preferred cell type to treat liver disease. Future work with hepatocyte-based therapy will need to focus on improving the engraftment and/or proliferation of donor cells posttransplant. Even two- to fourfold increases in liver repopulation by hepatocytes over the levels obtained with current transplant procedures could lead to substantial improvement in the clinical outcome of patients with liver-based metabolic diseases. It is likely that incorporating preconditioning regimens with hepatic resection [86], ischemia-reperfusion injury, and/or radiation-induced blockage of the growth of native liver [92] will provide the selective growth advantage to the donor cells required to attain the levels of liver repopulation required to normalize alterations observed in patients with metabolic disease. Because these types of studies are being conducted at medical centers around the world, the efficacy of these modified protocols should soon be apparent.

SUMMARY

Hepatocyte transplantation studies conducted in animal models of liver failure and liver-based metabolic disease have proven to be safe and effective means to provide short- or long-term synthetic and metabolic support of liver function. For certain organ transplant candidates such as those with metabolic liver disease, cell transplantation alone could provide relief of clinical symptoms. Cell transplant studies in patients with acute or chronic liver failure

or genetic defects in liver function clearly demonstrate the efficacy of hepatocyte transplantation to treat liver disease. In virtually all cases, a clinical improvement in the condition of the patient could be documented. Although all of the initial reports concerning hepatocyte transplants are encouraging, it must be realized that there are still no reports of long-term and complete corrections of any metabolic disease in patients. The report of a complete correction of a patient with a urea cycle defect is encouraging; however, the length of time that human hepatocytes will function after transplantation has not been determined. Studies in animal models of liver disease have documented that donor hepatocytes transplanted into the spleen or the liver function for the lifetime of the recipient and participate in normal regenerative events. Although it is likely that human hepatocyte transplantation will result in lifelong and normal function of donor cells, this needs to be clearly demonstrated in a clinical study.

Future work will have to be conducted to establish optimal transplant and immunosuppression protocols to minimize complications and maximize engraftment and function. A major problem for clinical hepatocyte transplant is the inability to track donor cells after transplantation. Except for the short-term tracking of hepatocytes prelabeled with radioactive substances such as indium^{111} [59], and following differences between donor- and recipient-secreted HLA [55], there are no reports of quantitative and facile methods to detect donor cells. Relatively noninvasive methods will be needed to optimize transplant and immunosuppressive protocols as well as for daily monitoring of the cell graft. None of the problems cited here seem insurmountable. There are reports of successful hepatocyte transplants from laboratories in many different countries. The cooperative spirit that has developed among investigators in the different transplant centers should benefit the research field and especially future recipients of hepatocyte transplants.

Cardiac Stem Cells: Biology and Therapeutic Applications

Konstantinos E. Hatzistergos, Sarah Selem, Wayne Balkan, Joshua M. Hare

University of Miami, Miami, FL, United States

The heart, which was previously considered a prototypic terminally differentiated and postmitotic organ, is now known to retain reservoirs of undifferentiated cardiovascular precursors and mitotic cardiomyocytes throughout adult life [1,2]. Multiple classes of precursor cells with the ability to contribute to adult cardiomyocyte turnover have been described, including postnatal remnants of bona fide embryonic heart lineages [3–5], multipotent circulating cells of noncardiac lineage [6], and adult cardiovascular progenitors generated de novo by reprogramming mature cardiac cells to a multipotent state [7,8]. The cardiac precursor and cardiomyocyte mitosis pathways remain fully operational up to the neonatal stage before becoming idle and limited in their ability to support regeneration in response to damage [9–12]. Cell-based therapeutics offers a promising strategy to overcome this limitation and induce regeneration in the diseased heart. It falls into two basic categories: (1) direct remuscularization and (2) stimulation of endogenous repair. In the first category, engraftment of billions of laboratory-grown cardiomyogenic cells derived from embryonic stem cells (ESCs) or induced pluripotent stem cells (iPSCs) is tested as an approach to remuscularize and revascularize a myocardial scar directly. In the second category, transplantation of cardiac and extracardiac adult multipotent stem cells aims to stimulate endogenous mechanisms of repair, which include the upregulation of cardiac precursors and cardiomyocyte mitosis, to induce regeneration. In this chapter, we review the biology of cardiac myogenesis in relation to cell-based therapeutics.

DEVELOPMENT OF THE HEART FROM CARDIAC STEM/PROGENITOR CELLS

Mammalian cardiogenesis involves the synchrony of function among a diverse population of cells that comprise the heart: atrial/ventricular cardiomyocytes, smooth muscle cells, endothelial cells, epicardial cells, conduction system cells, autonomic nerves, valvular components, and connective tissue [13,14]. The specification and differentiation of these cell lineages depend on spatially and temporally controlled developmental steps [15,16]. Four cardiac anlagen (the primary heart field [FHF], secondary heart field [SHF], and proepicardial organ [PEO], which are of mesodermal lineage; and the ectodermal lineage-derived cardiac neural crest [CNC]) are the principal sources of cardiovascular progenitor cells. Essentially, they are responsible for the development of the various cardiac structures [17–21].

The FHF and SHF lineages are specified before gastrulation, in the posterior epiblast of the early primitive streak embryo [22,23]. The epiblast, or primitive ectoderm, is the primitive cell layer from which all three germ layers (ectoderm, mesoderm, and endoderm) are derived during gastrulation. The primitive streak is the grooved structure that forms at the most proximal region of the posterior midline of the epiblast. The cardiogenic mesoderm gastrulates as the precardiac cells from the posterior epiblast ingress through the primitive streak [22,23]. This process involves the epithelial-to-mesenchymal transition of precardiac epiblast cells, mediated by the transient induction of the T-box transcription factors Brachyury and Eomesodermin, followed by expression of the mesoderm posterior 1 (*Mesp1*) gene. Precursors of the cardiogenic mesodermal progenitors express Mesp1, but the expression of this gene is downregulated upon formation of the cardiac crescent. At this stage in development, progenitors

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00017-5

irreversibly commit to the cardiac lineage, expressing the LIM-homeodomain transcription factor NK2 transcription related, locus 5 (*Nkx2-5*) [22].

A tetracycline-inducible, genetic lineage-tracing approach in mice carrying a Mesp1-rtTA transgene indicates that the FHF originates from an early wave of Mesp1$^+$ progenitors in the anterior splanchnic mesoderm and forms the Nkx2-5$^+$ cardiac crescent, from which the cells migrate medially to form the linear heart tube [24]. Ultimately, the FHF contributes to left ventricle and atria formation [17,21,25]. The SHF originates from a late wave of Mesp1$^+$ progenitors in the pharyngeal mesoderm medial to the cardiac crescent and lies anterior and dorsal to the linear heart tube. Ultimately, the SHF contributes to the right ventricle, outflow tract, and atrial tissue formation, accounting for two-thirds of the cells in the heart [17,21,25]. Although not all genetic markers unique to the FHF and SHF have been identified, some transcription factors and signaling molecules are known to characterize each population. Both are marked by Nkx2-5, but the FHF progenitors are distinguished by T-box transcription factor Tbx5 and basic helix-loop-helix transcription factor Hand1, whereas the SHF progenitors are distinguished by Hand2, Isl1, and Fgf10 [17,26,27]. Although a retrospective clonal analysis in the mouse embryo suggested the FHF and SHF progenitors originate from a common precursor [25], further investigations must be pursued to determine whether the FHF and SHF progenitors stem from a single precursor or perhaps a subset of precursors. As mentioned previously, the FHF and SHF are governed by both shared and distinct genetic programs. Overall, Nkx2-5 and GATA transcription factors mark the FHF progenitor population and Isl1, Foxh1, and Mef2c mark specialization of the SHF progenitors. However, the transcriptional control that comes with the lineage segregation is still uncertain.

The PEO organ, a cauliflower-like structure that arises at the inflow region of the looping primordial heart [28–30], arises from an early wave of Mesp1$^+$ progenitors, which are thought to be distinct from the FHF/SHF-forming Mesp1$^+$ cardioblasts [24]. Whether the Mesp1$^+$ cells of PEO lineage are also prespecified in the epiblast is not known [23]. The PEO progenitors will ultimately develop into the epicardium, a layer of cells that delineate the outer layer of the primordial heart and contribute to the development of the coronary vasculature, myofibroblasts, and other epicardial cells [31–34].

CNC cells are a population of vertebrate-specific, extracardiac, migratory multipotent progenitor cells of neuroectodermal lineage (Mesp1-negative), which arise transiently from rhombomeres 6 and 7 at approximately Carnegie stage 12 in humans [35]. The role of CNC cells in mammals is diverse. Part of their function is to contribute to cardiac and aorticopulmonary septation, valvulogenesis, and autonomic neurogenesis [36]. The traditional view is that neural crest cells are specified during neurulation through an epithelial-to-mesenchymal transition at the roof plate of the neural tube, the site where the surface ectoderm converges with the neural ectoderm. However, lineage-tracing experiments in chick embryos suggest that, similar to the mesoderm, specification of the neural crest lineage is independent of neurulation and starts before gastrulation in the epiblast, bilaterally to the Hensen node, about 300 μm from the primitive streak [37]. Intriguingly, transplantation of quail-donor Hensen node cells to precardiac and nonprecardiac regions of chick host epiblast indicates that neural crest cells may contribute to cardiogenesis [22]. Similarly, fate-mapping studies in fish and mice also indicated that about 10% of cardiac myocytes are developmentally derived from the CNC [3,38–40].

CARDIAC STEM/PROGENITOR CELLS IN THE ADULT HEART

Although the adult heart was traditionally thought to be a postmitotic and terminally differentiated organ, a number of studies indicate that cardiac myocytes regenerate continuously throughout the adult life, albeit at a seemingly slow pace (Fig. 17.1) [1,2,41]. Cardiomyocyte renewal occurs either via division of preexisting cardiomyocytes [1,41,42] or via pools of undifferentiated cardiac progenitor cells [41,43,44]. Some of these progenitor cell types are thought to be remnants of the embryonic cardiac progenitor cell programs, although their exact lineage relationships and plasticity remain unclear.

c-Kit$^+$ Cardiac Progenitor/Stem Cells

Beltrami and colleagues provided the first evidence of cardiac progenitor/stem cells residing within the adult heart [45,46]. These investigators described niches of stem/progenitor cells within the adult heart, identified by the expression of the proto-oncogene c-Kit on their cell surface [45,46]. c-Kit$^+$ cardiac stem cell (CSC) niches reportedly reside throughout the ventricular and atrial myocardium but have a higher density in the ventricular

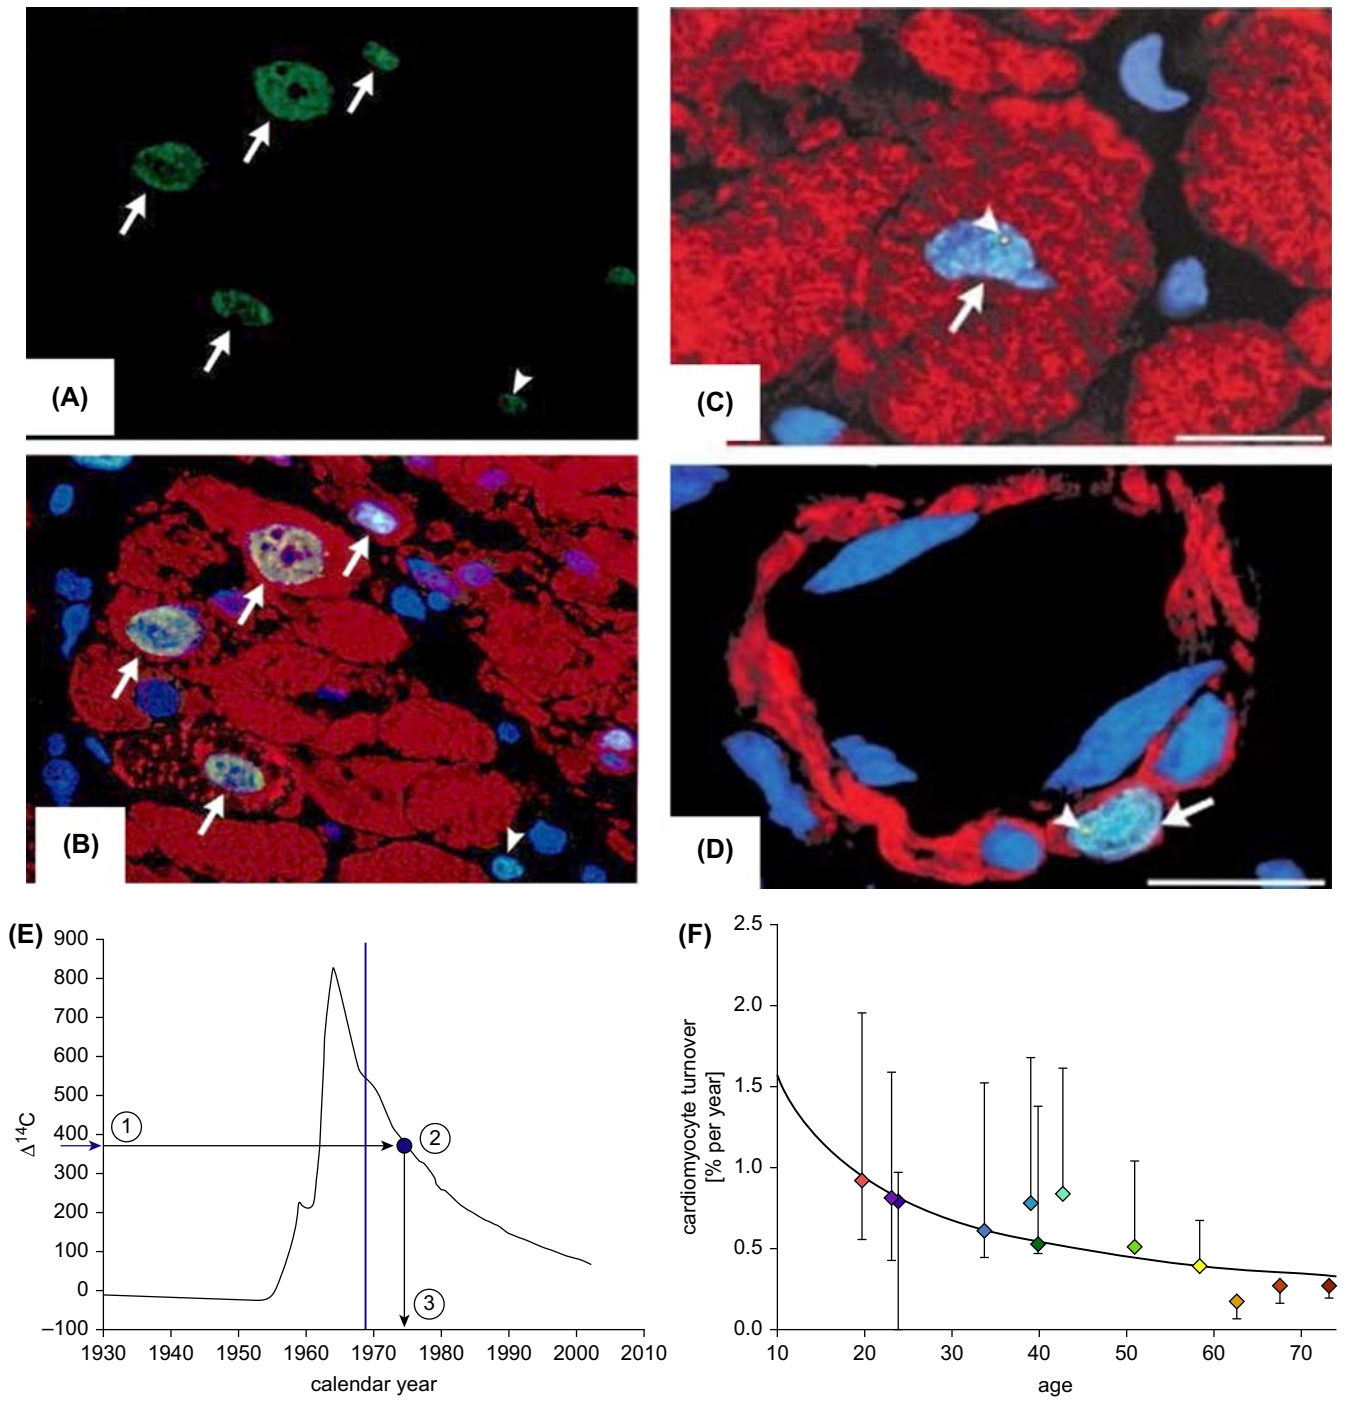

FIGURE 17.1 **Cardiomyocyte renewal in adult humans.** (A, B) By analyzing the presence of the cell proliferation marker Ki67 in adult human hearts, Beltrami and colleagues provided strong evidence that human cardiomyocytes divide throughout adulthood and in response to ischemic damage. Arrows point to cycling cardiomyocytes in an infarcted human heart, identified by confocal immunofluorescence for Ki67 and the cardiomyocyte marker α-sarcomeric actin. (C, D) By examining postmortem cases in which male patients received heart transplants from female donors, Quaini et al. detected a high level of cardiac chimerism caused by the migration of Y chromosome–bearing primitive cells from the recipient to the grafted heart. Putative stem cells and progenitor cells were identified in control myocardium and in increased numbers in transplanted hearts. Arrows point to a Y-chromosome^{+} cardiomyocyte (C) and coronary vascular cell (D) in a female heart transplanted into a male recipient. (E, F) Bergmann and colleagues took advantage of the integration of 14C, generated by nuclear bomb tests during the Cold War, into DNA to establish the age of cardiomyocytes in humans (E), and found that cardiomyocytes renew, with a gradual decrease from 1% turning over annually at the age of 20% to 0.3% at age 75; overall, less than 50% of cardiomyocytes are exchanged during a normal life span (F). These results support the original observations by Beltrami et al. and Quaini et al. *(A, B) Adapted from http://www.nejm.org/doi/full/10.1056/NEJM200106073442303#t=article; (C, D) Adapted from http://www.nejm.org/doi/full/10.1056/NEJMoa012081#t=article; (E, F) Adapted from https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2991140/.*

apex. c-Kit$^+$ cardiac progenitors do not express transcription factors or membrane and cytoplasmic proteins that may characterize them as bone marrow (BM), neural, skeletal, skeletal muscle, or cardiac cells. When isolated and cultured ex vivo, c-Kit$^+$ CSCs proved to be self-renewing, clonogenic, and multipotent, developing into cardiomyocytes, endothelial cells, and smooth muscle cells. More important, transplantation of culture-expanded c-Kit$^+$ CSCs results in their multilineage differentiation into cardiomyocytes and endothelial and smooth muscle cells, providing a potentially important cell-based therapeutic strategy for promoting heart regeneration in patients with heart disease [43,45–47]. Interestingly, genetic linage fate-mapping experiments in mice suggest that c-Kit$^+$ cardiac cells may not represent a common, multipotent cardiovascular stem cell, as was originally suggested [46], but distinct classes of cardiovascular cells with restricted lineage differentiation potentials [15]. For example, fate mapping of *c-Kit* expression in the heart indicates that most adult c-Kit$^+$ cardiac cells are endothelial lineage-committed cells (either undifferentiated endothelial progenitor cells [12,48,49] or fully differentiated coronary endothelial cells [12,50]), whereas only a relatively small fraction of c-Kit$^+$ cardiac cells represent cardiomyocyte progenitors [3,12,49,51]. *c-Kit* expression has also been reported to be retained in a small subset of differentiated adult cardiomyocytes [12,48,50,52]. However, other studies have failed to confirm expression of c-Kit in the coronary endothelium [3,8,51] and differentiated myocardium [3,49,51]. Temporal analyses of c-Kit expression during mouse cardiogenesis using tamoxifen-inducible *Cre*-reporter mouse lines provide compelling evidence that cardiomyogenic c-Kit$^+$ cardiac progenitor cells are derived from the CNC, whereas a vasculogenic c-Kit$^+$ cardiac cell originates in the cardiogenic mesoderm [3,10,15,50]. The origin of the c-Kit$^+$ cardiomyogenic progenitor pool in the CNC may partly explain their limited prevalence and contribution to the myocardial lineage [3,15]. iPSC models of cardiogenesis suggest that activation of canonical bone morphogenetic protein (BMP) signaling in the outflow tract of the mouse embryo during the invasion of CNC cells is a limiting factor for c-Kit$^+$ CNC progenitors, because transient BMP antagonism extensively induces their in vitro differentiation into beating cardiomyocytes (Fig. 17.2) [3].

Isl1$^+$ Cardioblasts

Following the seminal observation of adult c-Kit$^+$ CSCs by Beltrami and colleagues [46], Laugwitz and colleagues identified through *Isl1-Cre* reporter mouse line approaches the retention of a multipotent Isl1$^+$ progenitor cell pool in the postnatal mouse and human heart [4]. Isl1$^+$ cardioblasts are reportedly distinct from c-Kit$^+$ CSCs based on the lack of c-Kit antigen expression [4]. They have been isolated and expanded from embryonic and postnatal hearts and have been shown to differentiate into cardiomyocytes, endothelial cells, and smooth muscle cells, among others [4,53–55]. Based on the original observation that Isl1 is specifically expressed in SHF progenitors [26], postnatal Isl1$^+$ cardioblasts are thought to comprise remnants of the SHF program [53]. However, subsequent studies demonstrated that both SHF and CNC cells express Isl-1 at a stage-specific manner [3,56–59]. Other studies suggested that a subset of Isl1$^+$ cardiomyogenic progenitors in the postnatal mouse heart may be PEO derivatives [5,30,60]. However, this hypothesis has been challenged by subsequent work indicating the lack of cardiomyocyte differentiation capacity of epicardial progenitors [31,33,34,61]. Similar to adult c-Kit$^+$ CSCs [49,50], postnatal Isl1$^+$ cardioblasts minimally contribute to adult heart regeneration [59]. Nonetheless, the unequivocal presence of multipotent Isl1$^+$ cardiac progenitors in the adult heart has major implications for the prevention and treatment of congenital and adult heart diseases; therefore, further studies are warranted for delineating their developmental origin(s) and the molecular mechanisms regulating their expansion and cardiovascular fate commitment.

Cardiac Neural Crest–Derived Progenitors

Given its naturally limited role in cardiomyogenesis, one of the most intriguing and unexpected functions of the neural crest lineage in the heart is its contribution to postnatal cardiac progenitor cells. Tomita and colleagues used a neural crest–specific myelin protein zero (P0) *Cre*-reporter mouse line to explore the potential contribution of the neural crest in postnatal cardiac progenitor cells [40]. The investigators showed that a portion of *P0-Cre* derivatives in the postnatal heart are multipotent neural crest progenitors that, when isolated and expanded in vitro, could develop into peripheral nervous system-type neurons, Schwann cells, smooth muscle cells, and cardiomyocytes. Notably, some of these neural crest–derived progenitors reportedly express c-Kit at low levels and share common characteristics with other putative stem/progenitor cell types that have been reported in the adult mouse heart, such as the Abcg2$^+$ side-population (SP) cells [62] and cardiosphere-forming cells [9,63]. This suggests that most adult cardiac progenitor cell types, with the possible exception of Sca-1$^+$ progenitors [64], which are discussed

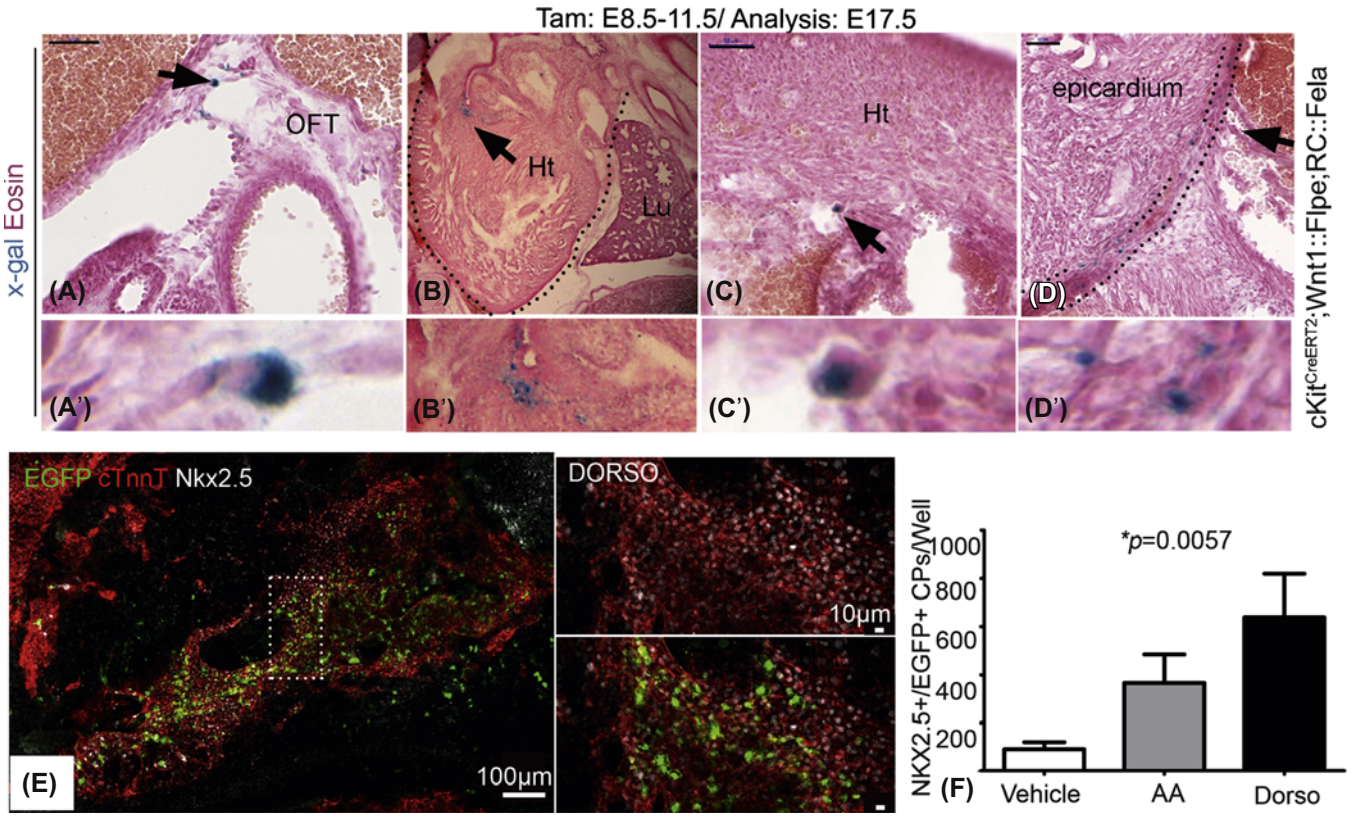

FIGURE 17.2 The cKit receptor is expressed on Nkx2.5^{+} cardiomyogenic cells of neural crest lineage whose contribution to cardiomyogenesis is limited by bone morphogenetic protein (BMP) signaling. (A, A′–D, D′) An intersectional genetic fate-mapping strategy with *Wnt1::Flpe and cKit-CreERT2/+* alleles allowed the lineage tracing of neural crest–derived cKit^{+} cells in the heart. Expression of the reporter gene β-galactosidase was analyzed via X-gal staining and indicated the presence of a limited number of neural crest–derived cKit^{+} progenitors in the outflow tract (A, A′), atrioventricular junctions (B, B′), ventricular myocardium (C, C′), and epicardium (D, D′). (E, F) An in vitro model of cardiogenesis with *cKit-CreERT2/+* reporter-induced pluripotent stem cells further suggested that the cardiomyogenic contribution of cKit^{+} neural crest progenitors is significantly enhanced when the canonical BMP pathway is transiently inhibited with the BMP antagonists noggin or dorsomorphin. Magnifications: 50 μM in A–D; 10 μm in E; and 10 μM in right two "DORSO" panels of E. *Adapted from Hatzistergos KE, Takeuchi LM, Saur D, Seidler B, Dymecki SM, Mai JJ, White IA, Balkan W, Kanashiro-Takeuchi RM, Schally AV, et al. cKit+ cardiac progenitors of neural crest origin. Proc Natl Acad Sci USA 2015;112:13051–6. https://doi.org/10.1073/pnas.1517201112.*

subsequently, may share a common neural crest origin. Subsequent studies using *Wnt1-Cre* [65] and *Kit-CreERT2/+* reporter mice [10] have corroborated the presence of cardiomyogenic neural crest–derived progenitors in the postnatal heart and raised the possibility of mobilizing them therapeutically in response to heart damage either pharmacologically, by activating the monocyte chemoattractant protein-/CCR2 axis [65], or by activating the stromal cell–derived factor 1 (SDF1)/CXCR4 axis via transplantation of adult BM–derived mesenchymal stem cells (MSCs) [10] (Fig. 17.3).

Epicardial Progenitor Cells

The epicardium is the cardiac structure with perhaps the highest proliferative and regenerative capacity after birth. Both mammals and fish vigorously activate epicardial cells via epithelial-to-mesenchymal transition in response to damage [66,67]. A genetic fate-mapping study in mice showed that compared with the adult myocardium, which holds minimal regenerative capacity, the adult epicardium requires about 3 days to regenerate itself fully in response to ischemic damage [67]. This dynamic epicardial injury response led to the original hypothesis that the epicardium is the primary postnatal source of multipotent cardiovascular progenitors for myocardial lineage regeneration in the adult heart [5,66,68]. However, subsequent studies in fish [61], mice [31,33], and humans [32,34] provided compelling evidence suggesting that the epicardial lineage is unlikely to contribute myocardial cells during cardiac development, homeostasis, or regeneration. Nonetheless, the adult epicardium is invested with undifferentiated progenitor cell pools that are generally identified in mice by the

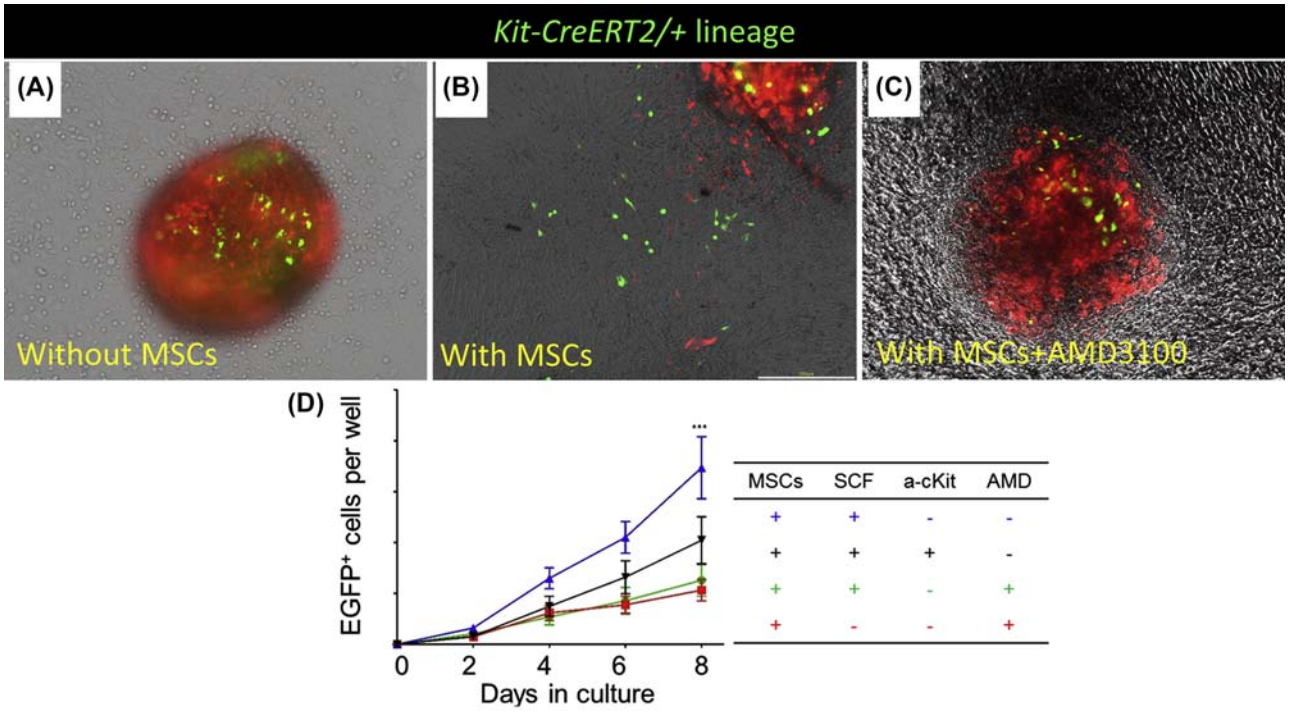

FIGURE 17.3 Regulation of cardiac cKit$^+$ cell (CSCs) self-renewal by mesenchymal stem cells (MSCs). (A) A tamoxifen-inducible *Kit-CreERT2/+;IRG* mouse line enables real-time imaging of CSCs based on *Cre*-mediated labeling with an enhanced green fluorescent protein (EGFP) reporter gene. Live-tissue fate-mapping analysis of EGFP plus CSCs in cultured myocardial explants indicates that migration and proliferation of CSCs are significantly impaired in the postnatal heart (A–D). (B) Coculture with MSCs stimulates proliferation and migration of CSCs from within the myocardial explants into the MSC culture (B–D). (C) The chemotactic effects of MSCs are blocked by the SDF1/CXCR4 inhibitor AMD3100 (C, D). These findings support the hypothesis that MSCs stimulate the proliferation and migration of CSCs via the SDF1–CXCR4 axis. *SCF*, stem cell factor. *Image adapted from Hatzistergos KE, Saur D, Seidler B, Balkan W, Breton M, Valasaki K, Takeuchi LM, Landin AM, Khan A, Hare JM.. Stimulatory effects of MSCs on cKit+ cardiac stem cells are mediated by SDF1/CXCR4 and SCF/ckit signaling pathways. Circ Res September 30, 2016;119(8):921–30. https://doi.org/10.1161/CIRCRESAHA.116.309281.*

expression of the cell-surface markers platelet-derived growth factor receptor-α (PDGFRα) [60] and/or stem cell antigen-1 (Sca-1) [69,70]. Intriguingly, adult PDGFRα$^+$/Sca-1$^+$ epicardial progenitors exhibit MSC-like properties, based on their ability to form colony-forming unit-fibroblasts and differentiate into osteogenic, adipogenic, and chondrogenic derivatives ex vivo. Other markers, such as the transcription factors Wilms Tumor 1 (WT1) and Tbx18, are also reported to be coexpressed in multipotent adult epicardial progenitors [5,60]. Adult epicardial progenitor cells have an important role in adult heart regeneration, either directly by contributing to coronary vessel, epicardial adipose tissue, and myofibroblast regeneration, or indirectly through paracrine mechanisms that support cardiomyocyte survival and proliferation [71,72].

CELL-BASED THERAPEUTICS FOR HEART DISEASE

The most important unmet need in cardiovascular medicine is that of a regenerative therapy. Although the heart has regenerative capacity, it is limited; and ischemic and other types of cardiac injury leave permanent injury and impairment in heart function, which in turn produce the major burdens of morbidity, mortality, and health care costs. As such, there is major impetus to translate the new knowledge of CSC biology into the therapeutic arena (Fig. 17.4). There have been attempts at cell-based therapy using both cardiopoietic cells (either endogenous adult CSCs or pluripotent stem cell–derived cardiac cells) and cells derived from other body sites, most notably BM [73,74].

Mortality rates from ischemic heart disease are falling, but paradoxically the incidence of heart failure (HF) is a growing cause of morbidity and mortality worldwide because of the improved short-term survival from myocardial infarction (MI) [73]. In the United States, it is estimated that the lifetime risk of developing HF is 1:5 [73]. Despite significant advances in the management of HF, 1-year mortality rates remain approximately 20%, with even higher

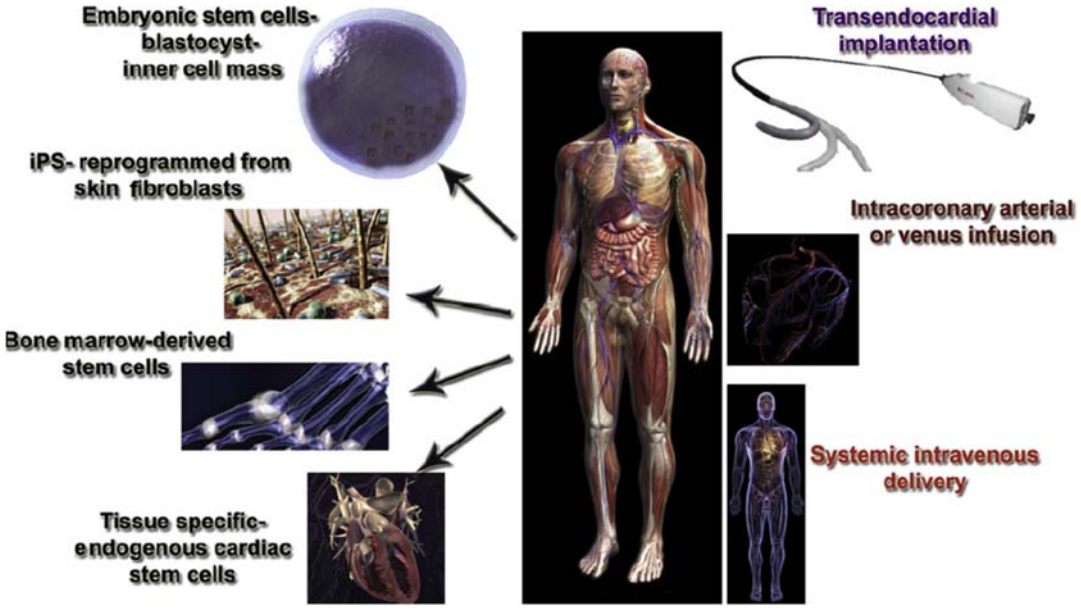

FIGURE 17.4 Stem cell–based therapeutic strategies for cardiac regeneration. Sources for stem cells with cardiac reparative capacities are numerous, including embryonic, bone marrow–derived, and cardiac-specific stem cells. After their expansion into therapeutic quantities, they can be transplanted into the patient using direct transendocardial implantation, intracoronary infusions, or subcutaneous intravenous delivery. *iPS*, induced pluripotent stem.

rates among patients hospitalized for HF [73]. Coronary heart disease is the predominant cause of HF in developed countries [73]. The pathophysiologic underpinning of this phenomenon is ventricular remodeling, which ensues after MI; therefore, regenerative therapies are targeted to preventing or reversing the remodeling process.

To date, most trials have employed BM-derived strategies to treat patients after acute myocardial infarction (AMI), with the goal of preventing remodeling largely through ameliorating infarct size [73]. Strategies have begun to be tested for revering remodeling in patients with HF and left ventricular (LV) dysfunction, both of ischemic and nonischemic etiology [75–80].

The basic premise underlying early attempts to repair cardiac injury is that of myocyte terminal differentiation [74]. Thus, early and ongoing attempts were designed around cell replacement with cells capable of differentiation. An early attempt at cell-based therapeutic myocardial replacement was reported in 1993, when Koh and coworkers used murine cardiomyocyte-like tumor cells to create intracardiac grafts [81]. By genetically manipulating murine hearts to overexpress oncogenes such as the simian virus 40 large T antigen, the investigators created a tumorigenic cardiomyocyte cell line with the capacity for proliferation both in vitro and in vivo. Implantation of these cells into healthy mouse hearts was accompanied by long-term engraftment in about 50% of the recipients without affecting heart function, introducing the notion of using cells to replace injured or lost cardiomyocytes. This experiment created a new field of investigation that has led to the exploration of multiple types and sources of cells as potential cardiac therapeutic agents. In 1998, Anversa and coworkers [82]reported evidence of mitosis in adult cardiomyocytes, which suggested cellular renewal throughout adult life. This discovery instigated the notion that myocyte renewal may not be attributed only to cardiomyocyte proliferation per se, but also to homing and differentiation of endogenous stem cells. To address this idea, Orlic and coworkers [83] demonstrated that transplantation of BM-derived, lineage-negative (Lin[−]/c-Kit[+]) stem cells into the infarcted mouse heart caused differentiation of the BM cells into cardiac myocytes and vessels and substantial recovery of cardiac function.

Cardiac engraftment of cells from distant sites was demonstrated in studies of sex-mismatched heart transplants [41]. In these studies, male cardiomyocytes were identified in female hearts transplanted into male patients (Fig. 17.1C and D). More important, the investigators also detected a subpopulation of cardiac precursor cells of donor and host origin, which suggested for the first time that the heart could contain its own CSC population. These observations opened up the field of adult stem cell–based therapy and led to a plethora of studies using multiple sources of cells to stimulate postinjury cardiac repair. Based on the observations by Orlic and colleagues, BM was preferentially used as a cell source, prompting a decade-long quest to establish the clinical value and mechanism of action of BM-derived, cell-based therapy for heart disease [73]. However, the quest is controversial and other

experimental observations have challenged the hypothesis of cell transdifferentiation as a dominant mechanism of action for cell-based cardiac repair [6,73,83,84].

MECHANISMS OF ACTION

Two major categories are thought to underlie the mechanisms of actions of cell-based therapeutics, each with varying degrees of experimental support: direct remuscularization and stimulation of endogenous repair (Fig. 17.5). The first category entails tissue-engineering approaches to remuscularize the dead, scarred myocardium by engrafting billions of new, healthy cardiac cells manufactured in the laboratory from pluripotent stem cells [85–87] or via genetic conversion of adult fibroblasts [88,89].

The second category entails using adult stem cells, isolated and expanded in vitro from the heart or extracardiac tissues and infused through the bloodstream or engrafted endomyocardially to stimulate endogenous mechanisms of heart regeneration. Most transplanted adult stem cells do not become heart muscle cells themselves, but induce

FIGURE 17.5 Cell-based therapeutic strategies for cardiac repair. (A, B) The two major categories of cell therapy are direct remuscularization strategies with human embryonic stem cell (hESC) or induced pluripotent stem cell (iPSC)-derived cardiomyocytes (CM) and progenitors (CVP), or stimulation or endogenous repair with adult stem cells (i.e., bone marrow mononuclear cells (BM MNC). Both strategies exert similar effects in cardiac repair. (C) Comparison of the mechanisms of action underlying the two therapeutic strategies. *Differentiation of adult stem cells (i.e., MSCs) to cardiomyocytes is minimal but not absent. *Non Card*, noncardiac. *(A, B) Adapted from Fernandes S, Chong JJ, Paige SL, Iwata M, Torok-Storb B, Keller G, Reinecke H, Murry CE. Comparison of human embryonic stem cell-derived cardiomyocytes, cardiovascular progenitors, and bone marrow mononuclear cells for cardiac repair. cardiac repair through other mechanisms, including stimulation of myocardial regeneration from endogenous cardiac progenitors and cardiomyocyte mitosis [10,90,91], fusion with host cells to promote survival and induce regenerative activity [6,49,92], as well as secretion of paracrine factors and exosomes that exert antiinflammatory, antifibrotic, and angiogenic effects [10,75,93–97].

CLINICAL TRIALS

The field of stem cell research has gained enormous attention. Experimental work has employed both pluripotent stem cell–derived and tissue-specific adult stem cells to treat heart disease [73]. Whereas consensus has emerged that there is some functional merit to cell-based therapies for heart disease [73,98–100], underlying mechanisms of action remain controversial. In addition to this central issue, other key issues that need to be settled include the role of host factors in cell functionality [101] and the exciting possibility of using allogeneic grafts because of the unique immunoprivileged properties of some cell types [75]. Despite much controversy, substantial work in the clinical arena with trials of growing size and sophistication has produced a major database of safety and efficacy that is paving the way to future clinical development. We next review developments using each cell-based strategy.

Cardiopoietic Stem Cells

Pluripotent Stem Cells

ESCs, the prototypic pluripotent stem cell, were first isolated from mice in 1981 [102,103] and subsequently from human blastocysts in 1998 [104]. These cells arise from the inner cell mass of late blastocysts and differentiate into cell types of all three germ layers, including cardiomyocytes. From a clinical standpoint, because undifferentiated ESCs are pluripotent, they have a high oncologic risk when they are used as a cell-based therapeutic. However, differentiation of ESCs to cardiac progenitors or cardiomyocytes before transplantation overcomes this important limitation and reduces the risk of tumor formation [105,106]. Early animal studies suggested that ESC-derived, cardiac-committed cells may have the capacity to improve myocardial function and structure after MI by directly remuscularizing the infarct area with new cardiomyocytes and vessels. However, later experiments revealed that the degree to which engraftment of human ESC-derived cardiac cells reduces scar size and improves heart function in animals with experimental myocardial ischemia is at best comparable to that seen with adult cell-based therapy (Fig. 17.5) [73,74,85–87,107]. Furthermore, although engraftment of human ESC-derived beating cardiomyocytes into the myocardial scar appears to be safe from an oncologic standpoint, it has been associated with an increased risk for arrhythmogenesis, which suggests that more work is necessary to improve the safety of this approach before clinical testing [85]. To date, the Transplantation of Human Embryonic Stem Cell-derived Progenitors in Severe Heart Failure trial (NCT02057900) is the only ESC-based clinical trial in the field of cardiovascular diseases to test the safety and feasibility of transplanting human ESC-derived cardiac progenitor cells expressing Isl1 and SSEA1 in patients with severe HF [108].

Another strategy to obtain pluripotent stem cells involves the induction of pluripotency in somatic cells through genetic reprogramming, so-called iPSCs. In a pioneering study conducted by the laboratory of Shinya Yamanaka [109,110], adult mouse and human skin fibroblasts were induced into pluripotent embryonic-like iPSCs by transfection with stem cell–related genes such as *Lin28*, *c-myc*, *oct 4*, *sox 2*, *klf-4*, and *Nanog*. This approach has stimulated enormous enthusiasm given the potential to develop pluripotent stem cells without using human embryos and offers substantial availability of the cells. Not the least advantage of this approach is the prospect of developing host-tailored stem cells that could escape immune rejection, or the development of pluripotent cell lines from hosts with genetic diseases providing an optimal in vitro experimental system for disease-modeling and drug-screening applications [111]. However, the production and derivation of patient-specific, autologous heart cell grafts from iPSCs still require expensive and labor-intensive processes, which makes the clinical translation of personalized, iPSC-based regenerative medicine practically unfeasible. An alternative strategy proposed is the development of immunocompatible iPSC master cell banks that can be used to derive "off-the-shelf" allogeneic grafts. Nonetheless, preclinical animal models of heart regeneration using immunocompatible, allogeneic, iPSC-based strategies indicate that engraftment of iPSC-derived cardiac cells still requires high-dose immunosuppression. In addition, similar to ESC-based strategies, direct remuscularization from iPSC-derived cardiac cells is disappointingly inefficient and may have important adverse effects, including arrhythmogenesis (Fig. 17.6) [112]. Other studies indicate that, similar to adult cell-based therapeutics, iPSC-based therapeutics may

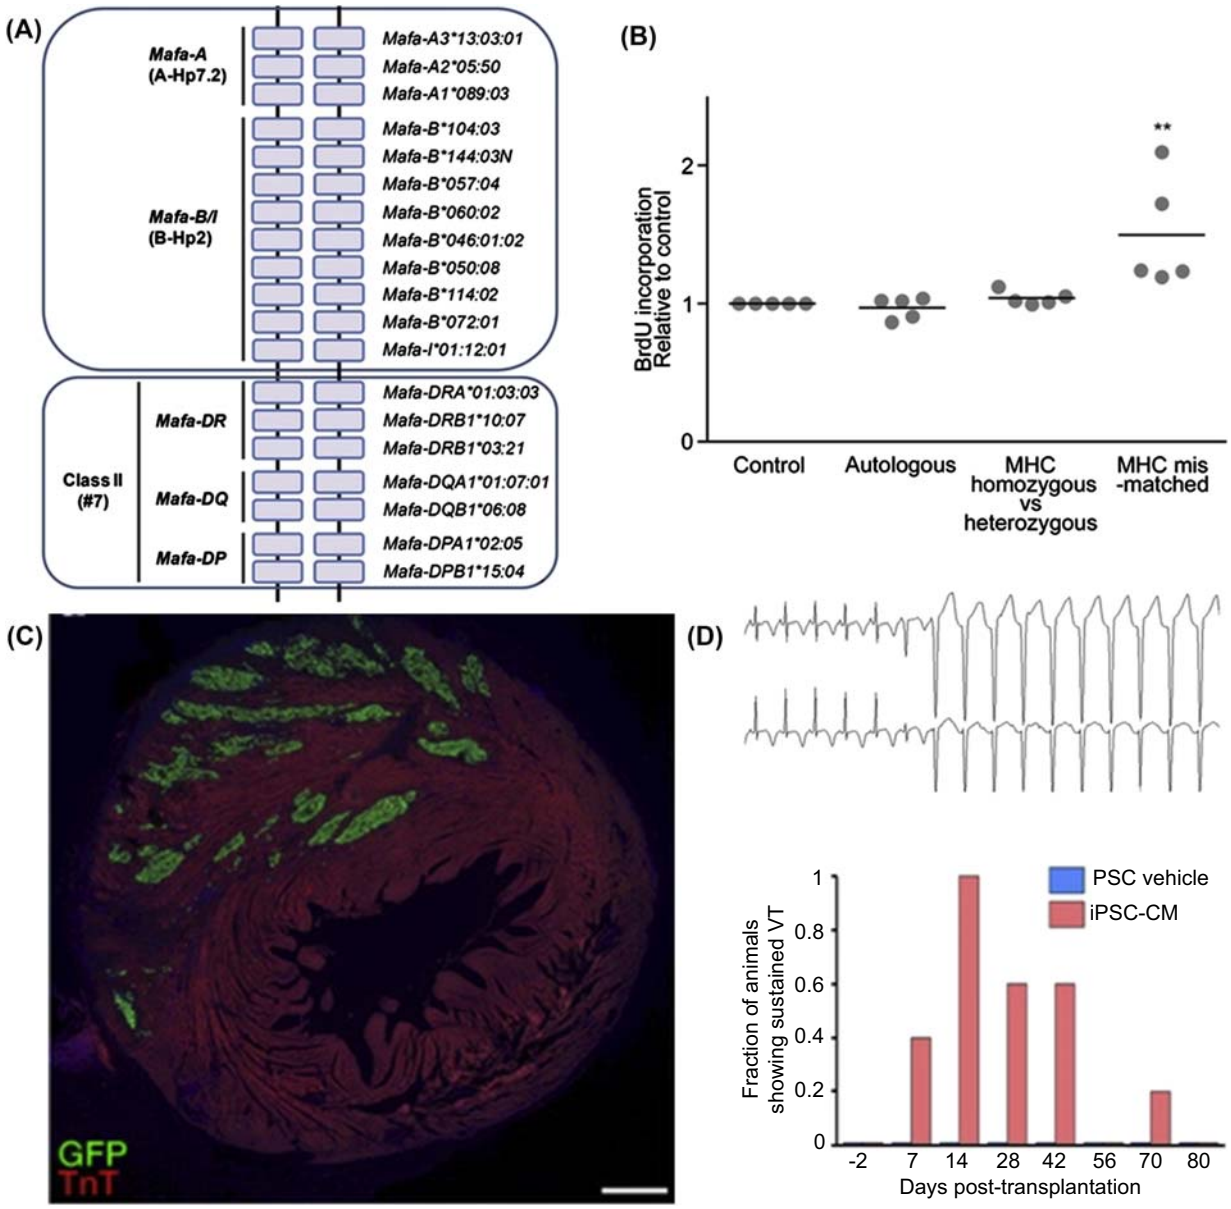

FIGURE 17.6 Induced pluripotent stem cell (iPSC)-based strategies for cardiac repair. A proof-of-concept preclinical study tested the allogeneic transplantation of beating cardiomyocytes derived from major histocompatibility complex (MHC) homozygous monkey iPSCs (A) into MHC heterozygous recipients. The allogeneic cardiomyocytes were not immunogenic in vitro (B) but required high-dose immunosuppression for in vivo engraftment (C). Another major concern raised by the study is that engraftment of terminally differentiated, allogeneic cardiomyocytes significantly increased the risk for arrhythmogenesis, whereas the effects on heart function and scar size were far from optimal (D). Future allogeneic iPSC-based strategies should focus on developing novel, cost-effective bioengineering approaches to enhance immunotolerance, improve engraftment, and reduce arrhythmogenicity of the allografts. *BrdU*, bromodeoxyuridine. *Adapted from Shiba Y, Gomibuchi T, Seto T, Wada Y, Ichimura H, Tanaka Y, Ogasawara T, Okada K, Shiba N, Sakamoto K, et al. Allogeneic transplantation of iPS cell-derived cardiomyocytes regenerates primate hearts. Nature 2016;538:388–91. https://doi.org/10.1038/nature19815. Epub 2016 Oct 10.*

be useful for bioengineering cardiovascular patches to stimulate the heart's innate repair mechanisms [96]. To date, iPSC cells have not entered the clinic for heart-related diseases.

Adult Stem Cells

The field of CSC therapy has been advanced substantially through the discovery that adult stem cells have the capacity to (trans)differentiate into lineages other than their tissue of origin. This stem cell plasticity allows the use of stem cells isolated from a variety of easily accessible sources such as BM, peripheral blood, fat, umbilical

cord, skeletal muscle, and the heart itself to be used for cell-based cardiac repair. The first generation of cell-based clinical trials was conducted with cells of extracardiac tissue origin and showed MSCs to be the safest and most promising strategy for stimulating the innate regenerative response mechanisms of the failing human heart [73,98]. The second generation of cell-based therapy supported the concept that the adult human heart contains its own stem cell compartment that may be expanded in culture and delivered back to the damaged heart muscle to enhance cardiac repair. Finally, given the stimulatory effects of MSCs on tissue-specific CSCs (Fig. 17.3), the third generation of cell-based clinical trials is testing whether the combined engraftment of the two stem cell types yields an additive regenerative effect [73,80,113].

Bone Marrow Stem Cells

Because of its various well-defined stem cell compartments and its ease of access, whole-BM and BM-derived mononuclear stem cells (BMMNCs) are the most widely studied type of cell for cellular cardiomyoplasty. Using different cell-surface markers, BMMNCs can be fractionated to hematopoietic stem cells (HSCs) or nonhematopoietic stem cells. The latter includes a number of distinct subtypes named SPs [114], endothelial progenitor cells (EPCs) [115], MSCs [73], multipotent adult progenitor cells [116], multilineage inducible cells [117], and very small embryonic-like stem cells [118].

Bone Marrow–Derived Mononuclear Stem Cells

Numerous experimental and clinical studies have tested BMMNCs for a range of therapeutic strategies involving their transplantation and/or mobilization to sites of cardiac injury. The totality of evidence of trials of BM cells and derivatives supports both the safety and provisional efficacy of this approach. Three metaanalyses evaluating data from approximately 18 trials and close to 1000 patients [7,100,119] concluded that BM cell–based therapies contribute to modest improvements in cardiac function by reducing infarct size, preserving LV dimensions, and increasing ejection fraction by 2%–3% within 6 months after transplantation. Long-term follow-up data derived from the Brain Oxygen Optimization in Severe Traumatic Brain Injury and Outcomes for Antiretroviral Therapy Patients Receiving Palliative Care (REPAIR)-AMI studies documented that the therapeutic results are sustained up to 5 years posttransplantation [73]. One of the most exciting observations derives from the Data and Safety Monitoring Board data of the REPAIR-AMI study [119a]. In this study, 204 patients with AMI underwent successful reperfusion of the culprit coronary vessel(s), and 3–7 days later were randomized to receive intracoronary infusion of autologous BMMNCs or placebo. By 4 months, patients who had received the cells showed a significantly improved left ventricular ejection fraction (LVEF) compared with the placebo, and the ones with larger infarcts (baseline LVEF $< 48.9\%$) were more responsive to the therapy than the others. Importantly, 1-year follow-up data from REPAIR-AMI demonstrated improved event-free survival (death, recurrence of MI, revascularization, or rehospitalization for HF) of the BMMNC-treated patients compared with the placebo. In addition to the post-MI setting, several trials employed BMMNCs for patients with established LV dysfunction and/or HF owing to either ischemic or non-=ischemic causes; data are sufficiently promising to warrant further study [73].

Endothelial Progenitor Cells

This subset of hematopoietic stem cells can be isolated from BMMNCs as well as peripheral blood mononuclear cells (PBMCs), based on the expression of HSC surface markers such as CD34, CD133, and vascular endothelial growth factor receptor 2. The main mechanism of action of these cells is the formation of new vessels in the infarcted myocardium; however, little evidence exists for their in vivo transdifferentiation into new cardiac myocytes [73]. In rats with AMI, intravenously injected EPC stimulated the development of collateral vessels from preexisting vessels as well as de novo capillary formation [120]. This was associated with decreased apoptosis of myocytes in the borderline zone, reduced fibrosis and scar formation resulting in prevention of LV remodeling, and improvement in myocardial function [120]. Infusion of EPC in the infarct-related arteries can improve vasomotor function, an effect that could contribute to improved myocardial function [121]. In patients with old MI and chronic coronary total occlusion, intracoronary infusion of EPC after recanalization of the occluded artery improved myocardial perfusion, reduced infarct size, and ameliorated myocardial function [122].

However, a clinical trial that compared the effects of granulocyte colony-stimulating factor and PBMCs as an alternative approach to recruit EPCs at the sites of MI was terminated prematurely owing to the potential adverse reaction of increased restenosis [123]. Approaches that involve EPC therapies combined with gene therapies or even the genetic manipulation of EPCs before transplantation have emerged in an attempt to minimize side effects and improve outcomes (NCT00936819).

Mesenchymal Stem Cells

The MSC, an adult stem cell with self-replication and multilineage differentiation capacity, represents a promising adult stem cell for regenerative medicine. MSCs can be isolated from a variety of tissues such as heart, adipose, umbilical cord/umbilical cord blood, and BM, although whether they all share common cardiopoietic and immunomodulatory properties remains unclear [73]. MSCs lack hematopoietic lineage markers such as CD14, CD34, and CD45 and express specific stromal cell-surface markers such as Stro1, CD105, CD90, and CD71. They adhere to plastic surfaces and grow as cell monolayers without losing their stem cell phenotype. Furthermore, they have reduced expression levels of major histocompatibility complex (MHC) class-I molecule and lack MHC class-II (although interferon-gamma will induce MHC class-II) and costimulatory molecules CD80 (B7-1), CD86 (B7-2), and CD40. MSCs are therefore the prototypic immunoprivileged cell-based therapy and have been tested in phase I double-blind, randomized clinical trials as an allogeneic graft [75,76,95,124,125].

The mechanism of action of MSCs as a cardiac regenerative agent appears to be multifactorial. Although definite evidence is reported of their in vivo transdifferentiation into cardiovascular elements, the degree to which they differentiate does not fully explain their substantial cardiac reparative properties [90,126,127]. Indeed, MSCs appear to have additional powerful effects mediated by secreted factors and cytokines that evoke the therapeutic response [10,75,94,95]. However, data document that MSCs facilitate cardiac regeneration through mechanisms that involve both differentiation and paracrine stimulation of innate repair pathways [10,90,128]. In particular, MSCs seem to have a unique capacity to gain control over the endogenous c-Kit$^+$ cardiac precursor cell content and establish the necessary cardiopoietic cues that instruct the latter to regenerate a myocardial scar [10,80,90,92,113,129].

In various animal models of AMI, intramyocardial injection of MSCs prevents ventricular remodeling by reducing scar formation, leading to a net improvement in myocardial function (Fig. 17.7) [126,127]. However, some studies in mice with AMI failed to show a sustained benefit of MSC therapy despite an early benefit [73]. In patients with AMI, intracoronary MSC infusion improved myocardial perfusion and function and reduced LV end-systolic and end-diastolic volumes [130]. In another small study, combined intracoronary administration of MSC and EPC improved perfusion and contractility of the infarcted area [131]. Although early uncontrolled animal studies suggested that intracoronary injection of MSCs could induce coronary artery occlusion and MI [132], this was not observed in humans [130]. A 53-patient, double-blind, placebo-controlled, phase I clinical study of allogeneic MSCs administered intravenously within 10 days after AMI demonstrated acute and long-term safety of the approach [124]. Although this study was primarily designed to test safety, four domains of prespecified safety monitoring supported an improved outcome in the patients treated with cells. These included a reduction in malignant ventricular arrhythmias, improved pulmonary function, an improved EF in the subset of patients with anterior MI, and finally, an improved patient well-being score at 6 months [124]. These provocative data led to the conduct of a completed phase II study, the results of which will be reported (NCT00877903). Similarly, in the Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (NCT01216995) and Allogeneic Mesenchymal Precursor Cell Infusion in Myocardial Infarction (NCT01781390) trials, patients with AMI were treated with adipose tissue−derived or STRO3-selected BM MSCs, respectively, via the intracoronary route. A third clinical study in which patients with AMI are treated with STRO3-selected MSCs via intramyocardial injection is also under way (NCT00555828).

The safety and efficacy of MSC-based therapeutics has also been demonstrated in patients with chronic ischemic heart disease. The Prevention of Contrast Renal Injury With Different Hydration Strategies [76] and Transendocardial Injection of Autologous Human Cells in Chronic Ischemic Left Ventricular Dysfunction and Heart Failure Secondary to Myocardial Infarction [77] trials compared autologous BM MSCs versus allogeneic MSCs and BMMNCs respectively, delivered transendocardially in patients with chronic ischemic cardiomyopathies. Both studies demonstrated that at 1 year, treatment with MSCs, but not BMMNCs, resulted in scar size reductions and improved contractility and functional capacity and reversal of LV remodeling (Fig. 17.8). Similarly, a phase I/II, randomized, double-blinded, placebo-controlled study of the safety and efficacy of intramyocardial injection of autologous MSCs in patients with chronic ischemic LV dysfunction resulting from MI undergoing cardiac surgery for coronary artery bypass grafting (the Prospective Randomized Study of Mesenchymal Stem Cell Therapy in Patients Undergoing Cardiac Surgery trial) found that MSC injections into akinetic yet nonrevascularized segments produces comprehensive regional functional restitution compared with revascularized and non−MSC treated segments, which in turn drives improvement in global LV function [78].

In a rat model of nonischemic dilated cardiomyopathy, intramyocardial injection of MSC exerted antifibrotic effects and improved myocardial perfusion and function [133]. Similarly, a randomized study comparing allogeneic versus autologous MSCs in 37 patients with nonischemic dilated cardiomyopathy (Percutaneous Stem Cell Injection Delivery Effects on Neomyogenesis in Dilated Cardiomyopathy Trial, NCT01392625) revealed that intramyocardial injection of MSCs was highly safe and efficacious [75]. Strikingly, this study demonstrated that patients receiving

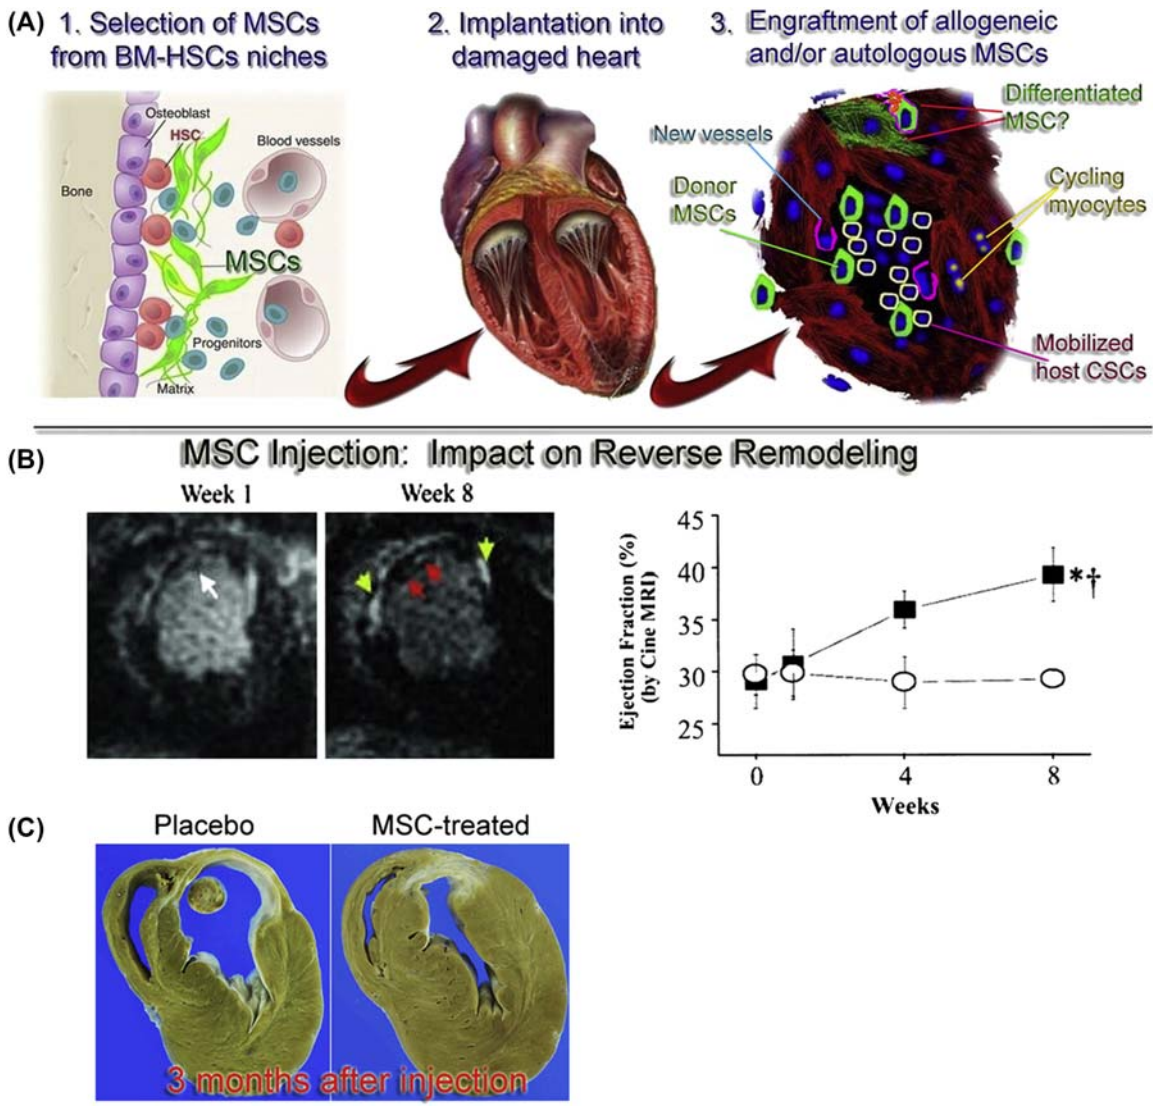

FIGURE 17.7 (A) Mesenchymal stem cells (MSCs) can provide a safe allogeneic source for cell-based therapies. Their mechanisms of action are believed to be multifaceted because activation of innate (stimulation of angiogenesis, cardiomyocyte proliferation, and cardiac stem cell [CSC] mobilization) and exogenous (differentiation onto cardiovascular lineages) repair pathways have been reported. (B) Prevention of remodeling in the porcine heart. Cardiac magnetic resonance imaging and multidetector computed tomography document the development of a subendocardial rim after MSC transplantation in the damaged zones of infarcted hearts. The newly formed tissue rendered an approximately 50% decrease in infarct size and restoration of the heart function. (C) Reverse remodeling induced by MSC injection in the porcine heart. *BM-HSCs*, bone marrow hematopoietic stem cells.

allogeneic therapy benefited more than did those receiving autologous cells, as indicated by significant differences in EF, 6-min walk test, Minnesota Living with Heart Failure Questionnaire, endothelial function, and, most important, a dramatic remodeling of immune cells toward a less inflammatory/exhausted phenotype [75] (Fig. 17.9). These findings are on par with earlier reports indicating that EPCs and BMMNCs from patients with established coronary heart disease or cardiovascular risk factors show impaired proliferating and migratory capacity [134,135]. Therefore, treatment of patients with cardiovascular diseases with MSCs obtained from healthy donors may be equally safe as and more advantageous than using autologous MSCs.

The total database of studies of MSC therapy for ischemic and nonischemic cardiomyopathies includes several proof-of-concept clinical trials described previously. Together, these studies illustrate that MSCs can be used successfully as either autologous or allogeneic grafts to treat heart disease [73]. Although safety has served as the primary end point thus far, an overall provisional efficacy of MSCs on reversing heart disease has also been strongly suggested. All studies report significant improvements in cardiac function accompanied by a substantial reduction in scar size. As a result, MSCs are now in phase III trials for AMI and chronic MI. In a phase I Cardiopoietic Stem Cell

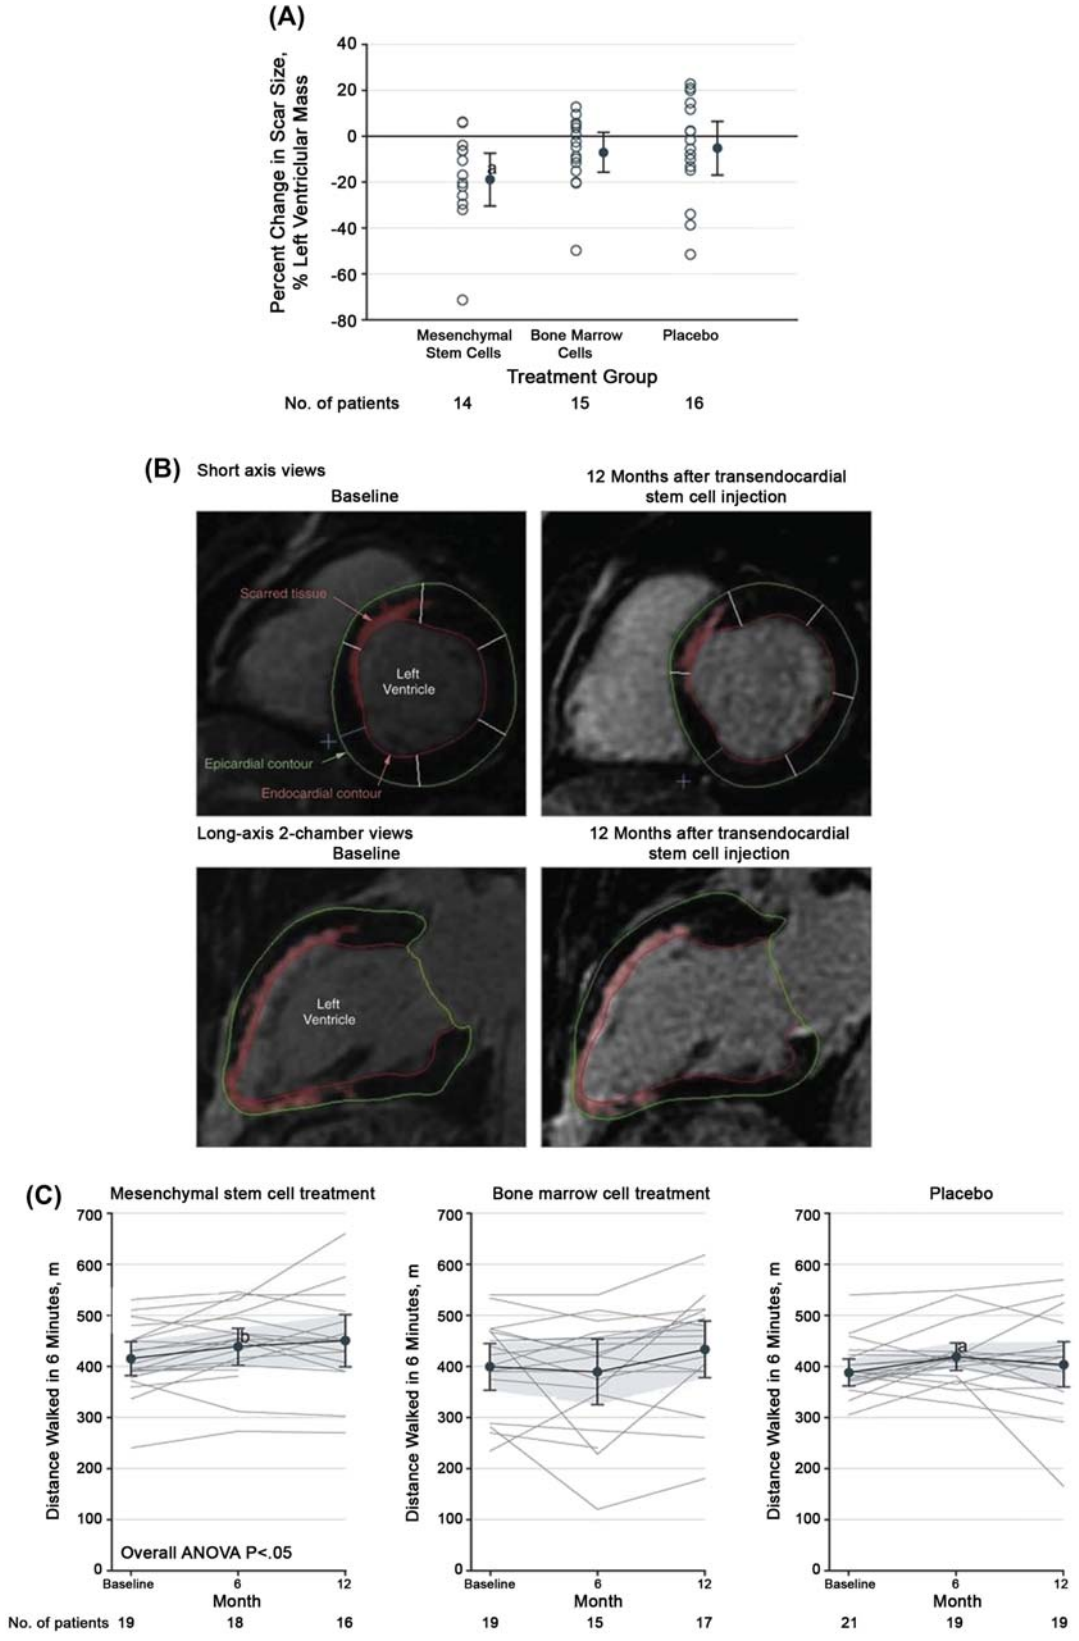

FIGURE 17.8 Transendocardial Injection of Autologous Human Cells (bone marrow or mesenchymal) in Chronic Ischemic Left Ventricular Dysfunction and Heart Failure Secondary to Myocardial Infarction trial: percent change in scar size as a percentage of left ventricular mass and impact on functional capacity. (A) The 14 patients treated with mesenchymal stem cells exhibited a significant reduction in scar size ($P = .004$) as a

Therapy in Heart Failure trial, patients with chronic ischemic cardiomyopathy who received intramyocardial injection of autologous BM MSCs pretreated with a cardiogenic cocktail reported significant improvements in LVEF, left ventricular end-diastolic volume, functional capacity, and quality of life compared with those receiving the standard of care [136]. This strategy was not borne out in the phase III Congestive Heart Failure Cardiopoietic Regenerative Therapy study, which used a composite end point (all-cause mortality, worsening HF, Minnesota Living with Heart Failure Questionnaire score, 6-min walk distance, LV end-systolic volume, and ejection fraction) to evaluate the safety and efficacy of autologous MSCs pretreated with the cardiopoietic cocktail to treat ischemic heart failure. Although the procedure was safe, efficacy between groups at 39 weeks posttreatment (the primary outcome measure) was neutral [137].

Myoblasts

Skeletal myoblasts were the first contractile cell type transplanted in the infarcted heart with the goal of restoring cardiac function [138]. These cells can be purified from the skeletal muscle of the patient; after expansion into therapeutic quantities, they can be transplanted into the myocardium. Transplantation of these cells to the heart is accomplished either surgically or by a catheter delivery system [139]. There have been several well-conducted phase I/II clinical studies [140–142]. The Medical Research Council Adjuvant Gastric Infusional Chemotherapy trial revealed that there was a dose-dependent attenuation in LV remodeling, but that it was not accompanied by functional improvements in cardiac function (Fig. 17.10). In addition, compared with MSCs, there are concerns that skeletal myoblast can precipitate arrhythmias (Fig. 17.10C) [140,142].

In experimental models of AMI, intramyocardial injection of myoblasts preserves myocardial function and abrogates the remodeling process [143]. Myoblasts can differentiate into slow-twitch myotubes in the infarcted area, which can contribute to myocardial systole [143]. It has been suggested that skeletal muscle–derived stem cells have greater potential for myocyte regeneration than myoblasts and can also stimulate innate angiogenesis. This cell population appears to be more effective in improving myocardial perfusion and contractility and attenuating remodeling in animal models of MI [144]. The failure of myoblasts to improve cardiac function in humans has been attributed to their inability to differentiate into cardiac myocytes and the in situ development of dysfunctional electrical coupling with resident cardiomyocytes (Fig. 17.10) [145]. Accordingly, some studies are focused on identifying and characterizing a more cardiogenic skeletal muscle-derived cell population that may improve cardiac repair [146].

However, studies have indicated that transplantation of skeletal myoblasts, bioengineered ex vivo into cell sheets, in patients with HF caused by ischemic heart disease is safe, nonarrhythmogenic, and clinically advantageous in facilitating LV reverse remodeling, improving HF symptoms, and preventing cardiac death, compared with cardiac resynchronization therapy [141]. Based on these studies, the Japanese government issued a 5-year conditional approval of autologous skeletal myoblast sheet transplantation as the first cell-based regenerative medicine product worldwide for use in patients with severe HF (EF $< 35\%$; III or IV on the New York Heart Association functional classification scale) [147].

Cardiac Stem Cells

CSCs are tissue-specific stem cells that reside within the heart itself. Cardiac progenitors were first reported in 2002, when Hierlihy et al. detected robust SP cells in the postnatal murine heart that expressed the adenosine triphosphate–binding cassette transporter Abcg2 and extruded Hoechst dye [148]. These cells represented about 1% of total cardiac cells and differentiated into cardiac myocytes in vitro. After this observation, in 2003, two different groups, Beltrami et al. [46] and Oh et al. [64], reported the isolation and characterization of two novel CSCs from the murine heart. These resident stem cells have been reported to correspond to 0.01%–2% (or approximately 1 CSC for every 13,000 cardiomyocytes) of the total cell population of the human heart and are mostly

percentage of left ventricular mass; there were no differences for the 15 patients treated with bone marrow cells or the 16 patients in the placebo group. (B) Short-axis and long-axis views of the basal area of a patient's heart, with delayed tissue enhancement delineated at the septal wall (short axis) and anterior and inferior walls (long axis) as well as the entire apex (long axis). Delayed tissue enhancement corresponds to scarred tissue and is depicted as brighter than the nonscarred tissue. The *red, green, and white lines* demarcate the endocardial and epicardial contours and borders of the segments, respectively. Twelve months after injection of mesenchymal stem cells, the scar mass was reduced from 30.85 g at baseline to 21.17 g (short axis) and delayed tissue enhancement receded in the midinferior and basal anterior walls (long axis). (C) Patients in the mesenchymal stem cell group exhibited a significant increase in 6-min walk distance when 6- and 12-mo time points were compared with baseline in a repeated-measures model ($P = .03$). No significant difference was observed for patients in the bone marrow cell group ($P = .73$) or the placebo group ($P = .25$). *ANOVA*, analysis of variance. *Adapted from Golpanian S, Wolf A, Hatzistergos KE, Hare JM. Rebuilding the damaged heart: mesenchymal stem cells, cell-based therapy, and engineered heart tissue. Physiol Rev 2016;96:1127–68. https://doi.org/10.1152/physrev.00019.2015.*

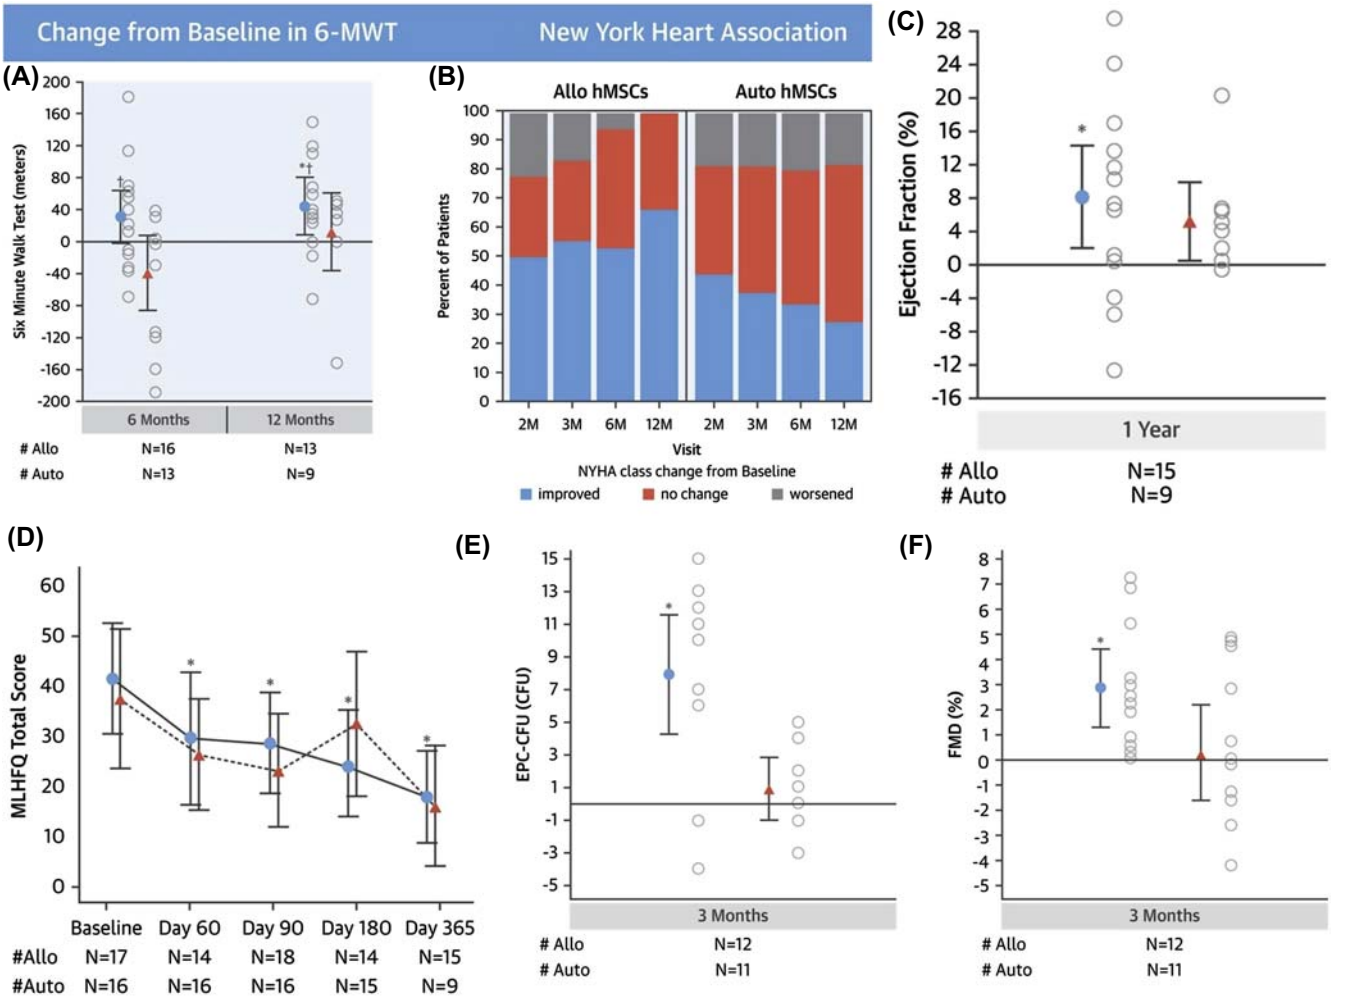

FIGURE 17.9 **Cell therapy with allogeneic mesenchymal stem cells (MSCs) may be more beneficial than autologous MSCs in patients with dilated cardiomyopathy of nonischemic etiology (NIDCM).** One-year results from a randomized comparison of allogeneic versus autologous MSC therapy in patients with NIDCM (Percutaneous Stem Cell Injection Delivery Effects on Neomyogenesis in Dilated Cardiomyopathy Trial) support that treatment of heart failure with MSCs may be further improved if the cells are of a healthy allogeneic rather than autologous origin. More specifically, treatment with allogeneic MSCs (Allo hMSCs) from young, healthy donors, results in greater improvements in 6-min walk test (6-MWT) (A), New York Heart Association class change (B), ejection fraction (C), and Minnesota Living with Heart Failure Questionnaire scores (MLHFQ) (D) compared with autologous MSCs. In addition, endothelial function is significantly improved, as indicated by the amount of endothelial progenitor colony-forming units (EPC-CFUs) from peripheral blood samples (E) and percent changes in flow-mediated vasodilation (FMD) brachial artery diameter (F). *Solid blue circle,* Allo hMSC; *solid red triangle,* Auto hMSC. *Adapted from Hare JM, DiFede DL, Castellanos AM, Florea V, Landin AM, El-Khorazaty J, Khan A, Mushtaq M, Lowery MH, Byrnes JJ, et al. Randomized comparison of allogeneic Vs. Autologous mesenchymal stem cells for non-ischemic dilated cardiomyopathy: POSEIDON-DCM trial. J Am Coll Cardiol November 14, 2016.pii: S0735-1097(16)36906-6.*

recognized according to the expression of three cell-surface markers: c-Kit (the receptor for stem cell factor), multidrug resistance protein-1 (MDR-1), and/or Sca-1. CSCs are self-renewing, clonogenic, and multipotent and are able to differentiate both in vitro and in vivo into myogenic, endothelial, and vascular smooth muscle lineages. Two different methods for isolating human CSCs have been reported, but whether the purified cells share the same properties is yet unknown. The first method involves homogenizing relatively large amounts of cardiac tissue (about 30–60 mg for successful isolation) and subsequent antibody-based selection of CSCs [45]. The applicability of this method is limited to patients who undergo major cardiac interventions such as coronary artery bypass grafting, left ventricular assist device placement, or heart transplantation. The second method has been adapted from the field of neurological sciences and involves the culture of a single biopsy from which CSCs are selected with antibodies as a subpopulation of the outgrowing cells. Alternatively, CSCs can be selected without using antibodies, based on their sphere-forming property [149]. The discovery of adult CSCs represents a major biological discovery furthering understanding of cardiac pathophysiology and facilitating cardiac cell–based therapeutics.

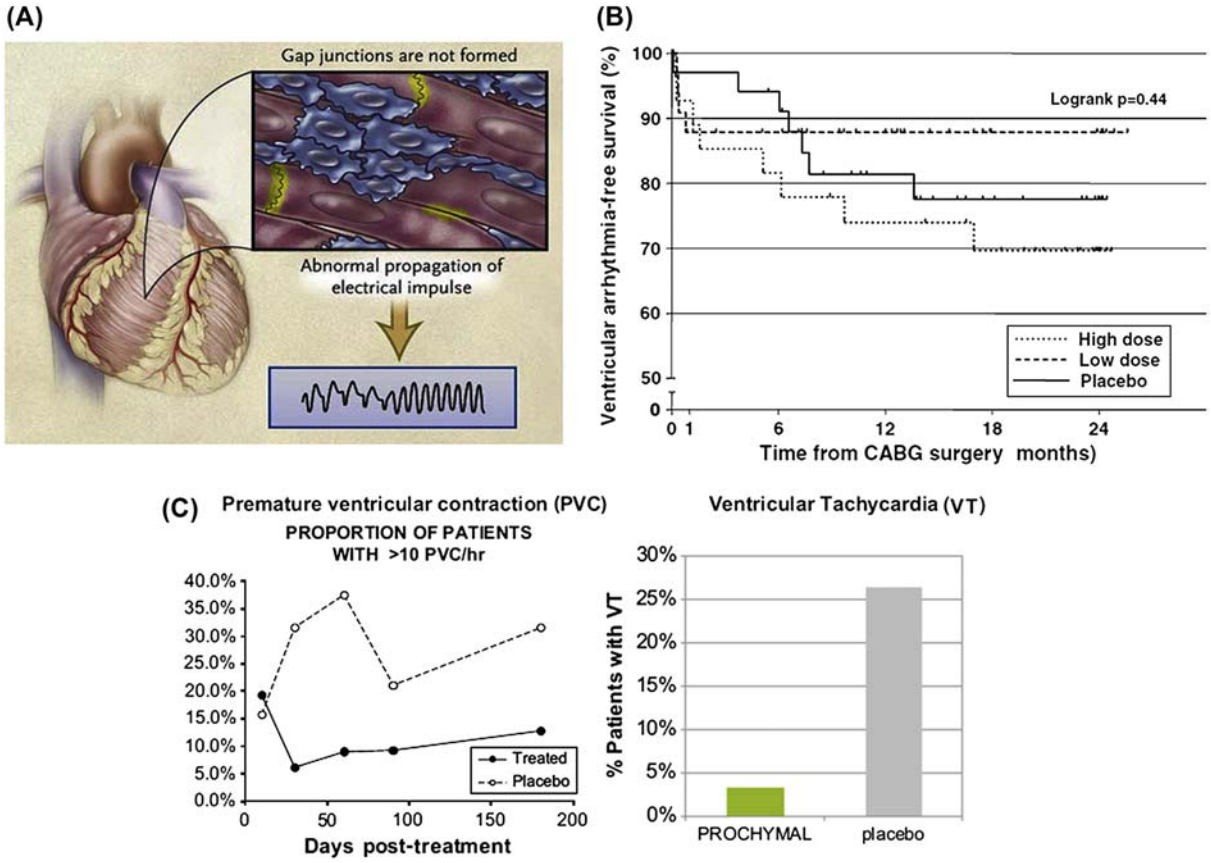

FIGURE 17.10 (A) Experimental studies have shown that skeletal fibroblasts engraft and survive in the damaged myocardium. However, these contractile cells do not express gap junctional proteins such as connexin-43 and fail to couple with the host myocytes. As a result, the transplanted cells cannot propagate the conduction signals, resulting in an arrhythmogenic substrate. (B) In the Medical Research Council Adjuvant Gastric Infusional Chemotherapy trial, patients with ischemic cardiomyopathy who received skeletal myoblasts were more prone to developing arrhythmias compared with the placebo-treated group. (C) Mesenchymal stem cell, in contrast, have an antiarrhythmic effect. *CABG*, coronary artery bypass grafting.

c-Kit$^+$ Cardiac Stem Cells

c-Kit$^+$ CSCs represent a promising candidate for cardiac-specific stem cell lineages. This cell type is described in multiple species ranging from rodents to large animals to humans and is likely heterogenous in nature [15]. Endogenous cardiac repair mechanisms are thought to involve the mobilization of c-Kit$^+$ CSCs to areas of cardiac injury soon after infarction [90,150]. However, genetic lineage fate-mapping experiments in mice suggested that endogenous cardiomyocyte regeneration from adult c-Kit$^+$ CSCs is likely minimal [49]. On the other hand, animal studies support that implantation of culture-expanded c-Kit$^+$ CSCs, genetically modified or not, can reduce infarct size and improve cardiac function, largely through paracrine effects [151,152] (Fig. 17.11). These findings led to the Cardiac Stem Cells in Patients With Ischemic Cardiomyopathy (SCIPIO) trial, the first phase I clinical trial of c-Kit$^+$ CSCs in patients with ischemic heart disease (www.clinicaltrials.gov, NCT00474461). The 1-year follow-up results from the SCIPIO trial support that intracoronary infusion of one million autologous c-Kit$^+$ CSCs in patients with HF of ischemic etiology undergoing coronary artery bypass grafting is safe and feasible and may promote significant improvements in global and regional LV function, decrease scar size, and induce regeneration of viable myocardium [153].

Other Cardiac Stem Cells

Sca-1$^+$ CSCs are an alternative adult CSC. Evaluation of the corresponding human cell is limited by the absence of the Sca-1 antigen in humans [154]. Lineage fate-mapping studies in mice indicate that Sca-1$^+$ CSCs likely represent a subpopulation of pdgfrα^+ adult epicardial progenitor cells that, similar to c-Kit$^+$ CSCs, minimally contribute to endogenous cardiomyocyte regeneration in response to myocardial damage [60,69,70]. The Isl-1$^+$ progenitors

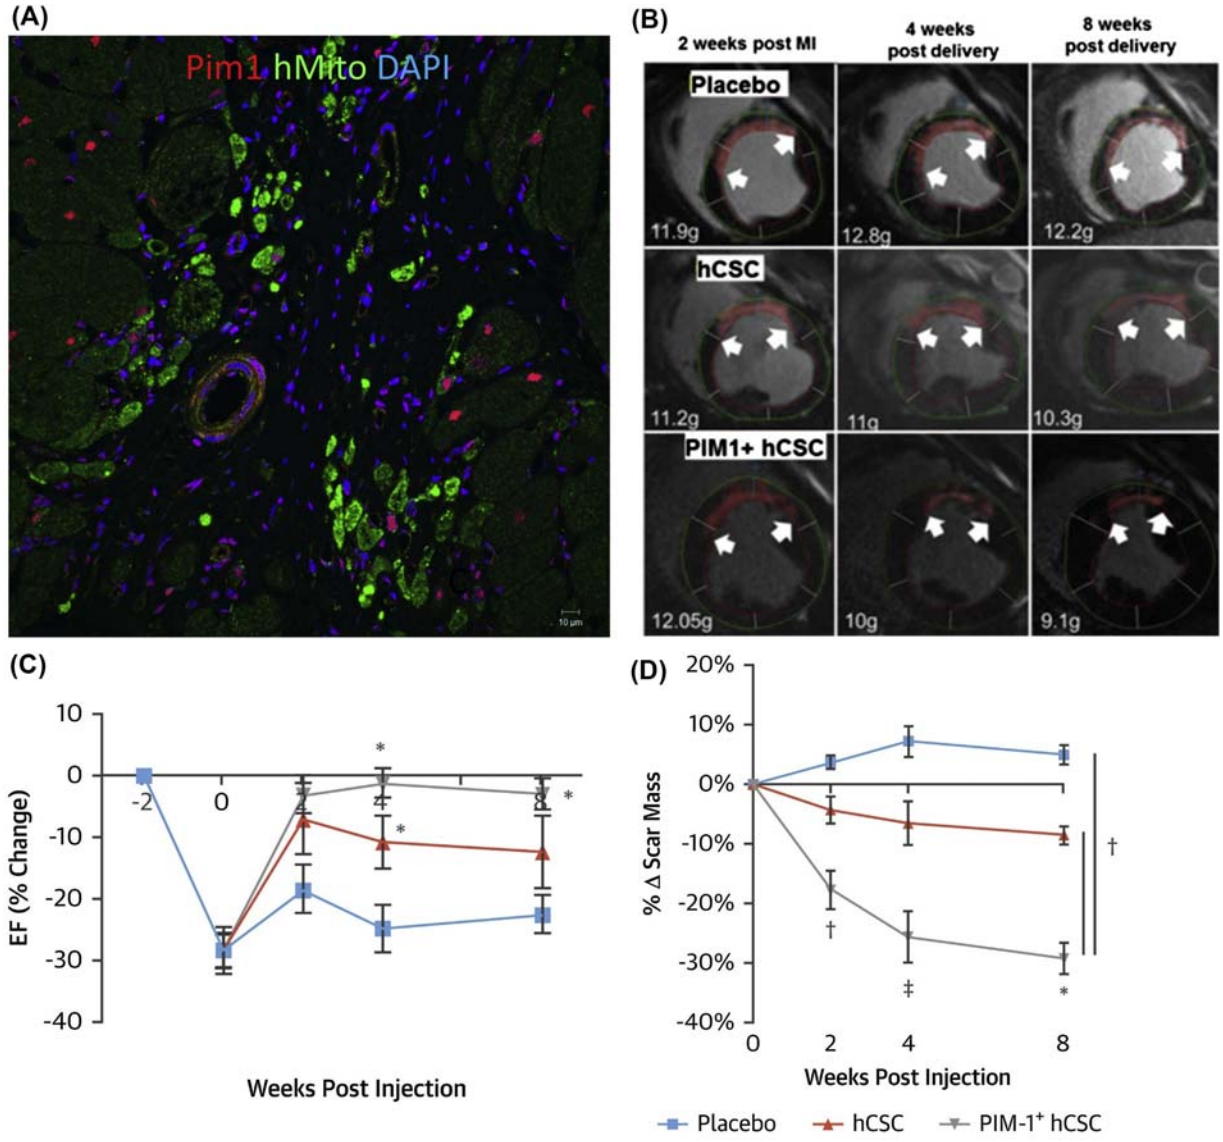

FIGURE 17.11 Genetic engineering of adult cardiac stem cells (CSCs) to enhance their therapeutic potential in response to myocardial damage. (A) Representative confocal microscopy image illustrating engraftment of human CSCs (green fluorescence), genetically engineered to overexpress the proto-oncogene protein kinase Pim1 (red fluorescence), in a porcine heart with experimental myocardial infarction. (B) Representative examples of delayed enhancement of the myocardium using gadolinium cardiac magnetic resonance images from placebo, CSC, or Pim1-overexpressing human CSC (hCSC)-treated animals depict the progress of the delayed enhancement at the same location throughout different points during the study. (C, D) At 4 and 8 weeks postinjection, both cell-treated groups exhibited improved ejection fraction and decreased scar formation compared with placebo. However, the PIM1-engineered CSCs exhibited three times greater antifibrotic effects compared with conventional CSCs. *MI*, myocardial infarction. *Adapted from Kulandavelu S, Karantalis, V, Fritsch, J, Hatzistergos, KE, Loescher, VY, McCall, F, Wang, B, Bagno, L, Golpanian, S, Wolf, A, et al. Pim1 kinase overexpression enhances c-kit+ cardiac stem cell cardiac repair following myocardial infarction in Swine. J Am Coll Cardiol 2016;68:2454–64. https://doi.org/10.1016/j.jacc.2016.09.925.*

have been isolated only from embryonic and very young murine cardiac tissues that do not exceed age 8 days [4]. Early studies suggested that they possibly represent cell remnants from the secondary heart field during embryonic development [26,53]. However, later studies indicated that a neural crest origin is also possible [56]. Isl-1^{+} cardioblasts have not yet been isolated from human heart tissue, but they have been derived in the laboratory from human pluripotent stem cells [53]. Genetic lineage-tracing experiments in mice have failed to document the contribution of postnatal Isl-1^{+} cardioblasts in endogenous cardiomyocyte regeneration in response to damage [59]. Abcg2^{+} SP cells are a cardiac precursor cell population found in rodent hearts [148]. However, although immunohistological studies have documented the existence of MDR-1^{+} and Abcg2^{+} cells in the postnatal human heart [41], isolation and expansion of these cells into therapeutic quantities have yet to be reported.

METHODS FOR EXPANSION OF ADULT CARDIAC STEM CELLS

Two general mechanisms have been employed to isolate and expand CSCs. These are antigen-panning techniques to identify cells such as c-Kit, sca-1, or abcg-2 or direct cell amplification. In the latter case, cells can be readily amplified from cardiac explants. These have been termed cardiospheres (CSs).

Cardiosphere Forming Cells

There have been several attempts to culture cells from the adult heart. Messina and colleagues reported on "cardiospheres" (CSs) structures akin to "neurospheres: [149]. CSs are self-aggregating structures arising from cultured cardiac cells and represent a heterogeneous population possessing cardiopoietic properties in vitro and in vivo [63]. CSs can be derived from human biopsies and are reported to contain $CD105^{+}$, c-Kit+, Sca-1+, and Flk1+ cells. When cocultured with neonatal rat cardiomyocytes, they transdifferentiate into cardiomyocytes, demonstrating calcium transients synchronous among the myocytes as well as spontaneous action potentials. When injected into infarcted rat hearts, ventricular function improved. In a study by Johnston et al., CSCs were injected into a porcine model of MI and were shown to abbreviate but not reverse progressive cardiac remodeling [155].

Cardiospheres represent a potential therapeutic opportunity because of their ability to expand potential cardiac stromal cells from smaller amounts of myocardial tissue, such as a cardiac biopsy. Cardiospheres are incompletely characterized, and whether they offer regenerative capacities superior to BM-derived or other stem cells will require formal testing. CS-derived cells (CDCs) have entered clinical trials [156]. The Intracoronary Cardiosphere-Derived Autologous Stem Cells to Reverse Ventricular Dysfunction trial was a phase I randomized, dose-escalation study of the safety and efficacy of intracoronary delivery of cardiosphere-derived stem cells in patients with ischemic LV dysfunction and a recent MI [156]. Patients who received infusion of CDCs exhibited an increase in viable heart mass, regional contractility, regional systolic wall thickening, and a reduction in scar mass. However, compared with c-Kit^{+} CSCs [153], CDC infusion did not improve LV end-systolic volume, end-diastolic volume, or EF [156]. Although early reports suggested that infused CDCs improve heart function via trilineage differentiation into cardiovascular derivatives [63], more recent studies indicate that the beneficial effects of CDC therapy are likely through paracrine signaling, such as secretion of exosomes [93].

COMBINED STEM CELL THERAPEUTICS

An intriguing effect of MSC therapy in response to ischemic heart damage is their ability to stimulate endogenous CSCs [10,90,92,97,129]. This observation has led to the hypothesis that mixing the two stem cell classes together may yield additive effects compared with each cell type alone. This hypothesis was explored in two proof-of-concept preclinical studies in a porcine model of experimental MI [80,113]. In the first study, intramyocardial injection of 200 million human MSCs combined with one million human CSCs in immunosuppressed pigs 2 weeks after MI resulted in twofold greater reductions in scar size and an increase in cell engraftment by sevenfold compared with treatment with each cell type alone. Moreover, these effects were accompanied by significant improvements in diastolic and systolic function (Fig. 17.12) [80]. The second study tested the combination of autologous MSCs and CSCs in a porcine model of chronic MI, to model its clinical application for HF more accurately. Again, combined transplantation of MSCs and CSCs resulted in significant reductions in scar size and increased viable tissue and cardiac function, which were accompanied by significant increases in endogenous cardiomyocyte mitosis [113]. These promising preclinical results are being tested in the Combination of Mesenchymal and C-kit+ Cardiac Stem Cells as Regenerative Therapy for Heart Failure trial, a multicenter phase II, randomized, placebo-controlled clinical trial designed to assess the feasibility, safety, and effect of autologous MSCs and CSCs both alone and combined compared with placebo as well as each other, administered by transendocardial injection in subjects with ischemic cardiomyopathy (NCT02501811). This ongoing trial, which is conducted by the National Heart, Lung, and Blood Institute's Cardiovascular Cell Therapy Research Network, will examine 144 patients. The results of this trial are highly anticipated and should provide future direction to the field.

Another promising approach of combined cell therapeutics is the mixture of adult BM MSCs with M2 macrophages [157]. Although the exact mechanism(s) of action remain unknown, it is hypothesized that this strategy combines the salutary effects of MSCs with the antiinflammatory actions of M2 macrophages to stimulate heart

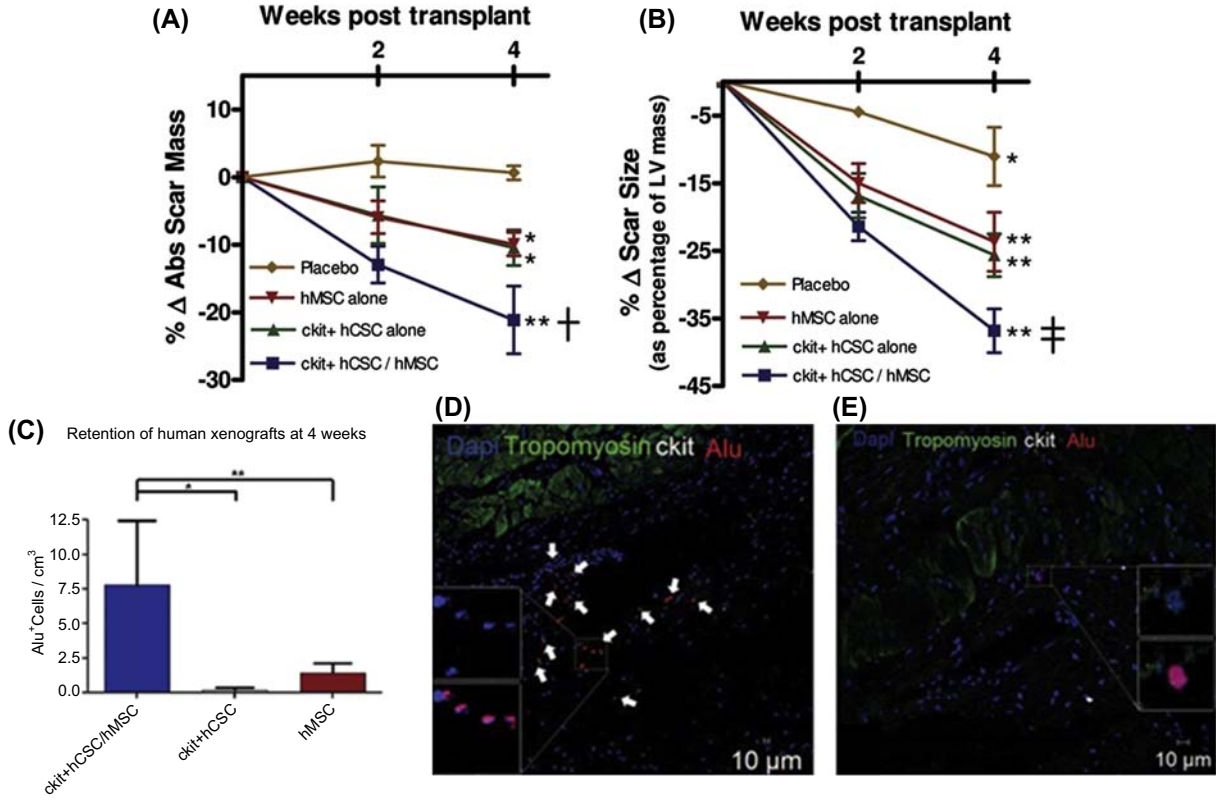

FIGURE 17.12 Combination cell therapy with mesenchymal stem cells (MSCs) and cardiac stem cell (CSCs). (A, B) Infarct size reduction after human CSC (hCSC) and bone marrow human MSC (hMSC) therapy in a xenogenic porcine model of myocardial infarction. Reduction in (A) absolute (Abs) infarct size and (B) infarct size as a percentage of left ventricular mass shows that all stem cell–treated pigs had reduced infarct size compared with placebo and combination therapy had substantially greater scar size reduction compared with either hMSC alone or hCSC alone. (C) Retention of Alu^+ human stem cells was sevenfold higher when hCSCs and hMSCs were injected together compared with either cell type administered alone. Immunohistochemical-stained images showing clusters of Alu-positive human stem cells (*white arrows*) engrafted in the (H) infarct territory and (I) vasculature at 4 weeks posttransplantation. *Adapted from Williams AR, Hatzistergos KE, Addicott B, McCall F, Carvalho D, Suncion V, Morales AR, Da Silva J, Sussman MA, Heldman AW. Enhanced effect of combining human cardiac stem cells and bone marrow mesenchymal stem cells to reduce infarct size and to restore cardiac function after myocardial Infarction Clinical perspective. repair. This hypothesis was initially tested in two open-label phase 2A trials, the Use of Ixmyelocel-T (Formerly Catheter-based Cardiac Repair Cell [CRC]) Treatment in Patients With Heart Failure Due to Dilated Cardiomyopathy [158]. In these trials, a total of 61 patients with congestive HF caused by ischemic or nonischemic cardiomyopathy were randomized to be treated with standard of care or transendocardial injections of ixmyelocel-T, an autologous BM cell product that underwent a 200-fold enrichment in $CD45^+/CD14^+$ M2 macrophages and a 50-fold enrichment in $CD90^+$ MSCs before transplantation. The results showed that the combination cell therapy significantly reduced major adverse events and improved symptoms in patients with ischemic heart disease but had no benefit in patients with nonischemic heart disease. These findings prompted the Ixmyelocel-T Administered Via Transendocardial Catheter-Based Injections to Subjects With Heart Failure Due to Ischemic Dilated Cardiomyopathy ix study, a randomized, double-blind, placebo-controlled phase 2B trial in which 126 patients with HF resulting from ischemic dilated cardiomyopathy were randomized to ixmyelocel-T ($n = 66$) or placebo ($n = 60$) [157]. The study is considered successful because it met its prespecified primary efficacy end point: a composite measure of the total number of clinical cardiac events as defined by all-cause deaths, cardiovascular admissions to hospital, or unplanned outpatient and emergency departments visits to treat acutely decompensated HF during the 12 months after administration of study treatment. However, the improved clinical outcome was not accompanied by significant improvements in LV function. Furthermore, only 109 of the 126 patients who were enrolled were finally included in the per-protocol primary efficacy analysis (58 in the ixmyelocel-T group and 51 in the placebo group), whereas the remainder of the patients were excluded for a variety of reasons including protocol violation, inadequate cell product, or catheterization/injection procedure-related adverse events that occurred within 7 days of treatment.

CONCLUSIONS

We have witnessed the rapid development of mechanistic and clinical trial support for the notion of a new paradigm in treating heart disease based on cellular therapeutics. Several important insights have emerged supporting this paradigm: (1) the discovery that the heart has capacity for self-renewal and harbors reservoirs of precursor cells that can be tapped or manipulated for therapeutic benefit; (2) remote cell sources, notably BM, also contain cellular constituents with profound therapeutic potential; and (3) cell-based therapies have a remarkable safety profile and can be delivered by diverse methodologies that range from intravenous administration in AMI to directed catheter-based injection systems in chronic HF. An emerging database of clinical trials and fundamental scientific enquiry provides a foundation for this strategy and holds promise for a treatment strategy aimed at a key pathophysiologic target in heart disease, that of ventricular remodeling.

Skeletal Muscle Stem Cells

Nora Yucel, Helen M. Blau

Stanford University School of Medicine, Stanford, CA, United States

INTRODUCTION

Skeletal muscle is essential for all voluntary contractile functions, including those of the limb, extraocular muscles, tongue, intercostal muscles, diaphragm, and sphincter. As a tissue, skeletal muscle comprises a major part of the human body, accounting for 28%–54% of total body mass depending on gender, age, and physical fitness [1]. It is composed of bundles of muscle fibers, or myofibers, that contract to generate force. Myofibers themselves are composed of contractile myofibrils, which are made up of hundreds to thousands of fused, postmitotic, terminally differentiated muscle cells. Each myofiber is sheathed by a cell membrane called the sarcolemma. Postnatal skeletal muscle growth, maintenance, and regeneration depend on a population of tissue-specific muscle stem cells (MuSCs) present in skeletal muscle, also known as satellite cells. Satellite cells are dedicated MuSCs that reside atop the myofiber between the sarcolemma and the basal lamina of the muscle myofiber [2]. Extensively characterized both functionally and molecularly as bona fide MuSCs, satellite cells have been shown to have a role in maintaining muscle mass in homeostasis and to be crucial for regenerating skeletal muscle in response to acute or chronic injury [3–8]. Other cell sources that contribute to muscle regeneration include muscle interstitial cells, fibrogenic/adipogenic progenitors (FAPs), blood vessel–associated mesoangioblasts, pericytes, and mesenchymal stem cells.

At homeostasis, normal adult skeletal muscle tissue undergoes relatively little turnover compared with other regenerative tissues such as the blood and skin, because only about 1%–2% of myonuclei are replaced weekly, [9]. Evidence has shown that the rate of myofiber remodeling may be higher, with 10% of myofibers showing contribution from a satellite cell per week [10,11]. In response to injury, healthy adult skeletal muscle has a remarkable ability to regenerate [12]. During regeneration, injury to myofibers first leads to a rapid immune response and an infiltration of inflammatory cells [13]. MuSCs are rapidly activated and proliferate as transient amplifying progenitors called myoblasts. A small proportion of activated MuSCs self-renew to replenish the stem cell pool. As regeneration proceeds, proliferating myogenic progenitor cells expand, differentiate, and subsequently fuse with existing myofibers or each other to form de novo myofibers. The newly formed multinucleated myofibers fuse into preexisting myofibers to replenish skeletal muscle mass and contractile function, thus repairing the injured tissue.

Inherited muscular dystrophies and noninherited muscle wasting diseases are characterized by extensive muscle degeneration, and thus are candidates for cell-based regenerative therapies. Heritable muscular dystrophies lead to progressive and often fatal muscle wasting. The most common form of muscular dystrophy is Duchenne muscular dystrophy (DMD), a severe X-linked recessive disorder that affects 1 in 3500 males [14]. DMD is caused by mutations in the dystrophin gene. The dystrophin gene is greater than 2.22 megabases and is one of the largest known genes in the human genome. The large dystrophin protein, which is 427 kDa, links the actin cytoskeleton network within the muscle myofiber to extracellular matrix (ECM) proteins of the basal lamina via the membrane-spanning dystroglycan complex [15,16]. Mutations in dystrophin result in a weakened sarcolemma that leads to loss of myofiber function and widespread muscle degeneration and necrosis. Patients with DMD progressively lose skeletal muscle mass, function, and regenerative potential, in part owing to the reduced stem cell proliferative capacity of MuSCs caused by the excessive demands of constant injury and regeneration [17–20]. As the disease progresses through early adulthood, patients with DMD develop severe muscle deterioration with the exception of facial muscles, increased

connective and fibrotic tissue deposition, loss of mobility, and kyphosis; the disease culminates in an untimely death from cardiorespiratory failure.

Treatments for muscular dystrophies and muscle wasting conditions such as aging-associated sarcopenia and pathology-associated cachexia have the challenge of rescuing defective postmitotic myofibers [21,22]. Although many pharmacologic and genetic therapies have been developed to minimize inflammation and support muscle regeneration for these diseases, they have met with little long-term clinical success, especially for the most devastating degenerative conditions [23,24]. Therefore, increased focus has been placed on developing regenerative strategies that target MuSCs to provide more effective therapies. There has been substantial progress in elucidating the molecular signals and myogenic gene regulatory mechanisms that underlie the regenerative capacity of MuSCs [25,26]. Thus, here we highlight the discovery of satellite cells as an endogenous source of MuSCs that contribute to adult muscle regeneration. Advances in regulating MuSC activation and self-renewal by biochemical and biophysical components of the MuSC niche microenvironment have been substantial. We evaluate the potential of satellite cells and other cell sources with myogenic regenerative properties for cell-based therapy for human muscle diseases. We also describe how technological advances offer promise for advancements in targeting endogenous stem cells in muscle wasting disorders or for cell therapy of heritable muscular dystrophies.

SATELLITE CELLS ARE MUSCLE STEM CELLS

To be considered a tissue-specific stem cell, cells must be able to (1) proliferate in a self-renewing manner that yields at least one daughter cell with a stem cell profile and (2) generate progeny capable of differentiating into all of the specialized cells of that particular tissue. For some tissues, stem cells must develop into a set of multipotent transient progenitors that can produce the complete diversity of terminally differentiated cells that make up the tissue. For example, a single hematopoietic stem cell (HSC) is capable of generating lymphoid, myeloid, and erythroid progenitors, which then generate all of the cells in the blood compartment. In contrast, MuSCs must give rise to only one single terminally differentiated cell type, the multinucleated myofiber. Consequently, a bona fide MuSC must be a self-renewing unipotent cell that is also capable of generating progeny that fuse with existing myofibers or generate new myofibers. The requirement of MuSCs to self-renew implies that MuSC division results in specialized progenitors in a manner that does not deplete the stem cell pool. This property distinguishes MuSCs from their myoblast progeny, which are able to undergo only a limited number of divisions before they undergo myogenic differentiation, thus causing their depletion. The long-term self-renewal characteristics of MuSCs confer the ability to contribute to myogenesis throughout the life span of an organism. Moreover, the stem cell capacity of MuSCs fulfills the requirements of an ongoing, continuous therapeutic cell source for long-term skeletal muscle regenerative medicine applications. In this section, we describe the molecular and functional characteristics that define MuSCs and how these can be combined to track prospectively isolated, transplanted cells and monitor their regenerative capacity.

THE MOLECULAR CHARACTERISTICS OF MUSCLE STEM CELLS DURING MYOGENESIS IN REGENERATION

Since their first identification by electron microscopy based on their anatomical position [2], our understanding of the molecular characteristics of satellite cells has greatly increased. Quiescent satellite cells, which have been shown to be MuSCs, are defined by the expression of the essential paired-box transcription factor *Pax7* [27,28]. Mice that lack PAX7 protein develop normally in utero, but only about half of expected homozygotes live to birth. Newborns that escape this early postnatal lethality typically survive only until about age 3 weeks and show approximately 50% reduction in muscle mass with vastly decreased numbers of satellite cells [28,29]. Conditional ablation of $PAX7^{+}$ cells in the adult mouse leads to acutely impaired muscle regeneration, including decreased myofiber area and increased fibrosis. Knockout of *Pax7* in isolated MuSCs in vitro results in cell-cycle arrest and premature differentiation [27]. In the diaphragm muscle, the paired box transcription factor PAX3 is constitutively expressed in satellite cells; however, this factor is transiently expressed only in hind-limb muscles, and its role as an essential factor in satellite cell maintenance is unclear [30–33]. Functionally, skeletal muscle satellite cells possess an intrinsic stem cell capacity; that is, they are able to develop into muscle and repopulate the stem cell niche independently.

After injury, PAX7^{+} MuSCs become activated and expand. As part of their stem cell identity, MuSCs undergo asymmetric cell divisions to generate both transiently amplifying progenitors that are committed to differentiation and new MuSCs to replenish the stem cell pool [34,35]. The discovery of the basic helix-loop-helix (bHLH) family began with MYOD1 and resulted from a clever strategy derived from the observation that treatment of fibroblasts with 5-aza-C yielded myogenic and adipogenic cells [36]. Upon activation, myogenic progenitors express a series of myogenic regulatory factors (MRFs), bHLH transcription factors that upregulate genes required for differentiation into muscle myofibers (Fig. 18.1E). The dynamics of these transiently amplifying progenitors have been characterized for the first time in vivo via multidimensional single-cell mass cytometry (CyTOF) [37].

In development, *Myf5* is the first bHLH factor to be expressed, and this transcription factor activates downstream myogenic genes in MuSCs and acts as a chromatin modifier of myogenic genes [38]. Lineage tracing experiments show that about 90% of all PAX7^{+} MuSCs express or have expressed the *Myf5* gene at some point, which indicates that it can lead to both stem cell self-renewal or differentiation [34]. Studies have shown that *Myf5* messenger RNA

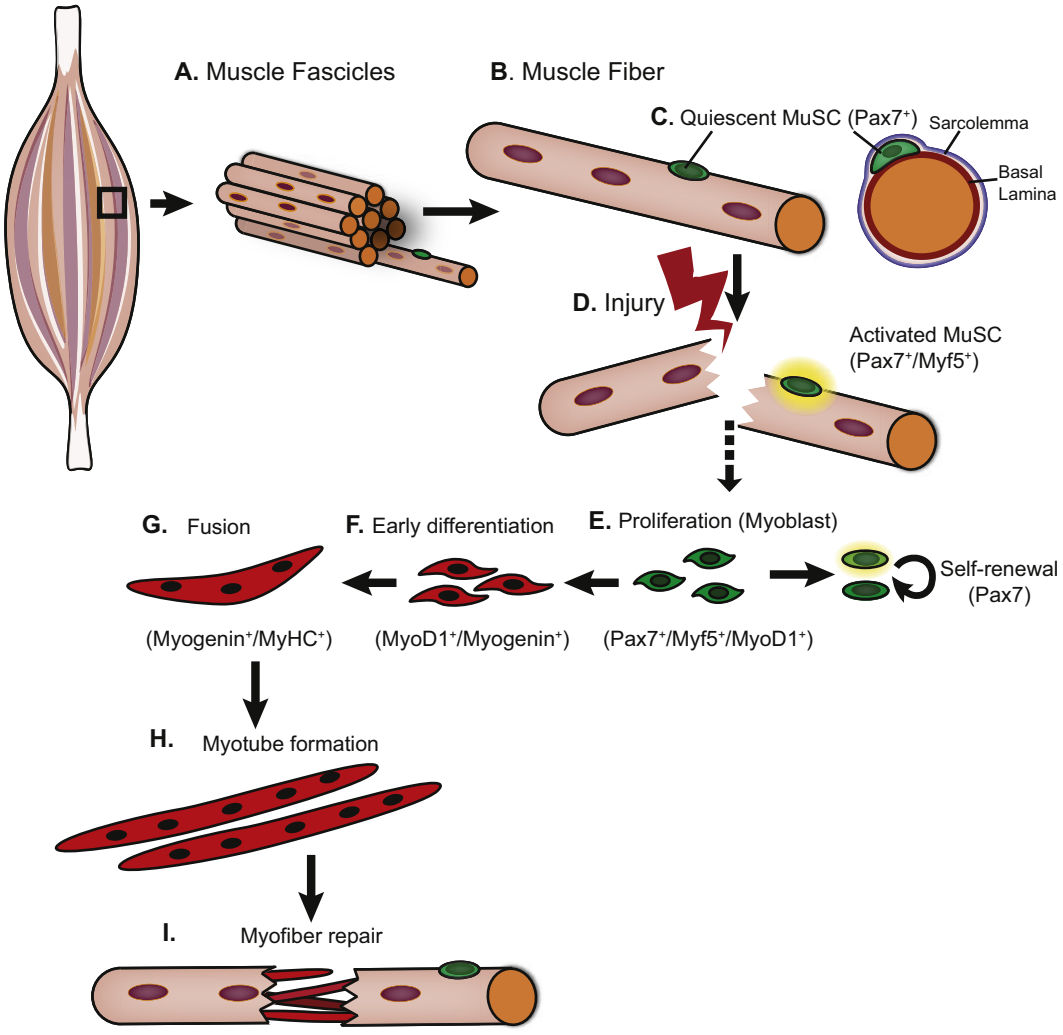

FIGURE 18.1 **Myogenesis during muscle regeneration.** Muscle is a primarily postmitotic tissue that consists of fused muscle cells. Muscle consists of bundles of (A) fascicles, which are in themselves composed of bundles of (B) muscle fibers. Muscle fibers are contractile, multinucleated nucleated cells formed from the fusion of myoblasts. They are sheathed by a cell membrane called the sarcolemma. (C) Muscle stem cells (MuSCs), which are not fused, reside atop the fiber between the sarcolemma and the basal lamina of the muscle fiber. They are maintained in their quiescent state by the expression of transcription factor Pax7. (D) Upon injury, MuSCS become activated and express Myf5. (E) During repair, activated MuSCs expand in the form of transiently proliferating progenitors known as myoblasts. Myoblasts downregulate Pax7 and express MyoD1. A fraction of activated MuSCs self-renew to repopulate the stem cell. After proliferation, myoblasts exit the cell cycle and (F) begin early differentiation, which is marked by expression of the transcription factor myogenin. (G) These cells eventually fuse together and form a multinucleated cell. Myosin heavy chains (MyHC) are expressed at this time. Multinucleated cells fuse to themselves to form (H) mature myotubes that eventually form the (I) new contractile myofibers at the end of regeneration.

(mRNA) is sequestered in quiescent satellite cells in messenger ribonucleoprotein (mRNP) granules, which suppress translation [39]. This sequestration of *Myf5* mRNA allows MuSCs to be poised for activation and entrance into the myogenic program while maintaining quiescence. After activation, mRNP granules become dissociated, allowing *Myf5* mRNA to be translated immediately and MYF5 protein to accumulate rapidly. Later during development, MYF5 function has redundancy with bHLH regulatory factor MRF4 [40], which promotes early muscle formation. In adult regeneration, MRF4 inhibits muscle growth and hypertrophy [41].

MuSC activation is later marked by the bHLH factor, MYOD1. MYOD1 is a potent transcriptional activator of myogenesis [42]. MYOD1 shares many similar genomic targets with MYF5 and can rescue myogenesis in the absence of MYF5 [43]. Because of their largely redundant function, knockout of either MYOD1 or MYF5 is not associated with skeletal muscle defects [44], but MYOD/MYF5 double knockouts lack expression of myogenic genes and have no discernible formation of muscle myofibers [43]. In the presence of high levels of mitogens, MYF5 and MYOD1 are highly expressed and define commitment to a myogenic cell fate but they do not activate the expression of differentiation genes. In particular, MYOD1 is known to associate with histone deacetylase 1 during proliferation to repress myogenic differentiation targets [45]. Removal of serum in vitro induces cell cycle exit, which is driven in part by MYOD1 upregulation of p21, a cyclin-dependent kinase inhibitor [46]. After cell cycle exit, MYOD1 associates with histone acetyl-transferases to induce acetylation and expression of myogenic differentiation genes [47,48]. The final stage of myogenesis is driven by expression of the transcription factor Myogenin (MYOG), the canonical marker of terminal differentiation (Fig. 18.1F) [49].

Myosin heavy chain isotypes distinguish fast and slow myofibers that differ in their stem cell and regenerative properties. They are expressed during late differentiation and upon fusion of myoblasts [50] (Fig. 18.1G). These proteins are highly conserved, actin-based motor proteins that use energy from adenosine triphosphate (ATP) to generate contractile force in mature myofibers [51]. Myosins are upregulated as fusion proceeds, forming multinucleated myotubes (Fig. 18.1H) that then fuse to each other to form myofibers and repair the injured tissue at the end of regeneration. A number of different myosin heavy chain isoforms define distinct fiber types in the adult muscle: I, IIA, IIB, and IIX [52]. Type I fibers are slow-twitch and mitochondria-dense and derive ATP primarily from oxidative phosphorylation of fat. These fibers are also known to have the highest density of $PAX7^+$ stem cells per fiber [53]. Rich in myoglobin, type I fibers can maintain contractile activity and are resistant to fatigue. Type II fibers rely on glycolysis to generate ATP rapidly. Type IIA fibers use oxidative glycolysis and have more mitochondria than type IIB fibers, which primarily use anaerobic glycolysis. Type IIB fibers are the fastest but generate force for the shortest time and are the first to be affected in DMD [54]. Type IIX fibers are mixed between IIA and IIB [52].

Expression of myosin isoforms is highly dynamic during development and regeneration [55] as well as in vitro differentiation [50]. Embryonic myosin isoforms, which typically are expressed during development, are reexpressed during early differentiation or regeneration [56,57]. Neonatal fast and slow myosins precede adult myosin isoform and can be distinguished from the adult myosin isoforms at the end of regeneration by monoclonal antibodies [58,59]. The functional basis for the observed developmental progression of myosin isoforms remains unknown. Reestablishment of fiber types during late regeneration and postnatal development is independent of cell lineage [60,61] and primarily caused by innervation [55,62,63].

The search for mediators of myogenic fusion, a step essential to muscle development and regeneration, has been under way for decades. A number of integral components implicated in myofusion have been implicated using a β-galactosidase (β-gal) complementation method [64], including neural cell adhesion molecule (NCAM) [65] and N-cadherin [66]. Additional studies pointed to α4-integrin [67], M-cadherin [68], vascular cell adhesion molecule (VCAM) [69], β1-integrin [70], MOR23 [71], and the metalloproteinase/disintegrin meltrin-α [72] as mediators of fusion. However, the proteins that are essential to muscle fusion been definitively identified only recently. The muscle-specific gene Myomaker (TMEM8c) [73] is absolutely required for fusion in vitro or during development. However, Myomaker alone does not suffice for fusion to occur, because overexpression of Myomaker causes fusion of fibroblasts with myoblasts but not fusion between myoblasts [73]. Myomaker's partner has been identified as the transmembrane protein Myomixer [74]. Although the molecular components required for muscle fusion continue to be discovered, the mechanism of fusion is still under investigation.

FUNCTIONAL CHARACTERISTICS OF MUSCLE STEM CELLS

One of the first indications that $PAX7^+$ satellite cells are MuSCs was established by transplantation studies. In these studies, satellite cells juxtaposed to single fibers were genetically labeled by Myf5-β-gal, and single fibers, which were confirmed to contain resident satellite cells, were transplanted into damaged recipient wild-type

(WT) muscles [5]. The donor myofibers resulted in new myofibers, and associated satellite cells were able to self-renew and develop into new satellite cells in the niche position in the recipient animals [5]. However, the use of entire myofibers for transplantation did not demonstrate definitively that $PAX7^+$ satellite cells could become the entire myogenic lineage on their own. The intrinsic stem cell capacity of satellite cells alone was demonstrated through later single-cell isolation strategies. Satellite cells were genetically labeled to express reporter genes such as green fluorescent protein (GFP) or β-gal and isolated from single-cell muscle digests or mechanical trituration of isolated myofibers. These cells were transplanted by intramuscular injection into recipient muscle of regeneration-deficient mice [30,75,76].

In transplantation assays to evaluate MuSC properties, recipient mouse hind-limb muscles such as the tibialis anterior are often irradiated pretransplantation to limit the contribution of endogenous stem cell populations, as in HSC transplantation scenarios. Sometimes mice are also injured acutely before and/or after transplantation, either with a chemical toxin such as notexin or by direct tissue injury (e.g., freeze-probe application), to assess the stem cell and proliferative capacity of donor cells. Alternatively, satellite cells are transplanted into recipients with a muscle regenerative defect, such as the *mdx* mouse model of DMD, to assess the ability of the stem cells to meet a chronic regenerative demand. Through these approaches, multiple investigators have demonstrated that $PAX7^+$ satellite cells are able to contribute to the regeneration of recipient myofibers, repopulate the myofiber membrane-defined satellite cell niche, and expand and self-renew upon activation by injury [5,30,34,75–77]. Using such regimens, isolated labeled satellite cells were shown to contribute directly to myofibers as well as the resident stem cell population.

ISOLATION OF MUSCLE STEM CELLS

A number of strategies have been developed to isolate MuSCs prospectively. Fluorescence-activated cell sorting is used to identify MuSCs based on their unique profile of surface markers. Prospective isolation strategies routinely employed a combination of markers, often including the absence of lineage markers such as CD31, CD11b, CD45, and Sca1 to obtain a highly enriched cell population. For mouse satellite cells, α7-integrin (ITGA) [77], which is also present on myoblasts [78], is the most commonly used marker for isolation in conjunction with β1-integrin [34,75], CD34 [76], CXCR4 [75], VCAM1 [79], syndecan (SDC)-3/4 [6], ABCG2 [6], and c-met [80]. Additional sorting strategies have used lineage depletion combined with the antigen for the SM/C-2.6 monoclonal antibody [81], and the calcitonin receptor CALCR [82]. Other mouse MuSC prospective isolation strategies use transgenic fluorescent protein reporters under the control of promoter elements of satellite cell-associated transcription factors such as *Pax7-eGFP* [83], *Pax7-ZsGreen* [84], and *Myf5-Cre/ROSA26-YFP* [34]. These genetically labeled models have been used to distinguish subpopulations further. Two cell surface markers, CD9 and CD104, identified by single-CyTOF profiling of injured muscles, enabled in vivo identification and prospective isolation of stem and progenitor cells [37]. It is likely that none of these markers encompasses all MuSCs, because there is known to be heterogeneity within MuSC populations.

Studies have uncovered cell surface markers that enrich for human satellite cells. Human satellite cell markers have long been sought, because human markers do not completely correspond to those on well-defined mouse satellite cells. For example, unlike mouse satellite cells, human satellite cells are not $CD34^+$ [85,86]. In addition, PAX7 expression does not appear to be necessarily restricted to satellite cells in human muscle but is also expressed by progenitors [87]. Human myogenic cells were first prospectively isolated using a monoclonal antibody to an antigen identified as NCAM [88]. $CD133^+$ and culture-expanded human muscle–derived myoblasts have also been shown to have engraftment potential and generate satellite cells [89,90]. However, the xenotransplantation efficiency of these cells is low. Studies have found cell surface markers of fetal [91] and adult [92], $PAX7^+$ muscle satellite cells with MuSC function. Fetal satellite cells were identified as negative for blood and fibroblast markers CD45/CD11b/GlyA/CD31/CD34, and intermediate for NCAM (CD56) and high ITGA expression. These $CD56^{Int}ITGA7^{hi}$ show bipotent myogenic and osteogenic activity with no adipogenic capacity in vitro and engraft when transplanted into mouse muscles. However, the same markers do not mark adult satellite cells with engraftment capacity. Adult MuSCs can be isolated by $CD31^-/CD45^-/$β1-integrin $(CD29)^+/NCAM(CD56)^+$ expression [92] or $CD31^-/CD45^-/$β1-integrin and epidermal growth factor receptor [93]. In addition, CD82 and CD318 have been identified as marking myogenic cells with high engraftment potential [94,95]. These cells express PAX7 and can both contribute to myofibers and repopulate the satellite cell niche when transplanted into mouse muscle. Similar to mouse MuSCs, these transplanted human adult MuSCs expand upon reinjury, an indicator of true stem cell capacity.

TRACKING MUSCLE STEM CELL BEHAVIOR THROUGH LIVE IMAGING (BIOLUMINESCENCE IMAGING AND INTRAVITAL IMAGING)

The development of noninvasive imaging techniques has greatly advanced our understanding of MuSCs. Bioluminescence imaging (BLI) enabled the first demonstration that a single satellite cell fulfills the stringent criteria of a MuSC [76]. BLI has been highly useful in studies to establish the regenerative potential of other tissue-specific stem cell types. These studies showed that only 4% of 144 mice injected with single MuSCs exhibited a positive BLI signal, a result that was difficult to ascertain by classical histological methods. Similarly, the ability to track the behavior of small numbers of transplanted cells in vivo (<10) revealed the intrinsic deficit of aged MuSCs to engraft, a finding not previously apparent through transplantation of larger cells numbers (>100) [26].

BLI uses luciferase-expressing satellite cells that are often colabeled with GFP, which allows for dynamic monitoring of the cells as they contribute to tissue regeneration, as well as end-point immunohistological analysis (Fig. 18.2). Temporal assessment of stem cell behavior upon stimulation with a drug, hormone, or growth factor is also possible by BLI, because the same mice can be imaged noninvasively repeatedly over time, whereas classical histological analyses require killing the mice [96]. BLI revealed that after reinjury, the progeny of transplanted satellite cells divide exponentially and then cease to divide, reaching a plateau upon achieving homeostasis when no more stem cells are required [76]. By contrast, 90% of myoblasts without self-renewal capacity die upon injection and no increase in numbers is observed over time, which explains in part why clinical trials with these cells have been disappointing [85,97,192]. Furthermore, it is possible to assess whether transplanted stem cells are transformed, because the exponential proliferation of tumorigenic cells does not cease and a plateau is never achieved [98]. This type of exponential increase is not typically observed with transplanted MuSCs and rhabdomyosarcomas

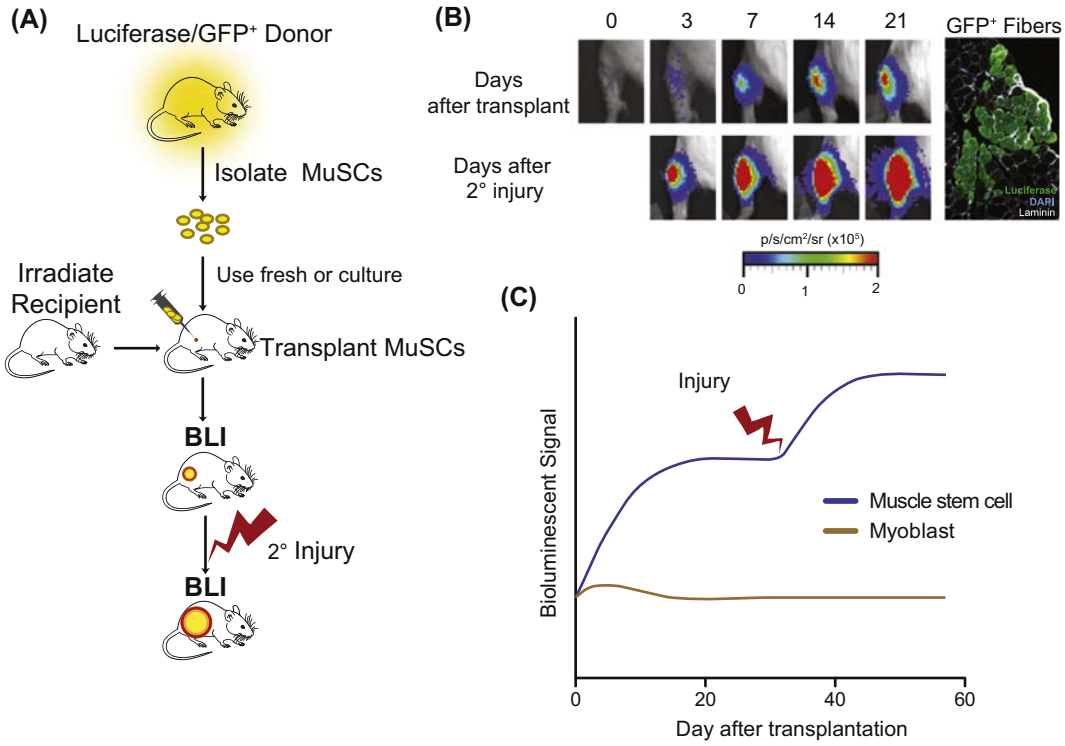

FIGURE 18.2 **Noninvasive bioluminescent imaging (BLI) to visualize the expansion and engraftment of transplanted muscle stem cells (MuSCs) dynamically.** (A) Transplantation scheme for BLI. MuSCs are isolated from a donor animal expressing luciferase and green fluorescent protein (GFP). These cells are then transplanted via intramuscular injection into the hind limb of recipient animals, which are immunocompromised and irradiated to deplete the existing stem cell pool and minimize immune rejection. (B) Example of BLI signal from MuSCs after transplantation and injury. Immunohistological analysis of muscles with transplanted MuSCs show GFP-positive myofibers. (C) Scheme of a theoretical comparison of the engraftment and proliferation of 100 transplanted MuSCs or committed myoblast progenitors. BLI used to track engraftment after injury, as well as expansion after secondary injury. While transplanted MuSCs expand and engraft, myoblasts have poor viability and do not engraft or expand. For MuSC transplantation, the BLI signal reaches a plateau when cells stop proliferating, differentiate, and fuse into mature myofibers. Expansion of transplanted MuSCs that have repopulated the stem-cell niche can be stimulated by injury and tracked by BLI.

are rare in childhood and virtually nonexistent in adulthood. That MuSCs and the muscle tissue microenvironment are nontumorigenic suggests that yet unidentified tumor-suppressive factors are at play.

BLI has been used to track in vivo regeneration and inflammation in skeletal muscle disease states [99,100]. The *Pax7*-driven luciferase reporter mouse (*Pax7Cre^{ER}/LuSEAP*) was created as a "regeneration reporter" line to study the expansion and differentiation of satellite cells during regeneration in vivo [99]. These mice had a low level of luciferase signal at baseline that increased after 3 days of injury by barium chloride injection. At the end of regeneration, once myofibers matured, the luciferase signal decreased. Luciferase-positive myotubes were apparent upon histological analysis, which was consistent with the contribution from luciferase-expressing MuSCs. To analyze the expansion of *Pax7*-expressing MuSCs during chronic muscle regeneration, *Pax7Cre^{ER}/LuSEAP* animals were crossed to dysferlin-deficient *Dysf$^{-/-}$* mice, which are a model of limb girdle muscular dystrophy. *Dysf$^{-/-}$/Pax7Cre^{ER}/LuSEAP* mice showed a persistent increase in luciferase signal over time, indicative of ongoing regenerative activity. Similarly, an inflammation-driven luciferase reporter line (*Cox2$^{Fluc/+}$*) was crossed with the *mdx* mouse model of DMD to analyze muscle inflammation during disease progression in vivo [100]. BLI showed increased inflammation in response to damage by exercise or cardiotoxin injury, and a decrease upon treatment with steroids to reduce inflammation. These studies highlight the promise for future application of BLI for the rigorous quantitative assessment of muscle regeneration in different mouse models of chronic and acute muscle injuries typical of human muscle diseases, as well the efficacy of therapeutic candidates.

Intravital imaging (IVM) with two photon-excitation microscopy has arisen as a technique to study the behavior and function of MuSCs and muscle progenitors during regeneration. This technique provides for high resolution, allows for use of multiple colors, and can be combined with bright-field and secondary harmonic imaging for higher detail of tissue structure in living animals. Two-photon excitation allows for virtual cross-sections of the tissue to be analyzed. A study showed a time course of one million myoblasts transplanted to treat muscle regeneration [101]. Another study used IVM to directly image for the first time MuSCs on uninjured and injured muscle myofibers [102]. Consistent with histological evidence that MuSCs are primarily quiescent, IVM showed neither division nor migration during the imaging period of 3 days. Using the ability of IVM to visualize sarcomere structure through secondary harmonic generation, Webster et al. [102] showed that muscle progenitors divide along "ghost fibers" during regeneration. These ghost fibers are the ECM scaffold surrounding muscle fibers, which remains intact when these myofibers are ablated through injury. Overall, live imaging is a powerful tool for the longitudinal analysis of MuSCs.

REGULATION OF MUSCLE STEM CELLS BY THEIR NICHE

A number of the molecular and biophysical components of the satellite cell niche in mice have been identified that are crucial for directing satellite cell quiescence, activation, migration, and self-renewal. Although the precise roles of these niche factors are still under investigation, current progress is summarized here and detailed in subsequent sections.

Extracellular Matrix Components

The myofiber basal lamina contains a range of ECM components that regulate MuSC fate. These include type VI collagen [103], fibronectin [104,105], tenascin-C (TNC) [106], laminin [107–109], and other proteoglycans and glycoproteins [110]. Collagen VI, which is primarily deposited by muscle-resident fibroblasts, is required for maintaining MuSC self-renewal during homeostasis and injury [103]. Fibronectin is a transient niche component present during regeneration that is secreted by progenitors and promotes self-renewal of MuSCs. It is a preferred ECM substrate for MuSCs, which adhere to fibronectin through integrins and the SDC4–Frizzled-7 (FZD7) complex [105]. Accumulation of fibronectin is thought to be detrimental to differentiation and regeneration. Loss of fibronectin, in particular during aging, leads to a reduction in the stem cell pool after injury [104]. Laminins are expressed on the surface of myotubes in vitro and myofibers in vivo and have been shown to promote migration of myoblasts and preserve differentiation potential [107–109]. A mechanical stress sensor, TNC is expressed in actively remodeling muscle [111]. Knockdown of TNC results in selective atrophy of fast muscle fibers in the adult. In addition, TNC is highly expressed during development and promotes MuSC expansion and regeneration in fetal muscle [106].

Satellite cells express numerous cell-surface molecules that interact with components of the ECM [110,112]. Integrins, which are heterodimers consisting of a α and a β chain, physically tether the satellite cell to the niche and mediate molecular and biophysical signal transduction [113]. MuSCs primarily express the α7/β1 heterodimer.

Evidence has shown that FGF2 signaling is mediated through β1-integrin, which is critical for maintaining MuSC self-renewal and expansion during injury [114]. Another integrin, β3-integrin, has been shown to mediate MuSC differentiation in muscle regeneration [115]. Other important ECM-signaling proteins include heparan sulfate proteoglycans such as SDC3, which promotes self-renewal and inhibits differentiation through Notch activation [116], and SDC4, which mediates asymmetric self-renewal through WNT7A and fibronectin [105].

Molecular Signaling Factors

Growth factors are secreted from systemic and local sources and stimulate satellite cell survival, activation, and proliferation. They can bind to proteoglycans in the myofiber basal lamina or on the satellite cell surface itself to provide a niche repository of signaling molecules. Circulating signaling factors can gain access to satellite cells, because of the close proximity of their niches to both muscle microvasculature [53] and neuromuscular junctions [117], and diffuse through the basal lamina. After injury, inflammatory cells secrete cytokines such as interleukin 1, interleukin 6, and tumor necrosis factor-α that regulate the activation, proliferation, and differentiation of MuSCs [118,119]. The small metabolite prostaglandin E2 has been recently identified as part of the inflammatory wave that is the first response to injury in muscle [120]. The addition of PGE2 transiently leads to a robust increase in muscle stem cell numbers in culture and boosts engraftment of treated cells post-transplantation. Notably, PGE2 delivered directly to injured muscles activates endogenous stem cells within the muscles and markedly accelerates regeneration, suggesting it may have therapeutic value. Other critical circulating factors include fibroblast growth factor (FGF) [114,121–123], hepatocyte growth factor (HGF) [124,125], and insulin-like growth factor-1 (IGF-1) [126,127], among others. FGF stimulates MuSC activation, which is repressed during quiescence by the receptor tyrosine kinase signaling inhibitor Sprouty1 (SPRY1) [128]. HGF, which is also secreted by MuSCs themselves [125], binds to the c-met receptor of MuSCs and promotes activation, proliferation, and migration [124]. IGF-1 is a circulating hormone that stimulates proliferation of MuSCs as well as differentiation. In the transforming growth factor-β (TGF-β) superfamily, myostatin, also known as GDF8, is a secreted factor that has been shown to circulate in serum. Myostatin is a negative regulator of MuSC proliferation as well as muscle hypertrophy, and knockout cattle exhibit profound increases in muscle mass [129–131]. Much attention has been focused on another TGF-β member, GDF11, which is a systemic factor that shares 89% homology with myostatin and signals through many of the same pathways. There have been conflicting reports on the function of GDF11. Some studies have shown that like myostatin, GDF11 inhibits muscle regeneration and decreases MuSC expansion [132], whereas other reports show that it can rejuvenate the regenerative function of aged muscle [133]. The debate remains unsettled, but TGF-β family members remain attractive therapeutic targets.

In addition, MuSCs, progenitors and mature myofibers themselves express factors that influence their own behaviors through juxtacrine signaling. These include ligands for Notch, which maintains the quiescence of adult MuSCs at homeostasis [34,134–136]. Moreover, the Wnt family of proteins is composed of secreted glycoproteins often associated with the ECM. WNT3A acts through canonical Wnt signaling to drive myogenic differentiation [137,138]. WNT7A has been shown to promote symmetric expansion of MuSCs through noncanonical signaling via the receptor FZD7 [21,105,139]. A report showed that the secreted R-spondin protein RPSO1 potentiates these Wnt signaling pathways, promoting WNT3A activation and suppressing WNT7A signaling. Stromal cell-derived factor-1 is secreted by the myofiber and binds the receptor CXCR4 on satellite cells. First identified as a migratory factor during development [140], it regulates the proliferation of progenitor cells and terminally differentiated myoblasts and is necessary for fusion [141,142]. Further elucidation of how satellite cell behaviors are regulated in normal muscle homeostasis and regeneration and are dysregulated in degenerative muscle conditions will be instrumental for the development of methods to maintain and expand MuSCs in culture and therapies directed toward endogenous MuSCs or using transplanted MuSCs.

Biophysical Cues

MuSCs are highly sensitive to changes in the mechanical and topological components of their niche. Cells can respond to extracellular biophysical cues through a variety of mechanotransduction mechanisms [143]. Rigidity of the surrounding matrix, characterized by Young's modulus, is known to direct cultured multipotent mesenchymal stem cells toward myogenic, chondrogenic, adipogenic, or osteogenic cell fates in culture [144]. In muscle, matrix rigidity has been shown to be highly important for maintaining MuSC self-renewal and stem cell functions. In vivo, skeletal muscle stiffness increases during age and disease as a result of increased fibrosis [145–148]. Elevated rigidity of skeletal muscle is apparent in the *mdx* mouse model of DMD, which has an elastic modulus of $E > 18$ kPa

after age 4 months [145,146]. MuSCs plated on hard plastic, which have a Young's modulus of E $\sim 10^6$ kPa, lose stem cell function within 7 days. A hydrogel material with the same rigidity as muscle tissue (E = 12 kPa) promotes cell survival, prevents differentiation, and maintains stem cell function, as measured by transplantation assay [149]. These findings suggest that alterations in the elasticity or rigidity of skeletal muscle tissue may have profound effects on the contributions of satellite cells and myogenic progenitors to muscle regeneration.

Metabolic Cues

Skeletal muscle is a highly metabolic tissue that is crucial for maintaining metabolic homeostasis in the organism and functions as a rheostat for metabolic health. Evidence has shown that metabolic cues are critical regulators of MuSC behavior and function [150]. Quiescent MuSCs have been found to associate closely with capillaries [53]; they have a high expression of oxidative phosphorylation and fatty acid metabolism genes and exhibit evidence of mitochondrial respiration with little anaerobic glycolysis [151]. Upon activation, MuSCs switch to more anaerobic glycolysis, concomitant with downregulation of fatty acid metabolism genes [151] as well as increased autophagy to support bioenergetic demands [152]. During muscle regeneration, the heightened inflammatory state also affects MuSCs outside the direct injury site, inducing cells into an "alert" state poised to enter the cell cycle, characterized by increased metabolic activity and activation of the nutrient-sensing mammalian target of rapamycin complex pathway [153].

The metabolic state of the tissue has important implications for the function of MuSCs. Aged MuSCs, which have reduced function compared with young controls, exhibit mitochondrial dysfunction and an aberrant expression of metabolic genes in mice [154]. Restoration of mitochondrial activity by treatment with nicotinamide riboside, a precursor of nicotinamide adenine dinucleotide (NAD^+), increased MuSC numbers and improved the function of both MuSCs and total muscle in aged mice. NAD^+, a by-product of a number of metabolic processes including the oxidative respiratory chain, has also been shown to be critical for the activation of MuSCs. MuSCs activated by short-term cell culture have decreased NAD^+ levels, concomitant with increased anaerobic glucose metabolism. These metabolic changes lead to increased histone acetylation mediated by decreased activity of the NAD-dependent histone deacetylase SIRT1. Knockout of *Sirt1* in $PAX7^+$ MuSCs results in aberrant activation and increased histone acetylation of quiescent cells, leading to decreased regenerative capacity [151]. Finally, short-term calorie restriction (12 weeks) of young or aged mice has been shown to enhance MuSC numbers and stem cell function, including increased ex vivo myogenic colony-forming capacity and the ability to engraft into recipient (WT) muscle tissue [155]. Caloric restriction also increased mitochondrial capacity and respiration and increased the fraction of MuSCs expressing *Sirt1*. MuSCs isolated from WT tissue and transplanted into calorie-restricted recipients also showed increased engraftment, which demonstrated that the benefits of calorie restriction are extrinsic as well as intrinsic.

In contrast, muscle regeneration is known to be impaired in obesity and type 2 diabetes (T2D) [156,157], conditions that result in muscle-specific metabolic inflexibility and increased mitochondrial stress [158]. Mice given a high-fat diet (HFD) (60% kcal) to induce glucose intolerance have reduced muscle regeneration after either short-term (3–6 weeks) [159] or long-term (8 months) [157] administration of the diet compared with normal diet (10% kcal) controls. These regenerative defects are also cell-intrinsic. MuSCs isolated from mice fed an HFD for 8 weeks have reduced proliferative capacity ex vivo, together with attenuated muscle regeneration after cardiotoxin injury in HFD muscle [160].

In humans, myoblasts derived from patients with metabolic dysfunction also retain intrinsic defects. Metabolic studies show that myotubes derived from patients with T2D retain a diabetic phenotype in culture, including increased lactate production, decreased glucose uptake as well as incorporation of glucose into glycogen, and increased expression of genes involved in mitochondrial and fatty acid metabolism [161,162]. A separate investigation showed increased pyruvate dehydrogenase kinase 4 expression after stimulation with fatty acids (palmitic or oleic acid) in T2D myotubes [163]. Furthermore, myotubes from extremely obese patients secrete 2.9-fold more myostatin, an inhibitor of skeletal muscle hypertrophy, compared with lean controls [164]. The effect of caloric restriction on MuSCs is considerably more difficult to assess in humans, but evidence suggests that, as in mouse models, it may have a beneficial effect on muscle metabolism in humans [165,166].

SATELLITE CELL SELF-RENEWAL MECHANISMS

The MuSC pool is maintained by self-renewal, which results from two proliferation mechanisms: (1) asymmetric self-renewal, in which a stem cell divides into one differentiated cell and one stem cell; and (2) symmetric self-renewal, in which a stem cell divides to become two equivalent stem cells. MuSCs can also remain quiescent or

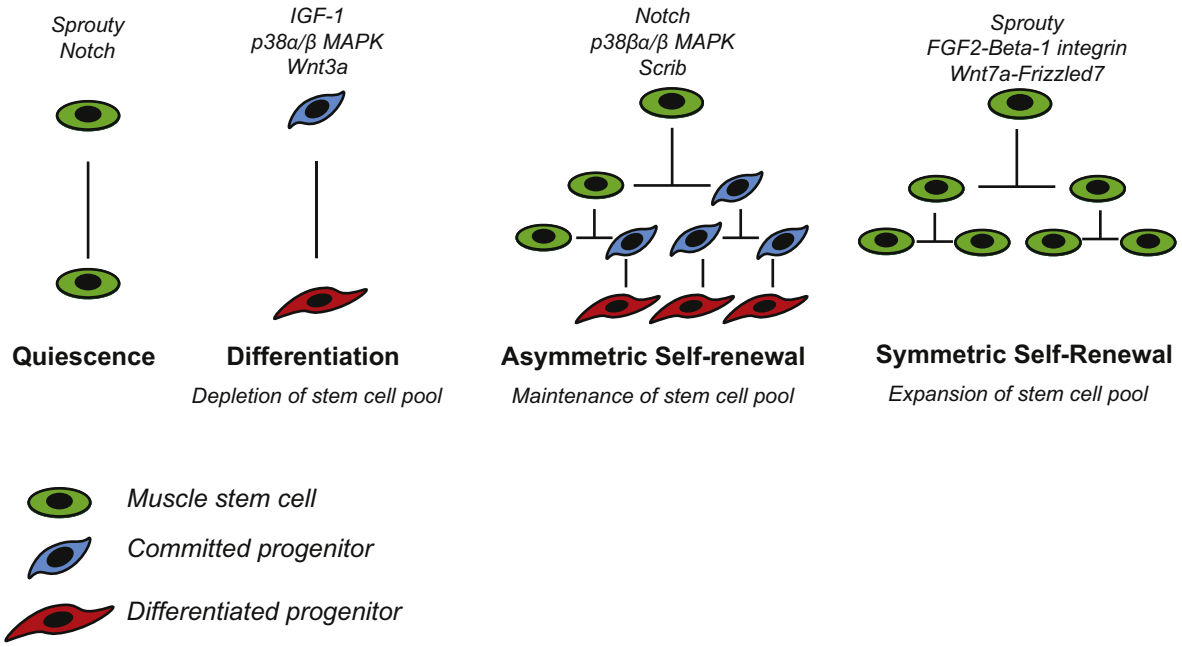

FIGURE 18.3 **Muscle stem cell (MuSC) fates during regeneration and promoting factors.** During regeneration, the quiescent MuSC pool can be depleted through death and differentiation. After activation by injury, this pool can be maintained through two types of self-renewal: asymmetric and symmetric. In asymmetric stem cell self-renewal, a stem cell divides into one committed progenitor that will eventually differentiate and one stem cell maintains the MuSCs pool. Expansion of the MuSC pool occurs with symmetric stem cell self-renewal when a stem cell divides to generate two equivalent stem cells. *FGF2*, fibroblast growth factor-2; *IGF-1*, insulin-like growth factor-1; *MAPK*, mitogen-activated protein kinase.

differentiate (Fig. 18.3). Under homeostasis, it is believed that asymmetric self-renewal is sufficient to meet the demands of normal cell turnover. However, during injury the demand for expansion of stem cells likely also requires symmetric self-renewal [167]. In the mouse, self-renewal mechanisms of MuSCs have been studied through lineage tracing with the transgenic *Myf5-Cre/ROSA26-YFP* mouse [21,34], which expresses yellow fluorescent protein (YFP) after expression of the MuSC activation gene *Myf5*. These studies showed that Notch signaling drives the asymmetric division of quiescent $PAX7^{+}MYF5^{-}$ MuSCs into one $PAX7^{+}MYF5^{-}$ and $PAX7^{+}/MYF5^{+}$ cell [34], and that WNT7A signaling drives the symmetric division of one $PAX7^{+}/MYF5^{-}$ MuSC into two $PAX7^{+}/MYF5^{-}$ cells [21]. Differences between symmetric and asymmetric division have also been demonstrated through dye-dilution studies, which identified slow-dividing MuSCs capable of generating progeny with long-term self-renewal properties [168,169]. Similarly, bromodeoxyuridine labeling of transgenic *Pax7-nGFP* mice showed that MuSCs that express high levels of *Pax7* ($Pax7^{Hi}$) have higher self-renewal capacity compared with MuSCs with low levels of *Pax7* ($Pax7^{Lo}$). Furthermore, in accordance to the immortal strand hypothesis, $Pax7^{Hi}$ MuSCs undergo asymmetric chromosome segregation, allowing the template DNA strand to segregate exclusively to one daughter cell to maintain its stem cell identity. In contrast, $Pax7^{Lo}$ MuSCs show random chromosome segregation [35].

The polarity of signaling components in the stem cell niche dictates whether MuSC division is asymmetric and symmetric. Apical-basal polarity cues orient the mitotic spindle during division, leading to asymmetric stem cell division perpendicular to the basal lamina [34,170], whereas symmetric divisions occur in a planar fashion [21,105]. During asymmetric division, quiescent $PAX7^{+}/MYF5^{-}$ MuSCs result in one $PAX7^{+}/MYF5^{-}$ and one $PAX7^{+}/MYF5^{+}$ cell. In most of these divisions, the $PAX7^{+}/MYF5^{+}$ cell is pushed apically toward the host myofiber whereas the daughter cell that remains on the basal lamina is $MYF5^{-}$ [34]. The Notch ligand *Delta1* is upregulated in the $PAX7^{+}/MYF5^{+}$ daughter cell. Pharmacological inhibition of Notch signaling decreased cell division and increased the number of differentiated $PAX7^{-}/MYOD^{+}$ cells, which implicates the Notch pathway in the maintenance of self-renewal through asymmetric divisions as well as quiescence [134]. It has also been shown that dystrophin, which is primarily expressed by the muscle fiber, also regulates the polarity of MuSC division through microtubule affinity regulating kinase 2 [170]. Dystrophin is expressed when MuSCs are activated and is localized asymmetrically to one side of the cell just before division. In the absence of dystrophin, asymmetric division is impaired, leading to the loss of apicobasal division and a reduction in the number of myogenic progenitors.

Evidence has shown that polarity may also be directed by the basolateral Scribble complex, which is expressed in MuSCs upon activation. During asymmetric division, it becomes segregated into the progenitor cell committed to differentiation. It can also segregate symmetrically when both cells differentiate [171].

Symmetric divisions result in two equivalent daughter cells and occur in a planar cell orientation. WNT7A is secreted by regenerating myofibers and directs symmetric cell division through noncanonical Wnt signaling mediated through the FZD7 receptor to stimulate the planar cell polarity pathway (PCP). Stimulation of MuSCs on isolated myofibers with WNT7a induces symmetric cell division and polarized localization of the PCP protein VANGL2 on opposite ends of daughter cells [21]. In addition, WNT7A increases motility and migration of MuSCs through the Rho-GTPase Rac1 [139]. Upstream, FZD7 is part of a coreceptor complex with SDC4, which binds to the ECM protein fibronectin [105]. Fibronectin is produced by myogenic progenitors and fibroblasts in the regenerating muscle. Transient upregulation of fibronectin enhances WNT7A-mediated symmetric expansion and inhibits differentiation, whereas loss of fibronectin impairs maintenance of the MuSC pool. STAT3 signaling has been shown to be involved in maintenance of quiescence; studies showed that acute inhibition leads to MuSC expansion, increased symmetric cell divisions, and improved muscle regeneration [172,173]. However, other studies showed that chronic, long-term ablation of *Stat3* leads to gradual depletion of MuSCs and the loss of regenerative capacity over time [174].

An alternative potential mechanism of satellite cell self-renewal is reversion from a committed myogenic progenitor back into a quiescent satellite cell. In mice, it was observed that a rare subset of myofiber-derived $PAX7^{+}MYOD^{+}$ progenitors do not differentiate further into myogenin^{+} cells but instead lose *MyoD1* expression and revert to a quiescent $PAX7^{+}/MYOD^{-}$ satellite cell state [175]. This reversion may be mediated by the upregulation of SPRY1, a negative regulator of growth factor–activated receptor tyrosine kinase signaling that is associated with the reestablishment of satellite cell quiescence after muscle regeneration [128]. These reports suggest that maintenance and expansion of the satellite cell pool are governed by self-renewal mechanisms that, although incompletely understood, are likely regulated by the active presentation of specific niche-associated extrinsic signals in a dose-dependent, temporally, and spatially controlled manner [139]. Ex vivo, inhibition of the tumor suppressors pRb as well as p19ARF has been shown to be sufficient to reverse committed postmitotic myocytes to the proliferative progenitor state [176]. This reversion process, known as dedifferentiation, has been shown to involve a mechanism characteristic of early programmed cell death [177]. Future studies that replicate the niche with bioengineered platforms or interfere with niche signals will facilitate maintenance and expansion ex vivo for subsequent transplantation; studies that target and activate the endogenous activation of MuSCs will find useful applications in regenerative medicine.

MUSCLE STEM CELL–INTRINSIC DEFECTS IN AGING AND DISEASE

With aging and disease, the stem cell capacity of MuSCs declines both intrinsically and extrinsically. Cellular turnover as well as extrinsic changes to the environment result in intrinsic alterations to MuSC fate, leading to compromised muscle mass and function. The number of $PAX7^{+}$ MuSCs per myofiber decreases with age, concomitant with a decline in regenerative capacity and muscle mass [119]. Even before MuSC numbers decline appreciably (>18 months in the mouse) [137,178], however, there is a shift toward greater heterogeneity in the MuSC population. With age, there is an increased proportion of MuSCs with reduced clonal proliferation capacity and a smaller fraction is able to develop into muscle myofibers when transplanted into recipient muscles [26]. Aged MuSCs exhibit increased expression of the senescence marker $p16^{Ink4a}$, elevated phosphorylation of the inflammatory p38α/β MAPK pathway, and upregulation of inflammatory cytokines and cytokine receptors [26,123,137,179]. These age-associated changes in MuSCs accompany sarcopenia, or age-related muscle wasting. During sarcopenia there is a reduction in the number of nuclei leading to myofiber atrophy [7]. Evidence showed that MuSCs contribute to myofibers even in the absence of injury [11]. There is also evidence suggesting that inducible depletion of MuSCs slightly worsens sarcopenia [11], although other studies claimed it is insufficient [8].

During aging there is also an accumulation of senescent cells that are alive but nondividing. These cells produce an array of cytokines, growth factors, and proteases, known as the senescence-associated secretory phenotype (SASP) [180], which has been shown to be beneficial for wound repair [181]. SASPs have also been causally implicated in generating age-related phenotypes in adipose tissue, skeletal muscle, and the eye [182]. The senescent marker $p16^{Ink4a}$ is upregulated in geriatric (age ~75 years) human satellite cells compared with young (age 25 years) counterparts and is reduced in myogenesis [179]. In geriatric mice (age >24 months), $p16^{Ink4a}$ expression leads to reduced activation after injury and accumulation of senescent MuSCs, resulting in impaired muscle regeneration. Conditional deletion of the $p16^{Ink4a}$ gene in $PAX7^{+}$ MuSCs restores the capacity of quiescent geriatric MuSCs to be activated and reduces the expression of senescence-associated genes.

In addition to senescence, a number of signaling pathways are dysregulated in aging. Many are pathways that are transiently upregulated or downregulated during activation in young, healthy MuSCs after injury. For example, the balance of Notch and Wnt pathways is critical during regeneration, with a temporal switch from Notch to Wnt during normal myogenesis [138]. Notch signaling is important for MuSC activation and self-renewal, whereas Wnt antagonizes Notch and promotes differentiation. However, during aging, expression of the Notch ligand Delta-1 decreases in muscle. Consequently, MuSCs are exposed to increased levels of WNT3A (wingless-type mouse mammary tumor virus integration site family, member 3A), which impair self-renewal and induce fibrogenic differentiation of MuSCs and muscle progenitors through β-catenin signaling [137]. Oxytocin is another signaling molecule that is altered in aged mice. Better known for its role in lactation and social behaviors, oxytocin is expressed systemically, and in young MuSCs it promotes muscle regeneration. Expression of oxytocin declines in aging. Depletion of oxytocin in young mice causes premature sarcopenia, whereas repletion results in proliferation and rejuvenates MuSC function [183].

Chronic inflammation and dysregulation of inflammatory pathways are particularly potent drivers of aging phenotypes in MuSCs. A temporally regulated, transient immune response is a critical component of regeneration. However, aging leads to chronic inflammation and elevation of cytokines, resulting in aberrant cell-autonomous activation of the stress-associated p38α/β mitogen-activated protein kinase (MAPK) and the cytokine-stimulated JAK2/STAT3 signaling axes, among others [26]. Increased activity of p38α/β suppresses *Pax7* expression through repressive chromatin modifications [184] and results in the loss of self-renewal capacity [26,185]. Inhibition of p38α/β activity has been shown to rejuvenate stem cell function of aged MuSCs [26]. Activation of JAK2 leads to activation of its target STAT3, which causes asymmetric division and *MyoD1* expression in MuSCs [172,173]. In vitro and transplantation experiments in vivo showed that acute inhibition of JAK phosphorylation or STAT3 activity promotes symmetric MuSC expansion and rescues muscle regeneration in aged and dystrophic mice [172,173]. Factors secreted by muscle fibers during regeneration are also dysregulated in aging. Aged muscle fibers aberrantly express the growth factor *Fgf2* in homeostasis, which causes a subset of MuSCs to exit quiescence and lose their self-renewing capacity owing, in part, to reduced SPRY1 levels [123]. Normal MuSCs from healthy young animals typically express SPRY1, which inhibits FGF signaling in vivo.

MuSCs isolated from diseased muscle have compromised regenerative capacity and stem cell function. In the *mdx* mouse model of DMD, which lacks the key muscle structural protein dystrophin, MuSCs in limb and diaphragm muscles are forced to undergo constant rounds of activation and proliferation because of the constitutive degeneration of the tissue. Early studies showed that myoblasts isolated from patients with DMD exhibit a reduction in proliferative capacity and senesce more readily than myoblasts isolated from healthy controls [18,186,187]. Reduced proliferation and self-renewal capacity are also observed in MuSCs from the *mdx/mTR*^{G2} humanized model of DMD [20]. To generate this mouse model, which has shortened telomeres with lengths approximating those of humans, *mdx* mice were crossed with the *mTR* mouse, which lacks telomerase activity because of the absence of the RNA component of the enzyme. MuSCs from these animals have reduced proliferative capacity after injury as well as a reduced capacity to engraft when transplanted into recipient WT muscle. This cell-intrinsic restriction of self-renewal and proliferation further revealed disease phenotypes in the mouse that are present in human patients, but were not previously observed in the *mdx* mouse alone: namely, progressive muscle degeneration across skeletal muscle types and premature death resulting from dilated cardiomyopathy [20,188]. The role of MuSCs in other genetic myopathies remains to seem.

CHALLENGES IN THE USE OF SATELLITE CELLS IN REGENERATIVE MEDICINE

MuSCs have a great potential to be used a cell therapy; however, many significant challenges remain unmet for the use of human satellite cells in transplant-based clinical regenerative medicine applications. Although much progress has been made toward identifying surface markers to isolate human MuSCs prospectively, satellite cell transplantations require intramuscular injections to deliver functional stem cells efficiently to recipient muscle tissue. This cell type is unable to access muscle tissue when delivered systemically through the vasculature [189,190]. Therefore, treating all muscles of the body is untenable. This limitation restricts the use of MuSC transplantations to small and easily accessible muscles and makes regenerative therapy impractical for all muscles or muscles that are difficult to access, such as the diaphragm.

Before the identification of satellite cell isolation markers, researchers and clinicians long proposed using human myoblasts as a source of cells for muscle therapeutic applications. Myoblasts can be generated from enzymatically digested muscle tissue or isolated satellite cells [191] and rapidly proliferate in culture. Because they can be

maintained and expanded in culture while retaining myogenic potential, myoblasts are an attractive source for cell-based therapies. In clinical trials in the 1980s, transplanted human myoblasts were shown to fuse with endogenous muscle fibers and led to the production of functional dystrophin in the myofibers of patients with DMD [85,192]. However, a large proportion of myoblasts die after injection, expansion is extremely limited, and they do not engraft into a stem cell niche and thus ultimately fail to provide long-term therapeutic benefit.

These clinical findings are corroborated by engraftment studies of satellite cells and myoblasts transplanted into damaged mouse muscles. A major challenge for preclinical and clinical studies is that MuSCs in mice and humans are rare (about 5% of all muscle nuclei), and cannot be maintained for more than a few days. Therefore, expansion ex vivo is limited. Culture of satellite cells for more than a few days in standard tissue culture conditions results in conversion to a myoblast phenotype with a dramatically diminished self-renewal potential [30,76]. Improvements have been made in culture platforms, which have allowed for the extended maintenance of MuSC potential in vitro. Biomimetic materials have been developed that can be precisely fine-tuned to mimic biophysical cues provided by the MuSC niche. Engineered poly(ethylene glycol) (PEG)-based hydrogels have been engineered that replicate the physiological stiffness of the MuSC environment [149], which is five orders of magnitude less stiff than tissue culture plastic, allowing maintenance of stem cell potential. These hydrogels can be functionalized with specific tethered ligands, including adhesion and growth factors, and are resistant to degradation and nonspecific protein absorption [193]. Hydrogels are advantageous over Matrigel, which is composed of uncharacterized amino acids and growth factors. Artificial muscle myofiber preparations have also been developed to mimic the stem cell niche of the myofiber, using collagen-based hydrogels to fine-tune the stiffness of the substrate [194]. Like PEG-based hydrogels, these artificial myofibers promote stemness combined with defined media conditions, leading to enhanced engraftment after transplantation. In addition to biophysical cues, cell culture media have been optimized. Screens have identified a number of defined factors, including forskolin, p38/MAPK inhibitors, and TGF-β, which promote MuSC expansion and self-renewal [26,194,195]. A synergy of biophysical and biochemical cues provided by 12-kPa hydrogels and the p38/MAPK inhibitor SB202190 rejuvenates the function of the aged MuSC populations. After transplantation, aged mouse muscles exhibit strength on par with young ones. Nonetheless, further experimentation is warranted to establish methods to extend the culture life span and propagation of MuSCs for cell therapeutic application. The need is even greater for satellite cells bearing genetic defects, such as those present in patients with DMD, that require ex vivo gene editing before transplantation.

GENE EDITING STRATEGIES

Advances in gene editing strategies have created the possibility of autologous cell therapy transplantation for patients with genetic disorders. Through gene editing, genetic defects such as dystrophin mutations found in DMD can potentially be corrected through systemic delivery, or in MuSCs isolated from patients, which would then be transplanted back into the tissue. A number of strategies have targeted muscle systemically, including viral delivery of mini- or microdystrophin genes by adenoassociated virus (AAV) vectors [196,197], and oligonucleotide mediated exon skipping to restore the dystrophin reading frame [198,199]. Notable progress has been made using the clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated-9 (Cas9) genome editing system, which targets DNA sequences with a single guide RNA and cleaves the target with the Cas9 nuclease [200]. Proof-of-concept studies have demonstrated the feasibility of AAV-mediated delivery of CRISPR/Cas9 to the skeletal muscle of the dystrophic *mdx* mouse model [201–203], partially restoring dystrophin expression and skeletal muscle function. Restoration of dystrophin was primarily shown for myofibers. However, these strategies still must be optimized to increase efficiency. Moreover, targeting MuSCs, which would lead to long-term correction, remains a challenge, and subsequent gene editing in a nondividing cell constitutes an additional hurdle. Also, specific CRISPR/Cas9 correction requires targeting sequences to be tailored for each patient's mutation. Regardless, progress is rapidly being made, offering hope for tenable gene therapy options.

OTHER STEM CELL TYPES WITHIN MUSCLE

Several other myogenic cell types have been proposed as alternatives to the satellite cell. A number of other alternative MuSC sources and muscle-resident nonmuscle cells that contribute to regeneration have been characterized.

These include blood vessel–associated mesoangioblasts [204,205], pericytes [189,206], and myogenic cells derived from induced pluripotent stem (iPS) cells [207]. These cell types are discussed in this section. Although many of these cell sources have potential characteristics for cell therapy applications, their roles in normal development and muscle regeneration and their anatomical locations have not been fully documented. They may not represent the native MuSC but they may have therapeutic utility.

Other Stem Cell Types Within Muscle

A number of other cell types in the muscle are integral to regeneration. Muscle-resident cell types including blood vessel–associated mesoangioblasts, pericytes, FAPs, and TWIST2$^+$ (Tw2$^+$) myogenic progenitors have been shown to be contribute to regeneration in addition to MuSCs. Mesoangioblasts are blood vessel–associated multipotent mesodermal progenitors that can be isolated from fetal muscle biopsy tissue fragments containing small blood vessels [205]. They are an attractive source because they can be expanded in culture and contribute to muscle regeneration effectively throughout the body without tumor formation after intraarterial delivery owing to their ability to extravasate from the vasculature. Reliance on fetal tissue to isolate mesoangioblasts can be overcome by using an alternative but related population of blood vessel–associated cells called pericytes that are present in adult humans [189]. The advantageous characteristics of mesoangioblasts have motivated their extensive preclinical evaluation, including in the Golden Retriever muscular dystrophy model, which closely mimics human DMD [204]. However, clinical trials have shown that although mesangioblast transplantation is relatively safe, it has limited efficacy in human patients [208].

Fibroblasts and adipocytes within the muscle tissue arise from FAPs, also characterized as nonmyogenic mesenchymal stem cells. FAPs can be isolated based on CD45$^-$/CD31$^-$, α7-integrin$^-$, SCA1$^+$, and CD34$^+$ cell-surface marker expression [209]. Mesenchymal stem cells can be isolated based on CD45$^-$/CD31$^-$, SM/C2.6$^-$, and PDGFRα^+ expression, parameters that select for a functionally and phenotypically equivalent population of cells to FAPs [210]. Both cell types are capable of differentiating into adipocytes and fibroblasts in vitro, producing both α-smooth muscle actin–expressing fibroblasts and perilipin/peroxisome proliferator-activated receptor γ–expressing adipocytes. Upon injection of glycerol, transplanted FAPs and mesenchymal progenitors underwent adipogenic differentiation in vivo. Although fibrosis is generally associated with aging and disease, muscle-resident fibroblasts are necessary for regeneration [211]; ablation leads to decreased myofiber size and premature MuSC differentiation. Reciprocally, during regeneration, muscle progenitors have been shown to regulate ECM deposition by fibrogenic cells within the muscle through secreted exosomes containing MiR-206 [212].

Finally, the transcription factor Tw2 was identified as a marker of a separate population of interstitial progenitor cells [212,213]. Tw2$^+$ progenitors are distinct from PAX7$^+$ MuSCs. When isolated, they can enter the myogenic pathway by activating PAX7 and MYOD1. In vivo, Tw2$^+$ progenitors contribute specifically to type IIB/X fibers during homeostasis and are required for maintenance of type-IIB/X fiber size. However, Tw2$^+$ progenitors cannot sustain regeneration in the absence of PAX7$^+$ MuSCs.

Induced Pluripotent Stem–Derived Muscle Stem Cells

IPS cell–derived MuSCs have been developed as a tool to study human myogenesis in regeneration and disease as well as to provide a source for cell therapy–based therapies. Human and mouse muscle cells have been derived from embryonic stem cells or iPS cells through overexpression of myogenic transcription factors such as MYOD1, PAX3, or PAX7 [207,214–217]. Studies have demonstrated the generation of human and mouse muscle progenitors capable of differentiating into mature myofibers using exogenous signaling factors [218–220] These protocols were derived from an understanding of developmental principles and sequentially expressed regulators. As such, they all share similar features of activating Wnt and inhibiting Notch signaling, a protocol that has also been used to derive skeletal muscle progenitors and myocytes from human pluripotent stem cells [221]. A major advantage of human iPS cells is that they constitute an unlimited cell source that can be infinitely propagated. A major drawback is that derivation of human iPS cells and subsequent differentiation into PAX7$^+$ MuSCs is lengthy and inefficient. Optimization is needed, but much progress has been made, and now that markers of adult human MuSCs have been characterized, flow cytometry enrichment protocols are at hand. As such, human IPS cells hold great promise for muscle cell therapies in the future.

CONCLUSIONS

Muscle satellite cells are essential for postnatal muscle regeneration and maintenance. They have been shown to be native MuSCs, and their study has provided critical insights into the mechanisms of muscle regeneration. However, their therapeutic use continues to be restricted by cell transplantation constraints, including the inability to contribute to myogenesis extensively when delivered systemically, and their limited capacity to be expanded and maintained in culture. Technological advances such as improved cell culture platforms and iPS cell−derived human MuSC strategies offer great promise to overcome these limitations. In addition to improving satellite cell transplantation in preclinical models, advances in MuSC in vitro technologies have led to the identification of SB202190 and should prove useful for identifying additional therapeutic agents that stimulate the regenerative contributions of satellite cells. Efforts to augment the function of endogenous satellite cells within muscle tissues are warranted for muscle wasting caused by sarcopenia or cachexia, but not conditions such as muscular dystrophy, for which such agents would exacerbate the disease. Furthermore, novel noninvasive imaging methods such as BLI and IVM enable the quantitative assessment of regeneration over time. Advances in isolating human MuSCs, iPS technology, and the validation of alternative cell types capable of contributing to human muscle regeneration may lead to the clinical realization of much-needed stem cell therapies for prevalent muscular dystrophies and muscle wasting conditions that accompany aging.

Stem Cells Derived From Fat

James C. Brown, Adam J. Katz

University of Florida, Gainesville, FL, United States

INTRODUCTION

Regenerative medicine aspires to restore the physiologic function of a target tissue by way of reconstitution and/or reproduction using a combination of medicine, engineering, and molecular biology. Emerging strategies require the use of multipotent cells, and given the controversies surrounding embryonic stem cells, adult stem cells (particularly those derived from autologous sources) have been targeted by scientists and physician alike to achieve regeneration. In the late 1980s, Caplan et al. coined the term "mesenchymal stem cell" (MSC). This name was chosen in light of the inducible differentiation of these cells into osteogenic, chondrogenic, and adipogenic lineages [1].

A growing body of evidence indicates that many different adult tissues contain MSCs, including bone marrow (BM), blood, nervous tissue, skeletal muscle, and fat. Because of their almost ubiquitous presence and because several studies microanatomically localized MSCs adjacent to blood vessels, many independent groups have proposed a "unified theory": MSCs are resident in the perivascular niche. Other groups have advanced this theory further: MSCs are *not resident in* but *originate from* a heterogeneous group of perivascular cells, namely pericytes ($CD45^-/31^-/34^-/146^+$) and adventitial cells ($CD45^-/31^-/34^+/146^-$) [2–5]. Histologically, pericytes are in close proximity to capillary endothelium whereas adventitial cells are resident some distance from the largest vessels in the tunica adventitia, far from endothelial cells. The cluster of differentiation profiles used to describe these populations has been classically defined using flow cytometric studies of culture-expanded populations. Because of the ability of adventitial cells to assume pericyte phenotypes in vitro, these phenotypes represent a multipotent cell population that, if tapped, may alter the trajectory of cell-based therapies and regenerative science.

Adipose tissue is unique as a source of MSCs. Historically, fat was relegated to energy storage and structural supportive roles. However, enzymatic dissociation and centrifugation of adipose yielding a single-cell suspension, called the stromal vascular fraction (SVF), allowed the characterization of its cellular components, including the adipose-specific MSC: the adipose-derived stromal cell (ASC) [6]. One gram of adipose tissue obtained with minimally invasive liposuction yields approximately 5000 putative stem cells, which is 500 times greater than the number of stem cells isolated from 1 g of BM [7]. In addition, approximately 400,000 liposuction surgeries are performed in the United States each year, routinely yielding volumes of up to 3 L of valuable tissue [8]. Thus, adipose offers autologous mesenchymal progenitors with multilineage differentiation potential in unrivaled quantity, accessibility, and expendability.

CELLULAR FRACTIONS

In 1964, Martin Rodbell described the first enzymatic dissociation of murine adipose tissue into a single-cell suspension. Since then, many studies have demonstrated reproducible collagenase digesting and isolating cellular fractions either intact (and subsequently minced) or aspirated with tumescent liposuction. After enzymatic neutralization, which is often achieved by albumin and/or volumetric dilution, lipid-laden, mature adipocytes are separated from remaining cellular fraction using differential centrifugation. The resulting cellular fraction, which is devoid of mature fat cells, is a primary, heterogeneous, mesenchymal cell array collectively termed the SVF. The uncultured SVF consists of leukocytes, erythrocytes, endothelial cells, perivascular cells, and of particular interest, putative stem and progenitor

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00019-9

cells. When the heterogeneous SVF cells are cultured in plastic, spindle-shaped cells attach and expand. These cells, selected by plastic adherence, are ASCs.

As the field of adipose science stands, the overwhelming majority of work has involved the biological evaluation and therapeutic projection of ASCs. Given the inherent heterogeneity of the SVF, there is a paucity of studies comparing the efficacy (and its dependent potency) of SVF in culture-expanded ASCs. Perhaps more important, the literature is unintentionally pervaded by the inaccurate transposition of SVF/ASC terminology. The cellular characterization of both populations has been a subject of scientific interest, as evidenced by even a cursory literature search, likely caused by acceleration in the methodology and technology used to isolate adipose-derived cell populations. To ensure the integrity of interstudy comparisons and subsequent scientific advancement within the field of adipose, a consensus biological profile of each adipose-derived cell population is required and can provide insight into biologic clarifications, best clinical practices, and safety profiles [9]. More important, this consensus profile must be dynamic and responsive to the newly acquired data and resulting advancements within adipose science, so as not to strangle the field at this juncture of critical growth.

CELLULAR CHARACTERIZATION

Stromal Vascular Fraction

The SVF, which is marked by its heterogeneity, is composed not only of perivascular cells, leukocytes, and endothelial cells, but also of a higher percentage of stromal cells compared with the BM nucleated fraction (which contains BM-MSCs). The SVF is composed of less than 0.1% of stem and progenitor cells. These cells of traditional interest (the stromal population) have a cluster of differentiation profile that includes positivity for CD34 and negativity for CD45 (leukocyte common antigen), CD235a (glycophorin A), or CD31 (platelet-endothelial cell adhesion molecule-1 [PECAM-1]); therefore, its immunophenotypic profile in common notation should be $CD45^{-}CD235a^{-}CD31^{-}CD34^{+}$. CD34, likely because of variation in the epitope of which class I/II/III-CD34 antibody detects, is positive with variable intensity [10]; for SVF cell characterization, Bourin et al. recommends the use of class III CD34 antibodies to obtain the most consistent signal [9]. In addition, the following surface antigens may be helpful in identifying the stromal population, particularly combined with the CD profile: CD13 (aminopeptidase N), CD73 (lymphocyte-vascular adhesion molecule-2), CD90 (Thy-1), and CD105 (endoglin).

Adipose-Derived Stromal Cell

The definitive cell surface identity of ASCs has historically been problematic. Surface protein expression is dynamic, partially depending on the passage and cell density, among other variables including the anatomic site of harvest, isolation methodology, and culture protocol. However, after two or more passages, ASCs express relatively characteristic and reproducible surface and adhesion molecules, cytoskeletal elements, and surface markers. The ASC immunophenotype is comparable to that of the SVF stromal population, with a lack of CD45, CD235a, and CD31 expression. With regard to surface antigens, however, CD13, CD29 (integrin β1), CD44 (homing cell adhesion molecule), CD73, CD90, and CD105 are the primary, consistently stable ASC markers. Overall, the ASC immunophenotype largely resembles that reported for other adult MSCs, such as BM-derived and skeletal muscle stem cells, with only a few differences [6,11–13]. However, in conjunction with selection by adherence to plastic, these immunophenotypic differences suggest that ASCs are indeed a distinct population. In light of this, several studies have hypothesized and confirmed preferential differentiation programs of ASCs versus BM-MSCs; ASCs demonstrate a greater tendency to develop into myocytes, and BM-MSCs into osteocytes and chondrocytes [14].

Ultimately, cell populations are best characterized by biological activity, multipotency, and differentiation program [6,13,15] ACSs have been shown to demonstrate phenotypes consistent with several different mesodermally, endodermally, and ectodermally derived mature cell types both in vitro and in vivo. This has been reflected in the adipose scientific industry; a prime example is the broad selection of lineage-specific inductive media and associated protocols. Although these developmental findings are remarkable and continue to evolve, many questions remain as well as some appropriate residual skepticism related to the "applied" in vivo developmental plasticity and functional integration of adult stem cells. Part of this relates to limitations of terminology, standardization, and existing technologies, and also to the human need to characterize the elusive nature of dynamic living systems with static labels and/or pathways. For example, establishing a scientific consensus regarding which "minimal threshold" definitively describes a particular phenotype/cell lineage is elusive, to say the least, and the "minimal essential threshold" continues to evolve as the field matures and realizes that there are few if any genes or proteins that

are truly "lineage specific." These issues are greatly interesting and important for basic scientists and developmental biologists, but the ultimate benchmark of these cells for many in the fields remains the reproducible and predictable therapeutic safety and efficacy in the clinical setting, regardless of the mechanism of action.

Cell Source

All fat is not the same. There are two main types of fat within the human body: brown adipose tissue (BAT) and white adipose tissue (WAT). BAT is mainly found surrounding the viscera in infants; in adults it has been identified in the neck, supraclavicular, paraaortic, paravertebral, and suprarenal areas [16]. BAT serves primarily to generate heat via a specific uncoupling mechanism identified in the cells' mitochondrial electron transport chain. WAT is found subcutaneously, is highly vascularized, and contains the ASC population; its primary function is to serves an energy reserve, but it is recognized as a dynamic and highly bioactive tissue with important roles in systemic inflammation and other processes [3,17]. Major depots of subcutaneous WAT in humans include abdominal, hip, thigh, and gluteal locations.

Population ratios of adipose-derived fractions vary depending on the anatomic site from which fat is harvested, as well as donor characteristics such as age, sex, smoking history, and medical comorbidities. In addition, studies indicate that the density of ASCs varies depending on many of these factors [18,19]; these may be of particular importance when considering ASC yield, plasticity, and potency.

CLINICAL DELIVERY OF ADIPOSE-DERIVED CELLS

Several potential ASC delivery routes exist, including systemic, parenteral, targeted injection, and topical application.

The systemic administration of ASCs as a cell suspension continues to have great translational appeal because it provides a minimally invasive treatment modality. Imperative to this delivery modality is the characteristic of ASCs of mobilizing to injured tissue, termed homing. However, the mechanism of homing is poorly understood in ASCs and other MSCs. Scientific insight into homing can be found in inflammation, which is composed of three major stages: the dilation of capillary beds and subsequent increase in blood flow; protein expression and microvascular structural changes; and the leukocyte adhesion cascade involving white cell capture, adhesion, and transmigration. Despite the native inability to bind endothelium via E-selectin, Pachon-Pena et al. described the differential expression of sialyllactosamines (i.e., oligosaccharide residues) on glycovariant cluster of differentiation markers, specifically CD44 [20,21]. These glycovariants can subsequently be fucosylated, creating hematopoietic cell E-/L-selectin ligand, a membrane constituent that permits the shear-resistant engagement of human adipose-derived MSCs to endothelium. Thus, differential protein expression and selective posttranslation modification may allow MSCs to bind selectively to sites of inflammation.

In addition, the leukocyte adhesion cascade is highly dependent on injured tissues' differential, attractant expression of chemotactic cytokines (chemokines), and leukocyte chemokine receptors. In fact, the chemokine receptor expression profiles of leukocytes and ASCs have been demonstrated to overlap significantly, including those with assigned functional roles of transendothelial migration, diapedesis, and vascular permeability (e.g., CCR1, CCR7, CXCR3, CXCR4, and CXCR6) [22–26]. Therefore, the "native" homing mechanism of ASCs may be similar to that of leukocytes, composed of differential chemokine receptor expression or differential glycoprotein expression first-pass removal through "filter organs," or the result of postinjury, increased perfusion in a damaged organ, or most likely, a combination of these.

With parenteral delivery, ASCs engraft into many organs and concentrate largely in first-pass organs (lung and liver) as well as the spleen. Several studies have indicated additional engraftment sites for MSCs (a group to which ASCs belong) including thymus, brain, spinal cord, and heart. There has been evidence that there is variability in the chemokine receptor expression profiles of ASCs [27,28]. This may indicate that there are phenotypic and induced protein expression differences to modifiable culture conditions (e.g., supplements, pH, cell density, and/or matrix). This variability may also confirm that ASCs have the ability to home to multiple tissues, as was previously demonstrated. Therefore, modulation of chemokine receptor expression has become an area of growing interest to increase the engraftment efficiency of cells to a specific, often injured target tissue. In 2016, Hasemzadeh et al. demonstrated that differential expression could be primed with valproic acid, which resulted in increased CXC chemokine expression without altering CC chemokine groups [29]. In turn, this may influence their migration and engraftment

patterns and improve the efficacy of ASC cell therapies while decreasing the cell dose and minimizing the side effect and morbidity profiles [30–32].

It has been reported that ASCs possess the ability to differentiate into cardiomyocytes, both in vitro and in vivo, with an intact electrolyte-dependent, spontaneous, rhythmic contraction ability [33–36]. Guided by this potential, a large portion of research involving the parenteral delivery of ASCs has been aimed at cardiovascular disease, with the goal of mitigating ischemic damage and/or regeneration of myocardium. There have been several articles reporting positive effects to this end, which have been attributed to improved vascular inflow, increased angiogenesis, and cell protection (i.e., reduction in apoptosis) [37,38]. In replications of studies using marrow-derived MSCs, independent groups demonstrated that ASCs differentiate into endothelial and vascular smooth muscle cells when injected in the coronary artery supplying acutely infarcted porcine myocardium, limiting infarct size, thickening the left ventricular wall, and improving cardiac function [39,40]. In 2011, intravenous administration at a distant site by Kim et al. demonstrated homing of ASCs to, and cardiomyocyte differentiation in, canine radiofrequency-ablated atrium [41]. Some studies indicated ASC engraftment into infarcted myocardium without adopting the cardiomyocyte morphology or phenotype; it is hypothesized that paracrine effects of ASCs assisted in remodeling because of improved cardiac wall architecture [42]. Two prospective, double-blind, randomized, controlled, phase I human clinical studies using ASCs were undertaken, both initiated in 2007: Adipose-Derived Stem Cells in the Treatment of Patients With ST-Elevation Myocardial Infarction (APOLLO) and Adipose-Derived Stem and Regenerative Cells in the Treatment of Patients With Nonrevascularizable Ischemic Myocardium (PRECISE). In contrast to most preclinical literature, both trials used the heterogeneous, autogenous SVF as opposed to culture-expanded ASCs. There is scientific thought that the heterogeneity of the SVF may offer measurable benefits if this heterogeneity can be recapitulated in the injected or implanted graft [23,43,44]. The APOLLO and PRECISE studies were completed with an estimated enrollment of greater than 80 patients, but preliminary experimental results for the former are not available [45].

Similarly, ASCs have demonstrated therapeutic potential in peripheral vascular disease. Intravenous administration of murine ASCs attenuates critical limb ischemia to lower limbs [46,47]. The ability of ASCs to alter the extracellular, ischemic micromilieu is not brought about solely by directed target tissue differentiation, but likely involves the adipose secretome, the entirety of ASC-secreted cellular products. Several independent groups have demonstrated ischemic recovery caused by the paracrine secretion of angiogenic and vasculogenic cytokines such as vascular endothelial growth factor (VEGF), hepatocyte growth factor (HGF), and fibroblast growth factor-2 (FGF2) [48–50].

The discovery of ASC-administered immunomodulatory effects broadened clinical interest in neurologic and autoimmune disease applications [51–53]. ASCs secrete cytokines and prostaglandins, predominantly interleukin (IL)-4, IL-8, IL-10, and prostaglandin-2, which are implicated in immunosuppression [54,55]. Through expression of these factors as well as selective human leukocyte antigen-II surface expression, ASCs reduce cell-mediated immunity by directing T-regulatory cell expansion [52]. In turn, ASCs have been used in experimental models of graft-versus-host disease, embolic and hemorrhagic stroke, multiple sclerosis and autoimmune encephalitis, spinal cord injury, allergic rhinitis, reactive airway disease, and rheumatoid arthritis [56–65]. Potential results in each of these models have been variable; adipose-derived therapies offer hope and insight into pathologies the cures of which remain obscure to scientists and clinicians alike.

The intravascular administration of stem cells has associated safety and efficacy concerns. Schrepfer et al. demonstrated in mice that within minutes, most BM-MSCs administered intravenously were trapped in the lungs and few cells arrived at the target destination [66,67]. Given the similar size of ASCs, these concerns were quickly transposed to intravenous ASC therapies. Subsequently, the most worrisome adverse event is the inadvertent creation of emboli. Takahashi et al. infused neural stem cells intravenously and did not detect engraftment of cells at the site of injury; worse, up to one-third of the mice died immediately after injection, presumably from pulmonary emboli [68]. Similar results, attributed to the large cell-to-capillary diameter, were obtained using adipose-derived murine ASCs with intraaorta injection [69]. In fact, case reports in humans exist demonstrating pulmonary sequestration and infarction after administration of intravenous adipose tissue-derived cell therapy [70]. There is conflicting evidence, however, regarding the relationship between simple embolism and resultant infarction. In 2011, Ra et al. demonstrated that cell doses as high as 5×10^6 cells/mouse could be administered without an adverse event, so long as the injection was slow enough to avoid bolus injection [71]. These results are similar to those found in BM-MSCs and speak to the absence of ASC-native toxicity. Specifically, with regard to stem cell emboli, Lee et al. found that despite pulmonary sequestration, BM-MSCs increased antiinflammatory protein translation and secretion, specifically tumor necrosis factor-inducible gene 6 [72]. This evidence further bolsters the therapeutic scope of stem cell secretomes and paracrine abilities and provides insight into the mechanism of efficacy without engraftment, safety, and dosing concerns.

The direct, local delivery of ASCs via in situ injection or topical application has been demonstrated successfully as an alternative to systemic delivery, with greater cell engraftment efficiency and mitigation of the necessity for cellular homing as well as first-pass clearance in the lungs, spleen, and liver. In addition, direct application in several clinical models and pathologies has been successful, including myocardial ischemia, peripheral vascular disease, acute and chronic wounds, degenerative joint disease, and inflammatory bowel disease.

Several murine studies have demonstrated not only the engraftment and concomitant expression of requisite cardiac proteins (e.g., myosin, troponin, and transcription factor Nkx2.5) but also improved cardiac function, as measured by stroke volume and ejection fraction, within 1 month after ASC injection into infarcted myocardium [38,73]. Furthermore, the transgenic delivery of hASCs into immunoincompetent mice resulted in engraftment and improved cardiac architecture and function [42]. These findings have also been extended to the SVF and patients with long-standing ischemic cardiomyopathy in the PRECISE trial. Results show that transendocardial injection of syngeneic SVF preparations preserve ventricular function, myocardial perfusion, and exercise capacity [74]. Combined, these results have furthered scientific interest in "cellular cardioplasty" using adipose-derived regenerative cells in the acute and chronic settings.

Many groups have documented the ability of ASC to undergo endothelial regeneration, and when deployed in vivo, they can aid in reestablishing vascular supply and general recovery of limb ischemia [34,46,75,76]. In murine models of hind-limb ischemia, $CD31^-$ ($PECAM\text{-}1^-$) cell inoculation in the proximity of ischemic tissue yielded de novo vessel production. These findings have been repeated and confirmed by independent groups [34,77]. As with other studies, it is postulated that engraftment and as well as its hypoxia-induced secretome (e.g., VEGF, HGF, and FGF2) are complementary in the ASC angiogenic capability [50,78]. Several phase I hASC/SVF trials were undertaken in Europe and the United States. Trial models include chronic limb ischemia in patients with diabetes, with diabetic/venous stasis ulcers, with nonsurgically amenable peripheral vascular disease, and with ASC-coated vascular bypass grafts.

The load-bearing tissue of a joint, the articular cartilage, has limited intrinsic repair capability once damaged, and therefore is a prime target for MSC therapies. Awad et al. in 2002 published data on the in vitro chondrogenic potential of hASCs on various biomaterials including agarose, alginate, and gelatin scaffolds in the presence of chondroinductive growth factors [79]. These studies were confirmed by Lin et al. in 2005 [80]. There has been evidence indicating that ASCs have an inferior chondrogenic potential compared with other MSCs, particularly BM-MSCs [81]. When seeded on a platelet-rich plasma scaffold, ASCs differentiated into functional chondrocytes and secreted cartilaginous matrix, although they were of a reportedly inferior histological quality compared with that of BM-MSCs [82]. However, because ASCs are obtained in large numbers by a minimally invasive procedure, they remain an area of interest for orthopedic pathologies [83]. When used in vivo, ASCs produce significant amounts of cartilage matrix molecules, including collagen type-II and type-IV, and chondroitin 4-sulfate, and subsequently demonstrate on histological, radiological, and biochemical analyses the healing of lapine full-thickness cartilaginous defects when seeded onto a supportive matrix such as fibrin glue [84,85]. Several human trials are being undertaken; a single 2011 case series demonstrated promising radiological and functional outcomes [86]. Intervertebral disks such as cartilage possess a limited regenerative capacity. When cocultured with nucleus pulposus (NP) (the intervertebral disc inner core) cells, ASCs increase extracellular matrix (ECM) production and improve the three-dimensional organization of the NP [87]; in vivo, ASCs have been found to be successful in regenerating experimentally damaged canine and murine intervertebral disks [88,89].

When cultured three-dimensionally and stimulated with osteoinductive growth factors and cytokines, hASCs adopt the characteristics of osteoblasts, including osteocalcin and alkaline phosphatase expression and mineralized ECM [90,91]. In addition, the gene expression profiles can be altered by applying shear stresses, with recapitulation of osteoblastic protein production (e.g., osteopontin and collagen type-$I_{\alpha 1}$) [92]. Collectively, these findings indicate that ASCs can differentiate into mechanosensitive osteoblasts. In vivo use demonstrated that hASCS not only produce osteoid when transplanted into severe combined immunodeficiency mice, they can heal critical-sized calvarial and long-bone defects in dogs, rabbits, mice, and rats [93–96].

Clinical interest in and efforts using ASCs to treat soft tissue wounds and defects continue to accelerate because of the relative unavailability of effective treatments. Some promising evidence of ASC-assisted wound repair has been reported and is likely mediated in large part by its secretome and production enhancement by tissue hypoxia. In 2007, Kim et al. first demonstrated that ASCs accelerate both in vitro and in vivo. When cocultured with human dermal fibroblasts (HDF), hASCs promoted HDF proliferation rates. Moreover, hASC-conditioned media enhanced HDF ECM secretion, specifically collagen type I and III and fibronectin. When these hASCs were mixed with collagen gel solution and injected directly into nude mice wounds, hASCs significantly enhanced wound-edge reepithelialization compared with collagen gel controls [97]. In a follow-up study by the same group, topically

administered ASCs improved reepithelialization rates, an effect of which was contributed to the paracrine ASC secretion of basic FGF, keratinocyte growth factor, transforming growth factor-β, HGF, and VEGF [97]. Other studies confirmed similar wound healing effects of ASCs. One interesting study, completed by Amos et al. in 2009, showed that ASCs applied to wounds in diabetic mice resulted in a faster rate of healing when the ASCs were delivered as multicellular aggregates compared with when the stem cells were delivered as a cell suspension. Furthermore, ASCs formulated as three-dimensional cellular aggregates produced significantly more ECM proteins and secreted higher levels of bioactive factors compared with a monolayer culture [98]. These results emphasize the importance of the cell culture, formulation, and delivery mechanism in the ASC biology and therapeutic effect.

Autologous lipotransfer (also known as fat grafting) was developed over a century ago. In 2008, Yoshimura and colleagues described a process called "cell-assisted lipotransfer," in which ASCs are combined with lipoaspirate in an effort to improve graft viability and long-term volume retention [43]. The presumed mechanisms of reported volume retention compared with controls included progenitor cell differentiation into mature adipocytes and/or improved vascularization and subsequent graft survival. There has been some conflicting evidence in follow-up studies, including a "head-to-head" trial of fat grafting to cell-assisted lipotransfer by Peltoniemi et al. In 18 women undergoing breast augmentation, volume retention trended lower (albeit without statistical significance) in the cell-assisted lipotransfer group as evaluated by magnetic resonance imaging [99]. Further double-blinded, randomized controlled clinical trials are required to establish the superiority of one treatment over another.

Finally, a few groups have used direct application of ASCs in the clinical setting for other therapeutic objectives, including fecal and stress urinary incontinence, inflammatory bowel disease and its fistulous sequelae, erectile dysfunction, Buerger disease, graft-versus-host disease, and spinal cord injury [45]. However, the clinical applications for which ASCs are being used often lack a solid foundation of preclinical data. For example, data demonstrating that ASCs are capable of differentiating outside an adipogenic lineage may require extreme chemical or culture modifications and, on occasion, genetic engineering. Often, "confirmation" of a particular cell phenotype is based on artifactual assays. For example, in ASC-driven osteogenesis studies, alizarin red S assay is frequently used; however, this assay does not distinguish between neo-matrix mineralization and dystrophic calcification caused by dying cells. In addition, if the cells express the characteristic enzyme alkaline phosphatase, it can cleave the donor phosphate group from the medium component, β-glycerophosphate; high concentrations of free phosphate will cause calcium phosphate precipitation, but this mineral in itself is not identical to the natural mineral component of human bony tissue, hydroxyapatite. Nonetheless, the plasticity that ASCs purportedly exhibit, and subsequent scientific interest in them, continue to expand. Continued confirmatory preclinical research efforts are required to validate differentiation potential and an understanding of therapeutic mechanisms of action to ensure that clinical translation is expedient, efficient, and efficacious.

ENGINEERED NEO-TISSUE

ASCs are traditionally cultured on two-dimensional plastic. These culture conditions allow expansion of the putative stem ASC population but do not necessarily mimic the in vivo microcellular environment experienced by a cell: that is, cell−cell and cell−matrix interactions. As focused research on the creation of ex vivo neo-tissue constructs becomes more successful, the ability to recapitulate that microcellular environment becomes increasingly granular, composed of inductive media, growth factors, cytokines, gas concentrations, matrix material and dimension, and even matrix nanodirectional and microdirectional topographies [100,101].

Investigators have used ASCs to repair cartilage, bone, adipose, bladder smooth muscle, trachea, skin, and blood vessels in vitro and in human subjects, using ASCs as the cellular foundation. Starting with a three-dimensional, polylactic-glycolic acid bladder dome combined with an outer porous sponge, Jack et al. seeded the construct with smooth muscle cells differentiated from ASCs and implanted it into rats. After explantation at 12 weeks, histological and functional analyses revealed increasing smooth muscle mass and compliance similar to de novo bladder, respectively [102]. ASCs applied to a collage scaffold and implanted in a rat tracheal defect demonstrated accelerated epithelialization and improved angiogenesis compared with controls and provided an adequate airway [102a]. The ability to tissue engineer skin would be enormously beneficial to patients with thermal injury. Trottier et al. successfully used ASCs in place of dermal fibroblasts to reconstruct the neo-skin's dermal layer. In addition, the authors concluded that using ASCs to create neo-skin resulted in a superior neo-organ because only the samples containing ASCs were found to possess a histologically distinct hypodermis [102b].

The use of a preformed scaffold seeded with cells has become common in tissue engineering paradigms. Because higher cell densities influence cell viability and total matrix production positively, improving neo-tissue survival

requires efficient, homogeneous seeding. This can be challenging, and a number of strategies have been described in the literature. Many groups have published on the seeding of cells onto osteoinductive and/or osteoconductive scaffolds in particular. Janssen et al. described the seeding of human BM stromal cells onto 2- to 6-mm granules of a biphasic calcium phosphate scaffold under both static and perfusion conditions. Static seeding was performed for up to 4 h, but constructs were further cultured for up to 20 days and seeding efficiency was judged qualitatively [103–107]. Silva et al. reported the seeding of bioactive glass scaffolds with cylindrical dimensions of 6 × 3 mm with culture-expanded hASCs using static conditions for 2 h, followed by incubation for up to 21 days, but no specific seeding efficiency was reported [107]. Chen et al. described the seeding of human amniotic MSCs onto porcine gelatin microspheres with diameters ranging from 130 to 380 μm. Their seeding protocol involved cycles of intermittent stirring alternating with static culture for 8 h and resulted in a seeding efficiency of greater than 90% [104]. Frohlich et al. reported the seeding of culture-expanded hASCs onto demineralized bone scaffolds with cylindrical dimensions of 4 × 4 mm. Using repeated pipetting of a highly concentrated cell suspension followed by static culture for 2 days, they report a seeding efficiency of 73% [106]. This was in direct contrast to findings reported by Jurgens et al. with regard to the attachment of SVF cells to scaffolds. They reported that SVF cells attached rapidly to two different scaffold types, but with only 10% efficiency. Interestingly, their findings also suggested that no additional benefit was achieved by prolonging the seeding-incubation step from 30 min to 2 h [106]. It is clear that seeding methods vary widely and efficiency depends on many variables including cell type, scaffold type, and cell concentration, to name a few. These many variables can seem even more daunting when considered in the context of point-of-care objectives. With this approach, constructs are meant to be fabricated in real time at a patient's bedside, in the operating room, or perhaps in a clinic. This reduced time frame adds an additional challenge to an already difficult objective.

Other potential, albeit completely experimental methods of producing engineered neo-tissue constructs using ASCs include techniques involving organ printing and/or explanted microcirculatory beds (EMBs) [108]. Tissue and organ printing may enable large-scale industrial robotic fabrication of living human organ constructs with a "built-in" perfusable intraorgan branched vascular tree (Mironov et al., 2009). These vascularized organ constructs could then be perfused with a solution containing predifferentiated ASCs, which would subsequently engraft and further differentiate, creating a functioning, physiologic neo-organ. However, the ability to regenerate a functional, physiologic, vascularized, three-dimensional organ remains an elusive goal for tissue engineers.

In short, the engineering of neo-tissue constructs from ASCs is at an early stage. The realization of the regenerative potential of ASCs will eventually improve clinical outcomes, but it is dependent upon further advancements in adipose biology including proliferation, differentiation, and signaling.

THERAPEUTIC SAFETY OF ADIPOSE-DERIVED CELLS

Carcinogenesis and Tumorigenesis

Despite a variety of preclinical and clinical studies demonstrating the safety of intravenous and site-directed injection of ASCs, conflicting reports exist indicating the induction or facilitation of tumor growth [109,110]. The resulting concern that multipotent mesenchymal cells, ASCs in particular, could inadvertently effect tumor tropism has surfaced. Proposed mechanisms permitting tumorigenicity/tumor tropism have been postulated to include immunomodulation, inhibition of caspase-induced apoptosis, and increased tumor vasculogenesis. For example, several studies have indicated that ASCs not only home and engraft into tumor and its vascular supply, but augment the tumor growth rate, cellular viability, and metastatic toolbox (i.e., invasion and motility) [110–112].

Because cells respond to the extracellular environment, it is of unsurprising that this milieu is important in the promotion and regulation of cellular functions including the cell cycle, transcription, and translation. It is therefore entirely possible that ASC-driven tumor tropism is caused in large part by its secretome and its paracrine–endocrine effects. Studies isolating the effects of this secretome using ASC-conditioned media (but devoid of adipose-derived cells) have demonstrated the ability of this conditioned media to increase cytokine and growth factor production of endometrial and breast cancer cells while simultaneously increasing tumor proliferation rates [113,114].

Other research directly contradicts the tumor-promoting behavior of ASCs. The proliferation of primary leukemia cells is inhibited by secreted Dickkopf-related protein 1 (DKK-1), the transcription of which is actively regulated via the ASC transcription factor NANOG [115]. In addition, ASC coculture studies of ASC and breast cancer cells report statistically significant reductions in cancer proliferation and metastatic rates, reportedly via the same DKK-1

expression [116]. Other in vivo modeling recapitulates these outcomes but is often attributed to other mechanisms, including downregulation of cell-cycle progression [117].

There is a large and growing number of humans who have received MSC therapies (both BM- and adipose-derived cells as well as allogeneic and autologous cells) for a variety of clinical indications, by a variety of delivery routes: for example, the RESTORE-2 trial, a prospective clinical trial using autologous ASC-enriched fat grafts to reconstruct postmastectomy contour defects. With only 2 of 71 total patients lost to follow-up, there was no reported local cancer recurrences at the 12-month end point [118]. Furthermore, the current authors are unaware of any reported oncologic-related adverse events associated with any human adipose cell-derived studies or therapies. Nevertheless, there is no doubt that the (putative) oncologic risks associated with regenerative cell therapies deserve focused and continued thorough evaluation. Moreover, the mantra of "First do no harm" must guide a clinician's activities no matter how noble the intent. On the other hand, worthy efforts to advance and translate the field of regenerative medicine will inevitably be associated with risks inherent to the new and unknown, even in light of thorough and meticulous science, and the extensive education and comprehensive and ethical consent of courageous, sometimes desperate patients.

CONCLUSIONS

Attempts to harness the pluripotent and paracrine potential of lipoaspirate cells (i.e., the heterogenous SVF and culture-expanded ASC) are increasing in number, and clinical translation of adipose science is in a fledgling but quickly growing stage. The mechanisms through which adipose-derived cells modify the extracellular micromilieu (e.g., secretome paracrine signaling, cell−cell interaction and induction, cellular homing, and engraftment) continue to be studied and elucidated, and with this expansion of solid, preclinical knowledge, further clinical discovery and subsequent therapeutic promise will continue to be realized. The relative accessibility of autologous adipose and abundance of stromal cells and putative progenitors facilitate these studies and subsequent scientific progression. However, current regulatory rules are not globalized, and they often depend on country-specific guidelines. As the understanding of adipose stromal cell biology becomes transparent, the maturation of policies governing their human clinical applications will soon follow. ASCs will likely become a cellular keystone in the field of regenerative medicine and improve our ability to treat countless diseases and disorders.

Peripheral Blood Stem Cells

Abritee Dahl, Graça Almeida-Porada, Christopher D. Porada, Shay Soker

Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

INTRODUCTION

Adult stem and progenitor cells have been isolated from a wide variety of sources. Lineage-committed progenitors are found in a number of tissues including skin, fat, muscle, heart, brain, liver, pancreas, and bladder. Adults have another source of stem and progenitor cells is are not restricted to a specific tissue. These "universal" stem and progenitor cells are found circulating in peripheral blood (PB), which allows them to reach and integrate into all tissues.

The various hematopoietic stem cells (HSC), and nonhematopoietic stem cells, and progenitor cells found within the PB are thought to originate primarily from the bone marrow (BM) in adults. Hemangioblasts are the embryonic precursors of HSC, which develop into the progenitors and mature cells of all of the various hematopoietic lineages. These progenitor cells complete their differentiation in the BM, PB, and thymus. Extensive research in hematology and oncology has resulted in the identification of a wide variety of cell surface markers that allow the characterization and isolation of hematopoietic cells at different stages of differentiation and lineage commitment. Initially, adult BM-derived mesenchymal stem or marrow stromal cells (MSC) were isolated, expanded in vitro, and examined for their multilineage differentiation potential. These early studies were followed by extensive research showing that this unique cell population can proliferate extensively in vitro without loss of potential, differentiate to multiple lineages in vitro and in vivo, and contribute to the regeneration of several tissues in vivo [1]. Like HSC, it is possible that MSC may leave the BM environment and circulate within the PB. Identification and isolation of MSC is based on the differential expression of cell surface markers that distinguish them from circulating HSC. Endothelial progenitor cells (EPC), another progenitor population within the PB, are derived from the same hemangioblast precursors as HSC, but they take a separate path of differentiation in the BM. The identification of circulating EPC suggested that the process of vasculogenesis, which was previously believed to be restricted to the embryonic stages, continues into adulthood. Circulating EPC have specific cell surface markers that are unique to their primitive state and are lost when EPC differentiate into mature endothelial cells (EC).

This chapter will briefly review the types and source of stem cells in PB, their specific cell surface markers, and factors that change their abundance in PB. We will focus on the isolation and in vitro expansion of MSC and EPC and describe their therapeutic applications for regenerative medicine. We will further describe the role of PB-derived stem cells in normal and pathological processes. Although much information has been gathered on the identification of different populations of PB stem cells, their clinical potential for therapy is just now being explored. Because PB is readily obtainable, their consideration as a viable source of cells for regenerative medicine deserves special attention.

TYPES AND SOURCE OF STEM CELLS IN THE PERIPHERAL BLOOD

All of the countless cells of all 10 hematopoietic lineages (erythrocytes, platelets, neutrophils, eosinophils, basophils, monocytes, T and B lymphocytes, natural killer cells, and dendritic cells) that are found within the circulation at any given time are produced within BM through the carefully orchestrated process known as

Principles of Regenerative Medicine, Third Edition
https://doi.org/10.1016/B978-0-12-809880-6.00020-5

hematopoiesis. In the adult, the process of hematopoiesis is supported by a rare population of cells within the BM known as HSC. Although HSC account for only about 0.01% of the total BM cellularity [2], it has been estimated that under steady-state conditions, this remarkable process must generate a remarkable 10^{10} erythrocytes and 10^{9} leukocytes each hour in a human while maintaining the circulating levels of each cell lineage within tightly regulated limits. Moreover, the BM can respond on-demand rapidly to increase the production (and release into the circulation) of the specific lineage(s) needed to counter a variety of insults and injuries, ensuring restoration of homeostasis. Although in the absence of disease BM remains the primary site of hematopoiesis throughout life [3], as early as the 1960s, it was recognized that small numbers of HSC are present at all times, circulating within in the PB stream as they transit from one site in the marrow to another, thus ensuring that the marrow is continuously and homogeneously "seeded" with these cells [3]. Interestingly, the levels of circulating HSC have been shown to fluctuate throughout the day, paralleling changes in Circadian rhythm, and increase in response to exercise and a variety of environmental and chemical stressors [4]. This process, known as “mobilization,” will be discussed in detail in the next section, covering both its mechanism(s) and clinical implications.

Although most of the cells in the PB are hematopoietic in origin, other nonhematopoietic stem/progenitor cells are present. The most abundant of these are EPC, which derive from the same precursor during ontogeny as the HSC: the hemangioblast. Throughout life, EPC participate in repairing endothelial damage arising from injury and disease, and can also contribute to vasculogenesis, a process that was previously thought to be restricted to embryogenesis. As a result, many preclinical and clinical studies are exploring the use of EPC to treat ischemia in various tissues arising as a result of a range of injuries and diseases. Like HSC, the levels of EPC in the PB can fluctuate fairly widely in response to a variety of factors and stressors, likely also as a result of the mobilization of reserves of EPC from the BM. These findings have raised the hope that it may be possible to trigger or enhance the release of endogenous EPC for therapeutic purposes.

Another important BM-derived stem/progenitor cell is the MSC. MSC reside in the perivascular regions of the hematopoietic niche of the BM, from which they provide a wide array of physical and chemical signals that are required to drive or regulate the hematopoietic process. MSC or MSC-like cells also exist throughout the rest of the body as pericytes in close association with the vasculature. MSC released from the BM or these pericyte reserves have been reported to have a key part in maintaining and repairing damaged tissues throughout life, and there have been a handful of reports describing the presence of MSC in the PB [5]. However, their presence in significant numbers and their ability to be “mobilized” are still contentious. Nevertheless, given their emerging role as cellular therapeutics in regenerative medicine and as vehicles for gene delivery, we will discuss these cells in detail in this chapter.

Mobilization of Bone Marrow Cells

Hematopoietic Stem/Progenitor Cell Mobilization

When HSC transplantation was first adopted as a clinical procedure, limited knowledge of the hematopoietic system at the time dictated that BM serve as the source of the HSC graft. To collect HSC for these early transplants, a substantial volume of BM had to be harvested from the pelvis or sternum under general anesthesia. While investigators were fine-tuning the details of conditioning regimens and graft composition, compelling evidence emerged that the absolute number of HSC present within the BM graft that was transplanted strongly correlated with the robustness of hematopoietic engraftment. Moreover, increasing the dose of HSC resulted in significantly lower mortality from infectious complications posttransplant [6]. These important realizations fueled the search for methods to increase the number of HSC that could be harvested for transplant.

Before it was possible to begin devising newer and more efficient ways to increase the numbers of HSC that could be obtained in a graft, a better understanding was necessary of the interactions between HSC and the BM niches in which they normally reside. Studies over the past decades revealed that the most primitive HSC are maintained in the BM niches by binding to the extracellular matrix (ECM) and stromal cells of the BM via multiple adhesive interactions [7]. Of these, binding of the ligands stromal-derived growth factor-1 (SDF-1α) (also known as CXCL12) and vascular adhesion molecule-1 (also known as CD106), which are expressed on the surface of cells in the BM microenvironment, to their respective receptors, CXCR4 and very late antigen-4 (also known as $\alpha 4\beta 1$-integrin), which are expressed on the surface of HSC, have emerged as essential signals for the retention of HSC in the BM niches and in the trafficking of HSC to and from the BM [8,9]. As early as the 1960s, it was recognized that HSC residing in BM could be released from their niches and circulate in the PB, albeit at low levels, under steady-state homeostasis [10]. In subsequent years, it was observed that the levels of these circulating HSC often increased after chemotherapy.

Further studies demonstrated that the levels of naturally circulating HSC follow changes in circadian rhythm [11,12] and that the number of circulating HSC increases in response to a wide array of physiological stimuli and

stressors, including systemic or local inflammation, strenuous exercise, psychological stress, and tissue or organ injury [8,9]. This process of so-called "mobilization," in which HSC are coaxed to leave their niches within the BM and enter the circulation, is still not well-understood but has been postulated to be orchestrated by (1) SDF-1α degradation and inactivation within the BM niches by proteolytic enzymes such as elastase, cathepsin G, and various metalloproteinases (MMP); (2) neurotransmitters released from nerves that innervate the BM microenvironment; and (3) reversal of the transendothelial chemotactic gradient between the BM microenvironment and plasma [13]. Evidence has also accumulated that the exodus of HSC from stem cell niches is significantly augmented in a complement cascade (ComC)-dependent manner [9]. The ComC is activated by the classical, mannan-binding lectin and alternative pathways. Activation of the ComC and generation of cleavage fragments of the fifth component of the ComC (C5) initiate events that are required for egress of HSC from BM into PB [14]. Further studies have provided compelling data to support the conclusion that the coagulation cascade is activated in parallel with the ComC during mobilization and that it has a supporting role in this process [13]. Additional support for the importance of the ComC in mobilization is provided by the fact that the ComC is activated in all of the mechanisms leading to mobilization of HSC (for example, systemic inflammation, infection, organ injury, stress, and strenuous exercise) [9].

In addition to these physiological triggers, studies in the 1970s and 1980s revealed that administering pyran copolymer to mice or dogs could induce primitive colony-forming HSC to "mobilize" from the BM into the circulation [15,16]. Moreover, the dose and number of times or frequency with which pyran copolymer was administered directly affected the resultant levels of circulating HSC. These findings led the authors to conclude that mobilized PB (mPB) could represent a viable source of HSC for transplantation. Subsequent studies showed that hematopoietic cytokines could mobilize primitive HSC with long-term repopulating ability into the PB with relatively high efficiency [17], and in the early 1980s, the first autologous transplants using HSC from mPB were reported [18]. After the discovery and clinical development of human granulocyte colony-stimulating factor (G-CSF) and the realization that immunoisolation could be used to obtain highly enriched primitive HSC from this cytokine-mPB, thereby removing malignant cells and making it possible to use autologous cells to treat hematological malignancies [19], G-CSF quickly become the standard and most widely used mobilizing agent for autologous HSC transplantation. It has been the standard of care for the past several decades. G-CSF is thought to mobilize HSC from the BM niche primarily by stimulating the secretion of neutrophil-associated extracellular proteases, such as matrix MMP-9, which can degrade SDF-1α, thereby releasing HSC from their niche [20]. Experiments with neutralizing antibodies directed against CXCR4 or SDF-1α have provided further evidence that uncoupling of the SDF-1α—CXCR4 axis is critical for G—CSF—mediated HSC mobilization.

The noninvasiveness and ease with which mPB could be collected (compared with the general anesthesia required for BM harvest and the pain that follows multiple aspirations from the BM), and the discovery that HSC were present at higher frequency in these mobilized products than in steady-state BM, quickly led multiple laboratories and centers around the world to begin replacing BM with mPB in the clinical setting [21,22]. Indeed, the use of mPB as an HSC source has dramatically increased and now accounts for approximately 75% of HSC transplants from unrelated adult donors [6] and about 99% of autologous HSC transplants [23]. Interestingly, this dramatic shift has taken place without much hard clinical data to support the superiority of mPB in terms of better patient outcome or safety [6], and despite concerns that the higher T-cell content present in mPB might lead to higher risk for graft versus host disease (GVHD) [24]. Support for this shift has come from numerous large, multicenter, randomized trials that have collectively shown that engraftment or reconstitution is often faster and more robust with mPB than with BM, shortening the duration of cytopenias, and that the use of mPB may be associated with a decreased relapse rate, but this appears to depend on the patient population and malignancy in question [25]. In the allogeneic transplant setting, the use of HSC from mPB, compared with those from BM, was shown to be associated with more rapid engraftment, reduction of infectious complications, and lower transplant-related mortality in patients with advanced hematologic malignancies [21]. However, as originally feared, these studies also revealed that the use of mPB is associated with a significantly higher rate of chronic (and perhaps acute) GVHD than BM and offers no significant improvement in survival [26].

Despite the marked clinical success of G-CSF and the dramatic change it has enabled in the practice of HSC transplantation, 5%—20% of individuals fail to mobilize a sufficient number of HSC into the PB in response to G-CSF, for reasons that are unclear. This inability to mobilize a significant percentage of patients requiring HSC transplantation has led investigators and clinicians to seek alternative means of mobilizing HSC. Besides G-CSF, other cytokines such as granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-7, interleukin-3, interleukin-12, stem cell factor, FLT-3 ligand, and interleukin-8 have been reported to mobilize HSC clinically or experimentally in animal models [27]. However, each of these molecules differs in the time to achieve efficient mobilization, the type of cells it mobilizes into the PB, and its side effects.

Plerixafor/AMD3100 is a bicyclam molecule that specifically and reversibly blocks SDF-1α binding to CXCR4 [28,29]. It was initially developed as an antagonist of the CXCR4 HIV coreceptor that is present on the surface of $CD4^+$ T cells, thereby blocking HIV cell entry. Subsequently, however, this agent was demonstrated to possess significant HSC-mobilizing activity. This is unsurprising because inhibition of this critical HSC–niche interaction induces the rapid egress of HSC from the BM into the peripheral circulation. Indeed, whereas cytokines induce HSC mobilization with delayed kinetics (over the course of days), mobilizing with agents such as Plerixafor that directly disrupt the critical SDF-1α–CXCR4 axis can generate peak levels of mobilized HSC within only hours of administration.

In addition to its much faster action, Plerixafor has also been shown to mobilize a larger absolute number of $CD34^+$ cells in patients who have failed to yield an adequate amount of $CD34^+$ cells upon mobilization attempts with G-CSF with or without chemotherapy. Importantly, compared with G–CSF–mobilized cells, a higher percentage of Plerixafor-mobilized $CD34^+$ cells are in the G1 phase of the cell cycle and belong to the more primitive $CD34^+/CD38^-$ subset of cells. Limiting dilution HSC transplant studies in animal models showed that Plerixafor-mobilized HSC have a higher frequency of true HSC with long-term repopulating activity [28]. Thus, in addition to an absolute increase in overall $CD34^+$ cells upon Plerixafor mobilization, a more primitive and potent progenitor cell population is also significantly elevated. Numerous clinical trials have demonstrated that combining G-CSF and Plerixafor can further increase the $CD34^+$ cell yield; they also showed that a higher proportion of the mobilized progenitors possesses the primitive and possibly more potent $CD34^+/CD38^-$ phenotype.

Studies over the past several years, largely spearheaded by the Ratajczak group, have provided greater insight into the mechanisms by which HSC are mobilized and have begun to provide possible explanations for why certain people are so-called "poor mobilizers." Studies by this group showed that heme oxygenase-1 (HO-1), which has well-documented antiinflammatory potential, has an important and previously unrecognized role in the retention of HSC in BM niches. HO-1 appears to exert this effect through several different means, the most important of which are: (1) negatively modulating activation of ComC; (2) maintaining SDF-1α levels in the BM microenvironment; and (3) attenuating the chemotactic responsiveness of HSC to SDF-1α and sphingosine-1 phosphate gradients in the PB. These investigators also showed that HO-1 activity inhibits HSC mobilization in response to G-CSF or Plerixafor/AMD3100 [30]. Further study revealed that upregulation of inducible nitric oxide (NO) synthase enhances HO-1 activity, thereby acting as a novel negative regulator of hematopoietic cell migration and preventing egress of HSC into PB during mobilization [31]. This group also made the astute and important observation that all of the processes that have been shown to induce HSC mobilization also trigger activation of several ancient proteolytic cascades, such as the ComC [9,14], the coagulation cascade, and the fibrinolytic cascade [32]. The researchers found that when HO-1 metabolizes heme, it produces molecules with potent antiinflammatory properties, including inhibition of the ComC. Intriguingly, mutations in the ComC pathway occur at a frequency similar to the observed rate of "poor responders," which strongly suggests that this pathway is critically involved in this important clinical problem.

Mobilization of Other Bone Marrow–Derived Cells into Peripheral Blood

Studies have provided compelling evidence that many of the same physiological stressors such as injury and intense exercise and pharmacological agents such as G-CSF and Plerixafor/AMD3100, which mobilize HSC efficiently from the BM niches into the circulation also mobilize EPC, and that this mobilization can create pronounced therapeutic benefit in a range of diseases [33]. However, although many of the pathways appear to be shared between HSC and EPC, such as the involvement of MMP-9 [34] and regulation by NO [35], the optimal parameters or combination of cytokines or growth factors to induce mobilization differ between HSC and EPC [36]. In addition, EPC are also mobilized in response to stress signals such as hypoxia-inducible factor-1α [37] and hormonal changes that occur during the menstrual cycle [38], which do not mobilize HSC.

In addition to EPC, another important BM-derived stem/progenitor cell is the MSC, the biology and properties of which will be discussed in detail in a subsequent section. Current thought holds that MSC released from the BM or other perivascular reserves throughout the body have an important part in maintaining and repairing damaged tissues throughout life. To accomplish this task, one would assume that they must transit to areas of damage or disease via the bloodstream. However, the detection of MSC in the PB has proven difficult, and there have only been a handful of reports actually describing the presence of MSC in the PB and their mobilization in response to injury or pharmacological agents [5]. As a result, their presence in significant numbers and their ability actually to be mobilized are still contentious. Indeed, other studies have shown a lack of mobilization, but rather alterations to the MSC secretome in response to stressors that provoke HSC and EPC mobilization [39].

ENDOTHELIAL PROGENITOR CELLS

Initial evidence that EPC can be detected in PB came from research conducted mainly by the groups of Isner and Asahara in Boston and Rafii in New York [40,41]. They showed that cells with EC characteristics can be isolated from PB and expanded in vitro. They and others showed that the numbers of EPC in PB were significantly increased as a result of acute vascular injuries, angiogenic stimuli, estrogen, and NO synthase but were reduced by certain chronic disease states (e.g., coronary artery disease) [42]. Circulating EPC originate primarily from the BM and can be identified by the differential expression of hematopoietic and EC markers. This is important because hematopoietic and EPC probably share a common precursor, the hemangioblasts [43]. Hemangioblasts reside mainly in the BM and differentiate into HSC and angioblasts. This process occurs mainly during early embryogenesis but was shown to exist in adults [42,44]. Angioblasts will develop into EPC that, upon stimulation with angiogenic factors such as vascular endothelial growth factor (VEGF) and placental growth factor, are mobilized from BM to PB [42,45]. Once in PB, EPC can be recruited to sites of active neovascularization such as those seen in wounds, diabetic retinopathy, and tumors [46]. The role of EPC in physiological and pathological neovascularization and their therapeutic applications are described next.

Identification and Isolation of Endothelial Progenitor Cells

Marrow and PB cells expressing CD34 can develop into EPC [40,47]. Although CD34 is commonly used to isolate EPC, CD34 expression is also shared by HSC and MSC and cannot be used to distinguish between these populations. Likewise, VEGF receptor 2 (VEGFR-2) (human kinase insert domain receptor [KDR] and mouse Flk-1), which is used to identify EPC, is expressed also on HSC [40]. In humans, CD133 (AC133) is used to distinguish EPC from mature EC, because CD133 is not expressed by mature EC [47]. CD133 is a stem cell marker with functions that have not yet been recognized [48]. In addition, Hebbel and colleagues have used P1H12 antibodies that recognize CD146 (MUC18) on circulating EC in PB but not on monocytes, granulocytes, platelets, megakaryocytes, or T or B lymphocytes [49]. Other markers common to progenitor and mature EC are the cell surface receptors KDR and Tie2 [46]. Purified populations of $CD133^+/KDR^+$ EPC proliferate in vitro in an anchorage-independent manner and can be induced to differentiate into mature adherent EC [46]. It is thought that $CD133^+/KDR^+$ EPC are a population of immature EC that are mobilized from the BM to participate in neovascularization. Because myelomonocytic cells have lost surface expression of CD133, this marker also provides an effective means to distinguish true EPC from cells of myelomonocytic origin. Yet, studies showed that cells expressing CD14, considered to be a typical monocytic lineage marker, can become EC [50]. Collectively, these studies suggest that identification of circulating EPC may be achieved using different markers that may define subpopulations of EPC based on their stage of differentiation and origin.

The number of EPC in BM is low (<10 per 10×10^5 mononuclear cells [MNC]) and the reported numbers vary based on which identifying markers are used among the different studies. For practical applications, the EPC fraction may be enriched using cell surface markers such as CD34, CD133, and KDR [40]. SDF-1 stimulates the mobilization of EPC via an enhancement of protein kinase B (Akt) and endothelial NO synthase (eNOS) activity [51]. Interestingly, VEGF has been found to promote EC to express SDF-1 and CXCR4 (the SDF-1 receptor) [52]; on the other hand, SDF-1 has the potency to induce the expression of VEGF [53]. Thus, in the BM vascular niche, the expression of VEGF and endothelial SDF-1 possibly modulate the microenvironment through proteolytic enzymes (MMP-2 and MMP-9) and by controlling EPC mobilization. In addition to these factors, data indicate that erythropoietin (Epo) [54], platelet-derived growth factor (PDGF) [55], and NO [54] stimulate EPC mobilization.

One functional assay capitalizes on in vitro growth kinetics to discriminate BM-derived EPC and circulating EC from vessel wall–derived mature EC [46]. In this assay, the isolated cells are incubated with VEGF, basic fibroblast growth factor (bFGF), insulin-like growth factor (IGF), and fibronectin or collagen. EC colonies that appear early are derived from the recipient vessel wall circulating EC, whereas late-outgrowth cells or colonies originate mainly from BM-derived EPC. Lin et al. [56]. and Gulati et al. [57]. reported that early EPC (7-day cultures) are derived from $CD14^+$ cells (monocytes), whereas late-outgrowing EPC (4–6 weeks of culture) are derived from $CD14^-$ cells that bear endothelial markers ($VE\text{-}cadherin^+Flk\text{-}1^+vWF^+CD36^+CD146^+$). In addition, Hur et al. [58] cultured total MNC obtained from human PB and reported two EPC types. Some cells organized into clusters as early as 3 days after plating; these were called early EPCs. These cells had limited proliferative capacity and disappeared after 4 weeks of culture. In contrast, another group of cells appeared later, at 2–3 weeks after plating. These cells demonstrated EC-like cobblestone morphology and were called late EPC. Late EPC proliferated robustly and

were positive for VE-cadherin, Flt-1, and KDR but were negative for CD45. The late EPC produced NO and formed capillary tubes. Yoder's group [59] reported the late outgrowth of cells from umbilical cord or circulating blood MNC that they termed endothelial colony-forming cells (ECFC). These cells appeared at 14–21 days after plating and formed adherent colonies with cobblestone morphology. ECFC expressed the cell surface antigens CD31, CD105, CD144, CD146, vWF, and KDR and took up acetylated low-density lipoprotein (AcLDL). ECFC did not express hematopoietic or monocyte/macrophage cell surface antigens such as CD14, CD45, or CD115. Whether isolated from cord or adult PB, ECFC display clonal proliferative potential and relatively high levels of telomerase [60]. Taken together, the consensus is that late-outgrowth endothelial colonies may be considered to be angioblast-like EPC.

The cell surface antigen CD31 (also known as platelet endothelial cell adhesion molecule-1) has been used as a marker for EC for many years [61]. It was suggested that CD31 could also be used as a marker for EPC [62]. However, because it has been shown that $CD31^+$ are fully differentiated EC, it could be argued that CD31 may not be a suitable marker for identification of EPC, because it may not distinguish between progenitor and fully differentiated EC. However, in those studies, CD31-selected EPC had a typical EC/EPC phenotype, proliferated robustly, and integrated into nascent vasculature. The close phenotypic similarity between mature and progenitor EC was highlighted by Ingram et al. [60]. Those researchers used single-cell colony-forming assays to demonstrate that populations of both human umbilical vein endothelial cells (HUVEC) and human aortic endothelial cells (HAEC), which were thought to be fully differentiated EC, contain a subpopulation of EPC with different clonogenic and proliferative potential. That work suggested that HUVEC and HAEC are not homogeneous populations and appear to contain some fully differentiated EC that are unable to proliferate, as well as other cell fractions that demonstrate more "stemness," as shown by their robust ability to proliferate and form colonies. It is not yet clear why HUVEC and HAEC populations demonstrate heterogeneity in ex vivo culture conditions, but these findings suggest that culturing and sorting for EPC may standardize experimental data obtained from different research groups.

Isolation of EPC is conventionally based on fluorescence-activated cell sorting or immunomagnetic techniques, which are complex, time-consuming procedures that need an experienced operator. New devices could be engineered to simplify the operation and shorten the time for obtaining EPC. Miniaturization of EPC isolation procedures by using similar strategies, adopted from microfluidic lab-on-a-chip devices, may significantly facilitate EPC isolation [63]. Plouffe et al. [64] developed a microfluidics chamber, coated with antibodies against CD34, VEGFR-2, CD31, CD146, or CD45, to capture EPC. When cells were flowing through the "EPC chip," they demonstrated specific affinity to EPC. Although this prototype device can be coated with only one antibody on a single chamber, it is potentially an alternative for easy and rapid separation of EPC. Tillman et al. [65] developed an extracorporeal cellular affinity column that can recover CD133-expressing progenitor cells with high efficiency. In a sheep model, 1.8 L of blood was passed through a Sepharose-based column with affinity for CD133 and unbound cells and plasma were returned to the animal. The results showed that this process had a minimal effect on the hematologic and physiologic parameters of the animal and EPC recovery was over 600-fold more efficient than conventional density centrifugation from a PB specimen. This technology may facilitate the generation of large numbers of progenitor-derived cells for clinical therapies and reduce the time required to attain clinically relevant cell numbers while minimizing loss of other important cell types to the donor.

In Vitro Expansion of Endothelial Progenitor Cells

The relative paucity of EPC in the circulation likely contributes to the difficulty associated with EPC culture [60]. Density-gradient separation procedures, designed for separating MNC from blood, may contribute to this problem. Thus, successful culture of EPC usually requires a relatively large amount (50–100 mL) of peripheral or cord blood, and yet few colony-forming units (CFU) or ECFC can be obtained (see Table 20.1 in [59]). The mononuclear fraction is placed in fibronectin-coated plates containing endothelial basal medium with contain angiogenic growth factors such as VEGF and bFGF. Other growth factors such as epidermal growth factor and IGF contribute to cell growth but not differentiation. In one of their earlier studies, Asahara et al. [66] showed that VEGF and not bFGF is important for EPC differentiation, and bFGF may be used by the differentiated EC for subsequent proliferation. Inclusion of angiogenic factors in the media prevents "contamination" by other cell types including lymphocytes, macrophages, and dendritic cells. VEGF appears to inhibit dendritic cell maturation from $CD34^+$ MNC fraction [67]. Within 7–10 days of culture in fibronectin- or collagen-coated dishes, colonies with spindle-shaped cells appear in the dish. These are "slow-growing" cells, defined as "late-outgrowth" EPC. They differ from the mature

circulating EC that readily proliferate in vitro [42]. The whole-blood culture method may be used to increase the likelihood of obtaining EPC cultures. This approach does not require MNC separation procedures, which may minimize cell damage caused by density gradient separation. Reinisch et al. [68] reported that whole-blood culture yielded nearly eightfold more ECFC colonies compared with density gradient separation. The whole-blood culture approach may simplify EPC culture procedures and increase the possibility that EPC will be used for clinical diagnostic and therapeutic purposes.

Commercially available media kits were introduced to facilitate EPC growth. These kits provide reagents and media for culturing EPC from PB. However, these culture kits may not be optimal for EPC expansion and differentiation. Hur et al. [58]. reported that cells isolated with such kits displayed limited proliferative capacity and did not integrate into nascent vasculature [69]. Further studies revealed that monocytes and T cells can contribute to CFU EC [70]; therefore, it is reasonable to argue that some of these kits are not suitable for EPC culture and assays. Instead, ECFC [59] should be cultured in endothelial cell growth medium-2 culture medium, which was developed from MCDB131 medium in the 1980s [71]. ECFC demonstrate late colony-forming, robust proliferation, endothelial morphology, the expression of EPC/EC-related markers, and the ability to integrate into nascent vasculature. Regardless of the EPC source, the cells assume a typical flat EC morphology after 2–3 weeks and present mature EC markers such as CD31, VE-cadherin, and CD146 (P1H12). They metabolize AcLDL, bind *Ulex europaeus* agglutinin-1, and produce NO, consistent with EC properties. Proper characterization of EPC-derived EC requires the analysis of a combination of cell surface markers.

The Role of Endothelial Progenitor Cells in Physiological and Pathological Neovascularization

Blood vessels form by two processes: (1) angiogenesis, or the sprouting of capillaries from preexisting blood vessels; and (2) vasculogenesis, or the in situ assembly of capillaries from undifferentiated EC. Vasculogenesis takes place mostly during the early stages of embryogenesis [72]. Vascular channels in the yolk sac originate from the mesoderm by the differentiation of angioblasts, which subsequently generate primitive blood vessels [73]. Early findings that EPC can participate in angiogenic processes indicate that postnatal neovascularization does not rely solely on sprouting from preexisting blood vessels (angiogenesis) but may be assisted by EPC via postnatal vasculogenesis [66].

BM-derived EPC contribute to adult tissue neovascularization in several models including wound healing, cornea, and tumor angiogenesis [66]. BM-derived EPC may be detected in normal organs including spleen, lung, liver, intestine, skin, hind-limb muscle, ovary, and uterus, which indicates their participation in maintaining

physiological neovascularization [66]. Hormonally induced ovulation cycles were also associated with the localization of BM-derived EPC in corpus lutea and in the uterus endometrium and stroma. These findings indicate that EPC contribute to physiological neovascularization associated with the postnatal regenerative processes.

Minami et al. [74] examined the presence of endothelial, smooth muscle, and Schwann cell chimerism in patients with sex-mismatched (female-to-male) heart transplants. The Y chromosome was used to determine chimerism. Biopsy specimens taken at subsequent times after heart transplantation showed that EC had the highest degree of chimerism (24.3%), Schwann cells showed the next highest chimerism (11.2%), and vascular smooth muscle cells (SMC) had the lowest (3.4%). Results of this study indicated that circulating progenitor cells are capable of repopulating most major cell types in the heart, but they do so with varying frequency. The signals for endothelial progenitor recruitment occur early and could relate to the injury during the surgery.

Cumulative evidences show that BM cells may improve ischemic myocardium function by paracrine stimulation of angiogenesis rather than differentiation into contractile cardiomyocytes [75]. In addition to contributing to neovascularization directly and indirectly, EPC may also provide paracrine survival signals to cardiomyocytes [76]. Clinical studies also suggested that cell-based therapy with EPC can improve myocardial function [77]. In parallel, EPC were found to be incorporated into the vasculature of pathological lesions such as atherosclerotic plaques, tumors, the retina, and ischemic brain tissue. Vascular SMC proliferation results in neointimal hyperplasia and the development of restenosis. BM-derived SMC can integrate into the hyperplastic neointima and atherosclerotic plaques [78]. Evidence for the contribution of BM MSC to human atherosclerotic plaques originated from a study showing donor-derived neointimal cells within the plaques [79]. Also, decreased EPC in the circulation have been correlated with a higher risk of cardiovascular complications [80]. It was hypothesized that lower levels of PB-EPC were associated with an impaired capacity to repair the damaged vessels, but the pathophysiological role of BM-derived EPC remains unclear. Recruitment of PB-EPC to damaged or diseased tissues depends on the underlying pathology and probably results from the release of specific growth factors and chemokines by these tissues [81]. Abnormal retinal neovascularization contributes to the pathogenesis of proliferative retinopathy in diabetes and age-related prematurity and macular degeneration. BM-derived hemangioblasts were shown to contribute to retinal neovascularization in models of proliferative retinopathy [82,83]. This study documented the incorporation of EPC into mature endothelium of the retinal blood vessels. Cerebral infarction is associated with neovascularization of the ischemic zone and new vessel growth. BM transplantation studies showed that EPC could be detected in the neovessels at the repair sites after 3 days [84]. EPC reduction is also considered to be a mechanism by which cardiovascular risk factors promote cardiovascular disease (CVD). A decrease in EPCs is also associated with the pathophysiology of rheumatologic disorders [85]. In this context, restoration of EPC function may prevent long-term cardiovascular complications associated with cardiovascular risk factors and attenuate clinical manifestations of rheumatic diseases.

Whereas restoring EPC function in CVD may prevent disease development, targeting EPCs in cancer may have potential therapeutic benefits. EPC recruitment during tumor progression contributes significantly to the cancer-associated neovasculature. Thus, targeting these cells could be used effectively to halt tumor progression by preventing vascularization of neoplastic deposits [85]. Studies have shown a correlation between increased VEGF and mobilization of EPCs to tumor sites [86,87], whereas inhibiting VEGF receptors halts tumor growth in vivo [88]. Other factors that have an integral role in mobilizing EPCs to tumor sites include interleukin-8 and NO [87].

Compelling evidence for the role of EPC in tumor vascularization comes from a study by Lyden and colleagues using an angiogenesis-defective mouse model. Mice lacking both alleles of Id1 ($id1^{-/-}$) and Id3 ($id3^{-/-}$) died by embryonic day 13.5 and exhibited massive vascular malformation [89]. The $Id3^{-/-}/id1^{+/-}$ mice survived but could not support the growth of several tumor types owing to insufficient tumor vascularization. However, transplantation of $id3^{-/-}/id1^{+/-}$ mutant mice with BM from wild-type mice resulted in tumors that were indistinguishable from tumors grown on wild-type mice [90]. Furthermore, 90% of the tumor vessels contained BM-derived EC, which indicated the contribution of EPC to tumor neovascularization. VEGF treatment failed to elevate the number of EPC in $id3^{-/-}/id1^{+/-}$ mutant mice but not in $id3^{-/-}/id1^{+/-}$ transplanted with wild-type BM. Further evidence was provided by a model in which transplantation of human BM-derived multipotent adult progenitor cells into tumor xenograft-bearing mice resulted in the incorporation of human cells as 40% of the tumor vessel endothelium, which indicated the importance of circulating endothelial cells (CEC) for tumor neovascularization [91]. Different tumors secrete different types and concentrations of angiogenic factors that may have a different capability of inducing mobilization of EPC. Although a formal correlation between tumor type/stage/size and number of EPC has not been established in human cancer, some tumor types may be more dependent than others on CEC as a source of endothelium [92].

Taken together, the results of these studies indicate that the contribution of EPC to neovascularization is not restricted to normal healing processes and that they contribute significantly to several pathological processes. One of the most intensively studied models of EPC and neovascularization is tumor angiogenesis, as described subsequently.

MESENCHYMAL STEM/MARROW STROMA CELLS

An especially critical BM-derived stem/progenitor cell is the MSC. MSC reside in the perivascular regions of the hematopoietic niche of the BM, from which they provide a wide array of physical and chemical signals that are required to drive or regulate the hematopoietic process. MSC or MSC-like cells also exist in close association with the vasculature throughout the rest of the body as so-called pericytes. MSC possess a set of unique properties that combine to make them ideally suited for cellular therapies and regenerative medicine, and as vehicles for gene and drug delivery. Much research has been focused on finding ways to mobilize endogenous MSC from the BM and/or from the widely distributed pericyte reserves or to administer exogenous MSC to mediate tissue repair and thereby treat a variety of injuries and diseases. Some important properties that make MSC one of the most promising stem cell populations for regenerative medicine and vehicles for gene delivery (to be covered in a later section) include (1) their relative ease of isolation; (2) the ability to differentiate into a wide variety of functional cell types of both mesenchymal and nonmesenchymal origin in vitro and in vivo; (3) the ability to be expanded extensively in culture without a loss of differentiative capacity; (4) the fact that they are not only hypoimmunogenic but produce immunosuppression upon transplantation; (5) their pronounced antiinflammatory properties; and (6) their ability to home selectively to damaged tissues after in vivo administration, while contributing little if anything to normal or healthy tissue [1,93,94]. In the section that follows, we will briefly discuss the discovery of MSC, their basic biology and characterization, and their ability to be expanded in vitro for therapeutic use.

Identification, Isolation, Characterization, and In Vitro Expansion

In pioneering studies [95] performed nearly 4 decades ago, Alexander Friedenstein demonstrated that fibroblast-like cells obtained from the BM were able to transfer the hematopoietic microenvironment to ectopic sites, thus establishing the concept that the marrow microenvironment resided within the so-called stromal cells of the BM. However, it was the pioneering work of Caplan that established the concept of the mesengenic process [96] and led to the realization that this population harbored cells with properties of true stem cells, termed MSC [96]. MSC are now known to make up a key part of the stromal microenvironment that supports the HSC and governs the process of hematopoiesis. Despite their essential role, MSC are exceedingly rare within the BM; they account for only 0.001%−0.01% of the total marrow cellularity [97].

Like many rare stem cell populations, MSC cannot be isolated to absolute purity, but numerous culture methods and purification procedures have been developed by various laboratories. The most straightforward method for obtaining MSC is simply to rely on the plastic adherence of MSC and their ability to be passaged with trypsin, to obtain a relatively morphologically homogeneous population of fibroblastic cells from a bulk MNC preparation after only two to three culture passages. This method is certainly straightforward, but true MSC account for only a small percentage of this highly heterogeneous population, which can greatly complicate the interpretation of experimental results obtained with cells prepared in this manner. To avoid this problem, numerous groups have worked for years to identify antigens that are unique to MSC. Interestingly, human MSC do not express markers associated with other stem cell populations (such as HSC), such as CD34, CD133, or c-kit. Indeed, no markers known to identify MSC uniquely. However, several markers have proven useful for obtaining cell populations that are enriched for MSC. The first such marker to be identified was Stro-1 [98]. Although the antigen recognized by the Stro-1 antibody has not yet been identified, we and others have shown that by tri-abeling BM cells with Stro-1, anti-CD45, and antiglycophorin A (GlyA) and selecting the $Stro^{-}1^{+}CD45^{-}GlyA^{-}$ cells, it is possible to obtain a homogeneous population consistently that is highly enriched for MSC [99,100]. In addition to Stro-1, other antibodies such as SB-10, SH2, SH3, and SH4 have been developed over the years, and numerous surface antigens such as CD13, CD29, CD44, CD63, CD73, CD90, and CD166 have been used to attempt to isolate MSC [101−103]. Unfortunately, all of these antigens appear to be expressed on a wide range of cell types within the body in addition to MSC. This lack of a unique marker suggests that to obtain a pure population of MSC that are functionally

homogeneous, investigators likely will either have to await the development of novel antibodies that recognize as yet unidentified antigens unique to primitive MSC or employ strategies in which multiple antibodies are combined, to allow for the positive selection of MSC and depletion of cells of other lineages that share expression of the antigens recognized by the MSC antibody in question, as we have done with Stro-1, CD45, and GlyA. To facilitate the comparison of results from different groups and encourage the use of a better-defined population of MSC in experimental and clinical studies, the International Society for Cellular Therapy stated that MSC must possess several characteristics aside from simple adherence to plastic. They must express CD105, CD73, and CD90, but not express CD45, CD34, CD14, CD11b, CD79, or CD19 and human leukocyte antigen (HLA)−D related surface markers. Furthermore, they must be able to differentiate into the three key MSC types found within the BM, i.e., bone, cartilage, and fat [104].

Although much has focused on MSC isolated from adult BM, cells that appear phenotypically and functionally to be MSC have been isolated by our group and others from numerous tissues including umbilical cord blood, cord matrix, amniotic fluid, placenta, brain, liver, lung, fetal blood, kidney, and even liposuction material [105−109]. The broad distribution of MSC throughout the body has led to the supposition that MSC are likely to have a critical role in organ homeostasis, perhaps providing supportive factors as in the BM, and/or mediating maintenance and repair within their respective tissue. Importantly, although MSC from each of these tissues appear similar with respect to phenotype and overall differentiative potential, studies at the RNA and protein levels revealed that subtle but important differences exist among MSC from these various tissues, with MSC from each tissue possessing a molecular fingerprint indicative of their tissue of origin [110,111]. Using a noninjury fetal sheep transplantation model, we showed that these differences result in a bias for human MSC to home to and develop into cells of their tissue of origin in vivo [112]. This suggests that the ideal source of MSC may differ depending on the specific disease to be treated and the desired target organ. Despite the apparent presence of MSC within many of the major organs of the body, however, the relatively noninvasive fashion with which adipose tissue or BM can be obtained, and the fact that both of these tissues could readily be obtained from each patient to be treated, suggest that these two tissues will likely be the predominant sources of MSC employed in clinical applications in the foreseeable future.

Although MSC constitute a small percentage of the nucleated cells present in the BM, they can be expanded exponentially while maintaining their original phenotype and differentiative potential [113]. Indeed, Bruder et al. [114] demonstrated that human BM-derived MSC can readily be propagated in vitro until passage 38 ± 4 before senescing. Moreover, by plating these cells at a low density ($\sim$1500−3000 cells/cm^2) and consistently passaging them before they reach confluence, it is possible to accelerate their growth rate, increase their expansion capacity, and avoid the spontaneous differentiation that often occurs at higher cell densities [115]. This ability to be expanded extensively in vitro has two important implications for their use in cellular-based liver therapies. The first of these is that a small BM aspirate could be taken from the patient and adequate cells may be obtained for transplantation through extensive expansion in vitro after isolation. Second, by virtue of their ability to be expanded in culture without loss of in vivo potential, MSC could be harvested from the patient's own marrow even if the disease to be treated is the result of an underlying genetic defect, because MSC can readily be genetically manipulated in vitro with both viral and nonviral vectors [1,94,116]. This will be discussed in detail subsequently. After genetic manipulation, a pure population of genetically corrected autologous MSC could then be propagated to generate sufficient numbers of cells to achieve meaningful levels of engraftment after transplantation.

However, additional in vitro and in vivo experiments will likely have to be performed to assess the inherent safety of the specific in vitro−expanded MSC in question rigorously before their clinical use, because at least one study suggested that MSC from adipose tissue may be inherently less genetically stable than MSC isolated from BM [117]. Indeed, two other studies showed that upon prolonged in vitro expansion, adipose tissue−derived MSC can exhibit aneuploidy [118] and have been shown to undergo transformation [119], which raises the possibility that these cells could prove tumorigenic when used in vivo. In stark contrast, however, are the results of another study investigating the inherent safety of adipose-derived MSC. That study showed that even if genomic instability is intentionally induced with genotoxic agents, adipose tissue−derived MSC respond to this insult by undergoing terminal adipogenic differentiation rather than transformation [120]. The reasons for the conflicting nature of the results from these different studies are not known, but one can speculate that differing methods employed for isolating and culturing MSC, differing levels of contaminating non-MSC cells in the cultures, as well as the duration of the culture (i.e., the number of times the cells were passaged) were likely contributing factors. With this possible instability in mind, at this point it seems prudent, regardless of the tissue source of the MSC, to make clinical use only of cells that have been passaged fewer than 25 times in culture [121].

THERAPEUTIC APPLICATIONS OF PERIPHERAL BLOOD STEM CELLS

The physiological role of MSC in tissue regeneration prompted researchers to evaluate their use in therapeutic applications. Ethical discussions regarding embryonic stem cells underscore the need to explore the clinical applications of adult stem cells, including MSC. MSC were first tested in several animal models and have been used in multiple clinical studies. Although the results are promising, the mechanisms behind the regenerative potential of MSC are not fully understood. Their therapeutic applications can be divided into three groups: tissue engineering, cell delivery applications, and as a vehicle for gene therapy [1,46,94].

Endothelial Progenitor Cells

Angiogenesis and Vasculogenesis

Blood vessels are constructed by two processes: angiogenesis, or the sprouting of capillaries from preexisting blood vessels and vasculogenesis; and the in situ assembly of capillaries from undifferentiated EC. Formation of the first capillaries takes place mostly during the early stages of embryogenesis [72]. Early vascular plexus in the yolk sac originates from the mesoderm by differentiation of angioblasts, which subsequently generate primitive blood vessels. Angiogenesis is a morphogenic process of new blood capillaries emerging from preexisting vessels. Angiogenesis has a major role in wound healing and collateral formation and in the female reproductive system. In wound healing and tissue repair, neovascularization is required to transport cells and nutrient into the wound. The new blood capillaries emerge from neighboring vessels during tissue remodeling. In the female reproduction cycle, neovascularization occurs physiologically in the uterus and ovary every 28 days. Placental tissues represent a major site for active angiogenesis [122]. Myocardial collateral vessels that sprout from preexisting capillaries are important to protect the heart from ischemic damage. In myocardial infarction, new vessels penetrate the necrotic area and the surrounding ischemic heart tissues [123]. Many serious diseases are associated with excess capillary growth. Most notably, angiogenesis is associated with cancer, tumor growth, and metastasis [124]. Intraocular neovascularization is usually associated with diabetic retinopathy and retinopathy of prematurity [125]. The new blood vessels are leaky and easily rupture, which may result in blindness. In chronic inflammatory diseases such as rheumatoid arthritis, new vessels invade the joint surfaces and degrade the cartilage by proteolysis [126]. The vasculogenesis process can be divided into five consecutive steps [127]: (1) EC are generated from precursor cells called angioblasts. (2) EC form the vessel primordia and aggregates that establish cell-to-cell contact but have no lumen. (3) A nascent endothelial tube is formed composed of polarized EC. (4) A primary vascular network is formed from an array of nascent endothelial tubes. (5) Pericytes and vascular SMC are recruited. Circulating EC originating from endothelial EPC in the BM are mobilized into the bloodstream and participate in angiogenic processes [66,89]. Based on the role of EPC in postnatal neovascularization [66], attempts were made to use EPC for therapy as a means to support tissue regeneration.

EPC can be used for therapeutic vascularization in two ways: by mobilizing of EPC into the circulation using growth factors and by first expanding them in vitro followed by systemic delivery or direct injection into the target tissue or organ [128,129]. Although EPC were shown to contribute to tissue revascularization, their function in a clinical setting remains controversial [130]. On the other hand, there have been significant advances in the use of EPC for tissue engineering. Several examples are provided subsequently of the use of EPCs for tissue regeneration and vascularization and as the endothelial source for bioengineered tissues and organs.

Tissue Regeneration

In many cases, organ and tissue regeneration require reestablishment of the vascular network. During healthy and pathologic neovascularization, reendothelialization can occur through mature EC that migrate from preexisting vessels via angiogenesis [131] and circulating EPC from PB that integrate with newly formed vasculature via vasculogenesis [47,128,132]. EPC can be obtained from the patient and expanded in culture to avoid immune rejection; they offer a robust cell source for tissue regenerations.

Several studies suggested that EPC participate in the vascular healing process, in part by recruiting EPC to the regenerated site [40,133]. Genetically labeled EPC were detected in ischemic limbs of mice and were shown to accelerate the revascularization process. In humans, EPC contributed to wound healing of patients implanted with a left ventricular assisted device [41]. The EPC adhered to the device and formed a nonthrombogenic surface. These studies suggested that EPC may be recruited to assist endothelialization and served as the basis for preclinical and clinical studies, as described subsequently. Administration of cytokines including G-CSF, GM-CSF, and

angiogenic growth factors appear to enhance the mobilization of EPC and revascularization. These factors are usually released into the circulation as a result of injuries [128]. Based on these observations, PB progenitors such as EPC were used for cell therapy to combat tissue ischemia and support tissue regeneration. Main clinical targets for the cell therapy studies were CVD, injuries in the brain, and retinal ischemia [129]. Animal studies showed improved vascularization and tissue function.

Systemic delivery of VEGF protein, one of the most potent angiogenic growth factors in vivo, and VEGF gene therapy resulted in a significant increase in EPC numbers in the circulation and their contribution to neovascularization [40]. Elevated Epo levels in the circulation were shown to increase the numbers of VEGFR-2−positive EPC [54]. In parallel, data from Epo-derived cell mobilization in humans demonstrated an increase in $CD34^{+}/CD45^{-}$ cells, probably circulating EC [134]. Gene delivery of the hematopoietic growth factor CXCL12 (SDF) also led to an increase in VEGFR-2−positive EPC [135]. Interestingly, AMD3100, the SDF receptor binding inhibitor, caused EPC mobilization to the peripheral circulation.

Melero-martin et al. [62] reported that when cord blood EPC and MSC were injected subcutaneously into nude mice, they formed vascular structures that were stable for 4 weeks. The vascular network had endothelialized lumen and pericytes expressing smooth muscle actin. Au et al. [136] engineered blood vessels from HUVEC and human MSC that remained stable and functional for more than 130 days in vivo. These findings could guide future practices in tissue engineering and regenerative medicine, allowing physicians to form stable and long-lasting vasculature for engineered tissue.

CVD are an attractive target for EPC-mediated tissue neovascularization as a means of improving regeneration and function. Accordingly, several promising animal studies led to clinical trials involving patients who had experienced acute myocardial infarction (AMI) and cardiac ischemia. BM-derived MSC were shown to contribute to myocardial regeneration and revascularization. In nude rats that underwent myocardial infarction, cytokine-mobilized EPC homed to the infarcted tissue and contributed to neoangiogenesis [137]. In similar studies, BM-derived MSC were injected into the infarcted border and were shown to differentiate into myocardial cells and EC [137,138]. In most studies, direct introduction of these cells into an active angiogenic site, such as infarcted or ischemic myocardium, was essential for the successful incorporation of the cells and improvement in cardiac function.

AMI or chronic ischemic heart disease results in the loss of cardiomyocytes and vasculature. Several animal studies showed that the introduction of autologous BM MSC contributes to neoangiogenesis in the ischemic myocardium [46]. In patients, whole autologous BM MNC were delivered into the coronary arteries feeding the infarcted and ischemic tissue [46]. In all of these studies, there was improved cardiac perfusion and left ventricular function, which suggested that delivery of autologous progenitor cells is feasible and safe and may have a short-term therapeutic benefit. However, follow-up studies in animals and humans detected only a few BM-derived cells in the regenerated vascular network, which suggested that only a small portion of the cells may contribute to revascularization.

Delivery of autologous MNC or G-CSF−mobilized MNC showed some improvement in left ventricle ejection fraction, especially when larger numbers of cells were infused directly into the heart [139−141]. However, no long-term information is available on the clinical outcomes of the patients. Other studies of clinical intervention with cell therapy for AMI showed some clinical benefits [142]. Yet, some adverse events such as restenosis and an increased risk for atherosclerosis were also reported after cell therapy with PB-derived cells [128]. Altogether, despite early promising results from animal studies and short-term data from clinical studies of cell therapy for CVD, there is a lack of long-term outcome assessment of clinical trials that would define the patient population most likely to benefit from the treatment of cell therapy. It remains unclear whether any long-term toxicity exists with this therapy. Such toxicity may result if myeloid cells are incorporated into regenerating myocardium and generate noncardiac or fibrotic tissues.

Given the morbidity associated with limb ischemia, EPC may be used for vascular therapy as an alternative to bypass approaches. In preclinical studies, the introduction of BM-derived EPC significantly improved collateral vessel formation and minimized limb ischemia [143]. In patients with peripheral arterial disease, injection of autologous whole BM MNC into ischemic gastrocnemius muscle resulted in the restoration of limb function [144]. The improvement in muscle perfusion suggested that it was caused by the presence of EPC in the cell preparation. However, it remains to be determined whether the improvement resulted in part from the introduction of myelomonocytic cells.

Diabetes is often associated with CVDs, which can be treated with systemic and directed injections of PB-borne EPC, as described earlier. In addition, EPC can directly support the regeneration of pancreatic tissue. Intraportal transplantation of pancreatic islets covered with EPC improved the survival of grafted islets and their function in

immune-deficient mice [129]. It appears that the islet-associated EPC remained at the implantation site and supported β-cell proliferation and insulin secretion. Subcutaneous implantation of EPC combined with porcine pancreatic islets in collagen/fibronectin gels resulted in a functional vascular network after 2 weeks [145], which suggests that EPC can be combined with other cell therapy applications to support reestablishment of the vasculature at the site of cell injection.

Pulmonary diseases are progressive lung disorders often manifested by smaller arteries associated with intimal hyperplasia and fibrosis, increased deposition of ECM, and prolonged inflammation, which may lead to respiratory complications [146]. Cellular therapies for pulmonary-associated diseases employed progenitor cells of different types that aimed to reduce the symptoms and potentially enhance regeneration of the diseased lung tissue. EPC were used for cell therapy in rats treated with monocrotaline (MCT) to create pulmonary arterial hypertension (PAH) [147]. When delivered 3 days after MCT treatment, they effectively prevented PAH. However, once a state of PAH was established after 3 weeks, the cells had only marginal effectiveness, but they prevented further worsening of symptoms. On the other hand, delivery of EPC recombinantly expressing eNOS significantly reduced right ventricle systemic pressures [147]. Based on these promising results, a phase I clinical trial was initiated to test the tolerability of eNOS-expressing autologous EPC in patients with severe PAH [147].

Tissue Engineering

Vascular diseases are the leading causes of morbidity and mortality in the United States each year [148]. Over 500,000 coronary bypass grafts and 50,000 peripheral bypass grafts are performed annually in the United States (www.americanheart.org) [149]. However, up to 30% of patients who require arterial bypass surgery lack suitable or sufficient amounts of suitable autologous conduits such as small-caliber arteries or saphenous veins [150]. Synthetic grafts such as polytetrafluoroethylene or Dacron (polyethylene terephthalate fiber) have been used successfully to bypass large-caliber, high-flow blood vessels. However, these grafts invariably fail when used to bypass small-caliber, low-flow blood vessels owing to increased thrombogenicity and accelerated intimal thickening leading to early graft stenosis and occlusion [151]. It has been shown that a confluent EC monolayer on small-caliber prosthetic grafts may provide immediate protection from thrombus formation after implantation [152]. However, the use of allogeneic EC is limited by rejection, whereas the use of autologous human EC to construct vascular grafts has not been widely explored. The idea of using EPC to seed the lumen of engineered blood vessels came from the observation that MSC contributed to the lining of vascular grafts in vivo [129,153,154]. We have shown that EPC might be an ideal source of autologous EC for seeding small-diameter grafts, which eliminates the need to remove native vessel from which to culture EC. By seeding EPC-derived EC onto a scaffold, a nonthrombogenic barrier between blood and the vessel wall is created, thereby promoting patency in vivo. EPC-seeded collagen matrices derived from decellularized porcine arteries were used for carotid artery reconstruction in sheep [155]. These bioengineered arteries remained patent more than 4 months, whereas control grafts without autologous EC occluded within 15 days. Thus, functional vessels can be engineered using decellularized arteries and EPC. Moreover, we have shown that after a brief period of healing in vivo, these bioengineered blood vessels develop a fully cellularized wall of three distinct layers analogous to normal adventitia, media, and intima. A similar approach was used to coat vascular stents with EPC to minimize neointimal cell growth and reduce the incidence of restenosis [156]. Yoder and colleagues used mobilized progenitor cells to coat left ventricular assist devices [157]. Although these are exciting results, bioengineered grafts and vascular stents will need to be preconditioned to blood flow before implantation. Neram et al. [158] showed that local blood flow properties induce changes in endothelial cell morphology and orientation. Further studies showed that the levels of shear stress and duration of exposure induced changes in EC morphology, proliferation, and differentiation.

EPC were used in several studies to coat the surface of bioengineered heart valves. Two endothelial cell types were used: valve-derived mature EC and EPC from PB [159]. The study showed that when seeded on polyglycolide/poly-4-hydroxybutyrate (PGA/P4HB) scaffolds, both sources of EC proliferate in response to VEGF. The EPC could be induced to transdifferentiate to a mesenchymal phenotype on PGA/P4HB in response to transforming growth factor-β1. These results indicate that EPC can respond to soluble signals that induce events that occur during valvulogenesis. Another approach to coating the valve surface with an endothelium layer was described by Jordan and Williams and colleagues [160,161]. Those authors used decellularized porcine pulmonary valves that were conjugated with CD133 antibodies on the leaflet surface. The valves were transplanted into the pulmonary position of sheep and harvested for analysis at different times up to 3 months. $CD133^+/CD31^-$ EPC adhered to the surface of anti-CD133–conjugated valves by 3 days and transitioned to $CD133^-/CD31^+$ mature EC by 30 days. ECs expressing von Willebrand factor lined the entire length of both ventricular and arterial surfaces of conjugated valves by 1 month after implantation. Interstitial cells expressing both α-smooth muscle actin and vimentin were observed

as early as 14 days postimplantation and their content increased from 1 to 3 months in valves conjugated with anti-CD133, with new collagen formation. In contrast, only a few EC or interstitial cells were associated with unconjugated valves at these times.

A new scaffolding technology for tissue and organ regeneration was introduced to the field. The technique is based on the decellularization of intact human and animal organs by infusing the organ's vasculature with mild detergents that completely remove the cellular components while not degrading the ECM [162]. We successfully made such acellular whole-organ scaffolds for liver, kidney, pancreas, and intestine. The decellularization process preserved an intact network of vascular channels that can be used to seed cells into the scaffold and later to infuse culture media to deliver oxygen and nutrients to cells [163] to ensure the successful implantation of these scaffolds into a recipient that must resist thrombosis caused by exposed ECM in contact with blood. We seeded both acellular porcine kidneys livers with EC and showed vascular patency upon implantation in vivo. These studies used an EC line that cannot be used for clinical applications. Instead, collection of mobilized EPC from PB and propagation of the cells in culture represent a logical path for the revascularization of bioengineered organs for clinical use in humans. To improve the reestablishment of functional vascular network further, EPC can be combined with other cell types such as mural cells. Combining EPC with pericyte progenitors such as MSC or with SMC or muscle progenitors significantly improves the stability and preserves functional blood vessels and subsequently tissue and organ function [129]. EPC were also used to support the bioengineering of bone. EPC combined with MSC in collagen/fibronectin gel were seeded into decalcified cancellous bone for calvarial defect repair [164]. Only in the presence of EPC did host blood vessels penetrate into the implant and induce bone formation.

Wound healing is a major problem that affects all aspect medical treatments. Studies over the past 5 decades clearly showed that wound healing greatly depends on the successful neovascularization of the injured tissue [165]. Tissue engineering technologies combining biomaterials and cells can provide both important coverage of the wound and improve wound healing. For example, silk-based scaffolds can be populated with EPC and used as a skin construct [166]. By adding other cell types to the scaffold, such as pericyte progenitors and keratinocytes, the construct can be used for skin transplantation. In other applications, EPC were combined with dermal fibroblasts to bioengineer skin substitutes [167,168]. The resulting skin constructs were well-perfused and showed adequate epithelialization and normal matrix deposition.

EPC represent an ideal cell source for tissue engineering because they are easily obtained from the patient and expanded in culture and are functional in the bioengineered tissue. However, in several cases, heterogeneous cell populations are being expanded for seeding onto scaffolds, which may lead to compromised function as a result of differential proliferation of cells with fibroblastic properties. To overcome this, one may use specific methods to obtain a pure EPC population before seeding, such as immune isolation. An additional problem is the occasional need for immediate availability. For instance, when an emergency bypass needs to be performed, the growth of a bioengineered blood vessel ready for implantation would take too much time if autologous cells are to be implemented. Alternatively, these bioengineered grafts could be seeded with autologous MSC cells that are differentiated into EC using a shorter protocol.

Mesenchymal Stem Cells

The ability of MSC to differentiate in vitro and in vivo into the various mesenchymal cell types found within the BM (i.e., bone, cartilage, and fat) has been described by numerous laboratories, and the conditions for bringing each of these differentiative pathways about have been delineated in detail [169]. Microarray studies [170] have shed light on the molecular mechanisms responsible for commitment to and progression along each of these lineages, providing information needed to enhance the efficiency with which MSC differentiate to each of these lineages, revealing some of the pathways that maintain MSC in an undifferentiated state, and enabling more robust in vitro expansion of this valuable stem cell population. Promising results from preclinical studies examining the use of MSC for bone and cartilage repair [171] quickly led to clinical trials using MSC to treat large bone defects [172], articular cartilage defects [173], and osteogenesis imperfecta [174]; these trials have highlighted the therapeutic potential of MSC.

Although these early studies quickly established MSC as a promising therapy for treating a wide range of skeletal injuries and diseases, further investigation over the past several years has provided compelling evidence that the differentiative capacity of MSC far exceeds that originally reported by Friedenstein. For example, MSC also have the ability to generate functional skeletal muscle cells in vitro and in vivo [175,176], which raises the possibility that MSC may eventually be used to treat muscular dystrophies. Even more surprising were subsequent studies showing that MSC had the ability to develop not only into cells of mesenchymal derivation, but into cells of all three

germinal layers. The first dogma-breaking study demonstrating that MSC had the ability to cross developmental boundaries and reprogram into cells of another germ layer demonstrated that MSC could become both neural and glial (ectoderm) cell types in vitro and in vivo [177–179]. These findings raised the exciting possibility that MSC could serve as a readily available source of cells to treat injuries or degenerative conditions within the central nervous system (CNS), clinical situations for which there are limited options, if any. Indeed, numerous in vivo transplantation studies have confirmed these exciting in vitro results by showing that MSC have the ability to mediate repair after spinal cord injury, ischemic injury and stroke, demyelinating conditions, and experimentally induced Parkinson disease, and potentially treat a host of other injuries and degenerative diseases of the CNS [180]. Although questions have been raised as to the mechanism by which this apparent "transdifferentiation" occurs [181], the demonstration by numerous groups that MSC can indeed develop into neural cells in various stages of differentiation and mediate functional improvement for a variety of injuries and diseases within the CNS provides the impetus for further studies attempting to increase the efficiency and predictability of this process and harness this potential for therapy.

After these groundbreaking findings, studies were published showing that MSC could develop in vitro into cells that appear phenotypically and morphologically like cardiomyocytes, and behave like them [182,183] and to endothelium [184,185], and to engraft within the injured myocardium [55,186–189] and form Purkinje fibers in vivo [190,191]. These preclinical studies generated tremendous excitement in the field of regenerative medicine, because they strongly suggested that MSC could be used as therapy to mediate cardiac repair postinfarction or diseases within the conduction pathways of the heart, or even, perhaps, to treat chronic progressive cardiac diseases such as congestive heart failure [192]. Coupled with preclinical animal studies showing functional cardiac improvement after infusion of MSC, or even MSC-conditioned media [193–195], these exciting results were the driving force for launching several clinical trials to investigate whether MSC are able to mediate repair in the postinfarct heart [196–198].

As a last major example of MSC in regenerative medicine, we will address their use in liver repair. Liver failure is a life-threatening condition for which the only curative treatment is whole or partial organ transplantation. Given the crippling shortage of donor livers available for transplantation and the high mortality and morbidity associated with the need for lifelong immunosuppression after liver transplantation, a major focus of regenerative medicine has been to identify cells that could be used to repopulate and/or repair the damaged failing liver. We and others have devoted a great deal of energy to demonstrating the ability of MSC from various sources to serve as therapeutics for liver disease [199,200]. It is clear that MSC isolated from a variety of mouse, rat, and human tissues have the ability to generate in vitro and in vivo cells that are indistinguishable from native hepatocytes, in that they exhibit the same morphology and antigenic profile as native hepatocytes, and they appear to be functional, based on the uptake of low-density lipoprotein, urea production, and glycogen storage. Whether these cells exhibit polarity like native hepatocytes has yet to be unequivocally demonstrated, however. Moreover, transplantation of MSC in a range of model systems has repeatedly been shown to result in the fairly robust formation of hepatocytes that repair a variety of inborn genetic defects, as well as mechanical and drug or toxin-induced injuries, including partial hepatectomy, treatment with the toxin C-C motif chemokine ligand 4, injury induced by allyl-alcohol, a high-lipid diet, treatment with 2-acetylaminofluorene, and even pathogenic infection [200]. This wealth of supportive data in several different species has led to the use of MSC for liver disease in multiple clinical trials [200]. Collectively, these clinical studies have provided hope that MSC may prove to be a valuable resource for cell-based therapies for liver disease. However, the results of these studies must be interpreted with trepidation because of the limited number of patients enrolled in each trial, the lack of appropriate controls in many cases, and the occurrence of adverse events. Furthermore, because the cells in these trials were derived autologously, there was no way for the investigators to assess the actual engraftment, persistence, or differentiative potential of the transplanted cells, which leaves the mechanism responsible for the observed clinical improvements open to speculation.

A key aspect to assessing the utility of MSC therapy for regenerative medicine is the mechanism by which the transplanted cells repair, replace, or repopulate the recipient tissue(s). Indeed, there has been much controversy regarding the mechanism by which MSC reprogram and differentiate into other cell lineages, such as hepatocytes. Whereas the previously summarized in vitro studies unequivocally showed that under the appropriate conditions, MSC can reprogram to generate what appear to be functional hepatocytes, it appears that in vivo, cell fusion could be one mechanism by which MSC appear to develop into hepatocytes, rather than true reprogramming or transdifferentiation [79,201,202]. To begin delineating the mechanism(s) of hepatocyte formation after transplantation of human MSC, we performed studies in the fetal sheep model [100], which we believed would be ideal for this analysis, given the robust generation of human-derived hepatocytes. By using carboxyfluorescein succinimidyl

ester- or DiIC18(3)-labeled human MSC and performing fluorescence in situ hybridization on liver sections from sheep transplanted in utero with these labeled human MSC, we were able to demonstrate conclusively that transplanted human MSC were able to generate significant numbers of functional hepatocytes in the absence of cellular fusion or membrane vesicle or organelle transfer [99,100] independent of fusion, and by true reprogramming or transdifferentiation [100]; this suggests that these cells indeed possess a degree of true plasticity. The lack of fusion as a requirement for liver repopulation was in stark contrast to other studies in which the transplanted stem cells' differentiative capacity was restricted to cells of the liver through drug- or genetically induced lesions or deficiencies [79,201,202], and suggests that the mechanism by which the transplanted MSC contribute to the recipient liver (and likely other tissues) depends on the model system employed.

The interpretation of data generated from these myriad studies looking at the potential of MSC to mediate repair in a variety of organ systems is further complicated by the observation that a therapeutic benefit is often observed in the absence of evidence of long-term engraftment of the transplanted MSC within the damaged or diseased organ. These findings led to much debate regarding whether MSC can actually generate tissue-specific cells after transplantation, and sparked additional studies showing that MSC can mediate tissue repair by acting as "trophic factories," releasing specific cytokines, growth factors, and matrix MMP that modulate the activity of tissue-specific cells, dampen ongoing inflammation and/or aberrant immune reaction present within the damaged or diseased tissue, and inhibit fibrosis and apoptosis, thus facilitating endogenous tissue regeneration [1,93,94,200]. However, under different conditions, other studies showed that transplanted MSC may actually contribute to the myofibroblast pool, enhancing the fibrotic process [203–205]. This has led to the current belief within the field that the effect of MSC will probably vary with the nature of the injury or disease that is being treated, the specific experimental model with which the therapy is being tested, and perhaps even the time frame of MSC application, such that MSC could be beneficial if administered at certain stages of disease progression and harmful if administered at others. Thus, it appears that the therapeutic potential of MSC may have to be investigated for each specific disease or injury to be treated, to delineate the optimal time frame and population to be administered to achieve the desired effect and ensure benefit is provided rather than harm.

The Use of Mesenchymal Stem/Marrow Stroma Cells for Gene Therapy

Although MSC possess tremendous therapeutic potential by virtue of their ability to lodge or engraft within multiple tissues in the body and both develop into tissue-specific cells and release trophic factors that trigger the tissue's own endogenous repair pathways, gene therapists have realized that these properties are just the beginning of the therapeutic applications for MSC [1,94]. By using gene therapy to engineer MSC to either augment their own natural production of specific desired proteins or enable MSC to express proteins outside their native repertoire, it is possible to broaden the spectrum of diseases greatly for which MSC could provide therapeutic benefit. Unlike HSC, which are notoriously difficult to modify with most viral vectors while preserving their in vivo potential, MSC can be readily transduced with all of the major clinically prevalent viral vector systems (adenovirus [206], the murine retroviruses [207], lentiviruses [208], and adeno-associated virus [209]), and efficiently produce a wide range of cytoplasmic, membrane-bound, and secreted protein products. This ease of transduction, coupled with the ability subsequently to select and expand only the gene-modified cells in vitro to generate adequate numbers for transplantation, combine to make MSC one of the most promising stem cell populations for use in gene therapy studies and trials.

Most studies using gene-modified MSC have been undertaken with the purpose of enhancing the natural abilities of MSC to mediate repair within various tissues. Using the heart as an example, once investigators discovered the identity of some of the most important trophic factors responsible for the beneficial effect of MSC on the injured myocardium, they undertook studies using MSC engineered to overexpress a number of factors [210,211]. As anticipated, the "gene-enhanced" MSC were substantially more effective than their unmodified counterparts and produced greatly enhanced therapeutic effects. Similar studies were performed to repair the damaged or diseased CNS using MSC engineered to produce neurotrophic factors [180], repair the injured liver using MSC-expressing proteins involved in hepatocyte differentiation and/or proliferation [212,213], repair ischemia-reperfusion injury [214], and repair the kidney [215]. In each case, MSC engineered to express higher levels of proteins known to be beneficial for the tissue in question and/or to promote survival have produced markedly better results than unmodified MSC.

Despite the many advantages of using MSC as gene delivery vehicles, however, relatively few studies have explored this potential to treat genetic diseases. One disease for which we and others are actively investigating MSC to deliver a therapeutic gene is hemophilia A (HA) [216–218]. We will use HA in the following discussion

as a paradigmatic disease to illustrate how gene-modified MSC could be used to correct essentially any genetic disorder that involves the absence of a specific protein.

HA is the most common inheritable deficiency of the coagulation proteins [219]. The severity of HA is traditionally based on plasma levels of factor VIII (FVIII) [220], and up to 70% of patients with HA present with the severe form of the disease (<1% of normal FVIII levels) and have frequent hemorrhaging leading to chronic debilitating arthropathies, hematomas of subcutaneous connective tissue or muscle, and internal bleeding. Over time, the collective complications of recurrent hemorrhaging result in chronic pain, absences from school and work, and permanent disability [220]. Current state-of-the-art treatment consists of frequent prophylactic infusions of plasma-derived or recombinant FVIII protein to maintain hemostasis. Although this treatment has greatly increased life expectancy and quality of life for many patients with HA, it is far from ideal because of the need for lifelong intravenous infusions and the high treatment cost, which often approaches $500,000/year. Moreover, this treatment is unavailable to a large percentage of the world's hemophiliac patients, which places them at great risk for severe, permanent disabilities and life-threatening bleeds. There is thus a significant need to develop novel, longer-lasting HA therapies.

In contrast to current protein-based therapeutics, lifelong improvement or permanent cure of HA is theoretically possible after only a single gene therapy treatment; indeed, several aspects of HA make it ideally suited for correction by gene therapy. First, in contrast to many other genetic diseases, the missing protein (FVIII) does not need to be expressed in either a cell- or tissue-specific fashion to mediate correction. Although the liver is thought to be the natural site of FVIII synthesis within the body, as long as FVIII is expressed in cells that have access to the circulation, it can be secreted into the bloodstream and exert its appropriate clotting activity. Second, levels of FVIII-expressing cells even as low as 3%−5% would be expected to convert severe HA to a moderate or mild phenotype, reducing or eliminating episodes of spontaneous bleeding and greatly improving quality of life [221]. Based on this knowledge, the American Society of Gene and Cell Therapy (www.ASGCT.org) provided National Institutes of Health Director Dr. Francis Collins with a road map of disease indications that it believed would be viable gene therapy products. The patients with hemophilia were identified as being in the most promising "Target 10" group of diseases.

As mentioned in the preceding section, the liver is thought to be the primary site of FVIII synthesis within the body. As discussed in previously we and others have devoted much energy to demonstrating the ability of MSC from various sources to serve as therapeutics for liver disease. In ongoing studies, we found that after transplantation into fetal sheep, human MSC engraft up to 12% within the recipient liver [99,100] and contribute to both the parenchyma and the perivascular zones of the engrafted organs, which makes them ideal for delivering FVIII into the circulation. Because FVIII levels of 3%−5% of normal would convert a patient with severe HA to a moderate or mild phenotype, these levels of engraftment should be highly therapeutic. Thus, these collective results suggest that MSC may represent an ideal cell type for treating HA.

However, although MSC engrafted (after transplantation in utero) at significant levels within organs that are natural sites of FVIII synthesis, only a small percentage expressed endogenous FVIII, which suggests that simply transplanting "healthy" MSC will not likely provide an effective means of treating or curing HA. By using gene therapy to engineer MSC to express FVIII, however, it is highly probable that the levels of engrafted MSC we have achieved thus far in utero would provide a marked therapeutic benefit in HA. By transducing the MSC in vitro, rather than performing gene therapy by injecting the vector directly, as is the current practice in clinical gene therapy trials for hemophilia B [222], there is no risk of off-target transduction, and the vector being employed simply needs a strong constitutively active promoter to ensure that all cells derived from the transplanted MSC continue to express FVIII and mediate a therapeutic effect. The only documented cases of viral vector-induced insertional mutagenesis were observed after genetic modification of HSC [223]; there is no evidence that MSC transform or progress to clonal dominance after transduction, which suggests that they represent safe cellular vehicles for delivering FVIII (or other transgenes).

Critical proof-of-principle studies have shown that MSC can be transduced with FVIII-expressing viral vectors and secrete high levels of FVIII protein in vitro and after transplantation in vivo [216−218]. FVIII purified from the conditioned medium of the transduced MSC was proven to have a specific activity, relative electrophoretic mobility, and proteolytic activation pattern that was virtually identical to that of FVIII produced by other commercial cell lines [217]. Given the widespread distribution and engraftment of MSC after their systemic infusion, the ability of MSC to develop in vivo into cells of numerous tissue types, and their ability to process and secrete high amounts of biologically active FVIII efficiently, unsurprisingly, they are being viewed as ideal vehicles for delivering an FVIII transgene throughout the body and thus providing long-term or permanent correction of HA [216−218].

In addition to their widespread engraftment and ability to serve as delivery vehicles for the FVIII gene, the unique immunological properties of MSC may further increase their utility for treating HA. MSC do not normally express major histocompatibility complex (MHC) class II or the costimulatory molecules CD80 and CD82, and thus viewed

are as being relatively hypoimmunogenic. As such, they do not provoke the proliferation of allogeneic lymphocytes or serve as effective targets for lysis by cytotoxic T cells or natural killer cells. In fact, a large body of evidence has accumulated suggesting that MSC can be transplanted across allogeneic barriers without eliciting an immune response. Thus, one could theoretically use off-the-shelf MSC from an unrelated donor to treat HA, which greatly increases the feasibility of obtaining and using these cells for therapy.

Perhaps even more important from the standpoint of their potential use as HA therapeutics, studies have demonstrated that MSC also have the ability to intervene at multiple levels with the generation and propagation of an immune response, and thus exert potent immunosuppressive and antiinflammatory properties both in vitro and in vivo [224,225]. In addition to interacting directly with cells of the immune system, MSC express a battery of factors that reduce local inflammation, blunt immune response, and counteract the chemotactic signals responsible for recruiting immune cells to sites of injury or inflammation. One could thus envision these immune-dampening properties enabling the delivery of FVIII without eliciting an immune response and subsequent inhibitor formation, thus overcoming the most serious clinical problem that plagues current treatment and management of HA [226].

In addition to these properties, preclinical animal studies examining the potential of MSC isolated from adult tissues have highlighted another interesting and clinically valuable characteristic of MSC: their ability to navigate to sites of injury and/or inflammation selectively within the body, as discussed in detail in the preceding section on MSC in regenerative medicine. Although the mechanisms responsible for this trafficking to sites of injury are still being elucidated, this observation raises the exciting possibility that after systemic infusion, FVIII-expressing MSC could migrate efficiently to sites of active bleeding or injury, releasing FVIII locally and focusing the therapy where it is needed most.

We have begun to explore whether it is possible to exploit these many advantages of MSC as a cellular vehicle to deliver an FVIII gene by testing the ability of FVIII-expressing MSC to correct HA in a unique line of sheep we reestablished and fully characterized, with respect to both the clinical parameters and the precise molecular basis for their disease [227]. Similar to mutations seen in many human patients, these animals possess a premature stop codon with a frameshift mutation. This is the only animal model of HA with this clinically relevant mutation type, which provides a unique opportunity to study therapies in this context. As with human patients with severe HA, a hallmark symptom in these sheep is repeated spontaneous joint bleeds that lead to chronic, debilitating arthropathies and reduced mobility.

To test the ability of MSC to serve as FVIII delivery vehicles and thus treat HA experimentally, we tested a novel, nonablative transplant-based gene therapy in two HA lambs [218]. During the first 3–5 months of life, both of these animals had received frequent, on-demand infusions of human FVIII for multiple hematomas and chronic, progressive, debilitating hemarthroses of the leg joints that had resulted in severe defects in posture and gait, rendering them nearly immobile. In an ideal situation, one would use autologous cells to deliver an FVIII transgene and thus avoid complications caused by MHC mismatching. Unfortunately, the severe life-threatening phenotype of the HA sheep prevented us from collecting BM aspirates to isolate autologous cells. We therefore elected to use paternal (haploidentical) MSC in the hope that immunologic incompatibility between the donor and recipient would be sufficiently minimized to allow engraftment.

Based on our prior work in the fetal sheep model, we knew that the intraperitoneal (IP) transplantation of MSC results in widespread engraftment throughout all of the major organs and durable expression of vector-encoded genes [99,100,228]. We further reasoned that using the IP route would have the advantage of enabling cells to enter the circulation in an almost time-released fashion after being engulfed by the omentum and absorbed through the peritoneal lymphatics. We also thought that the use of the IP route would enable us to avoid lung trapping, which hinders the efficient trafficking of MSC to desired target organs after intravenous administration and poses clinical risks owing to emboli formation [229,230].

After isolation, MSC were simultaneously transduced with 2 HIV-based lentivectors, the first of which encoded an expression/secretion optimized porcine FVIII transgene [218] that had previously been shown in human cells to be expressed or secreted at 10–100 times higher levels than human FVIII [231]. We thus believed that these high levels of expression and secretion might enable us to achieve a therapeutic benefit, even if we obtained low levels of engraftment of the transduced paternal MSC. The second lentivector encoded enhanced green fluorescent protein to facilitate the tracking and identification of donor cells in vivo. The first animal was then transplanted IP with the transduced MSC under ultrasound guidance in the absence of preconditioning.

After transplantation, this animal's clinical picture improved dramatically. All spontaneous bleeding events ceased and it had an event-free clinical course devoid of spontaneous bleeds, which enabling us to cease human FVIII infusions. Existing hemarthroses resolved, the animal's joints recovered fully and resumed normal

appearance, and it regained normal posture and gait and a normal activity level. To our knowledge, this represents the first report of phenotypic correction of severe HA in a large animal model after transplantation of cells engineered to produce FVIII, and the first time that reversal of chronic debilitating hemarthroses was achieved. However, despite this remarkable clinical improvement, FVIII activity (as assessed by chromogenic assay) was undetectable in the circulation of this animal after the MSC-based gene therapy treatment.

Based on the remarkable clinical improvement we had achieved in this first animal, we transplanted a second animal, increasing the dose of transduced cells in the hope of achieving detectable FVIII in the circulation. Similar to the first animal, hemarthroses present in the second one at the time of transplant resolved, and it resumed normal activity shortly after transplantation. The second animal also became factor-independent after the transplant. These results thus confirm the ability of this MSC-based approach to provide phenotypic correction in this large animal model of HA. However, as we had observed in the first animal, no FVIII was detectable in the circulation of the animal.

After the animals were killed, we performed a detailed tissue analysis to begin deciphering the mechanism by which this novel MSC-based gene delivery produced its pronounced therapeutic effect at a systemic level. Polymerase chain reaction analysis demonstrated readily detectable levels of MSC engraftment in nearly all tissues analyzed, including liver, lymph nodes, intestine, lung, kidney, omentum, and thymus. These molecular analyses thus proved that it is possible to achieve widespread durable engraftment of MSC after transplantation in a postnatal setting in a large animal model without the need for preconditioning or ablation, and in the absence of a selective advantage for the donor cells.

Confocal immunofluorescence analysis revealed large numbers of FVIII-expressing MSC within the synovium of joints that exhibited hemarthrosis at the time of transplant, demonstrating (as we had hoped and predicted) that the transplanted MSC possessed the intrinsic ability to home to and persist within sites of ongoing injury and inflammation, releasing FVIII locally within the joint. This explained the dramatic improvement we observed in the animal's joints. Confocal analysis also revealed engrafted cells within the small intestine, demonstrating that MSC could still engraft within the intestine after postnatal transplantation, as we observed in prior studies in fetal recipients [232]. Because of the ease with which proteins secreted from cells within the intestine can enter the circulation, future studies aimed at improving the levels of engraftment within the intestine have the potential to improve the systemic release of FVIII greatly.

The marked phenotypic improvement and improvement in quality of life we have observed in our studies in the sheep model thus support the further development of therapeutic strategies for HA and perhaps other coagulation disorders, employing MSC as cellular vehicles to deliver the required transgene. Extrapolating the work thus far in using MSC to deliver FVIII to treat HA, and combining this with the relative ease with which MSC can be isolated, propagated in culture, and modified with a variety of viral-based vectors, and their intrinsic ability to seek out sites of injury and inflammation within the body, one can readily see why MSC are widely viewed as being ideally suited not only as cellular therapeutics, but also as vehicles to deliver gene therapy vectors to numerous tissues in the body; thus, this is promising for finding a permanent cure for a diverse range of diseases.

CONCLUSIONS AND FUTURE DIRECTIONS

The BM is probably the source of PB stem and progenitor cells. Hemangioblasts are the embryonic precursors of HSC, developing into committed hematopoietic progenitors. The BM is also a source for other progenitor and stem cells, the MSC, which can be expanded in vitro and have multilineage differentiation potentials. Numerous studies, described earlier, showed that there is a constant exchange of cells from the BM to PB. These cells have shown proangiogenic properties and can be used for ischemic tissue neovascularization and tissue regeneration. The cells can be either mobilized using hematopoietic and angiogenic growth factors and recruited to the injured or regeneration tissues or they can be isolated, potentially expanded in culture, and delivered back to the same patient with or without a supporting scaffold system [128].

Future success in applying adult PB-derived stem cells for clinical applications will depend on the development of strategies to mobilize, isolate, expand, differentiate, and deliver these cells. For example, EPC may be isolated from PB and used for therapeutic angiogenesis directly or after a period of ex vivo expansion. Understanding the signals involved in recruiting these cells to the regenerating tissues will be crucial to optimizing this technology for clinical use. On the other hand, some concerns must be addressed before EPC can be used for therapeutic applications. First, there is the possibility that when allogeneic cells are implanted, a graft-versus-host immune reaction could occur, caused by a residual T-cell fraction derived from $CD34^+$ cells. Studies showed that

BM-derived $CD34^+$ cells can be differentiated into T cells both in vitro and in vivo [233]. CD34 is one of the most widely used surface makers used for EPC isolation. It is important to use CD34 combined with other surface markers to identify subsets of EPC that will be suitable for clinical use and to reduce the risk of subsequent T-cell differentiation. Second, to develop cells for clinical use, it is necessary to remove all animal substances, such as serum, from the culture environment, because they might be pathogenic or immunogenic. Conventional culture conditions use animal-derived components, especially sera (e.g., fetal bovine serum [FBS]). For clinical cell therapy applications, EPC culture conditions must be free of animal products to meet good manufacturing practice standards. Efforts were made to develop clinical-grade human embryonic stem cell lines and culture conditions [234]. Reinisch et al. [68] published results of clinically approved culture conditions to expand PB-EPC. Using pooled human platelet lysate to replace FBS in the culture environment, they reported the successful recovery of EPC (ECFC) from PB. The ECFC were characterized by robust proliferative potential (more than 30 population doublings), a normal karyotype, and vascular network-forming ability.

These summarized studies provide support for the presence of stem cells in PB and mechanisms by which they can be mobilized from BM to increase their numbers in blood. Although various attempts have been made to use PB-derived stem cells in humans and some encouraging results were obtained, standard clinical use of these techniques must await further validation and long-term toxicity evaluations.

From Adult Pancreatic Islets to Stem Cells: Regenerative Strategies for the Treatment of Diabetes and Its Complications

INTRODUCTION

Pancreatic islet β cells synthesize and release the hormone insulin, which is fundamental for the control of glucose metabolism and glycemia. β cells can be lost; they can also be or become impaired as the result of different mechanisms. The lack or insufficiency of their function of insulin release leads to a group of diseases that share characteristic pathological features: an abnormal metabolism of carbohydrates and elevated levels of glucose in the blood and urine. For this reason, this group of diseases is collectively referred to as "diabetes mellitus," or more frequently, "diabetes." In this chapter, we review cell-based strategies that have been developed for the treatment of diabetes mellitus and its complications.

In a group of patients with diabetes, β cells are progressively lost as the result of an autoimmune process, and beta-cell function is largely lost. This form of diabetes mellitus is termed *type 1 diabetes* (T1D) [1]. To date, there is no definitive cure for this disease. In patients with T1D, life-long exogenous insulin therapy is required as a life-saving intervention. In the long term, most patients fail to achieve satisfactory metabolic control. Moreover, T1D patients remain exposed to the risk for developing both short- and long-term complications, some of which can be fatal [2]. A subset of patients with T1D cannot be managed effectively with exogenous insulin therapy and have dangerous swings in glycemia ("brittle" T1D). In these patients, diabetes can be ameliorated or corrected by transplantation of pancreas or pancreatic islets from cadaveric donors.

In another group of patients, β cells develop functional impairments and produce an insufficient amount of insulin in the context of insulin resistance. This form of diabetes, termed type 2 diabetes (T2D), largely results from diet and lifestyle choices; it is by far the most common form of diabetes: more than 90% of cases of diabetes in the United States are T2D. β cells can also be impaired if genetic conditions compromise their development or function, which can determine monogenic forms of diabetes or increase the susceptibility for other forms of diabetes, mainly T2D. In the most severe cases of T2D and of monogenic diabetes, beta-cell transplantation or regeneration strategies may be beneficial.

FROM ADULT PANCREATIC ISLETS TO STEM CELLS

Transplantation of pancreatic islets may be considered one of the oldest forms of cell transplantation. It is also one of the safest and least invasive transplant procedures. It can restore normoglycemia in patients with T1D [3], it abates to minimal levels the risk for hypoglycemia owing to insulin treatment [4], it leads to a marked improvement in patients' quality of life [5], it relieves symptoms of the disease for up to several years [6], and it slows or prevents

disease progression [7]. Pancreas and pancreatic islet transplantations represent proofs of concept that transplantation of pancreatic islet cells can correct T1D in humans. These forms of transplantation present several limitations primarily connected to the low number of cadaveric organs available and the need for immunosuppression. Different forms of cell-based therapies aimed at beta-cell replacement for T1D are under investigation. β cells can be derived from stem or progenitor cells such as embryonic stem cells (ESCs), induced pluripotent stem cells (iPSCs), and adult stem/progenitor cells. Other regenerative strategies include reprogramming or the delivery of prodifferentiation signals. The design of differentiation methods is largely based on knowledge obtained from studies of embryonic and fetal islet development. Novel findings are emerging related to the existence of stem and progenitor cell niches in the adult human pancreas and to molecules that can stimulate their maturation into functional insulin-producing β cells. The involvement of these adult progenitor cells in normal tissue turnover and in regenerative phenomena in pancreas remains to be elucidated. This chapter will cover these fields. Moreover, we will discuss studies of the effect of mesenchymal stem cell (MSCs) transplantation in diabetes. MSCs can modulate immunity, preserve beta-cell function, and stimulate repair or regeneration of endogenous β cells. MSC had a good safety profile in initial clinical trials in patients with T1D; they are being tested also as a therapeutic option for complications of both T1D and T2D.

STRATEGIES FOR THE GENERATION OF β CELLS FOR REPLACEMENT THERAPY

The limited availability of donor pancreata and islets has prompted the search for alternative sources of β cells. Significant progress in developing strategies to direct cell differentiation has led to opportunities to generate β cells from different types of stem cells and provide high-yield supplies of β cells for replacement therapy. Diabetes mellitus is an attractive target for cell replacement strategies because a single cell type (insulin-producing β cells) is missing or insufficient; moreover, cells can be implanted using minimally invasive procedures and can also perform endocrine functions ectopically [8]. An unlimited supply of human β cells could extend currently used islet replacement therapy to millions of patients. Stem cell−derived β cells would also provide a unique platform for drug discovery and disease modeling for diabetes mellitus.

There are three major strategies for generating β cells in vitro [1]: directed differentiation [2], reprogramming (also referred to as transdifferentiation), and [3] transdetermination [1]. The directed differentiation strategy, which is the subject of intense studies, is based on the differentiation of stem cells into β cells through numerous intermediate stages, frequently in attempts aimed to recapitulate pancreatic development [2]. In the cell reprogramming strategy, terminally differentiated cells are converted into β cells without pluripotent or multipotent intermediate stages [3]. In the transdetermination strategy, adult multipotent stem cells or progenitors are induced to change the path of differentiation from a normal form closely related to β cells into β cells.

β CELLS FROM PLURIPOTENT STEM CELLS (EMBRYONIC STEM CELLS AND INDUCED PLURIPOTENT STEM CELLS)

Pluripotent stem cells (PSCs), including both ESCs and iPSCs, possess the robust potential to self-renew and differentiate into multiple lineages. The abilities of these cells to proliferate (extensively in undifferentiated form and to differentiate into any cell type have led to the idea that large numbers of β cells could be generated in vitro by artificially directing the process. Nevertheless, directing PSC differentiation into glucose-responsive, insulin-secreting, mature β cells has proved to be more difficult than initially expected.

Currently used methods of generating β cells from PSCs in vitro are based on findings from studies of embryonic development. To generate β cells, undifferentiated PSCs are induced to differentiate through series of intermediate stages, including definitive endoderm, primitive gut tube, posterior foregut, pancreatic endoderm, and pancreatic endocrine progenitors. This stepwise differentiation process recapitulating pancreas organogenesis can be directed in vitro by forced expression of defined transcription factors using DNA-based or non−DNA based strategies. The key transcription factors that direct undifferentiated progenitor cells toward fully mature, functional β cells have been identified over years of research in pancreatic development [9−15] (Table 21.1, Fig. 21.1). DNA-based reprogramming strategies use transgenic expression of key transcription factors to induce pancreatic lineage-specific gene expression and guide pancreatic endocrine cell differentiation. Transgenic expression of *pancreatic and duodenal homeobox 1* (*Pdx-1*), *neurogenic differentiation factor 1* (*NeuroD1*), *neurogenin 3* (*Ngn3*), and *musculoaponeurotic*

TABLE 21.1 Key Transcription Factors Involved in Pancreas and β-Cell Development

Pdx1	Pancreas and duodenum homeobox protein 1 (Pdx-1) is crucial for pancreas formation and β-cell differentiation.
Ngn3	Neurogenin 3 (Ngn3) is important for the development of the endocrine pancreas.
NeuroD1	Neurogenic differentiation factor 1 (NeuroD1) is required for pancreatic development and endocrine cell differentiation. It regulates expression of the insulin gene.
Nkx-6.1	Homeobox protein Nkx-6.1 is required for the development of β cells. It controls their expansion.
Nkx-2.2	Homeobox protein Nkx-2.2 is essential for the differentiation of pancreatic endocrine cells and is necessary for the maturation of β cells.
Pax-4	Paired box gene 4 (Pax-4) is involved in pancreatic islet development and in the formation of β and δ cells.
Pax-6	Paired box gene 6 (Pax-6) is necessary for β-cell differentiation and the normal expression of final differentiation markers such as insulin and glucose transporter 2.
MafA	The transcription factor musculoaponeurotic fibrosarcoma oncogene homolog A is important for the maintenance of β-cell function. In the pancreas, it is found predominantly in β cells.

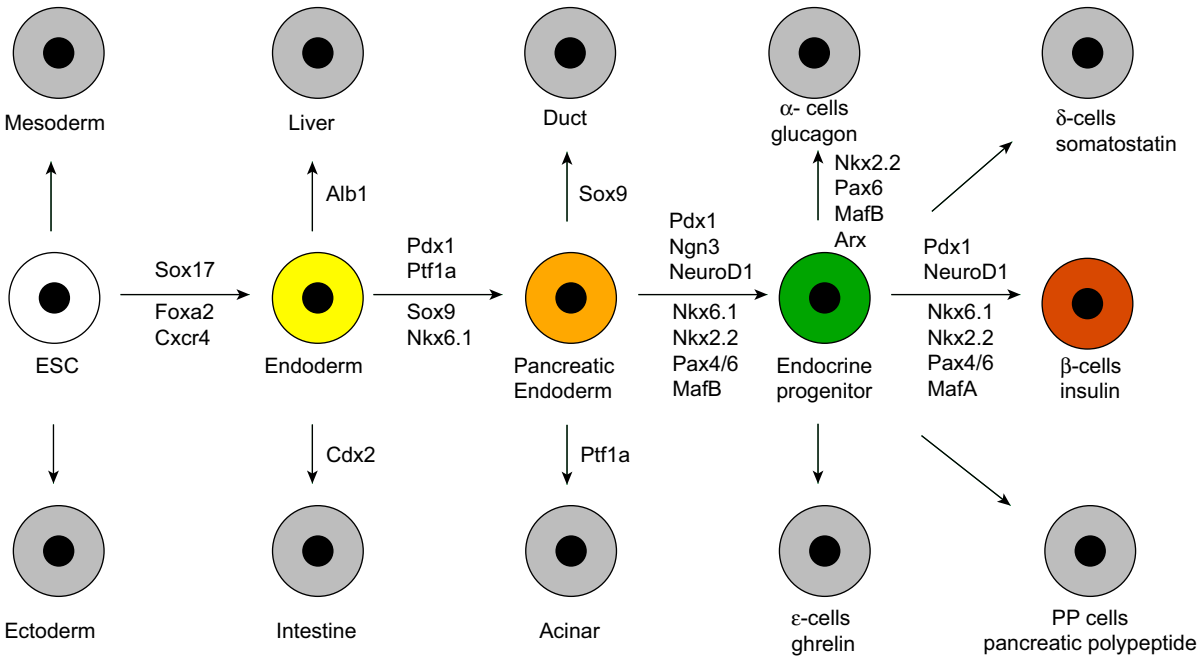

FIGURE 21.1 Pancreas and β-cell development. *ESC*, embryonic stem cell. The main transcription factors involved in fate determination are indicated along the arrows.

fibrosarcoma oncogene homolog A (MafA) has been used to differentiate ESCs into pancreatic endocrine cells, but potential risks for mutagenesis and oncogenesis associated with such genetic manipulation limit the clinical applicability of this method [16,17]. Therefore, non−DNA based strategies are preferred. The main strategies developed so far use signaling molecules (growth factors and small molecules) to activate or inhibit different signal transduction pathways leading to induction of key transcription factors specific for particular stages of pancreas development.

Early attempts to generate beta-like cells from ESCs were based on the spontaneous differentiation of ESCs [18,19] or on the selection and differentiation of cells positive for nestin, an intermediate filament protein expressed by neural progenitors [20−22]. Although pancreas and the central nervous system have different origins and functions, similar mechanisms control their embryonic development. On the basis of these similarities, it was hypothesized that strategies that induce the generation of neural cells from ESCs could be used to generate endocrine pancreatic cells [20]. In 2001, Lumelsky et al. reported for the first time the possibility of generating beta-like cells from mouse ESCs using a protocol based on the production of a highly enriched population of nestin-positive cells from embryoid bodies [20]. Two other groups repeated and improved these results and confirmed that ESCs could be

a source of new β cells [21,22]. However, insufficient characterization of the origin and phenotype of these cells, and later observation that insulin-positive cells did not produce insulin de novo but uptake it from the culture media, suggested that these progenitor cells could not be the reproducible source of bona fide β cells [23,24]. Lessons from these unsuccessful attempts to generate β cells emphasized the importance of understanding pancreas development, and especially the key signaling pathways that regulate stages of differentiation from PSCs to mature β cells in vivo. Therefore, efforts were made to control the differentiation process in vitro better by a stepwise manner that aims to recapitulate normal embryonic development in vivo.

In 2006, D'Amour et al. (Novocell, now ViaCyte) differentiated human ESCs into pancreatic hormone–expressing cells by directing them through definitive endoderm, gut-tube endoderm, pancreatic endoderm, and endocrine precursors stages [25] (Fig. 21.2). Cells derived with this protocol had strong expression of PDX1 and NK6 homeobox 1

(NKX6.1), transcription factors known to be highly expressed in pancreatic progenitors and mature β cells but did not secrete insulin in response to glucose [25]. Further studies indicated that these progenitor cells could be differentiated into glucose-responsive, insulin-secreting cells in vivo 3 months after transplantation and prevent streptozocin-induced hyperglycemia in mice [26]. These results confirmed previous observations that human fetal (6- to 9-week) islet-like cell clusters can mature into glucose-responsive, insulin-secreting cells after implantation and correct hyperglycemia in diabetic mice [27,28]. Different modifications of this multistep protocol based on pancreatic developmental paradigms were developed further to differentiate both human ESCs (hESCs) and hiPSC into pancreatic progenitor cells capable of maturing and functioning in vivo [29–36].

Different agents (growth factors and signaling molecules) were used to activate or inhibit signaling pathways to induce the expression of set of transcription factors specific to particular developmental stages of β cells. The first fundamental step in differentiating PSCs into β cells is specifying the definitive endoderm. Wnt and transforming growth factor-β (TGF-β) signaling pathways have a crucial role in regulating definitive endoderm formation in vivo. Activin A (AA)/Nodal and Wnt3a are among the most commonly used factors to induce definitive endoderm in vitro [25,26,30–32,37]. It was indicated that a combination of growth differentiation factor 8 (a TGF-β family member) and glycogen synthase kinase 3 inhibitor (which activates Wnt signaling) is more efficient for inducing definitive endoderm formation than the combination of AA and Wnt3a [29]. The combination of AA with bone morphogenetic protein (BMP) 4 and fibroblast growth factor (FGF) 2 [34] or AA with an phosphoinositide 3-kinase inhibitor, either LY294002 [38] or wortmannin [39], induces definitive endoderm more efficiently than AA alone. Cells of a definitive endoderm can be identified by analyzing the expression of endodermal markers, including *SRY-related HMG-box 17 (SOX17), FOXA2* (also known as *HNF3ß*), *CXCR4, brachyury,* or *cerberus*. The next steps in differentiating PSCs into β cells are induction of the primitive gut tube and the posterior foregut. Activation of FGF and WNT signaling pathways, along with inhibition of *sonic hedgehog (SHH)*, are required during specification of the primitive gut tube in vivo. Inhibition of the BMP signaling pathway used to be included in differentiation protocols, but it was found to stimulate precocious differentiation and thus decrease the potential differentiation yield. Therefore, BMP inhibition was removed in certain attempts [40]. FGF7/KGF, FGF10, and 3-keto,*N*-aminoethyl aminocaproyl dihydrocinnamoyl (KADD)-cyclopamine are used upon removal of AA to pattern definitive endoderm into primitive gut tube in vitro [25,26,31]. At this stage, cells continue to express *FOXA2* and *SOX17*, markers for definitive endoderm, and start to express *HNF4α* and *HNF1ß,* markers of developing gut tube [41]. Activation of retinoic acid (RA) and FGF signaling pathways and inhibition of SHH (and, in certain cases, BMP) signaling pathways promote posterior foregut formation. To induce posterior foregut differentiation in vitro, the primitive gut tube cells are treated with RA, SANT (an SHH inhibitor), or KADD-cyclopamine (SHH inhibitor), Noggin or LDN193198 (BMP antagonists), and FGF10 [25,26,29,31,42]. Differentiated posterior foregut cells start to express *PDX1*, *HNF6*, *HLXB9*, *PROX1*, and *SOX9.* The next step in differentiating of PSCs into β cells is induction of pancreatic endoderm and endocrine progenitors. During normal in vivo pancreatic organogenesis, all pancreatic lineages including endocrine, exocrine, and ductal cells arise from *PDX1*-expressing progenitors. Induction of *NKX6.1* in these progenitors restricts their differentiation potential to become endocrine and ductal cells, while induction of *neurogenin 3* (*NGN3*) further restricts their differentiation potential to become endocrine cells [43]. Endocrine linage commitment is induced by the inhibition of BMP, TGF-β, and NOTCH signaling pathways. *PDX1*-expressing posterior foregut endoderm cells are recruited to pancreatic and endocrine lineages using different combinations of the γ-secretase inhibitor DAPT, compound E, or L-685.458 (NOTCH inhibitors), LDN193198 or Noggin (BMP inhibitors), and ALK5 inhibitor (TGF-β type I receptor kinase inhibitor). Other factors may have an important role at this step, because the use of forskolin (adenylyl cyclase activator), indolactam V or TATA-binding protein (protein kinase C activators), CYP26 A inhibitor, and vitamin A (precursor of retinoic acid) enhance differentiation process [29,31]. Endocrine progenitors at this step can be identified by analyzing the expression of *PDX1*, *NKX2.2*, *NKX6.1*, *NEUROD1*, *NGN3*, *paired box gene (PAX)4*, *PAX6*, and *MAFB.* The final step of pancreatic differentiation involves the maturation of endocrine progenitors into β cells. The key signaling pathways and factors that regulate β-cell maturation have not yet been fully discovered. This maturative step is frequently obtained in vivo after transplantation of cells at the progenitor stage. Proposed factors used to stimulate β-cell maturation in vitro include insulin growth factor (IGF)1, hepatocyte growth factor (HGF), glucagon-like peptide 1 or its agonist exendin 4, ALK5 inhibitor, LDN193189 (a BMP inhibitor), vitamin A, or CYP26 A inhibitor [25,29,44]. Mature β cells maintain the expression of *PDX-1*, *NKX6.1*, *NEUROD*, *PAX4*, and *PAX6* and increase robustly the expression of *MAFA,* and insulin (INS). Despite numerous modifications of the multistep protocol originally proposed by D'Amour and colleagues using different growth factors, small molecules, and cell lines, none were able to direct pancreatic progenitor cells in vitro toward fully mature, glucose-responsive β cells; instead, they became polyhormonal (insulin$^+$/glucagon$^+$/somatostatin$^+$) [29–36]. These polyhormonal cells displayed many characteristics of early fetal pancreatic cells, which suggests that they may reflect a normal embryonic

differentiation process [45,46]. Although it was indicated that in vitro generated ESC-derived polyhormonal cells differentiate into mature insulin-producing β cells after implantation, the signaling pathways regulating this process are unknown. Moreover, increasing evidence indicates that hESC-derived polyhormonal cells generated in vitro preferentially differentiate into functional glucagon-producing α cells rather than insulin-producing β cells after implantation [47].

Despite these ambiguities, the U.S. Food and Drugs Administration determined that it would be reasonably safe to test the transplantation of encapsulated ESC-derived pancreatic islet progenitors in humans. In 2014, the company ViaCyte started the first Phase 1/2 clinical trial with hESC-derived pancreatic progenitor cells to determine the safety, tolerability, and efficacy in patients with T1D. The purpose of that trial was to test the safety, tolerability, and efficacy of the VC-01 combination product in subjects with T1D with a 2-year (NCT02239354) and 3-year follow-up (NCT02939118) (https://clinicaltrials.gov). The VC-01 combination product consists of PEC-01 cells (pancreatic progenitors obtained from the hESC line) and the Encaptra drug delivery system (immune-protecting encapsulation device). Devices with pancreatic progenitor cells were transplanted subcutaneously in the area of the lower back of patients with T1D. The results of the clinical trial are awaited with great interest. In patients with T1D, the stem cell–derived β cells (SC-β cells) could be destroyed by the autoimmune process after implantation. Encapsulation devices could protect SC-β cells against a deleterious immune attack and could enable the function of transplanted β cells even in nonimmunosuppressed patients. Although the implantation of incompletely differentiated cells derived from human pluripotent stem cells (hPSCs) could create the risk for the formation of teratoma, the implantation of these cells in encapsulation devices provides an opportunity to remove them in case of complications. Numerous preclinical animal studies indicated that PSC-derived pancreatic progenitor cells mature into functionally insulin-producing β cells after implantation [30–33,35]. Ongoing clinical trials will determine whether pancreatic progenitor cells will differentiate efficiently into β cells after transplantation in patients with T1D and whether eventual maturation into undesired cell types will cause toxicity.

Significant progress has been made in extending the differentiation of PSCs to mature β cells. Two independent groups developed differentiation protocols that produce glucose-responsive, insulin-secreting cells in vitro [48,49]. Monohormonal populations of NKX6.1$^+$/C$^-$peptide$^+$ cells [49] or NKX.6.1$^+$/INS$^+$ cells [48] were generated with about 30% and approximately 50% efficiency, respectively (Fig. 21.2). In contrast, the previous protocols generated NKX.6.1$^+$/INS$^+$ cells with an overall efficiency of less than 1%.

The seven-stage protocol developed by Rezania and colleagues is based on the differentiation of PSCs (hESCs or iPSC lines) toward pancreatic progenitors PDX1$^+$/NKX6.1$^+$ (S1–S4), endocrine progenitors PDX1$^+$/NKX6.1$^+$/NEUROD1$^+$ (S5), immature β cells PDX1$^+$/NKX6.1$^+$/NEUROD1$^+$/INS$^+$ (S6), and finally, maturing β cells PDX1$^+$/NKX6.1$^+$/NEUROD1$^+$/INS$^+$/MAFA$^+$ (S7). The first difference between the new and previously published protocols was the generation of pancreatic progenitors maintaining a high coexpression of PDX1/NKX6.1 and a low expression of NGN3. Previously it was found that the suppression of NGN3 during early stages of differentiation prevented the formation of polyhormonal cells [50]. Therefore, the expression of NGN3 was inhibited at early stages of differentiation (S2–S3) by adding vitamin C. The addition of ALK5 inhibitor (a TGF-β receptor inhibitor), LDN193189, SANT, thyroid hormone (T3), and RA at stage 5 (S5) to the air–liquid interface cultures of PDX1$^+$/NKX6.1$^+$ cells led to their differentiation into endocrine precursors maintaining robust coexpression of PDX1/NKX6.1 and NGN3, NKX2.2, or NEUROD1 markers. Up to 50% of cells generated with this protocol coexpressed NKX6.1/NEUROD1. Previously published protocols did not generate cells expressing endocrine precursor markers NEUROD1 or NKX2.2 at later stages in vitro. Further exposure of NKX6.1$^+$/NEUROD1$^+$ cells at S6 to gamma secretase inhibitor XX (GSiXX) (a NOTCH inhibitor) induced the expression of genes involved in β-cell maturation and inhibited expression of *PTF1A*, a marker of the pancreatic exocrine lineage (during the late stages of maturation). Combining GSIXX with T3 resulted in the generation of cell populations containing about 50% of NKX6.1$^+$/insulin$^+$/glucagon$^-$ cells. However, these cells did not secrete insulin in response to glucose in vitro. Applying an inhibitor of the tyrosine kinase receptor AXL at S7 induced expression of *MAFA*, a marker of mature β cells, at a level similar to that of human islets. Approximately 50% of cells obtained at S7 were insulin positive. This protocol enables the generation of PDX1$^+$/NKX6.1$^+$/NEUROD1$^+$/INS$^+$/MAFA$^+$ cells with an insulin content, glucose-stimulated insulin secretion, and a structure similar to that of human islet cells. However, the insulin and calcium response to glucose were delayed compared with human islet β cells. Despite these differences from human islet β cells, the S7 cells were capable of rapidly reverse diabetes in vivo [48].

Pagliuca et al. applied a scalable suspension-based culture system able to generate hundreds of millions of glucose-responsive human β cells. This six-staged protocol is based on the differentiation of PSCs (hESC and hiPSC lines) into pancreatic progenitors (S1–S4), endocrine progenitors (S5), and SC-β cells (S6). To generate highs numbers of pancreatic progenitors PDX1$^+$/NKX6.1$^+$ (>55% of cells), the group extended the time in culture with

KGF (FGF-7), SANT1, and RA. Further exposure of $PDX1^+/NKX6.1^+$ cells to ALK5 inhibitor, GS inhibitor XX1, T3, SANT1, and betacellulin (an epidermal growth factor [EGF] receptor ligand) at S5 followed by T3 and ALK5 inhibitor at S6 led to the generation of an average of 33% $NKX6\text{-}1^+$/C-$peptide^+$ SC-β cells. These SC-β cells fluxed Ca^{2+} and secreted insulin in response to glucose and displayed a gene expression pattern and ultrastructure similar to primary human β cell. Furthermore, SC-β cells were able to reverse hyperglycemia in diabetic mice [49].

Significant progress in the generation of β cells in vitro was made by Rezania and colleagues and Pagliuca and colleagues, but in vitro–generated β cells were not fully equivalent to mature β cells and the long-term function of these cells after implantation remains unknown. Therefore, further lessons have to be learned from pancreas development during prenatal and postnatal life generate fully functional β cells.

Stepwise pancreatic differentiation protocols were applied successfully to hiPSCs from nondiabetic individuals [39,48,49,51,52], patients with T1D [53,54] and patients with genetic forms of diabetes (maturity-onset diabetes of the young type 2) [55]. These studies indicate that a genetic predisposition for diabetes is not an obstacle in generating β cells in vitro. iPSCs derived β cells from patients with diabetes provide a platform for analyzing specific genotypes on β-cell function and enable gene correction strategies [55]. The differentiation efficiency of iPSCs for β cells differs significantly between patients [53,54], but this variability is also observed between different hESC lines [31,37,39,51]. Differentiation protocols with better consistency in yields may be developed in the future.

β CELLS FROM ADULT STEM/PROGENITOR CELLS OF THE BILIARY TREE AND PANCREAS

Studies in animal models indicate that the repair of mild and moderate injuries in the pancreas is supported mainly by the replication of mature parenchymal cells. Nevertheless, pervasive and chronic injuries could stimulate a contribution from more undifferentiated stem or progenitor cells. If such cells exist, they could be harnessed to treat patients with diabetes. The existence, phenotype, and anatomical location of stem and progenitor cells in the adult human pancreas are at the center of an active discussion.

Precursor cells for the pancreas, liver, and biliary tree exist at early stages of human development, in the endoderm forming the *foregut* [56,57]. From the foregut, a structure emerges, termed the *hepatic diverticulum* [58]. The cranial portion of this structure forms the rudiments of liver and common hepatic duct, developing into cells that will mature into hepatocytes and cholangiocytes. The caudal portion of the hepatic diverticulum, connected to the foregut, gives rise to the *extrahepatic biliary tree* and to the *ventral pancreatic bud*; this last bud will become the ventral portion of the pancreas. The caudal portion of the diverticulum harbors biliopancreatic stem and progenitors cells coexpressing SOX17 and PDX1. Subsequent segregation of pancreatic and biliary precursors depends on these two transcription factors [59]. In an opposite region of the foregut, the *dorsal pancreatic bud* emerges. Dorsal and ventral pancreatic primordia derive from PDX1-positive pancreatic stem and progenitor cells [60]. These progenitors branch into primitive epithelial tubules [60]. Exocrine acini derive from "tip progenitors" located at the ends of primitive tubules. Development of endocrine cells begins in the central duct area, where "trunk progenitors" transiently express NGN3 and commit to an islet fate [60]. On the basis of the progenitor segregation, multiple stem cell niches seem to persist postnatally in specific niches. Stem and progenitor cells have been observed within the extrahepatic biliary tree and in association with intrapancreatic ductal structures (Fig. 21.3A). The most primitive of the stem and progenitor cells, termed biliary tree stem cells (BTSCs) [61], are found in peribiliary glands (PBGs) within extrahepatic bile ducts, and primarily at branching points and in the region of the hepatopancreatic duct [62]. PBGs are crypt-like invaginations of the extrahepatic bile duct epithelium [56,61,63,64]. These niches harbor cells with markers of multipotency for pancreatic and liver maturation (SOX17, PDX1, and SOX9), and with surface markers related to endodermal stem and progenitor cells (epithelial cell adhesion molecule [EpCAM] and leucine-rich repeat-containing G-protein coupled receptor 5) (Fig. 21.3B). BTSC cells can be observed in (and may be isolated from) the fetal and adult biliary tree. They are capable of self-replication and multipotent differentiation toward pancreatic cells (including functional islet endocrine cells) and mature liver cells (hepatocytes and cholangiocytes) both in vitro and in vivo [56,62,64,65]. In the pancreas proper, more mature cells are observed: pancreatic ducts and pancreatic duct glands (PDGs) harbor committed pancreatic progenitors [66] (Fig. 21.3C). These cells could contribute to pancreatic organogenesis throughout life.

Niches containing cells related to BTSCs extend into liver and near the pancreas [64,65]. The largest pancreatic ducts display PDGs. Detailed anatomical studies in humans have revealed a proximal-to-distal axis for the BTSC niche organization going from proximal (the hepatopancreatic ampulla), the location of the most primitive stem cells, to distal (the liver or the pancreas), the location of mature cells [62,64,65]. This axis recapitulates the

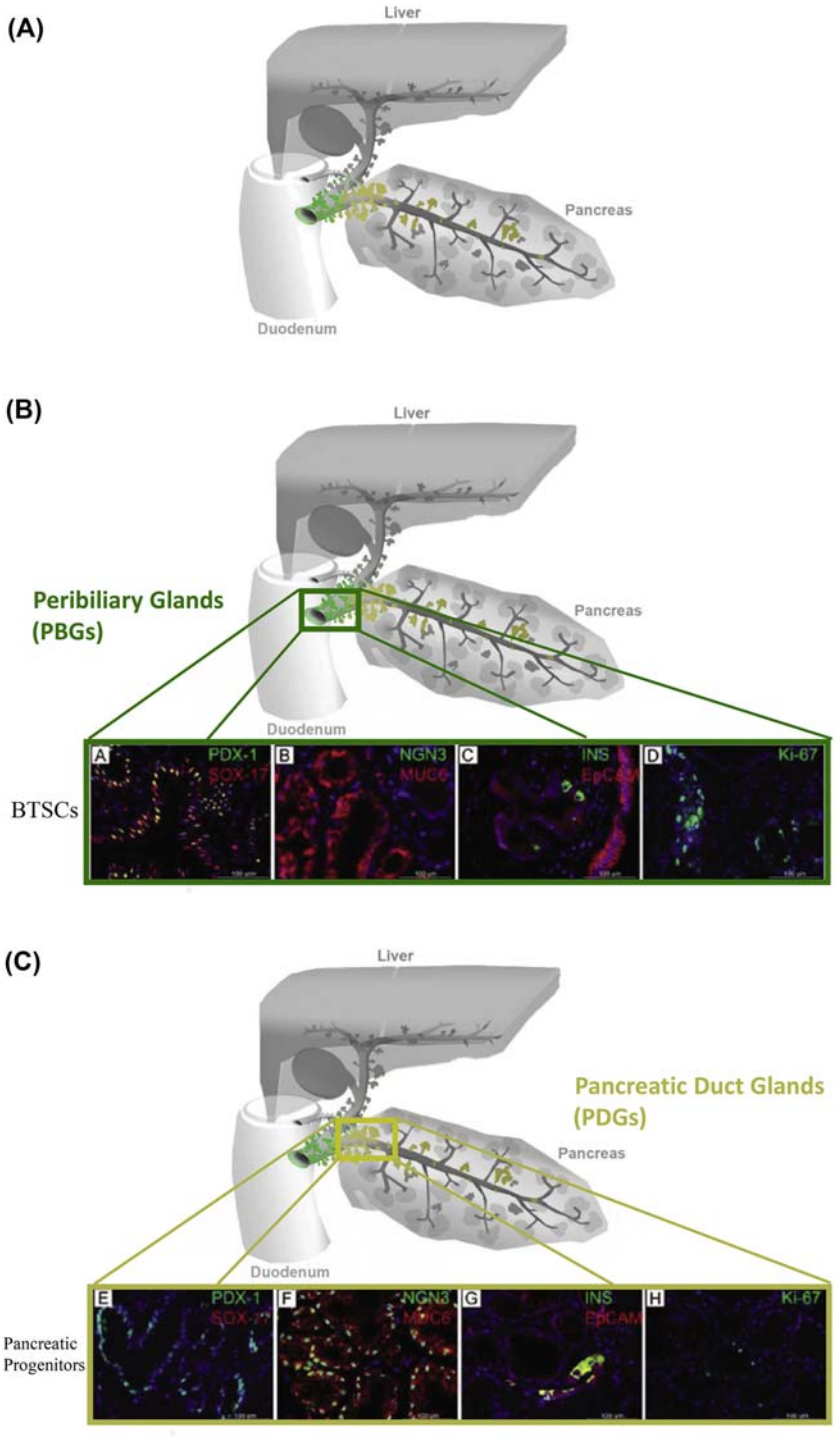

FIGURE 21.3 (A) Schematic representation of the pancreas, liver, duodenum, along with the biliary tree and network of pancreatic ducts. Peribiliary glands (PBGs) are marked in *green* and pancreatic duct glands are marked in *yellow-gold*. (B) PBGs exist along the hepatopancreatic duct harbor biliary tree stem cells (BTSCs), as well as more mature derivatives. PBGs display (A) cells with a range of pancreatic and duodenal homeobox 1—positive ($PDX1^+$) and SRY-related HMG-box 17—positive ($SOX17^+$) expression, (B) subsets of cells that are mucin 6, oligomeric mucus/gel-forming positive ($MUC6^+$) and $MUC6^-$, but negative for the islet progenitor marker NGN3, (C) scattered Insulin + cells embedded in the epithelial cell adhesion molecule-positive epithelium, and (D) several Ki-67-positive proliferating cells. (C) Pancreatic duct gland (PDGs), distributed along the largest pancreatic ducts, harbor pancreatic progenitors, including subsets of putative progenitors committed to islet endocrine phenotypes. PDG display (E) a large number of $PDX1^+$ cells, with low or no expression of SOX17, (F) subsets of $NGN3^+$ $MUC6^+$ cells, putative islet endocrine progenitors, (G) clusters of insulin-positive cells, (H) a limited number of Ki-67-positive proliferating cells.

organogenesis of these endodermal organs; it is based on their common embryological origin [56] and is in accordance with the presence of a stem cell compartment shared and in common for the pancreas and the liver [67].

Human BTSCs are endowed with the potential to mature into functional insulin-producing cells that ameliorate diabetes in rodents. For this reason, they are a candidate source of cells for regenerative strategies in T1D [65,68]. Beside cell therapy, the modulation of BTSC differentiation toward β cells via growth factors or other signals represents a possible therapeutic target [69].

Postnatally, islet cell proliferation is sustained after birth, but turnover becomes slow in adulthood. However, compensatory growth can occur in response to increased demand in both the endocrine and exocrine compartments [70,71]. The question remains related to the nature of the cells responsible for such regenerative phenomena. Few reports claimed that multipotent stem cells exist within the pancreas [72,73], but such cells are rare in the postnatal pancreas [74]. Cells with pancreatic stem cell traits seem to persist postnatally in the human biliary tree, especially in the region of the hepatopancreatic duct and of the ampulla of Vater, whereas more committed progenitors appear to reside in the pancreas proper [62]. Before the observations on the biliary tree niche of multipotent stem cells for the pancreas, investigators focused on whether mature pancreatic cells could be the source of regenerative phenomena. Pancreatic cells were hypothesized to be endowed with a flexible differentiation potential to respond to injuries. A number of studies suggested that in adults, new pancreatic cells arise mainly from preexisting cells of the same lineage. Lineage tracing studies in rodents showed that acinar cells can develop into to acinar cells but not islets [75]. Similarly, newly formed islet β cells were found to derive mainly from the replication of preexisting islet β-cells [76,77]. These findings do not preclude a contribution from multiple populations of stem or progenitor cells for the de novo formation of exocrine and endocrine cells, a contribution frequently observed after extensive and chronic damage [62,72,73,78,79]. β-cell impairment or loss, peripheral insulin resistance, and hyperglycemia may stimulate regeneration from endogenous progenitors [80].

The epithelium of most pancreatic ducts is composed of Sox9+ and carbonic anhydrase II^{+} cells [67]. Adult ductal cells were reported to be able to differentiate into pancreatic acinar and endocrine cells [78,81]. However, the contribution of this population to islet endocrine cell turnover is still a matter of debate [67,78,81]. Intriguingly, in response to pathological conditions that include pancreatitis and autoimmune diabetes, structures with heterogeneous ductal phenotypes expand in the pancreas, with a histological presentation that resembles liver ductular reactions [82,83]. PDGs of the adult human pancreas were found to harbor pancreatic endocrine progenitors [62]. PDGs occur in association with the main pancreatic duct and its immediate ramifications, and are abundant in proximity to the hepatopancreatic ampulla [62,84]. The anatomical distribution of PDGs along the pancreatic ducts of larger caliber has similarities to the distribution of PBGs along the biliary tree. PDGs harbor NGN3-positive cells, putative progenitors of islet cells [62]. PDGs undergo hyperplasia in murine models of chronic pancreatitis, displaying traits of mucinous intestinal metaplasia, and pancreatic intraepithelial neoplasia [84]. Hence, cells in adult human PDGs and along the larger pancreatic ducts have a phenotype consistent with that of pancreatic progenitors. Considered altogether, these observations suggest that the adult pancreas contains niches of progenitors that could mediate regenerative responses.

Studies have identified growth factors that can stimulate the maturation of insulin-producing β cells from adult pancreatic nonendocrine cells, including putative progenitor cells. A study was conducted in mice after the induction of diabetes with the chemicals alloxan or streptozotocin. EGF and ciliary neurotrophic factor were administered intraperitoneally. This resulted in diabetes reversal in 64% of the animals rendered diabetic with alloxan, and in 33% of animals rendered diabetic with streptozotocin [85]. A different study was conducted on cultured human nonendocrine cells, obtained as a by-product of islet isolation. This study analyzed the effect of BMP-7. BMP-7 is a growth factor in clinical use, with the dual ability to inhibit TGF-β and activate BMP signaling. Exposure of human nonendocrine pancreatic cells to BMP-7 led to the generation of glucose-responsive, insulin-releasing cell clusters that expressed insulin within the published range for research islets [86,87]. Preliminary lineage-tracing results suggested that cells that responded to BMP-7 were not adult acinar or ductal, but rather were pancreatic progenitor cells. Further anatomical and molecular characterization of these cells may shed additional light on their potential to regenerate the endocrine pancreas. Linking this field of research to that of ESC differentiation was the finding by Russ et al. [40] that BMP inhibition (commonly used in earlier methods to differentiate ESCs into β cells to promote efficient pancreatic progenitor cell generation) results in dysfunctional or polyhormonal β-like cells. Removal of these inhibitors corrected this problem, which further suggests that BMP signaling is important for the functional differentiation of β cells.

MESENCHYMAL STEM CELLS TO MODULATE IMMUNITY AND PROMOTE TISSUE REPAIR IN DIABETES

MSCs have created great interest. They possess important characteristics that could be exploited in cell-based strategies for T1D and for certain complications of T2D. MSCs are potent immunomodulators. They exert suppressive functions on immune effector cells and orchestrate the action of other regulatory cells. Moreover, they promote the repair and regeneration of endogenous tissues in recipients (Fig. 21.4). Furthermore, they have shown a good safety profile in clinical trials, including a limited risk of tumor formation. MSC transplantation has been tested extensively and has been shown to be beneficial in animal models of autoimmunity [2,88,89].

MSCs are endowed with the ability to modulate immune responses. Several mechanisms of action have been described. MSCs interact with immune cells such as dendritic cells (DC), natural killer cells, β cells, and T cells [90]. MSCs can inhibit DC differentiation and maturation, suppress the proliferation of $CD4^+$ and $CD8^+$ T cells, and impair the cytotoxic activity of cytotoxic lymphocytes [2]. MSCs can also induce and expand T-regulatory (T-reg) cells and can balance T-helper (Th) subsets [91]. Studies conducted in the Non Obese Diabetic mouse model (a model of autoimmune T1D) showed that MSCs can induce FoxP3+ T-reg cells that secrete the antiinflammatory cytokine interleukin (IL)-10 [92]. Moreover, MSCs could expand antigen-specific T-reg cells in vivo and stimulate long-lasting tolerance [93]. MSCs are also able to shift the cytokine profile from proinflammatory to antiinflammatory in the murine pancreatic microenvironment, polarizing the response from Th1 to Th2 in T1D animal models [2]. The ability of MSCs to modulate immunity should not be considered solely immunosuppressive; it depends closely on the microenvironment: MSCs acquire proinflammatory activity when homed into a low-inflamed microenvironment [91,93].

Dr. Arnold Caplan, who coined the nomenclature "mesenchymal stem cells" and the MSC acronym in the late 1980s, later preferred to call these cells "medicinal signaling cells." This is because MSCs have a prominent secretive activity. Great effort has been made to understand the effects of releasing these bioactive molecules. Interestingly, MSCs can home into inflamed tissues as a result of the interaction of receptors with ligands, which indicates inflamed environments, such as CXCR4 with its ligands chemokine (C-C motif) ligand-12, and stromal cell−derived factor-1, and very late antigen-4 with vascular cell adhesion molecule-1 [93]. MSCs secrete a number of bioactive molecules at their homing site, including IL-6, IL-8, TGF-β, nitric oxide, indoleamine 2,3-dioxygenase, tissue inhibitor of metalloproteinases-2, vascular endothelial growth factor, HGF, granulocyte macrophage−colony-stimulating factor, basic fibroblast growth factor, and insulin-like growth factor-binding protein (IGFBP)3, 4, and 7 [93,94]. These molecules can promote tissue repair and act as chemoattractants, recruiting macrophages and endothelial cells at the site of injury or inflammation. In addition, MSCs can signal through cell contact and via microvesicles, mechanisms that participate in immunoregulation [95]. Studies in rodent models of T1D seem to validate the hypothesis that MSCs boost endogenous tissue regeneration, because mice transplanted with human MSCs displayed higher serum insulin than do the control group, but in absence of human insulin [88]. Several clinical trials have tested MSC transplantation in patients with T1D and T2D [2] [65].

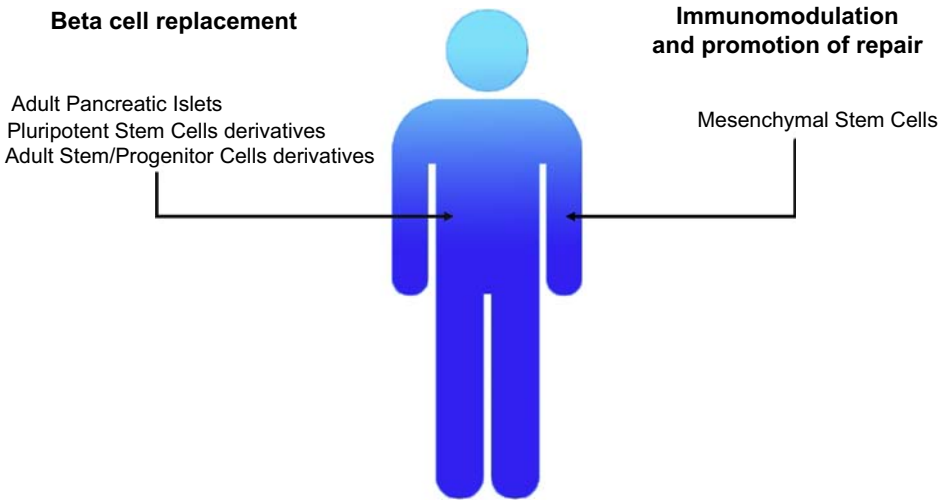

FIGURE 21.4 Visual summary of the main strategies for β-cell replacement, along with cell-based strategies for immunomodulation and to promote tissue repair.

As mentioned, T1D is a chronic autoimmune disease in which β cells are progressively lost, leading to severe complications such as hyperglycemia and ketoacidosis. Major hurdles for effective treatment of T1D are to halt immune destruction of β cells, preserve β-cell function and mass, and regenerate or replace β cells [1]. Because of their properties, MSCs could achieve these goals. Clinical trials have been performed to test the effect of MSC transplantation at different stages of T1D (Table 21.1). An open-label pilot trial [96] conducted in Sweden enrolled patients with T1D with recent onset of diabetes. Twenty patients were randomized to the group receiving transplantation of autologous bone marrow-derived MSCs or to the control group that received only insulin therapy. The treatment was found to be safe. Remarkably, most patients treated with MSC transplantation showed preservation of stimulated C-peptide secretion (a measurement of the function of insulin release from residual β cells) at 1 year after MSC infusion. The control patients showed a decline in C-peptide levels during the 1-year follow-up. Patients in both the treated and control groups continued to require insulin therapy and there were no statistically significant differences in insulin requirements and glycated hemoglobin (HbA1c) levels between the two groups. Another trial was conducted in China [97] and enrolled 42 patients with T1D who had diabetes for an average of 8.12 years. Compared with newly diagnosed patients, these patients had a severely lower level of residual β-cell function. The patients were randomized to a group receiving cell transplantation or one receiving standard diabetes care. The treated patients received cotransplantation of allogeneic umbilical cord−derived MSCs (UC-MSCs) and autologous bone marrow mononuclear cells (BM-MNCs). Given the design of the trial, the questions remain unanswered, because the individual actions of UC-MSCs and BM-MNCs could not be determined. This phase I/II trial aimed to test the safety and efficacy of this form of cell transplantation. Efficacy was assessed by measuring stimulated C-peptide, HbA1c levels, and insulin requirements. The therapy was found to be safe and resulted in a moderate improvement in β-cell function and metabolic parameters. After 1 year, stimulated C-peptide release during an oral glucose tolerance test was increased by 105.7% in recipients of cell transplant; in contrast, it declined in control patients. Moreover, HbA1c decreased by 12.6% in the treated group whereas it increased by 1.2% in the control group. Fasting blood glucose levels decreased significantly in transplant recipients, whereas it remained substantially unchanged in the control group. A change in the pattern of cytokine expression suggested that this form of cell therapy exerts immunomodulatory effects. Such improvements were achieved in patients with established T1D with fasting C-peptide less than 0.1 pmol/mL at entry. The reported improvement suggests some effect of the therapy on the mass of β cells, perhaps through the expansion of the residual β cells or differentiation of the transplanted cells into new β cells (although there is limited and controversial evidence for the differentiation of MSCs into pancreatic islet cells in vivo). The safety of MSC transplantation was corroborated in these clinical trials in patients with T1D [96,97]. The positive outcomes encourage larger, long-term studies of MSC transplantation in newly diagnosed and long-standing patients with T1D.

Ongoing clinical trials are also testing the safety and efficacy of MSC transplantation in patients with T2D [65,98]. MSCs could treat common complications of diabetes such as ulcers, limb ischemia, and nephropathy, and improve metabolic control in T2D [98−101]. Treatment with MSCs was reported to be safe and effective in facilitating wound healing in diabetic patients with foot ulcers [102], and the cells can exert an immunomodulatory effect by inducing T-reg cells in patients with T2D [103]. Allogeneic placenta-derived MSCs were transplanted in 10 patients with T2D and the infusion was reported to be safe. The patients experienced a reduction in the daily requirement for insulin; they had better control of blood glucose fluctuations and experienced improvements in quality of life [104]. Allogeneic adipose tissue-derived cells (not thoroughly characterized as MSCs) were also used in combination with bone marrow−derived cells in patients with insulin-dependent diabetes mellitus [105,106]. In that study, pancreatic endocrine differentiation was stimulated in vitro and induced adipose tissue-derived cells were co-infused in patients with culture-expanded bone marrow cells. No adverse side effects related to the infusion were observed, and transplantation was reported to result in reduced insulin requirements in the treated patients. Unfortunately, that particular study had caveats: the nature of the transplanted cells was not fully defined, the cell dose was not reported, and the mechanisms remained obscure, which raises some concerns regarding interpretation of the outcomes. Future studies are expected to provide a rigorous assessment of the efficacy of MSC transplantation in T1D, T2D, and related complications. Moreover, future efforts aim to elucidate the biological mechanisms of the effects of MSC transplantation in diabetic patients.

CONCLUSION

Thirty years of studies in islet transplantation paved the way to the transplantation of exogenously generated β cells as effective treatment for diabetes, chiefly in T1D. Some avenues of research are translating into clinical trials. The derivation of pancreatic progenitors from hESC proved successful in preclinical studies, and the safety of

encapsulated ESC derivatives is being tested in human recipients. Approaches are also emerging to stimulating the maturation of adult human pancreatic progenitors into functional endocrine cell types. Strategies that use cytokines or growth factors may soon reach the clinical testing phase. Regenerative approaches may not work efficiently in patients with T1D unless steps are taken to counteract autoimmunity. MSCs can act as potent immunomodulators and release trophic mediators. They are showing promising results in initial clinical studies in patients with T1D. MSCs can also stimulate the regeneration of endogenous cells in recipients, and findings in clinical trials with patients with T1D and patients with complications of T2D provide hints in that direction. There is no doubt that regenerative advanced therapies for diabetes are taking on momentum.

Stem Cells for Diseases of the Retina

Aaron Nagiel, Steven D. Schwartz

University of California Los Angeles Geffen School of Medicine, Los Angeles, CA, United States

INTRODUCTION

Retinal disorders represent a leading cause of permanent vision loss worldwide. Unfortunately, no approved treatments exist for this group of disorders, resulting in a huge unmet medical need. Diseases such as atrophic or dry age-related macular degeneration (AMD), Stargardt macular dystrophy (STGD), and retinitis pigmentosa (RP) feature an initial period of cellular dysfunction followed by frank cell loss that is the ultimate cause of permanent blindness. Transplanting replacement cells for these conditions represents an attractive therapeutic paradigm because it may be agnostic to the underlying pathophysiology. For example, although AMD and STGD feature disparate underlying disease processes, both disorders ultimately result in the loss of the retinal pigment epithelium (RPE), which represents a common target for cellular transplantation. Human embryonic stem cells (hESCs) and induced pluripotent stem cells (iPSCs) are promising sources from which to create fresh RPE cells that could be used to replenish compromised areas of the retina or even replace atrophic areas that are devoid of RPE. Other disorders that primarily feature photoreceptor degeneration such as RP may be treatable with stem cell–derived photoreceptor transplants. Because over 120 genetic variants of RP exist, this treatment approach might obviate the need to create custom treatments for each subtype.

Various stem cell types are being tested as sources of neurotrophic factors to stop or delay ongoing cellular loss. Human umbilical tissue-derived stem cells (hUTCs) as well as fetally sourced cells such as retinal progenitor cells (RPCs) and neural stem cells have shown promise for slowly progressive disorders such as dry AMD and RP. Adult stem cells such as bone marrow–derived hematopoietic stem cells have been employed in an autologous fashion for these degenerative conditions as well as for retinal vascular diseases. Any treatment strategy must be carefully scrutinized because there have been several cases of questionable stem cell therapies administered with minimal to no scientific validation or oversight [1].

In addition to studying stem cell–derived cellular products as potential therapeutic agents, scientists have become increasingly adept at differentiating stem cells into various retinal cell types in vitro. The capacity to recapitulate diseased retinal cells in culture (so called "disease-in-a-dish" modeling) has shown promise in characterizing particular patients' retinal disorders. Pluripotent stem cells can even be used to create three-dimensional optic vesicle-like structures that contain multiple retinal cell types in a laminar arrangement. This technology offers an unprecedented window into fetal retinal development at the cellular, developmental, and synaptic levels and may even serve as a source of cells for therapeutic use. The use of these in vitro differentiation methods can introduce artifacts, however, and any conclusions must be tempered with caution.

Stem cell–based translational research efforts have the potential to revolutionize the treatment and understanding of retinal disease, especially disorders with no treatments currently available. Furthermore, because the retina is embryologically derived from the central nervous system, it is likely this work will inform and instruct the use of cellular therapy in the brain. Compared with other central nervous system structures, the retina is more accessible, directly visualized, amenable to local immunosuppression, and requires fewer transplanted cells. These distinct advantages uniquely position retinal researchers and translational scientists to pave the way for cell-based treatments addressing a broad range of neurodegenerative diseases.

The Retina

The human eye is a complex organ composed of multiple elements meant to capture light from the environment and transmit to the brain in the form of neuronal stimuli. The cornea and lens focus incoming light onto the retina, which converts light into electrical responses, a process known as phototransduction. This information exits the retina to the brain in the form of electrical signals via the optic nerve, which is composed of retinal ganglion cells whose nuclei reside in the retina (Fig. 22.1).

The retina is a multilayered transparent structure that is embryologically derived from the inner and outer layers of the optic cup. The key function of the retina is to perform phototransduction via the photoreceptor cells, but the other resident cell types, both neuronal and nonneuronal, have important roles such as signal processing, transmission of neuronal stimuli to the central nervous system, and regulation of metabolic function (Fig. 22.2A). The macula is the central portion of the retina bounded by the vascular arcades and the optic disc. A central depression within the macula is known as the fovea and is responsible for high-acuity color vision mediated by cone photoreceptors. The retinal periphery contains mostly rod photoreceptors and provides peripheral vision especially in low-light conditions.

The outermost layer of the retina is the RPE. The RPE consists of polarized, pigmented epithelial cells that reside between the highly vascular choroid and the photoreceptor layer. It provides several essential supportive functions to the photoreceptors including maintenance of the blood−retina barrier, phagocytosis of photoreceptor outer segments, absorbing scattered light, secretion of growth factors and cytokines, and metabolism of vitamin A derivatives [2]. The RPE monolayer exhibits apicobasal polarity with the apical processes in contact with the photoreceptor outer segments and the basal side abutting the choriocapillaris, a rich vascular plexus. The basement membrane of the RPE, which lies between the choriocapillaris and the RPE basal surface, serves as a porous matrix for adequate diffusion of nutrients. In the elderly, it undergoes deleterious changes such as atrophy, thickening, lipid accumulation, and diminished diffusional capacity, which may have a role in diseases such as AMD [3].

The photoreceptor layer contains rods and cones, which are highly specialized neuroepithelial cells that transduce light into electrical potentials. Rods are sensitive to dim light and make up most of the photoreceptors in the peripheral retina. Cones provide high-acuity color vision in bright light conditions and are highly concentrated in the fovea. Hence the retina mediates both central fine color vision and peripheral low-light sensitivity. The rods and cones perform phototransduction via outer segments that abut the apical processes of the RPE. Changes in membrane potential triggered by light stimuli are transmitted to synapses with bipolar cells, which in turn relay these signals

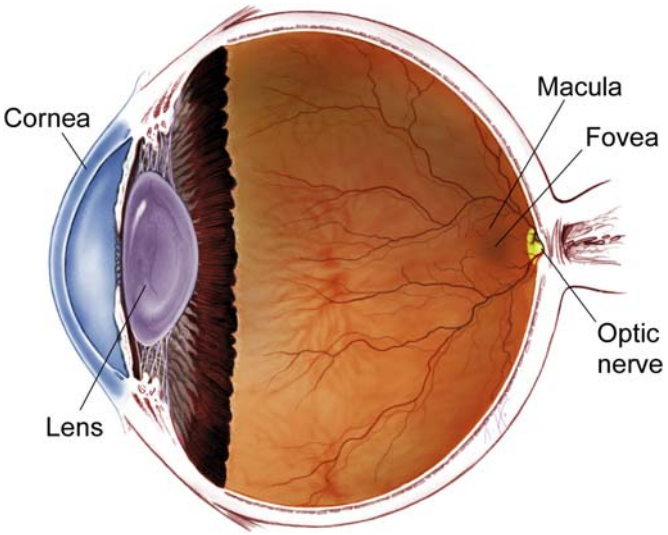

FIGURE 22.1 The eye contains multiple elements required for sight. The cornea and lens refract incoming light rays onto the retina. The retina is an extension of the central nervous system evolved to sense light. The retina can be grossly divided into a central portion and peripheral portion. The central retina, the macula, is bounded by the large vascular arcades emanating from the temporal aspect of the optic disc and is responsible for cone-mediated, high-acuity central vision. The peripheral retina is responsible for rod-mediated visual functions such as night vision, tracking, and peripheral vision. The visual cycle occurs in the photoreceptors and retinal pigment epithelium, initial signal processing occurs in the inner layers of the retina, and the optic nerve, composed of retinal ganglion cell axons, transmits the neural signal to the brain. *Illustration by Timothy Hengst.*

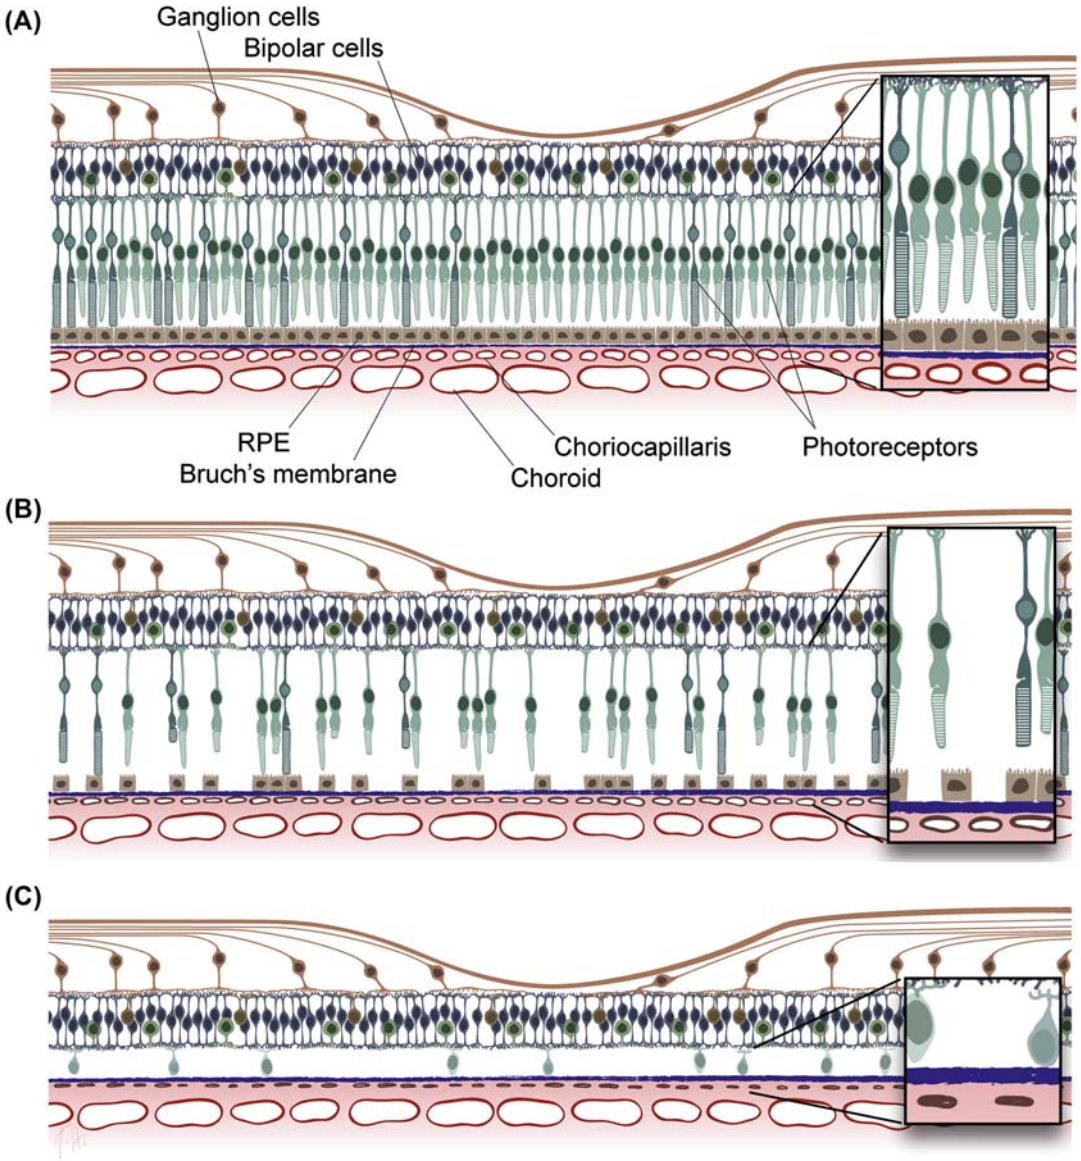

FIGURE 22.2 Schematic cross-sectional view of the normal and diseased macula. (A) The neurosensory retina consists of many cell types, including rod and cone photoreceptors, bipolar cells, and retinal ganglion cells. Note that the photoreceptor outer segments are in contact with the apical processes of the retinal pigment epithelium (RPE) monolayer (inset). The polarized, confluent monolayer of RPE cells rests upon the Bruch membrane and the innermost portion of the choroidal vasculature, the choriocapillaris. (B) The diseased retina in atrophic age-related macular degeneration (AMD), for example, may exhibit a diminution of RPE and photoreceptors along with a thickened Bruch membrane and drusen (metabolic and inflammatory debris; not illustrated). The underlying choriocapillaris can be thin or atrophic. Note that the remaining photoreceptors are compromised with shortened outer segments (inset). (C) The end-stage retina in advanced atrophic AMD with geographic atrophy demonstrates extensive RPE and photoreceptor loss, with only a few photoreceptor nuclei remaining (inset). The Bruch membrane is thickened and the choriocapillaris is atrophic. *Illustration by Timothy Hengst.*

to retinal ganglion cells. Retinal ganglion cells transmit neuronal stimuli to the central nervous system via long axons that make up the optic nerve and optic tract. Other neuronal cell types in the retina such as horizontal and amacrine cells have an important role modulating and processing the light-mediated neural signaling.

The retina is an ideal tissue for using cell-based treatments. First, the transplanted cells can be visualized directly via ophthalmoscopy or a variety of noninvasive, high-resolution imaging modalities, obviating the need for a tissue biopsy. Second, the size and architecture of the retina are conducive to the transplantation of a relatively small number of cells to a specific location. This includes the surgical transplantation of cells in suspension or on sheets into the precise space or layer in which they reside, or perhaps even into the vitreous cavity that lies adjacent to the retina and is accessible via a safe, in-office injection procedure. Third, in the healthy eye the subretinal space is an

immune-privileged site with significantly diminished cellular and humoral responses [4], which may prevent rejection of foreign cells as long as the blood−retina barrier remains intact [5,6]. Fourth, there are many functional and safety end points that are noninvasive, such as visual acuity, visual field analysis, color vision, contrast sensitivity, dark adaptation, autofluorescence imaging, and microperimetry. A final advantage of the retina is that although it is a part of the central nervous system, it contains a nonsynaptic layer (the RPE) that fails as a central feature of many blinding conditions and that may render it more amenable as an early target for cellular transplantation.

Age-Related Macular Degeneration

AMD is a multifactorial degenerative disorder in the elderly that primarily affects the macula and can lead to permanent vision loss [7]. It is a major cause of vision loss in patients age 65 years and older living in developed countries, with over 2 million affected by advanced AMD in the United States alone [8]. AMD has two main clinical presentations with distinct prognostic and treatment considerations. The nonneovascular, atrophic, or dry form of AMD is associated with the deposition of subretinal lipid deposits known as drusen and progressive RPE abnormalities that can result in geographic atrophy (GA) of the RPE, choriocapillaris, and photoreceptors (Fig. 22.2B−C). The neovascular or wet form of AMD presents with more sudden vision loss owing to hemorrhage, fluid accumulation, and eventual scarring caused by the development of neovascular tissue. This form can be treated with antivascular endothelial growth factor (anti-VEGF) agents. However, anti-VEGF therapy is far from perfect; it has pharmacokinetic and compliance issues among others. No treatment exists for GA in dry AMD, although a number of immune-modulating and other potential therapies are being studied.

Both genetic and environment factors contribute to the pathogenesis of dry AMD. One of the earliest insults is oxidative stress on the RPE owing to the accumulation of lipofuscin and other by-products of the visual cycle [9]. These toxic metabolites ultimately result in RPE apoptosis with subsequent photoreceptor loss and GA. The pathogenesis is certainly multifactorial, however, with a role for choroidal ischemia and lifestyle factors such as diet and smoking. Genome-wide association studies have implicated the complement system in the pathogenesis of AMD [10,11].

As of yet, there is no established treatment to reverse or slow the progression of GA. Several pharmaceutical classes are being tested in clinical trials, including complement factor pathway inhibitors, neuroprotectants, visual cycle modulators, and immunosuppressants [12,13]. Stem cell−based therapies for end-stage dry AMD have shown promise in small safety studies [14].

Stargardt Macular Dystrophy

The most prevalent childhood-onset macular dystrophy is STGD, with an estimated prevalence of 1 in 10,000 individuals [15]. Most often it presents in the first or second decade with diminished visual acuity and the classic examination findings of bull's-eye maculopathy, pisciform flecks, and relative hypofluorescence of the choroid on fluorescein angiography. Many individuals progress to central GA with profound central vision loss. Several genes have been implicated, the most common of which is an autosomal recessive mutation in the ABCA4 gene [16]. ABCA4 is transmembrane transport protein required for the removal of all-trans-retinaldehyde from photoreceptor outer segments, and when mutated, toxic visual cycle metabolites accumulate in RPE cells.

Although this disorder has been characterized genetically and biochemically, there are no established treatments for the disease. Gene therapy trials to replace the ABCA4 gene are under way, but limitations to these trials include the size of the gene, the limited choice of nonintegrating vectors, the slow course of neural degeneration, and the fact that improvements are unlikely in advanced cases in which atrophy has already set in. Stem cell−based RPE replacement therapy has been tested in phase 1 trials with promising results in patients with advanced disease. This regenerative strategy may prove to be safe and effective earlier in the course of disease by providing the patient with dose of healthy RPE, and thus theoretically preventing further damage to adjacent macular photoreceptors and preserving central vision [14].

Retinitis Pigmentosa

Inherited retinal dystrophies have myriad clinical manifestations but ultimately result in progressive and often profound vision loss owing to photoreceptor death. These disorders affect approximately 1 in 2000 individuals and have been mapped to over 120 genetic loci thus far [17]. A subset of patients with inherited retinal degenerations

have RP, which is a clinical entity presenting with symptoms of diminished night vision (nyctalopia) and peripheral vision (visual field loss), and can progress to profound central vision loss (visual acuity loss) and even total blindness. The causative genetic mutations affect the biochemistry or structure of photoreceptors and the RPE. Rod photoreceptor dysfunction and degeneration are a hallmark of the disease, but eventually cone photoreceptors, RPE, and other cell types degenerate within the retina.

Treatment for RP and other inherited retinal dystrophies is limited or nonexistent. Except for forms caused by an underlying metabolic disorder, dietary supplements have had limited success. There has been considerable excitement regarding gene replacement therapy via viral delivery of normal copies of the mutated gene. For RPE65-associated Leber congenital amaurosis, gene delivery of RPE65 via an AAV2 vector showed success in a canine model [18] and in human patients as well [19]. There are several issues with gene therapy in RP, however. One issue is that the currently available viral vectors are not ideal, with size limits and relatively inefficient transduction efficiency. Another issue is that gene delivery is unlikely to be effective in late stages of the disease when the target cells are severely compromised or already absent. Finally, in light of the genetic heterogeneity, it would be cumbersome to create custom vectors for each form of the disease. These issues have spurred interest in cell-based therapies that could replace lost cells in advanced stages of the disease regardless of the underlying mutation.

CELL-REPLACEMENT THERAPY

The use of stem cells as a source of replacement cells to treat disease has been one of the long-held promises of the technology. For many retinal disorders such as AMD and RP, however, the degenerative process begins in one cell type but eventually engulfs adjacent cell types and layers. Treatment of end-stage disease is thus a more complex endeavor, requiring the transplanted stem cell–derived cells to rejuvenate dormant and moribund cells or even induce the genesis or migration of healthy cells into the proximity of the transplant. Treatment of end-stage disease with the goal of restoration of function, as opposed to halting disease progression, therefore may necessitate the use of multilayered, multicellular tissue transplants. Ideally, intervention could be performed early when the transplanted cells can augment the affected cells and prolong the survival of adjacent tissues. This approach carries a higher chance of success but must be reconciled with the safety and efficacy profile of the transplantation procedure early in the course of the disease when the eye is still seeing well.

The RPE is an attractive target for cell replacement therapy for both medical and societal reasons. Efforts to replace the RPE via autologous or fetal RPE transplantation go back to the 1990s, but these efforts were fraught with difficulties including insufficient cellular material and scarring at the harvest site [20–23]. In addition, because the transplantation occurred in end-stage GA lacking choriocapillaris and photoreceptors, visual recovery was unlikely to occur. The use of human embryonic and iPSCs has since risen to prominence as an attractive source of replacement human RPE. The use of stem cell–derived photoreceptors is being tested in animals and may be available for human studies in the near future.

Human Embryonic Stem Cell–Derived Retinal Pigment Epithelium

The use of hESCs to generate RPE as replacement cells has stood out as a bright spot in the field of regenerative medicine, with promising data from first-in-human transplantation trials. Although many technical difficulties had to be overcome along the way, the cellular product maintained an excellent safety and functional profile from in vitro testing to animal models to human clinical trials. hESCs are an attractive source of RPE because of their scalability and diminished immunogenicity in animal models of xenorejection [24]. However, a significant concern regarding hESC-derived RPE is that they could proliferate, form teratomas, dedifferentiate, or trigger an unremitting inflammatory response that would eliminate the transplanted cells as well as adjacent areas of functional retina.

A primary goal of preclinical and human studies thus far has been to address the safety of the transplanted allogeneic cells. These terminally differentiated hESC-derived RPE cells are amenable to extensive testing ex vivo, including for purity, cellular function, and transcriptome analysis to demonstrate strong expression of RPE markers and downregulation of hESC markers [25]. When injected beneath the retina in rodent models of retinal degeneration, the transplanted cells integrate into the RPE monolayer and improve visual function and luminance threshold response. Studies in National Institutes of Health class III immune-deficient mice showed no proliferation of the cells or spread to other parts of the body.

Schwartz et al. first demonstrated the use of hESC-derived RPE in human subretinal transplantation studies in patients with advanced GA from dry AMD and STGD [26]. Although dry AMD represents a leading cause of blindness in the developed world, patients with STGD were included in initial trials to address the role of the Bruch membrane. Senescence of the Bruch membrane in advanced dry AMD could hypothetically limit the success of this strategy, because cells were transplanted in suspension with the hope that they might survive, engraft, and polarize on the Bruch membrane. Thus, the success of this strategy may depend on the relative viability of the Bruch membrane. Therefore, younger patients with STGD and a hypothetically healthier Bruch membrane were studied as well. In this trial, the patients were given solid-organ transplant doses of immunosuppression and received a vitrectomy with subretinal injection of a suspension of hESC-derived RPE (Fig. 22.3). The investigators in this trial selected for the transplantation site a region outside the center of the macula, termed the transition zone, that was compromised but still viable and included areas of frank atrophy at the central-most aspect and normal retina at the peripheral-most aspect. This transition zone was chosen for initial transplantation for a number of reasons. First, the central macula in advanced cases of both conditions has the longest history of tissue loss including adjacent structures such as the photoreceptors, the Bruch membrane, and choriocapillaris. Thus, the central macula in advanced disease is not only long devoid of visual tissue (photoreceptors) but also devoid of blood supply (choriocapillaris), and thus far less likely to accept a safe and effective transplant. Second, this site includes areas that mimic the state of the macula earlier in the course of disease, allowing investigators to query eventual disease stage targets for RPE replacement therapy.

These phase I/II studies included nine patients with STGD and 9 with AMD. Most important, none of the patients experienced significant safety issues including nonsurgical inflammation, teratoma formation, or unwanted proliferation of the cells. Although the initial trials were meant to address safety and tolerability, 13 of 18 patients (72%) featured increased pigment at the border of the atrophic area suggestive of stem cell–derived RPE survival, and many of the patients experienced sustained improvements in visual function [14]. However, the interpretation of functional end points should be made with caution because vision was studied as a safety end point in a study with relatively few patients, lack of a formal control group other than the fellow eye, and the advanced disease present at baseline.

This initial pilot study using hESC-derived RPE delivered as a cell suspension has spurred the development of alternative treatment strategies to address the challenges inherent in this approach. These include efforts to address engraftment, polarity, confluence, maturity, and survival concerns on the senescent Bruch membrane by transplanting RPE cells grown into a confluent monolayer on a biocompatible scaffold before surgery. Although the surgical transplant procedure is necessarily more complex and potentially complicated, and the degree of biocompatibility of the scaffold will be critical, the hypothetical advantages of these approaches at the cellular level may prove to be important. At least two groups have developed scaffold-based RPE transplants derived from hESCs. One group developed a thin polyester membrane approximately 3×6 mm in size, upon which they cultured hESC-derived RPE cells [27]. This approach is already being tested in human patients with subretinal hemorrhages or RPE tears, two potentially catastrophic manifestations of neovascular AMD. Another team has begun clinical trials in patients with advanced dry AMD employing hESC-derived RPE sheets grown on thin Parylene membranes. Subretinal transplantation in a rat model of retinal degeneration demonstrated photoreceptor rescue with associated improvements in visual function [28].

The scalability and safety of hESC-derived RPE make it an attractive treatment strategy regardless of whether the cells are delivered as a suspension or as a monolayer supported on a scaffold. The main concern with hESC-derived cells, however, is the potential need for significant systemic immunosuppression; most adverse events reported in the pilot trials were directly attributable to the tolerability of systemic immunosuppression. Future studies must explore to what degree immunosuppression is necessary. An alternative approach for generating replacement RPE has been the use of autologous or human leukocyte antigen (HLA)-matched iPSCs to alleviate rejection concerns and the dangers of solid-organ transplant-dose immunosuppressive regimens.

Induced Pluripotent Stem Cell–Derived Retinal Pigment Epithelium

The ability to create RPE cells from iPSCs theoretically reduces the risk of immune rejection, but in actuality this and other critical safety and efficacy parameters may depend on the reprogramming technique and the cell type produced [24,29,30]. Regardless, iPSC-derived RPE transplantation holds enormous promise and several research efforts with pathways to human use are under way.

Many of the iPSC-based strategies use biocompatible scaffolds to deliver the RPE cells as a sheet (Fig. 22.4). A pioneering clinical trial using iPSC-derived RPE was approved in 2013 for study in Japan. In preclinical studies,

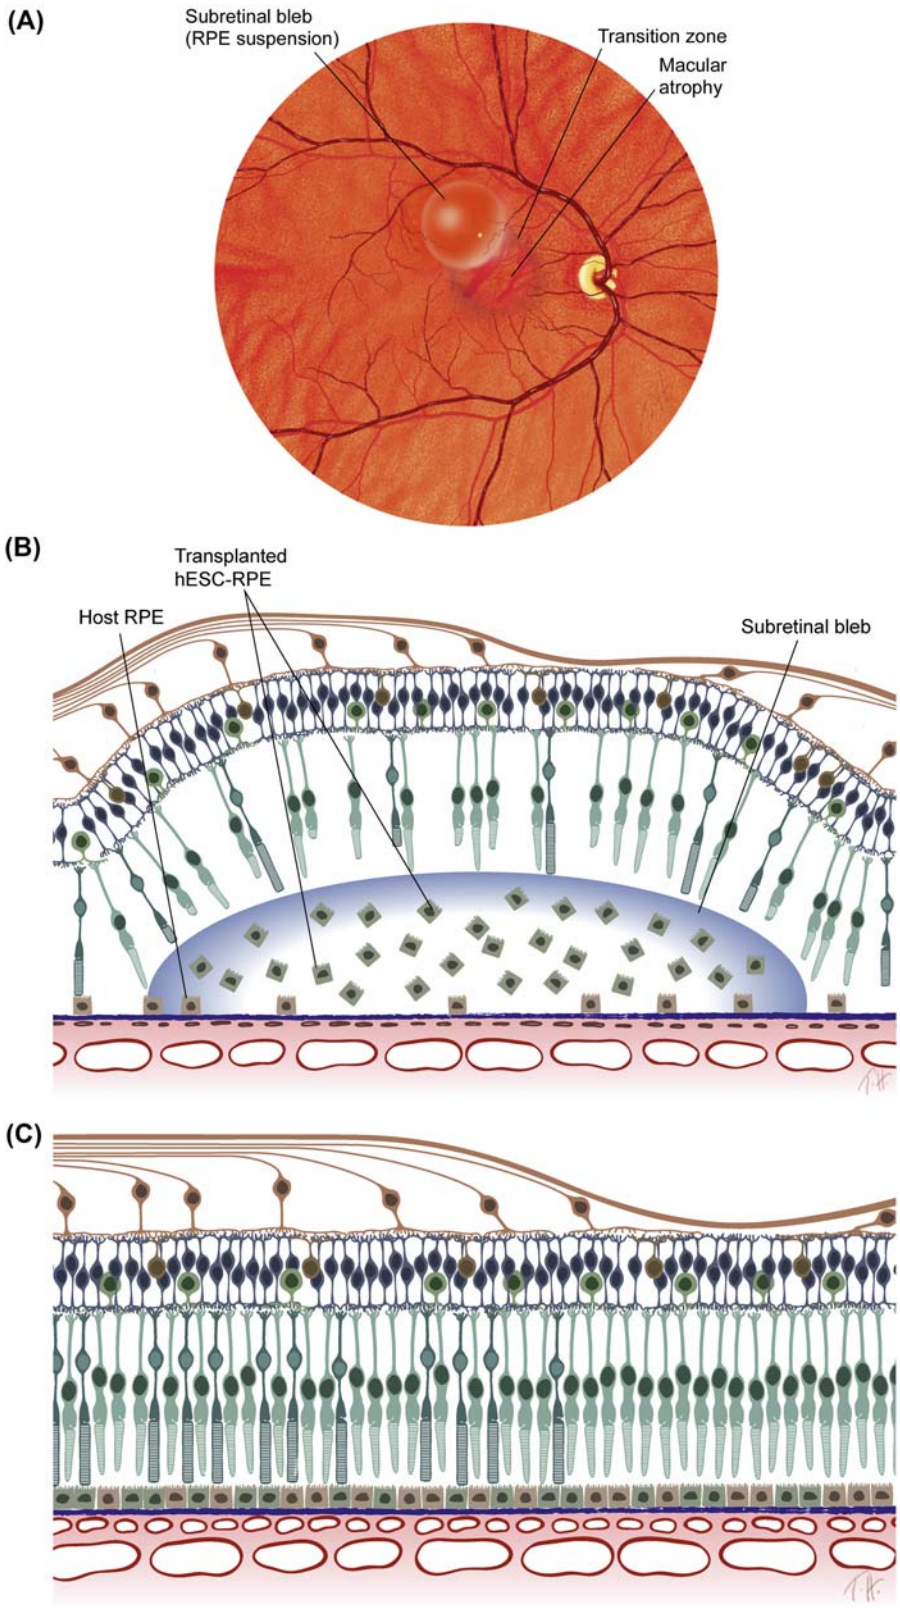

FIGURE 22.3 Schematic illustration of human embryonic stem cell–derived retinal pigment epithelium (RPE) transplanted as a suspension for macular degeneration. (A) A subretinal bleb containing a fixed volume of transplanted cells in suspension is created via a 39-gauge injection site, or retinotomy (yellow dot), in the macula. For experimental purposes, the hyperautofluorescent transition zone straddling the border of the atrophy was targeted. (B) Schematic cross-section through the bleb at the time of delivery to a diseased retina shows a suspension of transplanted human embryonic stem cell–derived RPE. (C) The ideal outcome is for the transplanted cells to survive the injection, engraft on the Bruch membrane, polarize, and then rescue or regenerate the remaining photoreceptors. *Illustration by Timothy Hengst.*

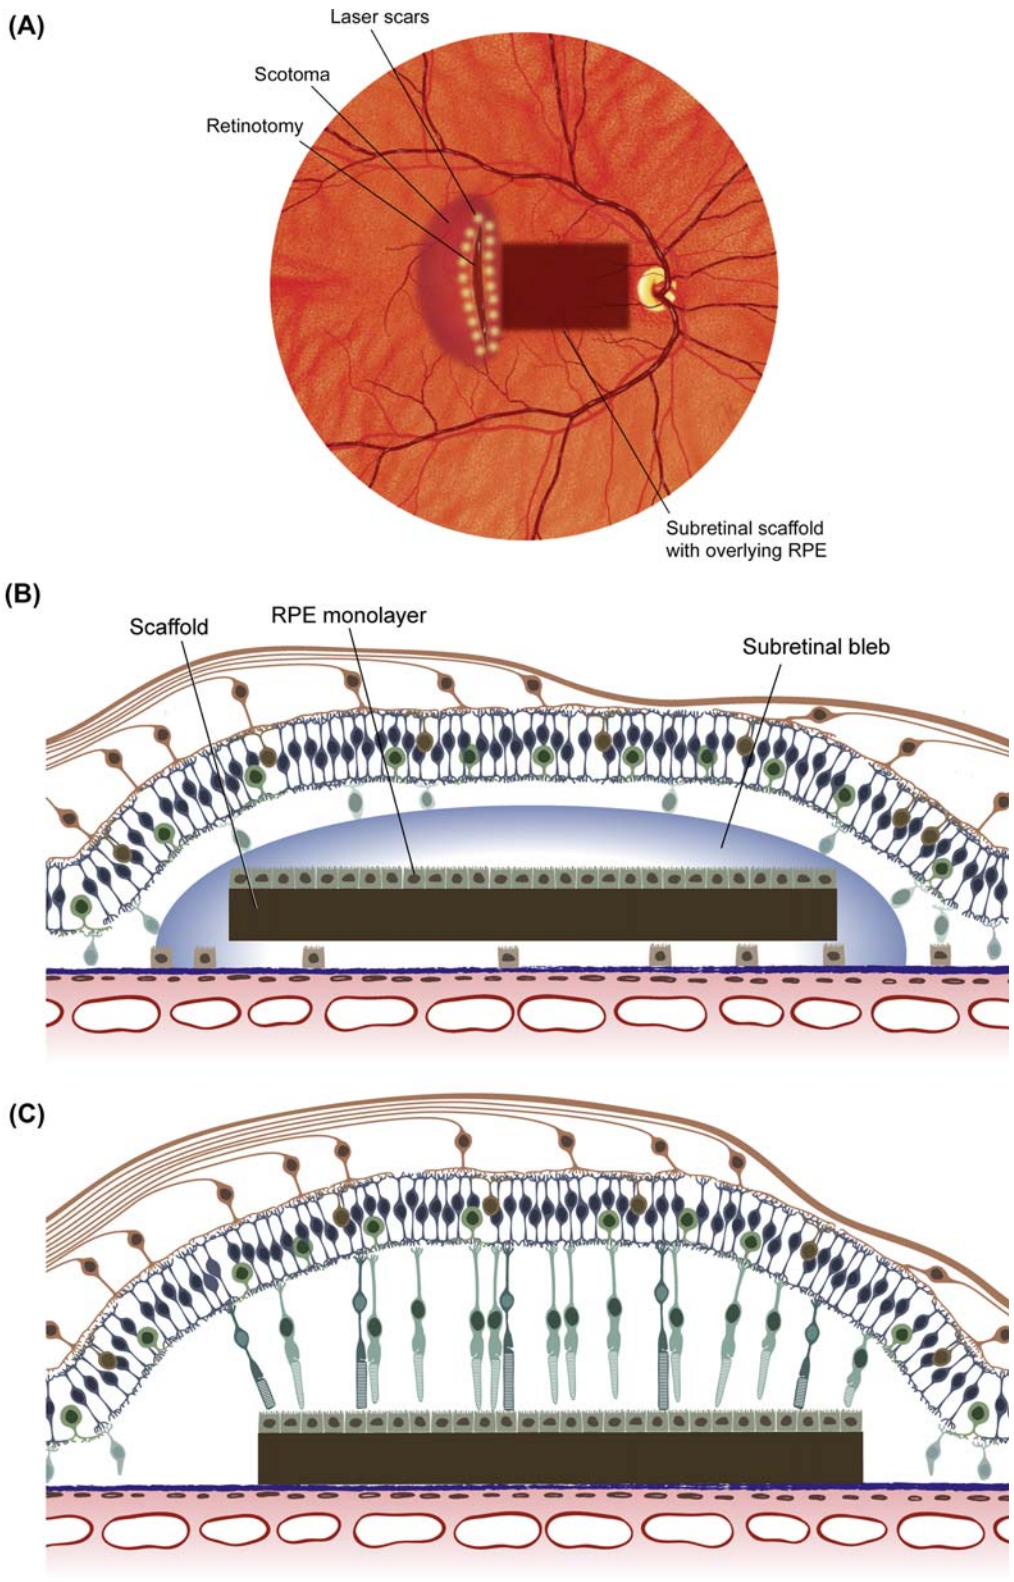

FIGURE 22.4 Schematic illustration of stem cell–derived retinal pigment epithelium (RPE) cells transplanted as a monolayer on a scaffold material. (A) The scaffold material with overlying RPE has been surgically delivered to the subretinal space. The incision in the retina (retinotomy) required to deliver the scaffold has been surgically surrounded by laser treatment to prevent postoperative retinal detachment. There is a scotoma in the nasal visual field corresponding to the crescent of injured retina including photoreceptors and ganglion cell axons. The size and thickness of the scaffold depend on design parameters. Similarly, the size of the retinotomy will vary depending on these design features and whether the scaffold and cells can be safely folded for delivery. (B) Schematic cross-section through end-stage geographic atrophy at the time of scaffold placement shows the transplanted RPE monolayer on the scaffold. (C) The ideal outcome is for the scaffold to rest directly upon the Bruch membrane and for the transplanted RPE cells to rescue the surviving photoreceptors cells. *Illustration by Timothy Hengst.*

sheets of human iPSC-derived RPE on biodegradable collagen gel scaffolds behaved like native RPE with similar gene expression profiles and functional rescue in animal models [31]. The human trials recruited patients with end-stage wet AMD and created iPSCs from skin fibroblasts. At least one patient received an autologous iPSC-derived RPE sheet, but the study was halted for safety reasons. Future work may involve the use of HLA-matched rather than autologous iPSC-derived RPE sheets owing to logistic, financial, and safety constraints.

At least two other centers are employing iPSC-derived RPE monolayers grown on a scaffold to treat GA in dry AMD. One group will use a polyester scaffold that is injected beneath the retina via a custom-designed device. Another team is developing an iPSC-derived RPE "patch" that uses a thin biodegradable poly(lactic-co-glycolic acid) (PLGA) matrix. These iPSC-RPE "patch" grafts will be delivered surgically to the subretinal space using a custom-built injector.

The use of iPSC technology to generate replacement RPE cells has the potential to mitigate the need for immunosuppressive regimens with unfavorable risk profiles, particularly in the elderly. Furthermore, the latest techniques permit the generation of xeno-free, integration-free iPSCs in clinical grade laboratory settings. Nevertheless, iPSCs are susceptible to mutations, chromosomal defects, and other transcriptional and epigenetic changes that require the implementation of stringent safety protocols. In addition, patient-derived iPSC derivatives will contain the same genetic defect, possibly precluding their use in certain disorders. However, gene-editing techniques have the potential to repair these mutations before the production of differentiated cells for autologous transplantation [32].

Scaffolds for Retinal Pigment Epithelium Transplantation

As discussed earlier, several clinical trials using stem cell–derived RPE as replacement therapy are implementing scaffold materials to deliver the cells as a monolayer. This approach has several theoretical advantages over delivery of the cells as a suspension. First, it does not require the RPE cells to engraft on a senescent Bruch membrane. Second, the cells are delivered as a monolayer, which avoids issues with cell clumping or incorrect polarization. Third, the potential is limited for the RPE cells to reflux into the vitreous cavity during surgical delivery. Despite these advantages, the delivery of RPE on a scaffold to the subretinal space requires more challenging surgical manipulations and a larger opening into the retina, both of which can result in serious vision-threatening complications. Furthermore, the biocompatibility of the scaffold material is a complex and critical issue because the scaffold must not only support cells at the time of the transplant, it must subsequently allow for physiologic processes to proceed unchecked between the RPE and the choriocapillaris. As such, the permeability of the scaffold material is critical to its success if it is not engineered to dissolve. It is still unclear which if any of these approaches will prove safe and effective, but research into scaffold materials is progressing rapidly with a wide variety of materials available.

Scaffold materials can have a broad array of characteristics including biodegradability, thickness, stiffness, and permeability. The materials themselves can be natural in the case of human donor tissue or entirely synthetic with additional surface coatings and microfabrication techniques to increase porosity or cell adhesion. Natural materials are derived from donor tissue or biologic molecules meant to simulate the properties of the Bruch membrane. These include anterior lens capsule, amniotic membrane, and biodegradable gelatin, collagen, and hyaluronate gel films. Aside from difficulties in fabricating these materials consistently, the materials are allogeneic and possibly even animal-derived, which poses immunogenicity and safety concerns. Nevertheless, the group at Riken in Japan transplanted autologous iPSC-derived RPE on a collagen gel scaffold into at least one patient [33].

Synthetic materials have a wide range of physical properties that can be leveraged to maximize RPE engraftment, permeability, and stability during subretinal delivery. Nonbiodegradable synthetic materials include Parylene, polymethyl methacrylate, and polyester. Ultrathin Parylene-C sheets (0.4 μm thick) are nonimmunogenic and mimic the permeability properties of the Bruch membrane. Sheets of hESC-derived RPE grown on micromachined sheets of vitronectin-coated Parylene have been used in pig and rat models with favorable cellular survival and safety at 3–6 months after transplantation [28,34]. An alternative material being used in human and animal studies is permeable polyester because of its strength and flexibility characteristics [27]. The biodegradable polymers such PLGA, poly(l-lactic-co-citric acid), and poly(ε-caprolactone) are potentially advantageous in that their fiber density, degradation rate, and thickness can be manipulated to achieve maximal RPE engraftment, survival, and polarization. For example, ratios of PLGA and poly(lactic acid) can be manipulated to achieve favorable porosity, degradation kinetics, and thickness, and various protein coatings such as laminins can be applied to improve RPE adhesion and survival [35]. A potential downside to these degradable scaffolds is that the materials could incite inflammation upon dissolution or that the survival of the transplanted cells would be compromised once they rest directly on the Bruch membrane. Furthermore, if any features of the scaffold become compromised during production or

transplantation, the functionality and survival of the transplanted cells may also be compromised. In essence, the scaffold itself represents a critical second variable to be considered as these programs move toward regulatory consideration.

Surgical Techniques for Retinal Pigment Epithelium Transplantation

Several surgical approaches can be employed to deliver the RPE cells. The procedure to deliver the cells must be carried out with acceptably low risk to the eye, regardless of the safety and efficacy of the transplanted cells themselves. For the delivery of RPE cells to the subretinal space, the least challenging surgical technique is injection of a cellular suspension via a subretinal cannula. This approach was used in the initial phase I/II studies of hESC-derived RPE for AMD and STGD [26]. It requires a standard three-port pars plana vitrectomy to be performed followed by insertion of a 38-gauge subretinal cannula through the retina (retinotomy) to deliver the cells into the subretinal space, raising a subretinal bleb. After the procedure, the bleb slowly flattens over a few hours as the fluid is absorbed; it is hypothesized that the RPE cells that survive the procedure may subsequently engraft and polarize. Theoretical surgical advantages to this approach are that the small retinotomy used to inject the cells seals spontaneously with little or no risk of subsequent retinal detachment and no discernible secondary scotoma formation from disruption of retinal tissue, and that it relies on skills with which most vitreoretinal surgeons are comfortable.

An alternative, more complex surgical approach must be used when delivering RPE sheets grown on a scaffold material. For the RPE sheet to be delivered in an atraumatic fashion, a large retinotomy must be made adjacent to the macula and a specialized delivery device must be employed to inject the scaffold. The size of the retinotomy depends on the dimensions of the scaffold and whether the material is foldable, but in general this will require the use of laser photocoagulation combined with a tamponade agent such as silicone oil to seal the retinal incision at the end of the surgery to keep the retina attached. Therefore, these techniques come with an increased risk for retinal detachment and a larger, potentially clinically significant scotoma associated with the retinotomy site and surrounding laser scars. Other potential downsides include the possibility the scaffold could be implanted upside down or that the cells slough off during insertion, although these risks should be mitigated with a short surgical learning curve.

A third method for subretinal delivery of cells is *ab externo* via a cannula that passes through the subretinal or suprachoroidal space. These techniques were pioneered in a trial studying delivery of human umbilical tissue-derived cells to the macula. (Note that these cells were not differentiated into retinal cell types but were instead intended to serve as neuroprotective cytokine-secreting cells.) This was necessary because initial trials using a standard vitrectomy with subretinal injection of a cellular suspension led to severe proliferative vitreoretinopathy (scarring on the retinal surface with subsequent contraction and complex retinal detachment) if any cells were exposed to the vitreous cavity. Thus, this alternative approach theoretically avoids the vitreous cavity by performing a scleral cutdown followed by insertion of a microcatheter into the subretinal space. However, the technique was plagued by difficulties including an inability to control the cannula tip and the creation of inadvertent retinal perforations. The refined methodology involves threading the cannula through the suprachoroidal space toward the macula. A microneedle is then extended under direct visualization into the subretinal space and the cells are delivered. This approach is promising but requires novel, nonstandard surgical techniques.

Regardless of the technique used, the transplant site must be carefully chosen on a case-by-case basis. The first patients to undergo hESC-derived RPE transplants received the cells in the peripheral macula owing to the large area of central atrophy and to avoid detaching the fovea. Subsequent transplantations occurred at the transition zone between the atrophic retina and the relatively healthy retina, an area with compromised but still viable RPE and photoreceptors. The preferred transplantation site for RPE cells on a scaffold may be within an area of atrophy, but RPE survival and function are questionable given the extent of photoreceptor and choriocapillaris loss [36]. Further study is necessary to determine where on the spectrum of disease the ideal candidates for cellular therapy will reside, although it seems likely that treating patients earlier in the course of disease will prove beneficial.

Photoreceptor Transplantation

Photoreceptor cell transplantation represents a possible treatment strategy for retinal dystrophies such as RP. As for RPE transplantation, the use of stem cell–derived photoreceptors to replace lost cells is advantageous in that it can be used in advanced cases and across many forms of the disease, regardless of the underlying genetic defect. However, the transplanted photoreceptor cells must integrate into the photoreceptor layer, form appropriate synapses, and extend outer segments toward the apical processes of the RPE. These requirements may be hampered by

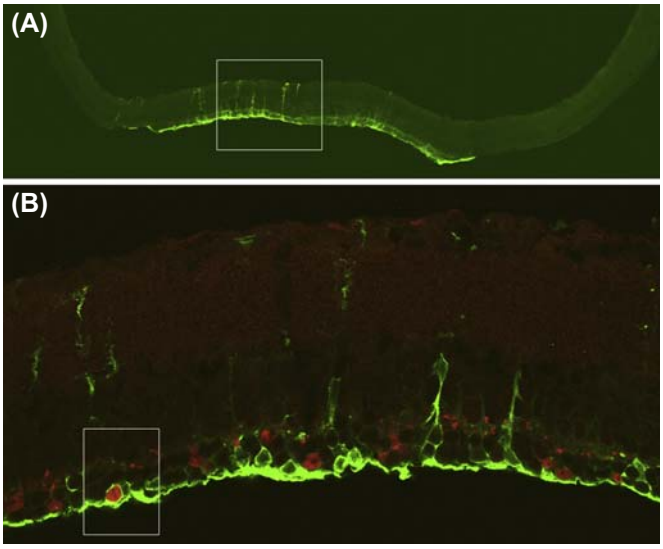

FIGURE 22.5 Integration and survival of transplanted human embryonic stem cell–derived retinal cells in Crx-deficient mice, a model of retinal degeneration. The transplanted cells (green) are found in the outer retina and some express recoverin (red), a photoreceptor marker. *Reprinted from Lamba DA, Gust J, Reh TA. Transplantation of human embryonic stem cell-derived photoreceptors restores some visual function in Crx-deficient mice. Cell Stem Cell 2009;4(1):73–9, Copyright (2009), with permission from Elsevier.*

ongoing cellular dysfunction, apoptosis, and inflammation in the disease state. As is the case for RPE transplantation, early intervention may provide the best opportunity for favorable anatomic and functional outcomes.

Several groups have published encouraging results in preclinical animal models of RP. MacLaren et al. demonstrated that mouse RPCs can be transplanted successfully into a mouse model of rod degeneration with the restoration of synaptic connectivity and light sensitivity [37]. The limited availability of human retinal tissue precludes the use of this approach in human clinical trials, but hESC-derived retinal progenitors can also integrate into the photoreceptor layer, form synapses, and partially rescue visual function in a mouse model of early-onset RP (Fig. 22.5) [38]. Investigators have migrated toward using photoreceptor precursors derived from three-dimensional rather than two-dimensional culture methods as a way to enhance the developmental verisimilitude of the transplanted cells [39]. In addition, sheets of developing three-dimensional retina cut out from iPSC-derived optic vesicle-like structures have been transplanted beneath the retina in diseased mice with evidence of photoreceptor integration and functional improvement [40,41].

Although efforts to transplant photoreceptors lag behind the RPE, advances in culture methods and promising results in animal models will make human photoreceptor transplantation studies a reality. Whether the transplanted cells can be delivered in sufficient quantities to improve visual function significantly and delay or even halt ongoing cellular loss in the disease state remains to be seen [42].

CELL-BASED NEUROPROTECTION

In addition to serving as a source of replacement cells, stem cells are being studied for neuroprotection and neurotrophic support. This strategy relies on the transplanted cells to secrete neurotrophic factors that halt ongoing pathologic processes including apoptosis and thus sustain the surviving tissues. A potential advantage to this approach is that the final cell product does not require the production of terminally differentiated cells from pluripotent stem cells. For example, bone marrow–derived hematopoietic stem cells can be harvested from the patient, purified, and transplanted in an autologous fashion without the need for systemic immunosuppression. Even allogeneic transplantation of other stem cells such as umbilical tissue-derived stem cells may not require immunosuppression. Furthermore, because the cells are functioning via a paracrine effect, it may be sufficient to deliver the cells in proximity to the target tissue, such as the vitreous cavity. Potential disadvantages to this approach include local off-target effects such as proliferative vitreoretinopathy and the need for repeated dosing.

Bone Marrow–Derived Stem Cells

Traditionally, two types of bone marrow–derived stem cells (BM-SCs) have been described (mesenchymal and hematopoietic) and both are being tested to treat retinal disease [43]. These cells must be harvested by bone marrow aspiration but they can be then used in an autologous fashion. Whether these transplanted cells integrate and differentiate into retinal cell types has not been clearly established, and it appears that the benefit more likely derives from the paracrine effect of secreted cytokines [43]. Hematopoietic $CD34^+$ stem cells are multipotent adult stem cells capable of self-renewal; they have been extensively characterized for use in hematologic disorders. Studies in several rodent models of retinal degeneration have shown a protective effect of human adult hematopoietic stem cells delivered via intravitreal injection [44,45]. The other bone marrow cell type, the so-called mesenchymal stem cells, have elicited controversy because this cell population may not have stem cell properties and instead represents committed multipotent progenitor cells [46]. Mesenchymal cells have been delivered beneath the retina with favorable initial results in animal models [47,48].

Anatomic and functional improvements observed in these animal models of retinal degeneration have spurred various sites to initiate clinical trials in humans using BM-SCs. Initial experience with autologous $CD34^+$ BM-SCs in human patients with RP demonstrated no adverse effects from the intravitreally delivered cells [49]. A subsequent study in patients with a variety of retinal conditions including retinal vascular disease, AMD, and inherited retinal disorders also showed no detrimental effects of the cells [50]. Convincing evidence is lacking that the cells provide a functional and anatomic benefit, however.

Umbilical Tissue-Derived Stem Cells

hUTCs are isolated from digested human umbilical cord tissue and can be tested extensively before use. Although they are allogeneic, there is evidence the cells may be minimally immunogenic with no expression of major histocompatibility complex (MHC) class II and lower expression of MHC class I [51]. The therapeutic benefit is thought to derive from the strong extracellular secretion of several trophic cytokines such as brain-derived growth factor, hepatocyte growth factor, and glial cell-derived neurotrophic factor [52]. Subretinal delivery of hUTCs in a rodent model of retinal degeneration led to improvements in visual function compared with untreated animals [53].

The functional benefit of hUTCs in AMD or RP remains to be established, but human trials are underway. The initial pilot study in patients with advanced RP delivered the hUTCs to the subretinal space via pars plana vitrectomy, but this approach was abandoned owing to concerns for epiretinal membrane formation and proliferative vitreoretinopathy. Follow-up studies are instead using a novel *ab externo* delivery system in patients with advanced dry AMD.

Neural and Retinal Progenitor Cells

Neural progenitor cells (NPCs) and RPCs are being evaluated as a treatment for atrophic AMD and photoreceptor degenerations such as RP. Both cell types are sourced from human fetal tissue, which may raise ethical concerns. In a rat retinal degeneration model, subretinally delivered NPCs persisted for months and improved visual function remarkably [54]. Transplanted mouse RPCs may even integrate and differentiate into photoreceptor-like cells in the correct retinal layer with expression of photoreceptor markers [55]. Human clinical trials using NPCs and RPCs are under way, and it may be possible in future trials to generate these cells from pluripotent stem cells [56,57].

DISEASE-IN-A-DISH MODELING FOR RETINAL DISORDERS

Efforts to treat retinal disease with cellular therapy represent an important application of stem cell technology. Some of these same techniques can also be used to model human retinal disorders in vitro in a patient-specific manner and even serve as a platform for testing customized therapeutic agents. Stem cells derived from skin fibroblasts or peripheral leukocytes can be differentiated into various retinal cell types and can even be coaxed into forming three-dimensional optic vesicle-like structures with a multilaminar architecture reminiscent of the human fetal retina.

Induced Pluripotent Stem Cell–Based Phenotyping

Traditionally, the study of human disease has occurred in animal models to allow for detailed molecular, genetic, cellular, and developmental analysis. However, it is common for animal models of retinal disease to recapitulate the human state only partially, or in some cases fail to do so entirely [58]. Human iPSCs serve as a promising tool to model disorders of the RPE and other retinal cell types [59]. This approach not only eliminates issues with cross-species differences and the expense of laboratory animals, it allows for the creation of patient-specific cell lines containing the precise genetic mutation in the same genomic milieu.

The first "disease-in-a-dish" model for a retinal disorder was created using iPSCs from patients with RP [60]. In this study, five iPSC lines were created from five patients with distinct causative mutations. Photoreceptors differentiated from these lines showed accelerated degeneration compared with controls, and application of the antioxidant vitamin E had a differential effect depending on the causative gene. This demonstrated the utility of patient-derived iPSC lines for modeling human disease and testing therapeutics in a customized fashion. Another study created iPSC-derived RPE cells from patients with Best vitelliform macular dystrophy [61]. Photoreceptor outer segment degradation was impaired in these RPE cells, leading to oxidative stress. Furthermore, iPSC-derived cells can be used to verify the pathogenicity of previously undiscovered mutations. This approach has been used to determine the pathogenic mechanism of novel disease-causing variants, such as a cryptic splice site mutation in the RPE65 gene [62] and a splice site mutation in USH2A [63].

Disease-in-a-dish modeling has also been employed to validate a variety of treatments such as small molecule therapeutics, gene therapy, and gene editing. iPSC-derived RPE cells have been subjected to chronic oxidative stress to simulate AMD [64] and then treated with various compounds that reduce oxidative stress [65]. A similar approach was used to test the effects of vitamin B6 supplementation in gyrate atrophy [66] and inhibitors of endoplasmic reticulum stress in RP [67,68].

Gene delivery via viral vector to patient-derived iPSC lines can also be used in preclinical studies, especially when animal models do not recapitulate the phenotype. Choroideremia is an inherited condition resulting from mutations in the REP1 gene that lead to degeneration of the choriocapillaris, RPE, and retina. The mouse knockout is lethal, but viral gene delivery rescued REP1 function in iPSCs derived from patients with choroideremia [69]. This approach has also been used in several other iPSC-based disease models including MFRP-mutant RP [70], CEP290-mutant Leber congenital amaurosis [71], and CLN3-mutant Batten disease [72].

Genome engineering represents a promising avenue to augment these treatment strategies [73]. Gene editing can correct a specific mutation in situ so that the wild-type gene is expressed under the endogenous promoter and avoids issues with size limits on genes delivered via viral vector. This rapidly evolving technology has been applied in two studies that show the feasibility of clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 gene targeting in rodent eyes via intravitreal [74] and subretinal delivery approaches [75]. Eventually, it may even be possible to differentiate gene-edited iPSCs into a particular retinal cell type and then transplant the differentiated cells autologously in humans.

Three-Dimensional Retinal Organoids

The ability to generate complex human tissues that resemble organs in vitro has generated excitement within the field of regenerative medicine [76]. Eiraku et al. first demonstrated the capacity of mouse ESCs to form self-organizing optic vesicle-like structures containing all major cell types of the retina including photoreceptors, bipolar cells, and ganglion cells in a laminar arrangement [77]. This landmark publication set the stage for future refinements including the use of human iPSC (Fig. 22.6) [78,79], the demonstration of beautifully arranged functional photoreceptors [80], and technique modifications to accelerate the process [81]. Despite these advances, the process of culturing human retinal organoids can be labor-intensive and produce variable results and has yet to recapitulate important components of the retina including the optic nerve and vessels, for example.

Besides their use in the modeling of human retinal development and disease, three-dimensional retinal organoids may also be used as a source of replacement cells for diseases such as dry AMD and RP. It is possible that the generation of replacement cells in this fashion may provide more biologically authentic cells because their development occurred in a three-dimensional environment adjacent to other neuroretinal cells. Rod photoreceptors generated via a three-dimensional culture protocol have been dissociated and then injected beneath the retina in a mouse model of rod degeneration with evidence of functional integration into the host retina [39]. Another approach is to transplant entire sheets of stem cell–derived retinal tissue. Mouse ESC- and iPSC-derived retinal sheets transplanted into an RP mouse model can reconstitute the photoreceptor layer and form synapses in the outer plexiform layer [41]. There is also evidence these transplanted sheets elicit light-dependent behaviors and electrophysiologic responses [40].

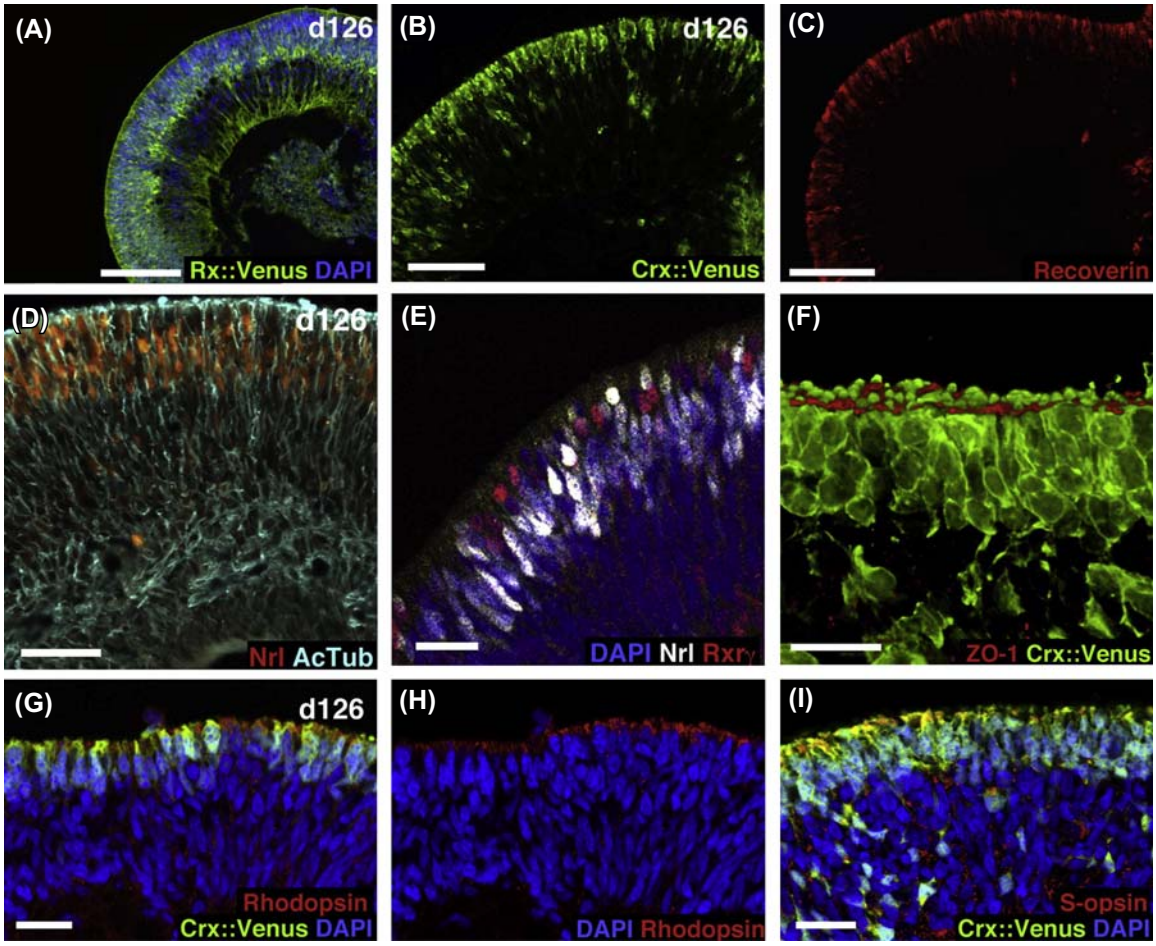

FIGURE 22.6 Self-organizing optic vesicle-like structures derived from human embryonic stem cells display remarkable complexity. The neuroretinal epithelium is multilayered and contains densely packed photoreceptors (recoverin$^+$) along the apical side. Rods (Nrl$^+$) and cones (Rxr-γ^+) are present with ZO-1$^+$ apical junctions. The visual pigments rhodopsin and S-opsin are expressed along the apical surface, but outer segments do not form. *Reprinted from Nakano T et al. Self-formation of optic cups and storable stratified neural retina from human ESCs. Cell Stem Cell 2012;10(6):771–85, Copyright (2012), with permission from Elsevier.*

CONCLUSION

Research in regenerative medicine is accelerating at a remarkable pace owing to the exceptional promise it holds for understanding and potentially treating a variety of medical disorders, many of which are currently untreatable. This is especially true for diseases of the retina. The next revolution in retina may be driven by novel gene and cell delivery approaches, both of which benefit from advances in stem cell technology.

The ideal treatment is one that restores the anatomical and functional integrity of the retina with minimal risk to the eye and to the patient. Although advances have been made and many more are imminent, there is much work to be done. The use of systemic immunosuppression carries significant risk, especially in the elderly population. Surgical delivery techniques need to be refined to minimize iatrogenic complications. Autologous iPSC-derived cells may reduce the risk of rejection, but they are costly and associated with a risk of mutations and chromosomal anomalies. Some of these issues may be resolved by ongoing initiatives such as the creation of HLA-matched iPSC banks and optimizing scaffold materials to simplify the surgical delivery. Nevertheless, other hurdles remain, such as the reconstitution of synaptic connectivity after cell replacement and the functional recovery of end-stage GA in which multiple layers have degenerated.

The future of stem cell–based treatments in the eye will rely heavily on tissue engineering approaches, such as three-dimensional microfabrication of scaffolds populated with various retinal cell types in a laminar arrangement. This could include the creation of a capillary network populated with iPSC-derived endothelial cells [82]. Many of these treatments could emerge from improvements in cell differentiation protocols and retinal organoid technology.

Despite the obstacles that lie ahead, there is substantial optimism for cell-based therapies in the retina. Several clinical trials using stem cell−derived treatments are either under way or due to begin within the next few years. The ability to recapitulate human retinal development in culture using patient-derived pluripotent stem cells may also generate deep insights into the pathophysiology of retinal disease. It is hoped that these advances will not only provide cures for untreatable blindness but also lead the way for neurodegenerative disease and the entire field of regenerative medicine.

Stem Cells for Traumatic Brain Injury

Christopher M. Schneider, Margaret L. Jackson, Supinder S. Bedi, Charles S. Cox, Jr.

McGovern Medical School at the University of Texas Health Science Center at Houston, Houston, TX, United States

INTRODUCTION

Epidemiology

Traumatic brain injury (TBI) is a leading cause of death and disability in the United States. Approximately 1.5 million people experience a TBI yearly in the United States. The Centers for Disease Control and Prevention (CDC) estimate that 275,000 people are hospitalized annually as a result of a TBI. The yearly TBI mortality rate exceeds 50,000 and it is responsible for 30% of all injury-related deaths [1]. In addition, TBI is the leading cause of death in children and adolescents. Surviving patients have varying levels of long term-sequela. Overall, 6.5 million patients are burdened by the physical, cognitive, and psychosocial deficits associated with TBI, leading to a total economic impact of approximately $76.3 billion in medical costs and lost wages [2].

The CDC collects data on TBI mechanisms of injury and trends in patient outcomes. Fig. 23.1 illustrates the leading causes of TBI in the United States from 2006 to 2010. Falls were the leading cause of TBI, accounting for 40% of all

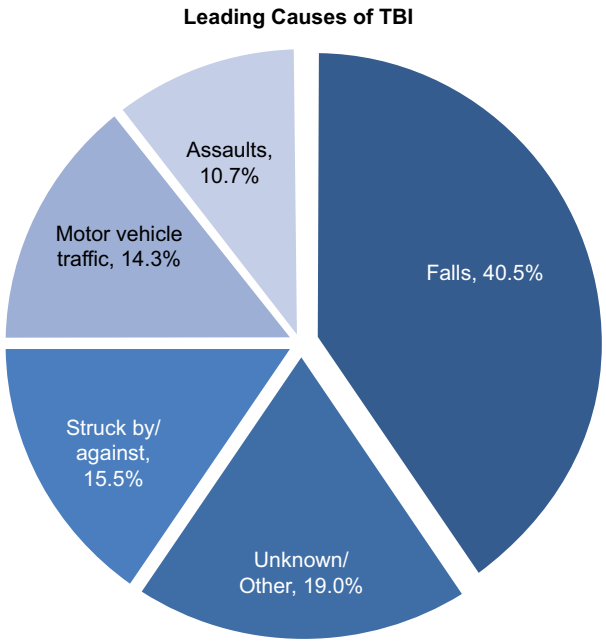

FIGURE 23.1 Centers for Disease Control and Prevention (https://www.cdc.gov/traumaticbraininjury/get_the_facts.html) pie chart demonstrating the most common causes of traumatic brain injury (TBI) in the United States from 2006 to 2010. Falls were the leading cause, followed by unintentional blunt trauma, motor vehicle accidents, and assaults.

injuries that resulted in an emergency department visit, hospitalization, or death. Unintentional blunt trauma (being hit by an object) was the second leading cause, accounting for 15% of TBIs, followed by motor vehicle accidents, which made up 14%, and finally, assaults at 10%. TBI-related emergency department visits increased by 70% from 2001 to 2010. However, the death rate during this period decreased by 7%, largely owing to postinjury supportive care that focuses on modulating intracranial pressure (ICP) and cerebral perfusion pressure (CPP). Unfortunately, this medical management of TBI is still merely supportive care that focuses on preventing further damage without the ability to restore function.

Classification of Traumatic Brain Injury

Development of successful TBI treatments requires a clear classification of brain injury severity. Multiple clinical scoring systems have been used to classify TBI. The Glasgow Coma Scale (GCS) has been adopted to assess TBI severity and is now one of the most used scoring systems. The GCS gives a clinical score based on the patient's ability to open his or her eyes, communicate, and follow motor commands. The scale ranges from 3 to 15; GCS scores of 3–8 are classified as severe TBI, scores of 9–12 are classified as moderate TBI, and scores of 13–15 are classified as mild TBI. The abbreviated injury scale and injury severity score are additional criteria to stratify TBI based on anatomic injury, which are often available only late into a clinical course.

Several imaging classifications have been developed as an adjunct to scoring TBI severity. The Marshall classification of TBI is a computed tomography (CT) scan-derived prognostic metric that places patients into one of six categories of increasing severity. The scoring system is primarily concerned with the degree of swelling (midline shift and/or compression of basal cisterns) and the presence or size of contusions and hemorrhages. It has been able to predict both the risk of increased ICP and outcomes in adult patients with TBI [3]. Limitations of the Marshall classification system include difficulty categorizing patients with multiple injury types and standardization of certain features of the CT scan [4]. The more recently developed Rotterdam CT score of TBI includes four independently scored elements: basal cistern compression, midline shift, epidural hematomas (EDH), and intraventricular blood or traumatic subarachnoid hemorrhage (SAH) [5]. The Rotterdam scoring system may become a more preferable imaging measure of TBI severity after further validation.

Identifying biomarkers for TBI could have many potential applications in the way TBI is diagnosed and treated. A point of care test could identify TBI early and assist in the initial stages of management. Other biomarkers could serve to highlight the specific neuropathophysiology behind the injury or even injury severity. With regard to stem cell therapeutics for brain injury, a biomarker could be used in the acute and chronic stages of TBI to follow the response to different therapeutic interventions. A literature review performed in 2016 examined 12 biomarkers (S100β, glial fibrillary acidic protein [GFAP], ubiquitin C-terminal hydrolase-L1, neuron-specific enolase, neurofilaments, myelin basic protein, spectrin breakdown products, Tau, microtubule-associated protein 2, amyloid β, cytokines such as tumor necrosis factor-α (TNF-α), and interleukin (IL)-6, and autoantibodies against brain proteins such as GFAP) that have been studied to diagnose TBI [6]. The review found that nearly all 12 biomarkers were rapidly elevated after injury and may serve as a diagnostic tool. Although not specific for TBI, the negative predictive value of the biomarkers could be a clinical tool to rule out a brain injury. Although the clinical use of biomarkers in TBI is still in its infancy, the potential for broad clinical application is promising and many clinical trials are ongoing.

PHASES OF BRAIN INJURY

Primary Versus Secondary Brain Injury

TBI is divided into two distinct phases: "primary" and "secondary" brain injuries. The primary injury occurs at the time of the trauma, when energy is dissipated within the substance of the brain, either from a closed blunt injury or a penetrating wound. The primary injury is irreversible and includes direct neuronal, glial, and vascular disruption. The primary injury may be caused by contusions, shear injuries, or compression from hemorrhage. Contusions can occur under fracture sites, the point of impact (coup contusion), or at regions distant from the initial impact (contrecoup contusion). Shear injury, often referred to as diffuse axonal injury, occurs when axons tear as the brain shifts and rotates inside the bony skull. Hematomas and hemorrhages are classified by location within the brain. EDH are often caused by temporal bone skull fractures that lacerate the middle meningeal artery. EDH can develop into large, lens-shaped, extraaxial hematomas that compress the brain parenchyma and increase ICP. Subdural hematomas are found between the dura and arachnoid mater from tearing of the bridging veins in this subdural space. Large

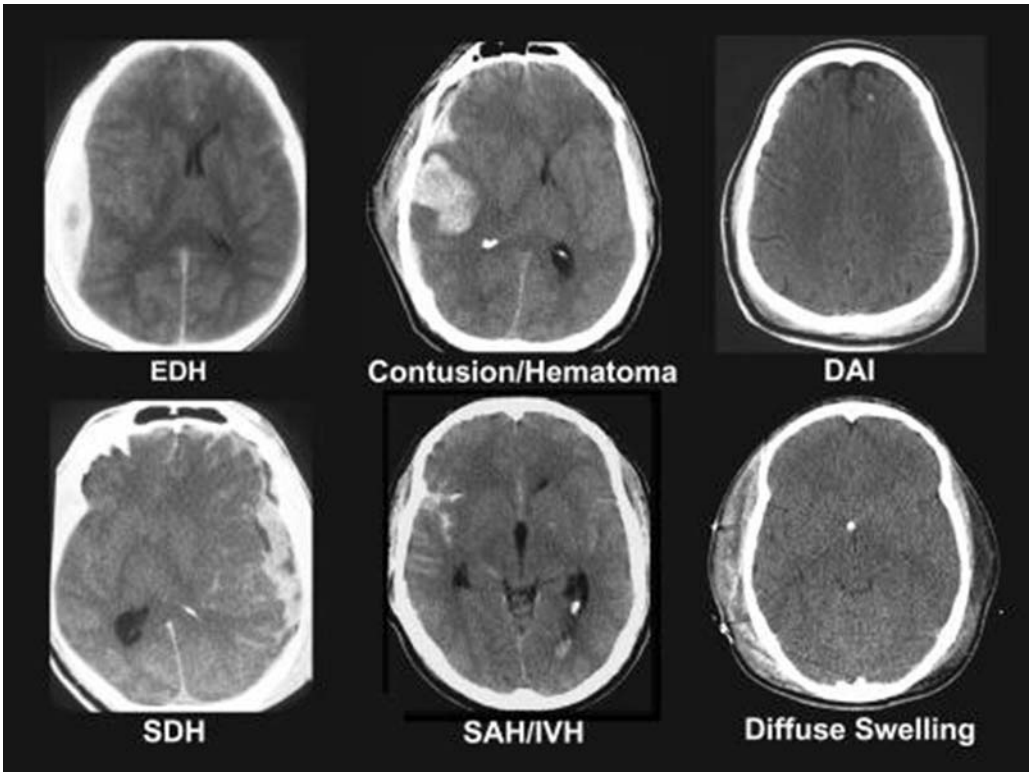

FIGURE 23.2 Different types of traumatic brain hemorrhages. *DAI*, diffuse axonal injury; *EDH*, epidural hematoma; *IVH*, intraventricular hemorrhage; *SAH*, subarachnoid hemorrhage; *SDH*, subdural hematoma.

crescent-shaped blood collections can lead to an elevated ICP and uncal herniation. SAH is bleeding between the arachnoid and pia mater. Patients with SAH can develop cerebral vasospasm, which worsens further ischemic injuries (Fig. 23.2).

The second phase of TBI begins hours after the trauma and can last decades after the initial injury [7]. Secondary injuries are the result of biochemical events that may accelerate initial cellular injury or cause new injury altogether [8,9]. The effects of secondary brain injury are caused by increased neuronal excitotoxicity, disturbances in ionic homeostasis, neuronal apoptosis, and the initiation of inflammatory and immune responses. Secondary injury mechanisms are cumulative and create a toxic local environment around the site of injury. The resulting increase in blood–brain barrier (BBB) permeability and the ensuing cerebral edema serve to amplify the neuroinflammatory signal by exacerbating the initial ischemic injury.

Neuroinflammation

TBI increases neuronal excitotoxicity and prompts disturbances in ionic homeostasis that contribute to secondary neuronal cell injury. Both human and animal models have found elevated levels of the excitatory amino acid glutamate in the brain after TBI [10,11]. Increased glutamate levels lead to neuronal excitotoxicity and a resulting hypermetabolic state. Positron-emission tomography (PET) imaging in patients with severe TBI found hyperglycolysis regionally at the site of injury and diffusely throughout the cerebrum [12]. Hyperglycolysis leads to the depletion of neuronal cell adenosine triphosphate stores and resultant disturbances in ionic homeostasis resulting from active ion pump failure. Electrochemical equilibrium across the neuron is lost owing to inactivation of the Na^+/K^+ pump and activation of ion channels by the increased glutamate levels. A massive intracellular influx of calcium occurs leading to calpain-mediated spectrin proteolysis triggering increased levels of membrane breakdown and axonal injury. These pathways result in the sustained secretion of proinflammatory cytokines and cytotoxic molecules from the damaged neurons. Fig. 23.3 demonstrates elevated intracerebral proinflammatory cytokines identified in specific areas and at specific time points relative to a TBI carried out in a rodent model using a controlled cortical impact (CCI) injury [13].

Central to the secondary inflammatory responses to TBI are microglia, the macrophages of the central nervous system (CNS) [14]. Consistent with their role as CNS macrophages, microglia are responsible for clearing dead cells

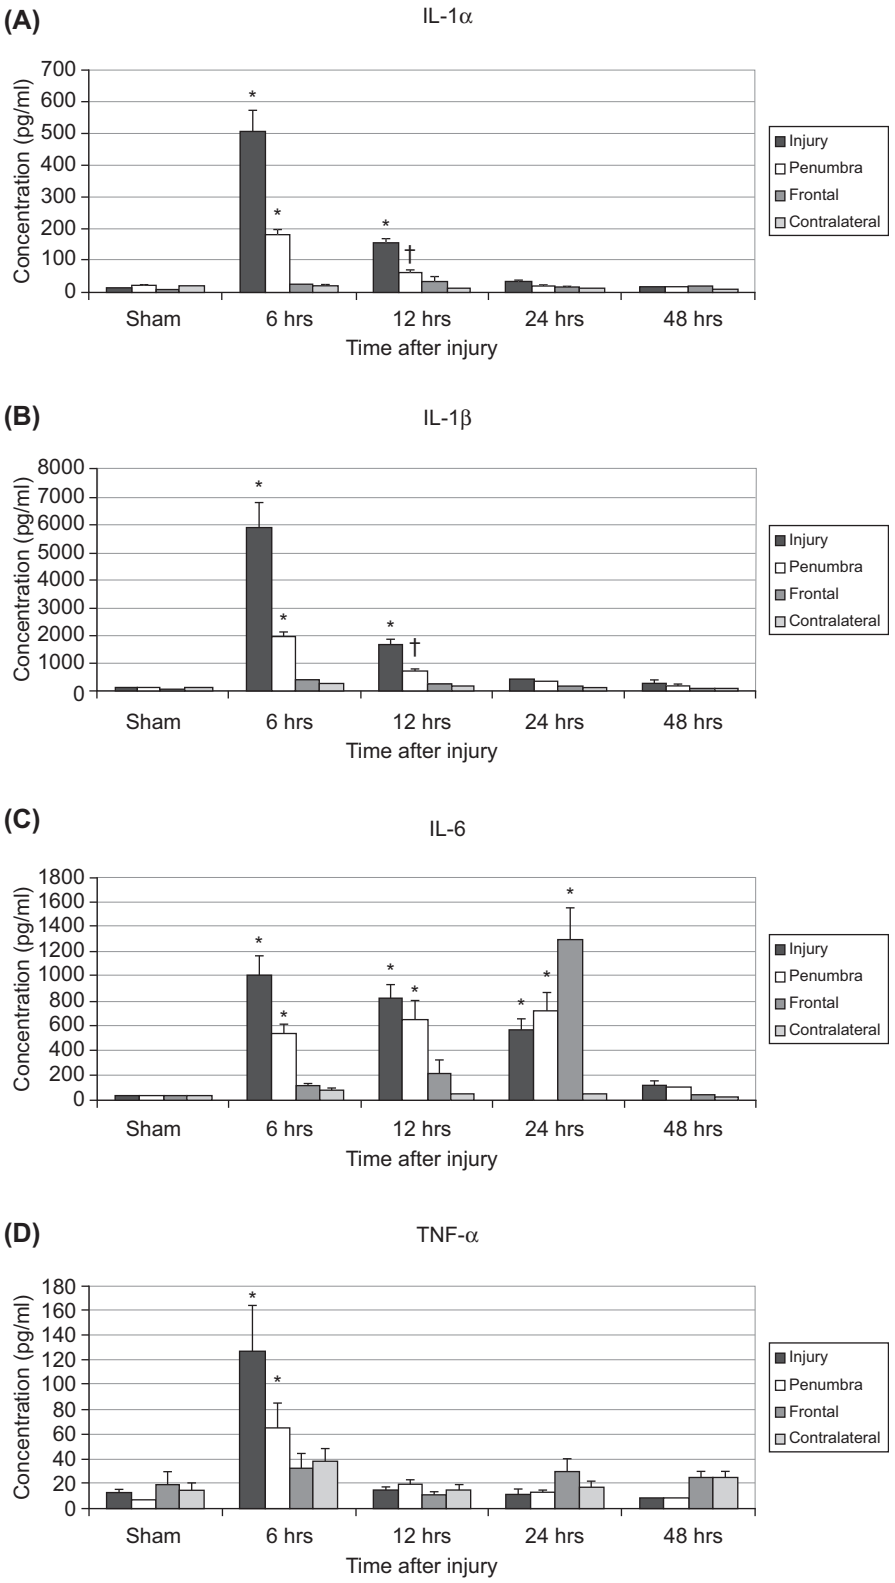

FIGURE 23.3 Elevated intracerebral cytokines identified in specific areas and at specific times relative to the traumatic brain injury (TBI). The proinflammatory cytokines interleukin (IL)-1α (A), IL-1β (B), and IL-6 (C) and tumor necrosis factor (TNF)-α (D) were significantly elevated 6 hours after controlled cortical impact in the injury and penumbral regions compared with sham animals (*$P < .01$ for all). IL-1α, IL-1β, and IL-6 remained elevated through 12, 12, and 24 h, respectively (*$P < .01$ or $^{\dagger}P < .05$). In the frontal area, IL-6 was significantly increased at 24 h (33- to 50-fold, $P < .01$, Dunnett test), but not at 6 or 12 h after TBI.

and other debris such as astrocytes and myelin. Under homeostasis, microglia are highly mobile and provide continuous surveillance of their cellular milieu (M0-phenotype) [15,16]. The hostile local milieu that results from the proinflammatory molecules during the secondary phase of TBI causes microglia to differentiate into a neurotoxic, proinflammatory state (M1-like phenotype). M1-like microglia worsen secondary neuronal cell injury by perpetuating the production of proinflammatory cytokines and cytodestructive substances. Moreover, M1-like microglia upregulate chondroitin sulfate proteoglycans, which are powerful inhibitors of axon regrowth [17,18]. Animal models have shown that within 1 week of a brain injury, there is a phenotypic shift toward the M1-like microglial response [19]. The ratio of M1-like (proinflammatory) to M2-like (antiinflammatory) microglia can be attenuated with stem cell therapy, which leads to improvements in cognitive behavior [20]. Fig. 23.4 illustrates a TBI that resulted in chronic activation of microglia that was attenuated with multipotent adult progenitor cell (MAPC) treatment (CCI-10) in the dentate gyrus. Similarly, Zanier et al. demonstrated that human bone marrow mesenchymal stem cells (MSC) infused into brain-injured mice promoted an M2-like polarization of microglia. This favorable dichotomization resulted in M2-like mediated repair responses and long-term neurologic recovery [21].

TBI also elicits a dramatic rise in the number of infiltrating macrophages at the site of injury. The pathways responsible for macrophage infiltration are still not well-understood, but they may deal with the binding of C−C-chemokine receptor 2 (CCR2). Hsieh et al. used a CCI injury model to demonstrate a greatly reduced number of infiltrating macrophages (about 80%−90%) after TBI in mice that were CCR2-deficient compared with wild-type animals. CCR2-deficient mice showed improved functional recovery (spatial learning/memory) and neuronal survival, although there was no difference in the volume of tissue loss [22]. Other preclinical works have shown that infiltrating macrophages activate microglia by releasing proinflammatory cytokines such as IL-1 and TNF-α [23,24]. In the absence of infiltrating macrophages, there is a reduction in microglial activation [25] and therefore a reduction in neuroinflammation. These discoveries have important implications for progenitor cell therapy for TBI and also question the inflammatory roles of the different myeloid lineages. The results of these studies could lead one to postulate whether infiltrating macrophages are proinflammatory and resident microglia are antiinflammatory until provoked by these hostile invaders. In this scenario, stem cell therapy would have a stronger role in downregulating the peripheral macrophage response to TBI, possibly as demonstrated through their effect on the reticuloendothelial system.

Assessment of microglial activation patterns in vivo may soon serve as a marker of TBI severity, as demonstrated by an in vivo proinflammatory response to CCI using PET/CT imaging with the PET radioligand [^{11}C]PBR28 [26]. Peripheral benzodiazepine receptors, also known as the translocator protein, are upregulated on the mitochondrial membranes of activated microglia (M1-like). Uptake of the radioligand [^{11}C]PBR28, as measured by standardized uptake values (SUV), was increased in a dose-dependent manner based on the severity of the TBI, as seen in Fig. 23.5. These SUV findings were confirmed ex vivo by quantifying the cellular morphology of activated (M1-like) versus semiactivated versus nonactivated microglia (M2-like) in thalami of the same rodents. Similar to the in vivo results, the most severely injured animals had the highest numbers of activated microglia (M1-like), followed by the moderately injured animals, and finally the sham group, as seen in Fig. 23.6. Future experiments are being planned to determine the utility of the radioligand [^{11}C]PBR28 as a marker of stem cell therapeutic efficacy after TBI in a rodent model.

Blood−Brain Barrier Permeability

The BBB is an anatomical structure that controls the flow of molecules in and out of the CNS. Cells that contribute to the structure of the BBB include endothelial cells and tight junction proteins. The opening and closing of tight junction proteins regulate transport of essential molecules and maintenance of a stable environment. There is communication between the cells of the BBB and the cells of the CNS, which include astrocytes, neurons, and microglia. Interaction between cells of the BBB and CNS has an important role in the control of cerebral blood flow [27,28].

TBI opens the BBB, allowing progression of the neuroinflammatory response. In addition, breakdown of the BBB after TBI increases microvascular permeability, exacerbating vasogenic cerebral edema with concomitant elevations in ICP. Shortly after TBI, an array of effector cells, including neutrophils and monocytes, migrate from the peripheral blood to the site of injury [29]. Infiltrating macrophages can further amplify microglia activation into the neurotoxic, proinflammatory phenotype. In the absence of closure of the BBB, macrophage infiltration is left unchecked and contributes to a prolonged inflammatory response. A prolonged inflammatory response with chronic microglia activation is associated with deleterious effects on cognitive behavior.

Stem cell therapy in preclinical experiments restores the BBB. Repair of the BBB was demonstrated using a CCI injury model in rodents with either human MAPC or autologous cells from the tibia of the animal. Administration of multiple doses (MAPC) or a single dose (autologous cells) resulted in a decrease in BBB permeability after TBI as

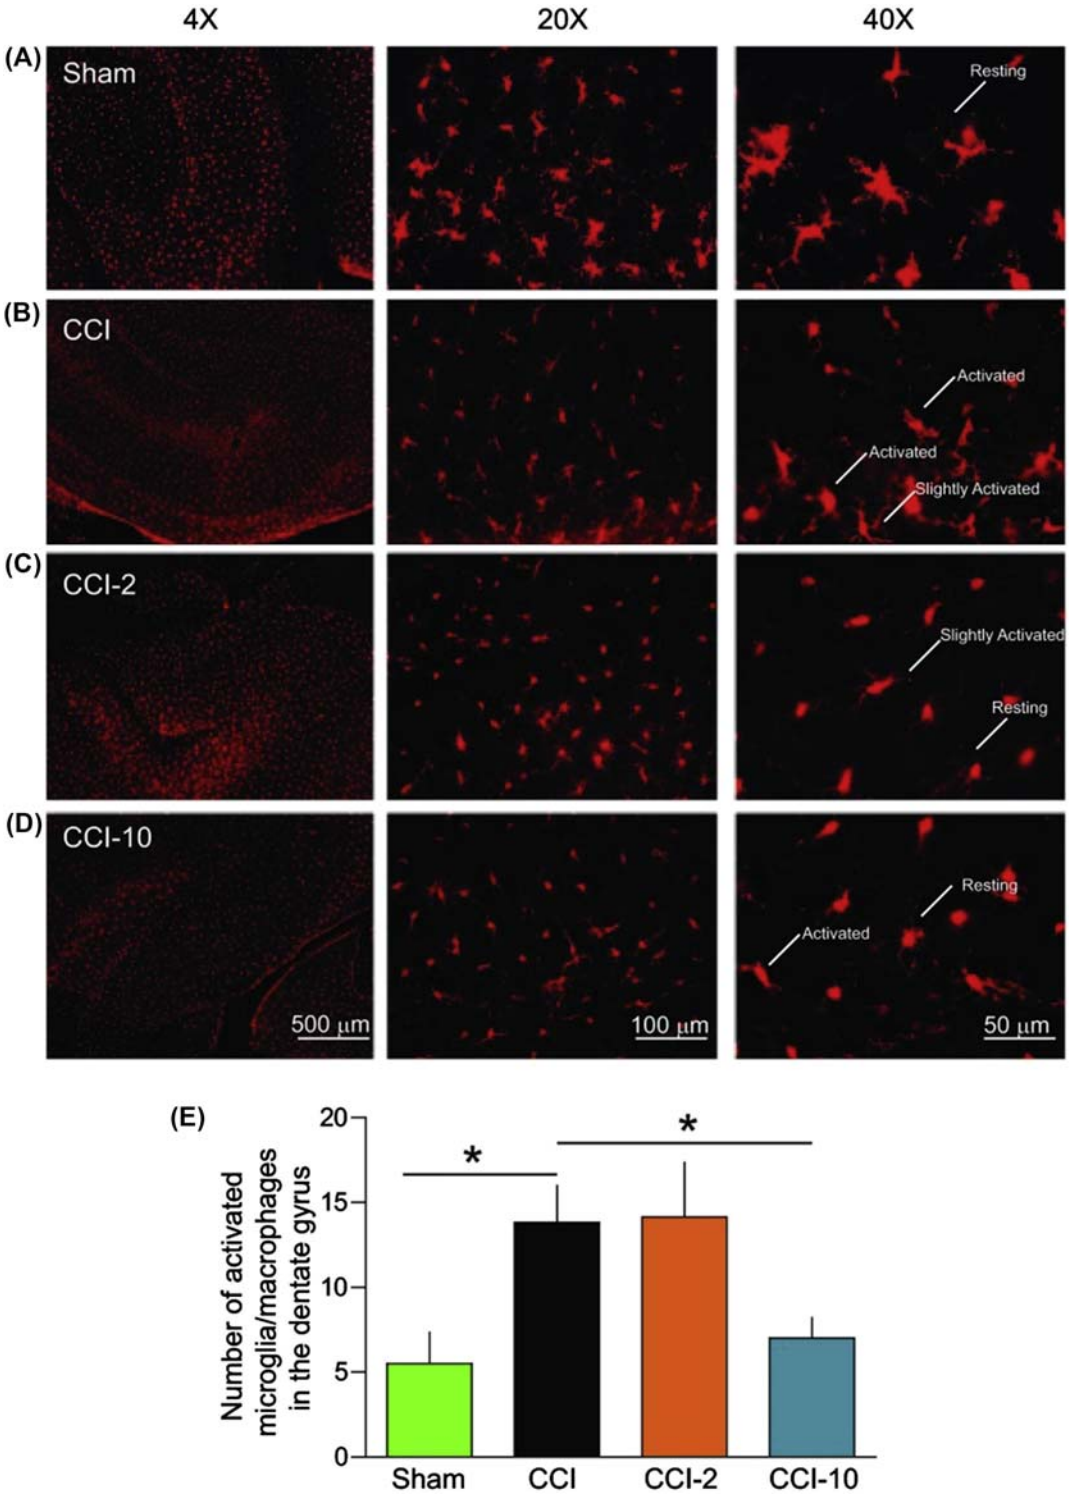

FIGURE 23.4 **Multipotent adult progenitor cell treatment reduced the number of activated microglia in the dentate gyrus.** (A–D) Photomicrographs of microglia from sham (A), CCI (B), CCI-2 (C), and CCI-10 (D) animals using IBA1 antibody (*red*). Scale bars = 500 μm (magnification ×4), 100 μm (magnification ×20), and 50 μm (magnification ×40). (E) Number of activated microglia in the dentate gyrus of the ipsilateral hippocampus. *$P \leq .05$. *CCI*, cortical contusion injury (untreated); *CCI-2*, cortical contusion injury treated with 2 million cells/kg; *CCI-10*, cortical contusion injury treated with 10 million cells/kg.

There was a dose-dependent increase in the amount of [^{11}C]PBR28 uptake depending on the severity of the injury. *2.1 mm CCI*, 2.1-mm controlled cortical impact simulating a moderate TBI; *3.1 mm CCI*, 3.1-mm controlled cortical impact simulating a severe TBI.

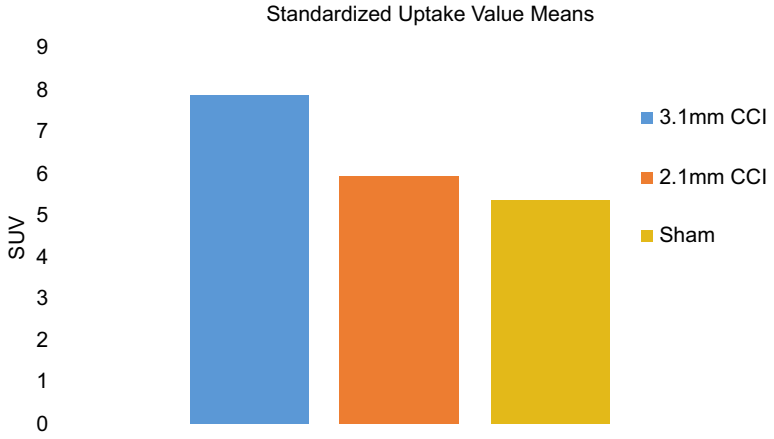

FIGURE 23.6 Microglial counts based on morphology in the thalami after a traumatic brain injury (TBI) in a rodent model. Severely injured animals had the highest counts of all cellular morphology types, all of which were statistically significant at $P < .05$. Microglia were identified via immunohistochemistry using the antibody Iba-1. Manual counts based on specific morphologic criteria were then carried out. *2.1 mm CCI*, 2.1-mm controlled cortical impact simulating a moderate TBI; *3.1 mm CCI*, 3.1-mm controlled cortical impact simulating a severe TBI; *SUV*, standardized uptake values.

measured by extravasation of Evans blue dye [30,31]. BBB integrity was further examined by immunostaining for the tight junction protein, occludin. A qualitative increase in occludin staining occurred in CCI-injured animals that received both forms of cell therapy, compared with the CCI-injured animals alone. Pati et al. were able to clearly elucidate a molecular mechanism for the effects of MSC on the BBB in TBI. They found that a soluble factor produced by MSC, tissue inhibitor of matrix metalloproteinase-3 (TIMP3), inhibits vascular endothelial growth factor A—induced breakdown of endothelial adherens junctions. Increased circulating levels of TIMP3 led to the replacement of endothelial function and BBB compromise. In addition, they discovered that the attenuation of TIMP3 expression in MSC negates the effects of MSC on BBB permeability, whereas intravenous (IV) administration of recombinant TIMP3 alone inhibits BBB permeability [32].

Cerebral Edema

Cerebral edema results in reduced cerebral microvascular perfusion, leading to significant secondary neuronal injury after TBI. Cytotoxic and vasogenic cerebral edema lead to increased brain tissue water and a subsequent

rise in ICP [33]. Cytotoxic edema is caused by the establishment of an osmotic gradient causing water flow into the intracellular space. The osmotic gradient is established when there is an influx of intracellular ions from active ion pump failure and increased membrane permeability. Vasogenic edema is also caused by an osmotic and oncotic gradient; however, the ion and protein flux is from the intravascular to extracellular space. Vasogenic edema follows disruption of the cerebral vascular endothelial cell lining that makes up the BBB [34]. The consequential elevations in ICP serve as a clinical target and surrogate marker of cerebral edema. Restoration of the BBB with stem cell therapy allows better treatment of cerebral edema; clinical trials have shown a reduction in therapeutic intensity required to counter cerebral edema in brain-injured patients treated with bone marrow mononuclear cells (BMMNCs) [35].

CURRENT TRAUMATIC BRAIN INJURY MANAGEMENT STRATEGIES

Current TBI management strategies are designed to minimize secondary injury, because the primary injury is considered irreversible [36–38]. The current treatment paradigm can be divided into surgical or medical management, depending on the severity of the injury. Surgical intervention focuses on evacuating extraaxial fluid collections and the placement of ICP monitors. Medical management of cerebral hemodynamics involves optimizing the CPP. The definition of CPP is the difference between the mean arterial pressure (MAP) and the ICP (CPP = MAP − ICP). Thus, maximization of CPP can be achieved by either increasing the MAP or reducing the ICP [39,40]. Variations in the precise techniques used to manage these variables do nothing to reverse the primary injury. Moreover, currently there are no effective treatments to prevent the secondary brain injury mechanisms after TBI. Therefore, significant advances in reducing the disability associated with TBI are unlikely using current management strategies alone [41].

PRECLINICAL DATA SUPPORTING STEM CELL THERAPIES FOR TRAUMATIC BRAIN INJURY

Cell Types

Two major classes of stem cell–based therapies have emerged for CNS insults: autologous and heterologous (allogeneic). The allogeneic class can be broken down into embryonic, embryonic-like (induced pluripotent stem cells cells), and adult cells. Adult stem cells are derived from a niche in a developing or developed organism [42]. These cells are considered multipotent or pluripotent because they can differentiate into multiple adult cell types. The adult subdivisions includes fetal, specialized niche cells (for example, subventricular zone derived neural stem cells [NSCs]), bone marrow–derived adherent cells (mesenchymal stromal cells [MSC] and MAPC), and nonadherent cells (BMMNCs and human umbilical cord blood cells [hUCBCs]). Autologous cells include cells used in heterologous applications, including BMMNC, expanded MSC, harvested niche cells such as NSC, and privately banked hUCBC.

Mechanisms of Action

The proposed biologic mechanisms for using cell-based therapy for TBI fall into one of two major categories: neural/supporting element replacement or an antiinflammatory/immune biologic response modifier. Early preclinical work focused on neural replacement mechanisms. The term “transdifferentiation” was popularized after studies showed that in vitro “adult” or nonembryonic progenitor cell types could be coaxed into neural phenotypes and express neural protein [43–45]. In vivo murine models replicated this intuitive hypothesis that progenitor cells migrated to an area of injury, transdifferentiated into neurons, and replaced neurons that were lost during the primary and secondary injuries [46–54]. Those reports showed impressive improvement in murine behavioral outcomes (improved locomotor recovery and temporospatial cognition) as well as apparent “engraftment” of these cells through 5-bromo-2′-deoxyuridine (BrdU) labeling identification. Immunohistochemistry sections of the injured brains demonstrated BrdU-labeled cells near the site of injury with neural phenotypes. However, this engraftment and transdifferentiation theory was later disproven and abandoned by most investigators. In 2006, Coyne et al. showed that the BrdU that was used to label MSC persisted in the area of injury, but it was merely the BrdU from dead MSC that persisted, not the cells themselves. Specifically, the thymidine analogues were taken up by other cells in the area of injury (endogenous NSC or microglia) and gave a false signal [55]. However, discarding the engraftment hypothesis did not change the improvement shown in behavioral outcomes in murine models.

Although some investigators still work with the hypothesis that progenitor cells transdifferentiate into neurons, most have turned to investigating progenitor cells as systemic neuroinflammatory modulators. The overall neuroinflammatory modulation of stem cells in TBI is downregulation of the intrinsic proinflammatory responses to injury and upregulation of antiinflammatory responses. Through probable pleiotropic mechanisms, systemic administration of cellular therapies improves outcomes compared with placebo. In this way, progenitor cell therapy preserves neurons that have not yet died from the primary injury but are vulnerable as a result of ongoing secondary injury [31,55–60]. Potential mechanistic pathways for this include downregulation of the activated microglia population to downregulate phagocytosis/neuron programmed cell death [31,60] and the study of antiinflammatory proteins secreted by progenitor cells such as TNF α–stimulated gene 6 product (TSG-6), Wingless-type MMTV Integration Site Family, Member 3a, and TIMP3 [61–64]. The success that was seen with TIMP3 and BBB preservation led Pati et al. to investigate this MSC-derived soluble factor for a neuroprotective role. They found that rodents treated with IV TIMP3 did not experience the significant loss of NSCs that is routinely seen in the preclinical literature [62]. NSC upregulation is important because NSC develop into immature neurons that migrate into the granule cell layer and integrate into neural circuitry. Others have produced some evidence of stem cell fusion with injured cells and the possible exchange of cytoplasm to preserve the damaged neurons. There is a growing body of literature that supports the concept that progenitor cell infusions profoundly upregulate multiple antiinflammatory neuroprotective pathways mediated by the reticuloendothelial system and possibly the lung [65,66]. Yang et al. demonstrated immunomodulation of the splenic response to stroke using human MAPC. MAPC treatment restored spleen mass reduction caused by stroke, elevated $T_{regulatory}$ cells within the spleen, increased IL-10, and decreased IL-1β released by splenocytes. In addition, MAPC treatment enhanced recovery in rats with intact spleens [67]. Prockop et al. revealed that IV infused human multipotent stromal cells (hMSC) become trapped as emboli in the lungs but upregulated a large increase in the antiinflammatory protein TSG-6. IV hMSC or TSG-6 administered during the initial mild phase of a mouse model of TBI decreased neutrophil extravasation, expression of matrix metalloproteinase-9 by endothelial cell and neutrophils, and subsequent BBB leakage. TSG-6 administered alone decreased TBI lesion size at 2 weeks and administration within 24 h showed improvements in memory, depressive-like behavior, and the number of newly born neurons 6–10 weeks after the injury [68].

Timing of Infusion

Stem cell delivery must take the acute injury time window into consideration. The secondary phase of brain injury occurs within hours of the initial trauma and is characterized by a rapid increase in proinflammatory cytokines at the site of injury and surrounding regions [13,69]. The peak in cerebral edema, and thus ICP elevations, follows the early inflammation after cytokine levels start to subside by 72 h. To downregulate the proinflammatory processes (or upregulate the antiinflammatory responses) associated with TBI, delivery of cell therapy likely must occur before or during the period of maximum inflammation. In clinical trials, this time point has been within 36–48 h of the trauma. The 36-h time window has been clinically reaffirmed in patients with stroke treated with MAPC. Patients treated before 36 h after a stroke had significant improvement relative to controls, whereas those treated after 36 h did not have the same benefit [70].

One potential error with this rationale is that the toxic cellular microenvironment may significantly affect the potential therapeutic benefit of the treatment. Cellular engraftment or even transient residence of the cells would cause most of the cells to die upon reaching the noxious region of interest. Harting et al. used immunohistochemistry to reveal that only 1.4%–1.9% of 400,000 infused NSC remained in the neural tissue at 48 h and 2 weeks after direct implantation after a CCI injury in rats [71]. This hypothesis led some investigators in the field to suggest that cell-based therapy be given 72 h after the brain injury to minimize the risk of transplanted cell death.

Two antiinflammatory mechanistic views have been hypothesized to explain the clinical benefits that are evident despite the seemingly uninhabitable injury area. First, stem cells of various types exhibit a paracrine secretion of growth factors and cytokines to salvage “at-risk” cells in the penumbral regions around the primary injury [72,73] Second, infusion of stem cells systemically alters the innate, cellular immune response to injury favorably such that tissue is preserved and functional outcomes are improved [65,74]. The exact window for cell therapy delivery remains ill-defined. Further understanding of cell therapy mechanisms of actions will define clinical timelines for maximum therapeutic benefits.

Conventional Cell Delivery Routes

A fundamental question of stem cell therapy for any disease process is how to administer the cells. Optimization of stem cell therapies for TBI requires a route of delivery without a significant effect on cell viability and function. Routine routes of delivery for animal models and human clinical trials include infusions IV, intraarterially, or intrathecally, and direct stereotactic implantation.

IV infusion of cells is minimally invasive; it provides widespread cellular distribution and has demonstrated promising preclinical data. The reported low levels of cell engraftment in the toxic injury site likely make the IV route more efficacious than stereotactic delivery or intrathecal infusion. Furthermore, TBI is not typically confined to one region of the brain, in contrast to a stroke that manifests symptoms in a defined arterial distribution. The disseminated injuries of TBI thus make direct stereotactic injection or targeted intraarterial infusion appear less effective than the widespread IV route of delivery. The Chopp laboratory exhibited both motor and cognitive improvements after the IV infusion of MSC 24 h after a CCI injury in rats. IV infusions of hUCBCs have exhibited enhanced neurogenesis [75], oligodendrocyte, and white matter (WM) protection [65], and decreased messenger RNA of proinflammatory cytokines and nuclear factor-κB (NF-κB) in rodents [76]. Similar to their work with MSC, the Chopp laboratory found significantly reduced motor and neurological deficits in brain-injured rats treated with IV hUCBC compared with control groups [47]. IV hUCBC therapy combined with granulocyte−colony-stimulating factor (G-CSF) demonstrated vigorous and long-lasting motor recovery compared with hUCBC therapy alone [77].

Pulmonary "First-Pass" Effect

IV-infused cells must first pass through the pulmonary vasculature, during which they are subjected to sequestration, the "pulmonary first-pass effect." Investigations in multiple laboratories have shown that IV-injected MSC (15−19 μm in diameter) undergo a significant pulmonary first-pass effect and become trapped in the pulmonary vasculature (5−7 μm in diameter) [78,79]. Fischer et al. found that less than 1% of injected MSC cross the pulmonary vasculature into the arterial circulation. As seen in Fig. 23.7, infrared imaging of the lungs, heart, kidney, spleen, and liver of rats immediately after IV infusion of varying cell types revealed accumulation of most MSC, MAPC, and NSC in the lungs [78]. Antiadhesion molecule strategies and rheologic agents (P188) did not improve the transpulmonary passage of these cells. In contrast, BMMNC (5−8 μm in diameter) pass through the pulmonary vasculature to the arterial circulation at a 30-fold higher rate [78]. A large volume of the infused BMMNC was noted in the spleen. The neurologic benefits that continue to be seen from IV MSC therapy, despite their significant pulmonary first-pass effect, challenge the idea of engraftment at the site of injury as a requirement for therapeutic efficacy.

Conventional Cell Delivery Routes, Continued

Intraarterial infusion of stem cells via the carotid artery is an attractive infusion method because of the focused delivery of cells and the potential for improved levels of cellular engraftment. Although it is invasive to access the carotid artery, consolidated injury areas close to the cerebral vasculature may see benefits from this style of delivery. Osanai et al. used in vivo optical imaging and immunohistochemistry to demonstrate significant engraftment of bone marrow stromal cells (BMSC) transplanted through the ipsilateral internal carotid artery. The authors also used near-infrared fluorescence imaging to demonstrate the transplanted BMSC migrating from the cerebral capillary bed to the injured CNS within 3 h of infusion [80]. Improved MSC engraftment rates are likely evident because these cells avoid the significant pulmonary first-pass effect that is seen with IV infusion. A major limitation of intraarterial infusion was observed when the large size of the injected MSC resulted in impedance of cerebral blood flow [81].

Intrathecal infusion via lumbar puncture allows stem cells to circulate rapidly in the cerebrospinal fluid (CSF); preclinical work has shown the potential for better engraftment rates by avoiding the pulmonary first-pass effect. Intrathecal delivery of stem cells has largely been used in preclinical spinal cord injury studies; however, the promising results invited TBI investigators to explore this route of delivery. Liu et al. found improved cortical engraftment and motor functioning when comparing MSC injected intrathecally versus IV in a rabbit model of TBI [82]. Walker et al. demonstrated enhanced neuroprotection when intrathecally transplanted MSC activated resident NSC NF-κB activity, which led to an increase in IL-6 production and a decrease in apoptosis [83]. Additional preclinical work on intrathecal delivery has been minimal. However, several clinical trials that used this mode of transport will be discussed in the clinical trials section subsequently.

Preclinical work that used direct stereotactic implantation of various stem cell lines displayed amplified engraftment and encouraging functional outcomes. However, this mode of delivery would require an invasive

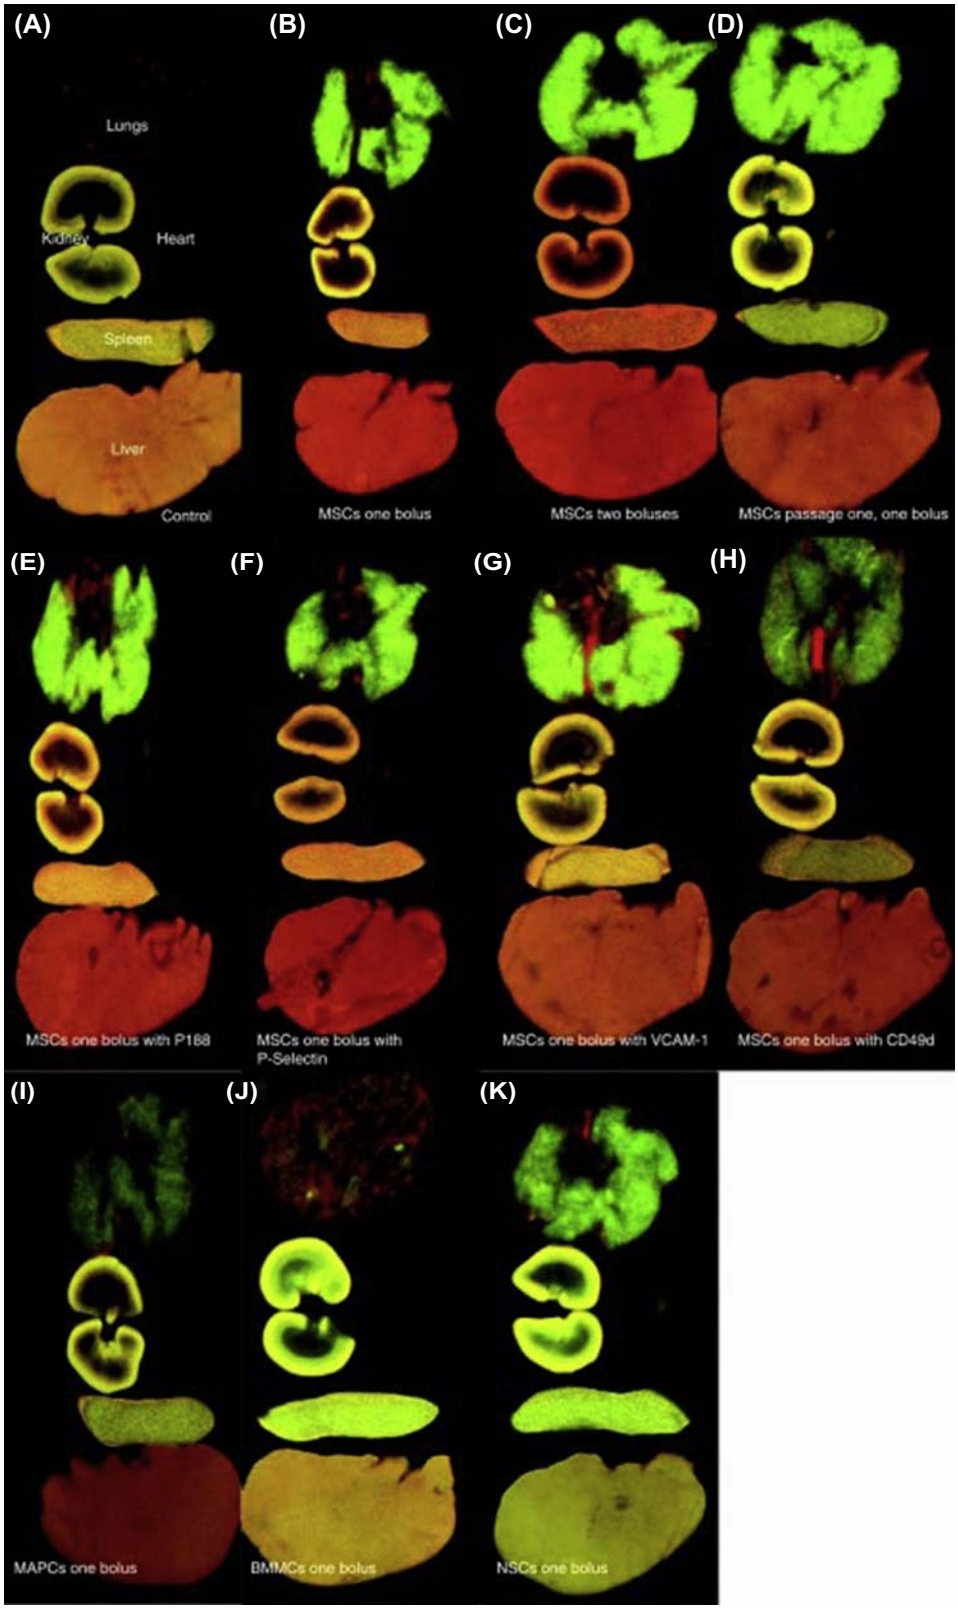

FIGURE 23.7 Infrared imaging of organs immediately after intravenous stem cell infusions. Lungs, heart, kidney, spleen, and liver of rats immediately after intravenous stem cell infusion (B–K) or vehicle (A, control) imaged ex vivo on the Li-COR Odyssey infrared imaging system. *BMMCs*, bone marrow mononuclear cells; *MAPCs*, multipotent adult progenitor cells; *MSCs*, mesenchymal stem cells; *NSCs*, neural stem cells; *VCAM*, vascular cell adhesion molecule.

neurosurgical procedure. Despite this constraint, rodent experiments displayed migration and engraftment of MSC at the injury site, increased endogenous cellular proliferation, and functional improvement up to 8 days after injury [51,84]. Several studies have been performed with direct implantation of NSC. As mentioned earlier, Harting et al. found that stereotactically placed NSC 1 week after a CCI injury in rats displayed a 1.4%−1.9% engraftment rate along the injection tracks 48 h and 2 weeks after placement. These animals had an observed improvement in motor function via the rotarod test; however, no improvement was found in cognitive function [71]. Li et al. examined and compared stereotactically placed NSC and NSC that were activated with *N*-acetyl aspartyl-glutamate synthetase (NAAGS/NSC). Both treatment groups displayed significant recovery of motor behavior compared with the control group. However, animals treated with NAAGS/NSC showed significantly improved motor behavior at 14 and 21 days compared with the NSC group ($P < .05$). In addition, NAAGS/NSC treatment inhibited cell apoptosis detected by terminal deoxynucleotidyl transferase deoxyuridine triphosphate nick end labeling staining and the expression of proinflammatory cytokines (IL-1B, IL-6, and TNF-α) analyzed by enzyme-linked immunosorbent assay [85]. Wu et al. found that CCI-injured mice injected intracerebrally with primed human NSC showed significantly reduced injury-dependent accumulation of the axonal injury protein amyloid precursor protein. Intracerebral human NSC transplantation also reduced microglia activation and showed a transition toward the M2 antiinflammatory phenotype [56]. However, in addition to the invasive nature of this delivery route, another major barrier to direct implantation regards TBI as a diffuse injury with multiple large injury cavities. Multiple stereotactic injections would be needed in most instances to deliver cells to all injured areas of the brain. In addition to the risks associated with each procedure, the repetitive injections could exacerbate the underlying inflammatory response to injury.

Novel Cell Delivery Routes

Each of these conventional routes of cell delivery have major limitations; therefore, novel delivery methods are needed to enhance cellular migration, survival, and engraftment. Novel forms of delivery include nasal administration, scaffold constructs, hydrogels, and enhancement of stem cells to promote engraftment at the site of injury. Effective intranasal administration of stem cells has been reported in several neurologic disorders, stroke, neurodegenerative disorders, etc. [86]. The trigeminal nerve or cranial nerve V is a large sensory and motor nerve with many branches. Nerves providing sensation to the surface and interior structures of the face converge and enter the brain at the level of the pons. Intranasally administered cells follow the path of the trigeminal nerve and enter the brain parenchyma and CSF to carry out their functions on the CNS.

Success with transplantation of stem cells onto three-dimensional bioactive scaffolds in other injury paradigms have led to a large number of preclinical studies in TBI research. Natural materials such as collagen, hyaluronic acid, and porcine urinary bladder are the most commonly employed materials used for scaffolds. Wang et al. transplanted NSC cultured in a bioactive scaffold derived from porcine urinary bladder matrix (UBM) to a rat brain after a CCI injury. UBM has intrinsic antiinflammatory properties and it degrades rapidly in vivo, which makes it an ideal scaffold. Exposure to UBM alone decreased the loss of sensorimotor skills; however, only UBM containing NSC attenuated memory and cognitive impairments [87]. Guan et al. used PET imaging to show increased retention of human bone marrow MSC transplanted on collagen scaffolds in the lesion site of injured rats versus those transplanted without a scaffold. Brain metabolism was also improved in the collagen scaffold−implanted group as demonstrated by PET [88]. Synthetic materials are not as commonly employed in the use of scaffolds. However, Skop et al. were able to use a chitosan-based scaffold impregnated with growth factor (fibroblast growth factor-2) successfully to deliver fetal rat neural precursor cells to the injury site [89].

Hydrogels are three-dimensional networks of cross-linked hydrophilic polymers held together by covalent and hydrogen bonds that allow attachment, growth, and migration of surrounding cells onto the scaffold. Hydrogels have excellent nutrient and oxygen permeability allowing for stem cell survival [90]. The polymer networks expand when in contact with water; as such, they form in situ after injection. Hydrogels can be modified with proteins, glycosaminoglycans, cytokines, drugs, and other factors that will stimulate cell adhesion and growth [91]. Cheng et al. linked the laminin adhesion motif isoleucine-lysine-valine-alanine-valine (IKVAV) to a self-assembling peptide AcN-$RADA_{16}$ to form a hydrogel with mechanical stiffness similar to that of brain tissue. Rat neural precursor cells were encapsulated in the $RADA_{16}$-IKVAV hydrogel and transplanted into rats after a 2-mm biopsy punch neocortical injury. Immunohistochemistry revealed that the hydrogel enhanced survival of the transplanted cells compared with cells infused in saline [92]. The broad capabilities of hydrogels to retain water, provide structural support, modify cell behavior, and take on many different forms make them attractive scaffolds for use in cell therapy for TBI.

In their metaanalysis, Chang et al. evaluated preclinical TBI data to determine behavioral effect sizes for both modified and nonmodified stem cells [93]. "Modified cells" are those genetically programmed to overexpress certain proteins such as G-CSF or TSG-6, or those implanted onto biological scaffolds before being applied as treatment. The authors found an increased treatment effect with modified treatments over and above that found with naive progenitor cell treatment when analyzed in aggregate. This finding suggests that cells enhanced by gene modification or impregnated on scaffolds may survive longer in vivo or potentiate downstream mechanistic effects. The mechanisms by which modified cells produce their treatment effect is continually under investigation.

CLINICAL TRIALS

Phase 1 Bone Marrow Mononuclear Cell Pediatric Trial

Background

Autologous bone marrow mononuclear cell therapy for severe traumatic brain injury in children [94] was a phase I clinical trial (NCT00254722) in pediatric patients who experienced a severe closed-head TBI as defined by a GCS of 5–8. The purpose of the study was to determine whether autologous BMMNCs are a safe treatment for severe TBI in children. Each patient received 6×10^6 mononuclear cells per kilogram body weight within 48 h of the TBI. After the bone marrow harvest and infusion, infusion-related toxicity was determined by pediatric logistic organ dysfunction scores, hepatic enzymes, Murray lung injury scores, and renal function. No detectable infusion-related toxicities occurred during this phase 1 trial.

Rationale for Using Bone Marrow Mononuclear Cells

We have focused on the use of autologous BMMNC for several reasons: (1) There are no immune barrier considerations; (2) these cells are 5–8 μm in size (versus 13–19 μm for MSC), which prevents the significant pulmonary "first-pass" effect and makes IV delivery more feasible [78]; (3) there are no in vitro culture or scaling issues for autologous application; (4) they are readily available; (5) there are no issues with uncontrolled replication as with embryonic stem cells or fetal cells; (6) there are no ethically objectionable issues with the cell type; and (7) there are evolving data on the efficacy and putative mechanism of action.

Longitudinal Outcome Measures

Clinical outcome measures and the imaging date were used to evaluate the children's response to stem cell treatment at 1 and 6 months after the TBI. All functional and neurocognitive outcome scores showed significant increases at 1 to 6 months follow-up. Volumetric magnetic resonance imaging (MRI) data obtained at 1 and 6-month after the TBI revealed no loss of whole-brain intracranial volume, gray matter (GM), or WM, or increase in CSF space. MRI is being planned for this group of patients to evaluate chronic structural changes. In addition, PET imaging using the radioligand [^{11}C]PBR28 will evaluate chronic microglial activation.

Reduction in Therapeutic Intensity: Pediatric Intensity Level of Therapy Scores

A retrospective cohort study was completed after this phase 1 trial to study the intensity of treatment required to counter cerebral edema caused by neuroinflammatory responses to injury [35]. Investigators compared the degree of neurointensive care intervention in the 10 patients with severe TBI treated with BMMNC versus age-, severity-, and time-matched controls. In the pediatric population, the Pediatric Intensity Level of Therapy (PILOT) scoring system for treatment intensity directed toward ICP management was developed [95]. The PILOT score for each patient was calculated at 24-h intervals starting from the time of admission through 21 days. The group treated with BMMNC experienced a statistically significant reduction in PILOT scores beginning at 24 h after treatment through week 1 ($P < .05$). The treated group received autologous BMMNC infusion between 24 and 48 h from time of admission, which correlated to the time of divergence of the PILOT curves. In the first week, the control group treatment intensity remained elevated whereas the treated patients followed linear deescalation in treatment intensity after cell therapy. The treatment group continued to follow a linear decline in therapeutic intensity through 21 days. The control group required equal or escalated therapy and did not approach the treatment group scores until after 2 weeks postinjury. Fig. 23.8 illustrates these trends.

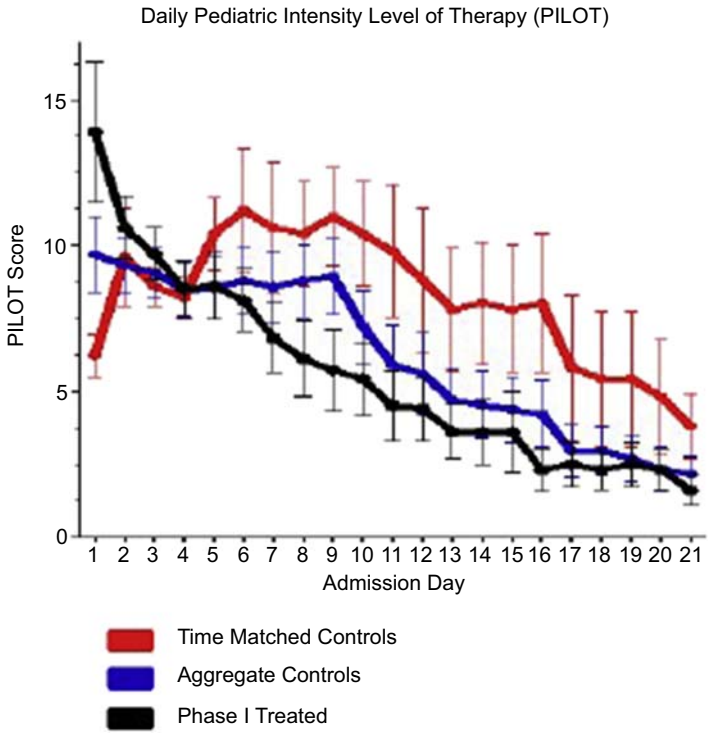

FIGURE 23.8 Pediatric Intensity Level of Therapy (PILOT) scores calculated from time of admission with divergence seen after time of cell therapy (patients were treated within 48 h of admission) ($P < .001$) compared with both 2006–2008 and 2000–2008 controls.

Conclusions

The pediatric phase 1 trial data demonstrate that autologous BMMNC infusion is safe, does not result in infusional toxicity, results in lower therapeutic intensity of neurocritical care, and preserves brain GM and WM. Although the study was not designed to study these parameters, outcomes suggested continued improvement in functional measures.

Phase 1/2a Bone Marrow Mononuclear Cell Adult Trial

Background

After completion of the phase 1 pediatric trial, a phase 1/2a study (NCT01575470) was carried out in adult patients aged 18 to 55 years who experienced a severe TBI [96]. In addition to safety and the logistic feasibility of autologous BMMNC for severe TBI, the investigators sought to determine a potential treatment effect size of WM structural preservation. Biomarkers of the inflammatory response to TBI were also evaluated sequentially before and after injury. A dose-escalation format was performed in 25 patients: five controls followed by five patients in each dosing cohort (6, 9, and 12×10^6 cells/kg body weight), and then five more controls. No serious adverse events were related to the study protocol.

Imaging Data

Imaging was performed at 1 and 6 months from the time of the TBI to acquire volumetric data and diffusion tensor imaging (DTI) comparisons. Significant differences and trends in structural preservation in global volumetrics of WM were seen in the treated versus untreated groups despite two confounding patients. These two patients had higher severity of injury and both required decompressive surgery before cell infusion, which altered the imaging readouts.

Prior imaging studies reported major impacts of TBI on the corpus callosum (CC) and corticospinal tract (CST), which led investigators to select these regions for the analysis of DTI metrics [97]. DTI data yielded measures of WM integrity, which included fractional anisotropy (FA) and mean diffusivity (MD). FA is a summary measure of microstructural integrity. Oversimplified, high FA values are a surrogate measure of coherent, tightly packed, and

myelinated fibers; higher FA is "good." The FA values of the CC in the untreated group were lower relative to the low-, middle-, and high-dose treatment groups at 1 and 6 months. The pooled treated patients exhibited higher FA values at 1 and 6 months relative to the untreated patients. MD is an inverse measure of cell membrane density and is sensitive to edema and necrosis; lower MD is "good." The MD values of the CC in the untreated group were higher relative to the low- and middle-dose treatment groups at 1 and 6 months. Pooled treated patients exhibited lower MD values of the CC at 1 and 6 months relative to the untreated patients.

The CST at the level of the brain stem exhibited similar characteristics of better WM integrity in the pooled group of treated patients as measured by DTI metrics (FA, MD, and radial diffusivity). FA values were higher and RD/MD values were lower in the pooled treatment group relative to the untreated group of patients.

Biomarker Analysis

Whole blood was collected in the acute and chronic periods for biomarker analysis. Cytokine levels of IL-1β, IL-4, IL-6, IL-10, interferon gamma (IFN-gamma), and TNF-α were assessed by enzyme-linked immunosorbent assay. The biomarker data showed a dose-dependent downregulation of the proinflammatory innate immune response to TBI, similar to the preclinical data in cell therapy models for TBI mentioned earlier. Investigators found a dose-dependent trend for TNF-α suppression and a statistically significant reduction in IL-1β, IL-10, and IFN-gamma in the high-dose group.

Conclusions

The adult phase 1/2a severe TBI trial found that autologous BMMNC infusion for adults with severe TBI is safe and logistically feasible. In addition, the investigators found a potential signal of treatment effect in terms of structural preservation of critical CNS architecture.

Phase 1 Mesenchymal Stromal Cell Subacute Traumatic Brain Injury Trial

Background

Autologous Bone Marrow Mesenchymal Stem Cell Therapy in the Subacute Stage of Traumatic Brain Injury by Lumbar Puncture was a phase 1 clinical trial (NCT02028104) in patients aged older than 6 months of age who were diagnosed with a chronic TBI of at least 1-month duration [98]. The study was a nonrandom, open-labeled, interventional cohort study. Patients with a persistent vegetative state (PVS) or disturbances in motor activity admitted to the Department of Neurosurgery at Yichang Center People's Hospital were selected for inclusion. A total of 97 patients (24 with a vegetative state and 73 with motor disturbances) voluntarily received bone marrow MSC via a lumbar puncture. Lumbar puncture was used as the delivery route in this study because the authors cited better cell engraftment rates, tissue sparing, and reduced host immune responses. No serious adverse events occurred upon MSC infusion. The primary outcome measure was change in the clinical symptoms of TBI within 6 months.

Rationale for Using Mesenchymal Stromal Cells

The authors highlighted MSC therapy as a novel method to treat TBI and discussed the potential mechanisms by which MSC improve functional disorders associated with TBI. Human bone marrow MSC have been the most widely studied progenitor cells for TBI therapy because of their ease of access and their multipotent differentiation potential. As discussed earlier, MSC accelerated neuroplasticity, facilitated neuronal regeneration, and improved functional recovery in preclinical data. Several mechanisms of potential therapeutic benefit are hypothesized, including the secretion of growth factors, exchange of genes and proteins through cell-to-cell fusion or contact, and induction of angiogenesis, and the effect on immunomodulation [99]. The authors acknowledged that engraftment and transdifferentiation were a controversial topic as the primary mechanism of MSC action. MSC were identified in this trial by the cell surface markers CD73, CD90, and CD105, which is the minimal criterion for characterizing MSC set forth by the International Society for Cellular Therapy.

Results

Despite long-term sequela (PVS or motor disturbances), 38 of 97 patients showed improvements 14 days after MSC therapy. The authors reported that 11 patients (out of 24 with PVS) showed posttherapeutic improvements in consciousness, which was evaluated according to the grading principle of PVS. The improvements seen were in responsive eyeball tracking, groaning, or tearing. Of 73 patients with motor disturbances, 27 showed improvements in motor function based on neurologic examinations.

Conclusions

The investigators concluded that MSC therapy through lumbar puncture is safe and effective in patients with severe TBI complications, such as PVS and motor disorders. In addition, the MSC effect was more pronounced in young patients and an inverse relationship was found between the time elapsed after injury and the outcome of cellular therapy.

Ongoing Clinical Trials

Phase 2 Multicenter Bone Marrow Mononuclear Cell Pediatric Trial

Pediatric Autologous Bone Marrow Mononuclear Cells for Severe Traumatic Brain Injury is a multicenter (Children's Memorial Hermann Hospital/UT Health and Phoenix Children's Hospital), prospective, randomized, placebo-controlled, blinded phase 2 safety/biological activity study (NCT01851083). A Bayesian adaptive dose escalation design is planned to assess doses of 6×10^6 and 10×10^6 cells per kg body weight versus placebo in children aged 5–17 years who are hospitalized for severe TBI (GCS 3–8).

The primary objective of the study is to determine the effect of autologous BMMNC on CNS WM and GM structural preservation. MRI-based quantitative indices of macroscopic (volume) and microscopic (FA and MD) integrity will be evaluated over time and compared with immediate postinjury measurements. Secondary objectives hypothesize autologous BMMNC infusion improving functional and neurocognitive deficits and reducing the neuroinflammatory response in children after TBI. Spleen size will be evaluated using ultrasound, because preclinical data have shown that the spleen responds to injury in the brain by releasing stored immune cells into the bloodstream. These cells then infiltrate the brain and promote a secondary inflammatory response that enhances neurodegeneration. Finally, infusion-related toxicity and long-term safety evaluations will be completed. Study enrollment commenced in August 2013 and is ongoing.

Phase 2b Bone Marrow Mononuclear Cell Adult Trial

Autologous Stem Cell Study for Adult TBI (Phase 2b) was designed in a fashion similar to that of the pediatric phase 2 trial (NCT02525432). It is a randomized, blinded, Bayesian continual reassessment method dose-escalation, placebo-controlled study design to treat severe, acute TBI in adults ages 18–55 years with an IV infusion of autologous BMMNC. The primary and secondary objectives between the two studies are the same. Enrolled patients are randomized to receive a single IV infusion of BMMNC (6×10^6 or 9×10^6 cells/kg body weight) or placebo. After cell infusion, safety data monitoring and MRI data acquisition have a timeline similar to that of the pediatric phase 2 BMMNC trial. Study enrollment commenced in November 2016 and is ongoing.

Phase 2 Modified SB623 Cells Trial

SanBio, Inc. is conducting a multicenter phase 2 trial entitled *A Double-Blind, Controlled Phase 2 Study of the Safety and Efficacy of Modified Stem Cells (SB623) in Patients With Chronic Motor Deficit From Traumatic Brain Injury* (NCT02416492). Patients aged 18 to 75 years with stable, chronic motor deficits resulting from focal TBI at least 12 months after the injury are eligible for enrollment. SB623 cells are adult bone marrow–derived cells that are transiently transfected with a plasmid construct encoding the intracellular domain of human Notch-1. These cells produce trophic factors that protect neurons in models of ischemic insult. In a rat contusion model of TBI, implantation of SB623 around the area of the injury resulted in significant improvement in motor function. A phase 1/2A dose-escalation study (NCT01287936) of SB623 cells stereotactically implanted into the brains of patients with chronic motor deficits caused by ischemic stroke showed statistically significant improvements in motor with no serious adverse events. The primary outcome is clinical efficacy of the cells as measured by changes in the Fugi–Meyer Motor Scale. In addition, the study will evaluate the safety and tolerability of the intracranial route of delivery. Enrollment opened in January 2016 and is ongoing.

Phase 1/2 Adipose-Derived Stem/Stromal Cells

Use of Adipose-Derived Cellular Stromal Vascular Fraction (AD-cSVF) Parenterally in Postconcussion Injuries and Traumatic Brain Injury is a randomized phase 1/2 trial for patients aged 16 to 70 years with concussion syndrome or mild TBI (NCT02959294). Patients must be 1 month postinjury and demonstrate repetitive TBI events (such as those that occur with contact sports), depression, cognitive disability, attention disorders, headaches, or other persistent changes after the TBI. Patients enrolled in the intervention arm will undergo microcannula harvest of autologous adipose-derived stem cells. Primary outcomes are concerned with safety, as measured by the number of adverse events, and changes in clinical symptoms associated with concussion TBI. Enrollment opened in November 2016 and is ongoing.

Phase 2 Mesenchymal Stromal Cell Neurologic Stem Cell Treatment Study (NCT02795052)

Neurologic Bone Marrow Derived Stem Cell Treat Study, or NEST Study, is a nonrandomized phase 2 trial for patients aged over 18 years with documented damage to the central or peripheral nervous systems. This study is not specific to TBI, but patients who have residual disability 6 months after the injury may be enrolled. Two intervention arms exist in this trial: (1) bone marrow MSC injected IV, and (2) bone marrow MSC injected IV and applied topically to the lower one-third of bilateral nasal passages. Primarily, the authors will be looking at activities of daily living, but they will secondarily examine deficits of neurologic function, such as speech, balance, hearing, and gait. Enrollment opened in June 2016 and is ongoing.

Phase 1 Collagen Scaffold–Mesenchymal Stromal Cell Study

The Safety and Efficacy Assessment of Injectable Collagen Scaffold Combined With Mesenchymal Stem Cells Transplantation in Patients With Brain Injury is a phase 1 trial for patients aged 35–75 years who are diagnosed with a severe TBI and CT evidence of intracerebral hemorrhage (NCT02767817). Patients who underwent craniotomy for hematoma evacuation are excluded because the sham group undergoes stereotactic hematoma evacuation. Treatment groups undergo stereotactic drainage of hematomas; however, one treatment arm then receives 10 million MSC via the drainage tube and the other treatment arm receives an injectable collagen scaffold with 10 million MSC. The primary outcome measure is the number of adverse events. Secondary outcome measures will survey functional outcomes (self-care and motor recovery), pain intensity, electrical brain activity, brain electrophysiology, and brain pathology diagnosed by CT scan. Enrollment opened in March 2016 and is ongoing.

CONCLUSION

There has been a growing body of preclinical literature supporting the use of various progenitor cell types to treat acute neurological injuries such as TBI and stroke. Preclinical work has laid the foundation for clinical trials, and although the exact mechanism of action is still not completely defined, it is complex and pleiotropic. There have been three metaanalyses that analyzed the efficacy of progenitor cell therapies for TBI in murine models [93,100,101]. Although each metaanalysis has limitations and includes studies with significant heterogeneity, all show statistically significant improvements in behavior outcomes. Jackson et al. also analyzed 14 studies that presented lesion volume metrics and the metaanalysis showed improvement in the size of lesion volumes after progenitor cell treatment. To date, this is the only histologic outcome metaanalysis in the preclinical TBI progenitor cell therapy literature. These findings from three independent metaanalysis teams are striking support that progenitor cell therapies are effective treatments for TBI. In addition, the authors of each metaanalysis performed multivariate regression to identify which cells were most beneficial, at which doses, and via which routes of administration (e.g., IV, intraarterial, direct injection in the lesion cavity). However, each metaanalysis found that there are not enough comparable data to make significant conclusions. This lack of conclusion is itself interesting: If there were large differences in effect size when different cells are administered different ways, we would expect that at least one of three metaanalyses would find it. This again suggests that a factor intrinsic to a progenitor cell administered in a systemic fashion has a role as the putative treatment mechanism.

Clinical trials in the acute, subacute, and chronic stages of TBI have highlighted the safety, logistical feasibility, and benefits of using stem cells as therapy for TBI. Ongoing clinical trials are seeking to demonstrate safety, CNS structural preservation, and improved functional outcomes. A variety of modified and nonmodified stem cells are being delivered via multiple routes and doses. The future of stem cell therapy for TBI will likely include genetically modified cells and repeated dosing regimens. Further preclinical understandings of cell therapy mechanisms of action will guide future clinical trial design.

As cell therapy becomes a more widely available treatment for TBI, it will become increasingly important to monitor these patients chronically. Equally important to administering cell therapeutics for TBI is the long-term ability to observe their clinical benefits. Patients enrolled in the pediatric phase 1 trial (NCT00254722) will undergo PET/CT imaging with the radioligand [^{11}C]PBR28 to identify chronic microglial activation years after the primary injury. These data will also highlight the role that stem cells have in the chronic neuroinflammatory response to TBI and will be correlated with long-term functional outcomes. Research efforts dedicated to imaging and laboratory techniques that can be used to observe response to cell therapy both in the acute and chronic stages of TBI will guide future preclinical works.

Continuing to find treatments that improve clinical outcomes after TBI is vital to decreasing the global burden of TBI, and we believe that progenitor cell therapy will have a fundamental role in these efforts.

Mechanical Determinants of Tissue Development

Volha Liaudanskaya, Disha Sood, David L. Kaplan

Tufts University, Medford, MA, United States

INTRODUCTION

In biology and medicine, it has been common to study different diseases and pathologies from genetic and chemical factor perspectives that affect tissue development and function. In contrast, the effect of external mechanical forces has only more recently been documented for a significant role in cell signaling and tissue development and function [1,2]. Mechanical forces have been found to contribute significantly to the development and function of a variety of organs such as lung, heart, bone, cartilage, muscle, and brain, establishing a new field of science, called mechanobiology. Mechanobiology is an interdisciplinary field that combines developmental and cellular biology to understand the cellular response to mechanical stimulation and the mechanotransduction mechanisms by which these stimuli are translated into a cascade of biochemical events. Mechanical stimuli have an essential role in regulating cell functions such as survival, reproduction, and fate determination through changes in gene expression, protein synthesis, and assembly, which are crucial to maintain tissue homeostasis. Deviation from normal mechanical stimulation can affect cellular functions and, in turn, the composition and assembly of the extracellular matrix (ECM), which can lead to tissue and organ diseases. Examples of such malfunctions include fetal deformities, osteoporosis, osteoarthritis, tendinopathy, atherosclerosis, and fibrosis of different tissues [3–8]. An improved understanding of mechanotransduction mechanisms will unveil the pathogenesis of many developmental diseases to find treatments to cure or mitigate the consequences of these maladies. One way to explain mechanotransduction is to examine step-by-step mechanical signal propagation in the body from organs to single-cell nuclei in response to gravity or other mechanical loads applied to the body. First, skin receptors sense gravity or mechanical stimuli, which then transfer the signal to different types of tissues (e.g., bones, muscles, connective tissue, vascular tissue). Every tissue consists of different cells that are interconnected by an extensive network of ECM, including collagens, proteoglycans, and glycoproteins. This ECM network transfers the mechanical signals to the plasma membrane of cells, where signal transduction results in a cascade of biochemical reactions through cytoskeleton filaments toward the nucleus. The nucleus then regulates gene expression, resulting in the expression of new ECM components secreted from the cells as the external outcome of the input signals, finalizing the adaptation of the tissue to the mechanical stimulus.

The ECM senses changes in environmental forces and responds to these inputs by regulating gene expression inside the cell through signaling cascades from cell membranes to the nucleus. The nucleus transduces these signaling inputs to respond by secreting soluble and insoluble molecules as outputs from the cells as part of the cascade in mechanotransduction events. Thus, it is crucial to understand the major factors of the ECM, soluble molecules, and mechanisms of mechanotransduction, and they will be reviewed here.

MECHANOTRANSDUCTION MECHANISMS AND MAJOR EFFECTORS

Cell Structure and Composition

The cells in the human body are routinely exposed to different types of external stimuli ranging from gentle touch to music and sensing gravity [8,9]. Mechanosensory transduction is the ability of living cells to sense a variety of mechanical stimuli and to convert these signals into electrical or biochemical intercellular signals [10–12]. Continuous responses to mechanical stimulation are possible owing to the evolutionary accumulated adaptations in cell structure and environment. All cells are surrounded by ECM and composed of complex plasma membranes with embedded ion channels and sensory receptors, and cytoplasm with organelles and a nucleus (except for red blood cells) [1,13,14]. The plasma membrane encloses the cells, defines their boundaries, and contains protein receptors that act as sensors of external signals. These receptors allow the cells to adapt continuously to changes in the extracellular environment [15]. Plasma membranes are composed of a 5-nm-thick phospholipid bilayer that serves as a relatively impermeable barrier to water-soluble molecules [16,17]. The membrane is composed of lipids containing hydrophilic, phosphorylated heads and hydrophobic tails, with embedded sensory receptors. In response to mechanical forces, the plasma membrane regulates cell attachment, cell–cell communication, and the motion of molecules across the lipid bilayer [18]. Moreover, the membrane has a key role in antigen recognition because of the high number of embedded receptors [5,14,19–22]. The cytoplasm contains cytoskeleton proteins and a variety of organelles such as mitochondria, Golgi apparatus, ribosomes, and the nucleus, which regulate cellular processes including mechanotransduction through the expression of genes (Fig. 24.1).

Extracellular Matrix

All cells reside in an ECM, which provides mechanical support to the cells through cell-attachment sites and functions as a reservoir of bioactive molecules that have a role in cellular functions. These matrix proteins interact with

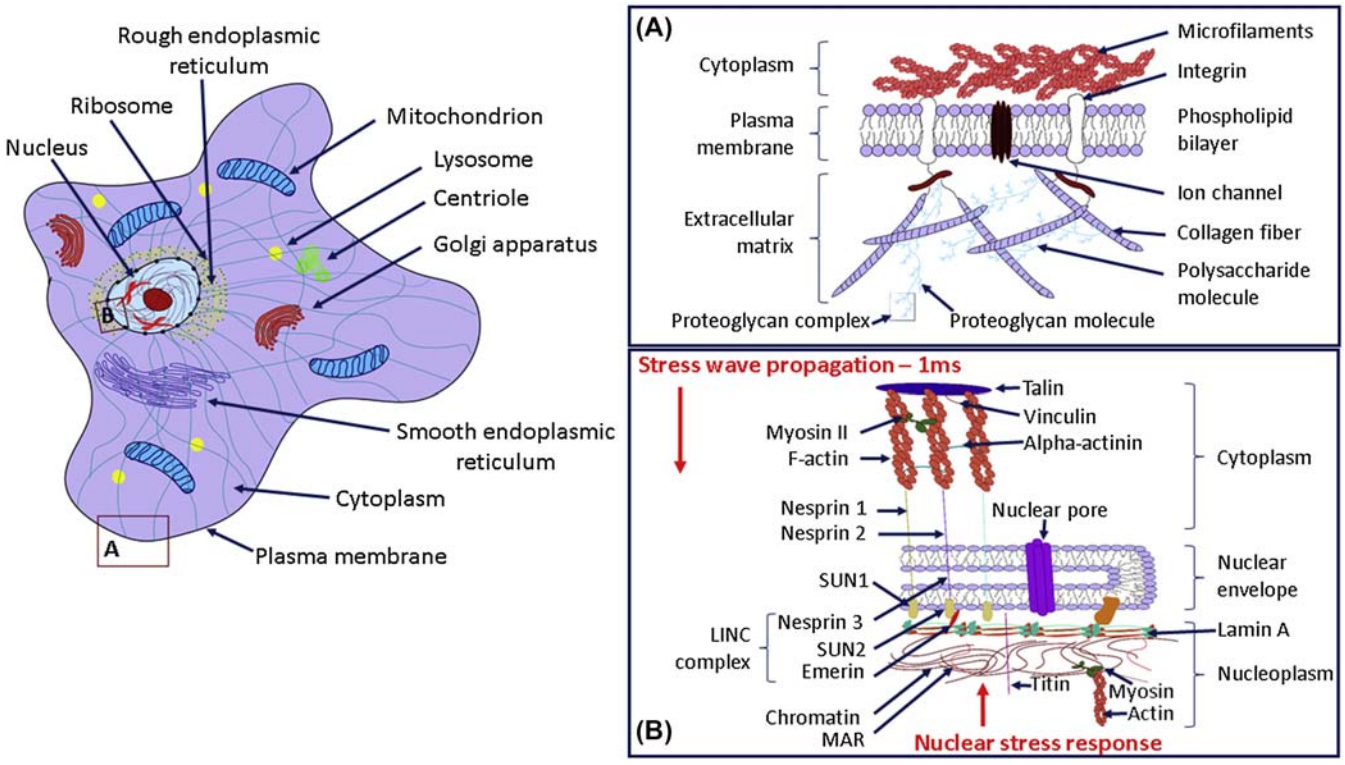

FIGURE 24.1 **Schematic of cell structure and the main mechanoeffectors.** (A) Various stimuli applied to the extracellular matrix (ECM) transmit the signal through integrins and other transmembrane receptors inside the cell cytoplasm, where microfilaments and microtubules transmit the inputs to the nuclear membrane. (B) The nuclear envelope is tightly connected with the cell cytoplasm and receives mechanical signals through nuclear pores and LINC complexes. After the nucleus receives the stimuli, there is a response through changes in gene expression, and subsequent regulation of the assembly of cytoskeletal and ECM components.

cells through cell surface receptors [14]. Collagens are a major component of the ECM in most tissues, about 28 different types of which have been characterized [23]. Molecules of collagen types I, II, and III constitute the bulk of the fibrillar collagens present across all tissues, particularly in dense connective tissues, and are arranged as insoluble fibrils. Such fibrillar structures resist compressive, shear, and tensile forces in tendons, bone, arteries, and skin. Collagen IV forms mesh-like scaffolds present as the basement membranes of vascular structures and in other tissues. The remaining dozens of collagens regulate fibril initiation, fibril diameter, and other factors in tissues; functions are still being discovered [14].

Proteoglycans are another important class of macromolecules in the ECM that form complexes with the protein structural components. Proteoglycans are macromolecules that consist of a core protein covalently bound to glycosaminoglycan (GAG) [24] chains. These molecules vary in function depending on the core protein, the GAG chains, and the sulfation patterns [25]. Aggrecan, for example, provides compressive stiffness in tissues. GAGs, which include chondroitin sulfate, dermatan sulfate, and keratan sulfate, are the major functional components of proteoglycans. Hyaluronan, a nonsulfated GAG, is hydrophilic and imparts enhanced lubrication in tissues such as cartilage. Many cell surface receptors for hormones and growth factors are also proteoglycans. Thus, proteoglycans fall into two categories: membrane-associated and secreted forms.

Glycoproteins such as fibronectin, laminin, vitronectin, and tenascin are found in the ECM and further mediate cell−cell and cell−ECM interactions by binding to collagens, proteoglycans, and cell surfaces. The expression of tenascins, found mostly in the nervous system, heart, smooth and skeletal musculature, tumors, and healing wounds, is mechanically regulated, which is turn controls cell adhesion and spreading [26,27]. The elastic recoil capabilities of various tissues such as dermal, pulmonary, and vascular are mainly controlled by elastin and fibrillin as insoluble elastic fibers [28].

All of the components of the ECM are uniquely organized in different tissues within a steady yet dynamic state. There is reciprocal cross-talk between the ECM and the resident cells, such that the cells with their mechanosensing capabilities offered through integrins and the cytoskeleton maintain the mechanical properties of the ECM; in turn, ECM deposition, rearrangement, or degradation is a critical regulator of cell and tissue health [14].

Ion Channels and Mechanoreceptors

Evolutionarily, the human body has accumulated a variety of cellular and molecular structures that can sense and respond to applied external forces; these includes but are not limited to mechanosensitive (MS) ion channels, G protein−coupled receptors (GPCR), integrins, and tight junction (TJ) proteins [29−31]. MS ion channels, among others, are believed to be the oldest and the most essential molecular force transducers owing to their ability to operate on a millisecond time scale, passing millions of ions per second through membranes [29]. MS ion channels change their confirmation in response to external forces such as pressure, gravity, shear stress, and osmolarity [31,32]. The existence of ion channels gated by mechanical stimuli was first suggested in 1950, when the phenomenon was described in association with the electrophysiological response of sensory neurons when stretching frog muscle [33]. Later, this phenomenon was observed with hair cells [34], skeletal muscle cells [35,36], red blood cells [37], cardiomyocytes [29,31,35,38], osteoblasts [39], skin cells [40], neurons [29,31,41], and many others cells.

The activity of MS ion channels is observed in all vital body functions, such as the maintenance of the synaptic cleft; synapse formation [5,41]; regulation of heart rate [42]; arrhythmia [3,38]; regulation of cell volume [30]; tactile [32,43], auditory, and visual sensations [44,45]; pulmonary arterial hypertension [46]; muscular dystrophy [36]; polycystic kidney disease [6]; and tumor progression [47]. The diversity of MS ion channels in prokaryotic and eukaryotic cells potentially involved in mechanosensory transduction has been summarized in prior studies [3−42]. Here, the attention is on the major eukaryotic MS ion channels and their function in health and disease.

Degenerin (DEG) and epithelial sodium channel (ENaC) proteins belong to a family of eukaryotic amiloride-sensitive, Na^+-selective ion channels that are touch-sensitive receptors [48]. Mutations in DEG genes in *Caenorhabditis elegans* triggered confined degeneration of touch-receptor neurons [49]. ENaC channels are expressed on the apical surfaces of diverse epithelial cells, including distal nephrons, gastrointestinal tract, skin, and cerebral arteries, where they regulate pressure-induced myogenic responses and are involved in maintaining tissue homeostasis and ion balances [50]. ENaC channels are active, have low voltage sensitivity, and can be blocked by some diuretics [51]. Studies have shown that ENaC mutants with upregulated expression display severe hypertension, whereas the opposite loss of function mutants demonstrate hypotension [52,53].

The transient receptor potential (TRP) channels received their name after they were first discovered in the *trp* mutant strain of fruit fly *Drosophila*, with its main feature of transient photoreceptor activity in response to light

[54]. In humans, there are 27 members of this family and they are encoded by 33 genes. There are six major groups of TRPs: TRPC (canonical), TRPV (vanilloid), TRPA (ankyrin), TRPM (melastatin), TRPP (polycystin), and TRPML (mucolipin) [29,31]. Here, we focus only on TRP receptors that are widely expressed in different tissues and perform critical functions. TRP channels are permeable to cations and are activated by a variety of physical and chemical stimuli; they have a crucial role in sensory regulation, calcium signaling, and the maintenance of homeostasis. TRPA1 (subfamily 1, member 1) receptor was described as a mechanical stress sensor and is highly expressed in nociceptive neurons [55], mechanosensory epithelia of the inner ear [35,56], pancreatic β cells [57], and periodontal ligament cells [58]. TRPC1 (subfamily C, member 1) receptors are widely expressed in brain cells, spinal neurons, cardiomyocytes, smooth muscle cells, endothelia cells, and others [21,29,31]. Another highly expressed receptor is TRPC6 in dorsal root ganglia neurons, cardiomyocytes, and variety of epithelial cells in the colon, esophagus, and stomach [29,59]. These TRPC6 receptors respond to most mechanical stimuli, tension, or osmotic forces. The function of these channels was controversial; they were activated upon sensing mechanical stimuli; however, they can also assemble into more complex heteromeric structures and mediate the activity of GPCR. Thus, they appear to perform different functions. Other members of the TRP family of ion channels perform functions ranging from thermosensation to sensing shear stress and pressure. For instance, TRPV4 channels are activated when physical forces are applied to integrins, allowing Ca^{2+} ions to flow into cells, which in turn leads to the activation of phosphatidylinositol-3-OH kinase (PI3K) and Rho [60,61], both of which are crucial molecular pathways that regulate cellular response to mechanical stimuli.

Piezo receptors were more recently discovered and have only two members, Piezo 1 and Piezo 2. They have a critical role in the function of hollow organs, such as the stomach, bladder, lung, and blood vessels, where they trigger transduction mechanisms by sensing shear stress [62–64]. Piezo 2 channels also have a critical role in proprioception; Piezo 2 knockout mice presented uncoordinated movement [5,43,62].

N-methyl-D-aspartate (NMDA) receptors are oligomeric cation channels that are present in the central and the peripheral nervous system, where they regulate essential physiological and pathological processes such as long-term potentiation, synaptic plasticity, and neurodegeneration via Ca^{2+} signaling [29,31,65–67]. These receptors are gated by mechanical forces and respond to changes in the osmotic and hydrostatic pressure. In addition, glutamate and glycine ligands are crucial for activation of these channels [65–67].

Besides ion channels gated by mechanical forces, some voltage-gated cation channels are also considered MS and activated in response to mechanical stimuli; however, they act through different activation mechanisms [29,31]. For instance, voltage-gated sodium channels $Na_v1.5$ or voltage-gated calcium channels $Ca_v1.2$ are present in electromechanical tissues such as muscle, heart, and gut [5,68,69]. Another large group of channels is potassium channels, $K_{2P,}$ with a unique two-pore structure; they are present in excitable and nonexcitable cells [70]. These channels regulate potassium flow conductance that is crucial to establish membrane resting potential, cell excitability, and transport of water and solutes to support ionic balance.

Cytoskeleton

The ECM is a complex structure of proteins directly linked to the cell cytoskeleton via cellular receptors, integrins, and other transmembrane proteins that regulate cell–cell attachment and cell–ECM interactions [71]. The cytoskeleton is a complex interconnected network of filaments that forms unique structures critical for the mechanical stability of the cells and for rapid responses to external stimuli. The cytoskeleton provides resistance to deformation; hence it maintains the mechanical stability of cellular structures (Fig. 24.2). The cytoskeleton is composed of three main components: semiflexible actin microfilaments [72], hollow microtubules (MTs), and stiff intermediate filaments (IFs). The actin cytoskeleton is composed of filamentous (F) actin, helical globular (G) actin, and a variety of actin-binding proteins that regulate the overall actin cytoskeleton structure [17,22,73]. The actin cytoskeleton is associated with both focal adhesion (FA) complexes at cell–ECM sites and with TJs at cell–cell sites (adhesion complexes attached to small binding proteins such as α-actinin, talin, or vinculin) [74]. Moreover, it has been shown actin MF can generate tension through the activity of molecular motors that convert adenosine triphosphate (ATP) into mechanical force. Actin filaments also serve a critical role in cell motion and migration through self-regulated ECM polymerization [1,17]. Alterations in actin assembly and structure triggered by mechanical forces regulate cell proliferation and gene expression [17,75]. A variety of cells (endothelial, osteoblasts, and mesenchymal stem) adhered to stiff substrates showed a shift toward higher F-actin versus G-actin ratios, which in turn triggered the activation of transcription factor Yes associated protein 1 (YAP1) [76,77]. YAP1 is a key effector of the Hippo molecular pathway, which is responsible for cell proliferation and differentiation [78]. This process is mediated

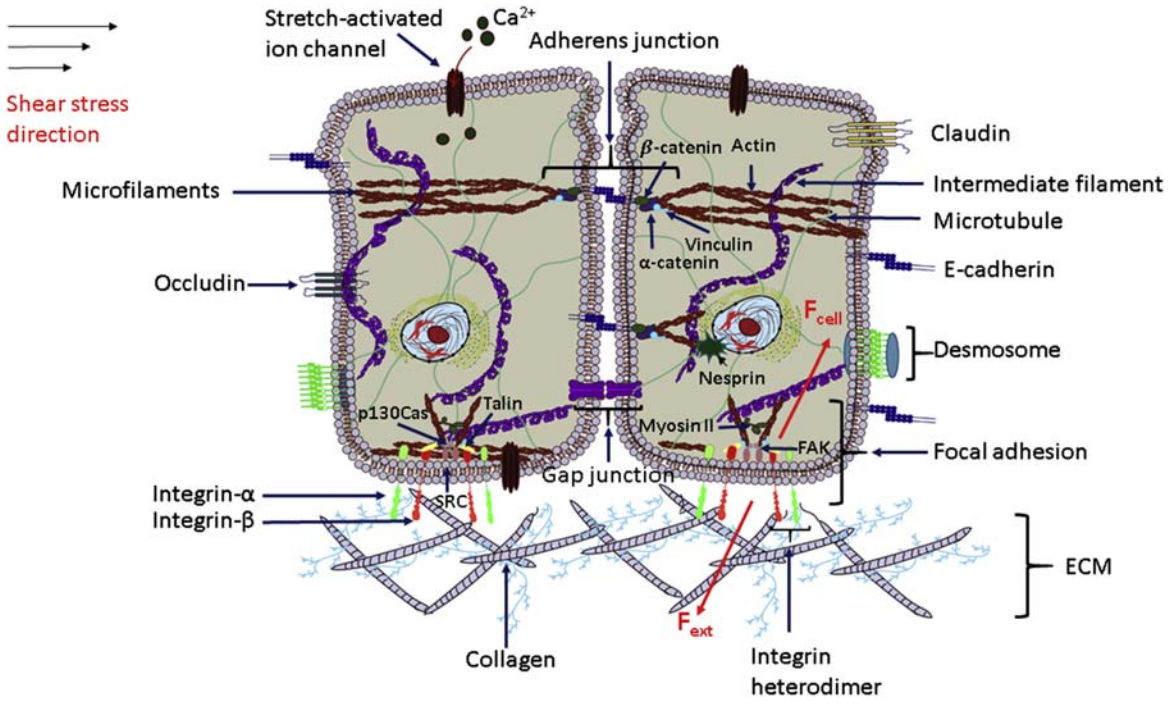

FIGURE 24.2 **Key players of cellular mechanotransduction.** Cell−cell connections transmit mechanical signals through adherent junctions, desmosomes, gap junctions, and tight junctions, which are ubiquitously present among cells. The signals between cells and the extracellular matrix (ECM) are transmitted through complexes of proteins called focal adhesions, which are mostly composed of integrins. The connections receive signals, perform sensory functions, and after microfilaments [72], microtubules [131] and intermediate filaments, they transmit the signal to the nucleus and then perform transmission functions. *FAK*, focal adhesion kinase.

by the formation of a complex with another transcription factor, transcriptional enhancer factor domain family member [79]. If these cells adhere to a soft surface, YAP1 coactivator becomes phosphorylated by serine/threonine-protein kinase, which in turn leads to YAP inactivation and, as a result, cell death [77]. Tubulin-based microtubules associated with the centrosome regulate the cell cycle. Microtubules are essential in cell mitotic spindle formation, vesicle transport, cell polarity, and cilia formation [80,81]. MTs have a major function in cell polarity and spindle orientation during the mitotic cycle, with associated regulation of chromatin orientation. Moreover, cilia axoneme consists of MTs and are crucial in regulating sperm motility and the flow of mucus, cerebrospinal fluid, and other bodily fluids upon sensing mechanical forces. Finally, elastic IFs (lamin, vimentin, desmin, and keratin) link nuclei and cell attachment sites (desmosomes) [82]. Lamin proteins form the inner support structure for the nuclear net and have an essential role in mechanotransduction. Compared with actin filaments and microtubules, IFs are relatively stable structures. IFs are highly expressed in neuronal (especially axons) and epithelial and muscle cells, which are constantly undergoing high mechanical stresses [83,84].

The assembly of more complex cytoskeletal structures is possible when microfilaments, microtubules, and IFs are supplemented by other proteins such as actin-bound myosin chains, which combine to form stress fibers around the periphery of cells. Cytoskeleton components in combination form a complex network and fill the interior of the cell. These components are continuously remodeled, such that monomers can be rapidly added or removed.

Microfilaments and microtubules are essential to maintain cell shape and polarization; they support a vast range of fundamental cellular mechanisms such as vesicle transport, cytoplasmic organization, chromosome segregation, and cell migration. IFs complexed with other components are crucial for cell−cell interactions and attachment and are required for healthy tissue and organ function during development and adult life. Actin and myosin coat the interior side of the plasma membrane and perform contractile and supportive functions for the membrane. The external forces that are propagated through integrins of the plasma membrane can be transduced as chemical modifications of the cytoskeletal structure at information-receiving sites and later transferred along the network as cascades.

To understand the function of the cytoskeleton in mechanotransduction better, tensegrity has been suggested [22,85]. This model proposes compensatory stress−strain organization of cytoskeletal components, in which compression-bearing elements (microtubules and ECM adhesion sites) withstand the stretching of surrounding

elastic elements (microfilaments and IFs). This complex organization of cytoskeletal elements thus allows the rapid exchange of energy with the surroundings and immediate cellular responses to fluctuating microenvironmental and mechanical stimulation. Continuous movement of actin–myosin complexes, formation of new FA sites and ECM adhesions, as well as osmotic forces result in the accumulation of physiological prestress or isomeric tension in many components of the cytoskeleton, according to the tensegrity model. Thus, these cytoskeletal adaptations and the compensatory stress–strain organization and physiological isomeric tension could explain the ability of cells to transduce signals over long distances and to convert mechanical stimuli into the cascade of complex biomechanical reactions in the nucleus [85]. Cellular mechanics have been described by other models, such as the cortical network, open cell foam, and percolation. However, these models do not account for the contribution of the ECM and microtubules toward cellular mechanics [86].

NUCLEUS AS THE CENTRAL ORGANELLE IN REGULATING MECHANOTRANSDUCTION

The nucleus is the central administrative organelle of the cell. This organelle performs three crucial functions: the storage of hereditary information, the regulation of key cellular processes such as cell growth, metabolism, proliferation, and protein synthesis; and mechanotransduction [87]. The cell nucleus is composed of the nucleolus and chromatin–DNA complexes that are protected by the nuclear envelope (NE), which has a high number of nuclear pores [88]. The nucleus is supported by the endoplasmic reticulum covered with ribosomes that are responsible for rapid RNA synthesis [89]. Although the nuclear content seems to be isolated from the cytoplasm by the NE, these two compartments are tightly linked structurally and physically by two protein complexes, the nuclear pore complex and the Linker of the Nucleoskeleton and Cytoskeleton (LINC) [90]. Because of this tight connection with the cytoplasm, the nucleus senses physical forces applied to a cell in seconds and transduces these signals into a cascade of biochemical reactions to remodel and adapt the cell to changing environmental conditions. Nuclei respond within short periods by physical changes to lamina, relocation of nuclear markers, and the nuclear position itself. Over longer durations, nuclei change their stiffness, thus affecting the stiffness of cell cytoskeleton and the microenvironment of the cell [91]. All of these observations demonstrate the communication of all cell compartments in response to external stimulation and the critical role of nuclei not only for immediate responses but for long-term changes in cell structure.

These studies support the tensegrity model, in which proximal stimuli can affect distal cell structures owing to the connectivity among all cell compartments [10]. The nucleus is tightly associated with integrins such that the distortion of adhesive sites, followed by realignment of the NE structure, nuclear displacement, and stiffening are regulated by the underlying net of lamin A/C proteins. In response to integrin stimulation, plasma membrane ion channels transmit the signals of changing forces through the actin network to mitochondria bound to microtubules [7]. Mitochondria immediately respond by the significant release of reactive oxygen species and trigger activation of numerous signaling molecules such as nuclear factor κB and vascular cell-adhesion molecule 1 [92].

To understand these cascades better, the molecular organization of the nucleus is important, with a double-layered membrane or NE that connects chromatin-containing nucleoskeleton to the cytoskeleton. The inner and outer membranes of the NE are interconnected with pores that mediate this communication between compartments. The inner membrane of the NE is supported by nuclear lamina composed of lamin proteins (lamins A, B, and C) and other incorporated membrane proteins such as lamina-associated protein 2α, emerin, inner nuclear membrane protein Man1 domain–containing members [91]. The organization of the NE is similar to that of the cell plasma membrane, with a high number of ions channels and inner actin support. The nuclear lamina is a dynamic structure linked to the nuclear chromatin domains and is responsible for the structural organization of chromatin and gene expression. Moreover, earlier research confirmed the association of the lamina with the cytoskeleton, observed via electron microscopy; molecular studies based on nuclear migration have supported this conclusion [89,93]. The complex of two protein families, synaptic nuclear envelope protein/nesprin and SUN (**S**ad1p and UNC-84) colocalized within the NE linked the nuclear lamina and cytoskeleton and were accordingly named the LINC [90]. Disruption of the LINC complex or ablation of lamina A/C proteins caused the disruption of cytoskeleton actin organization, which presumably was required to be linked with nuclear pores for proper assembly and organization. Intriguingly, independent physical force responses of isolated nuclei has been shown in in vitro studies, which points to the critical role of the nucleus in cell responses to mechanical forces [94,95]. Similarities in the organization of the cell plasma membrane and NE suggest the presence of resembling signal amplification mechanisms, well described for the cell membrane through FA sites, but not proved for NE. It was speculated the nesprin family of

proteins performs this amplification function [94]. Nesprin proteins unfold under tension, exposing binding sites and triggering further nesprin dimerization and the recruitment of other factors to support LINC complex stability and rigidity. Mainly lamina A and C proteins are responsible for nuclear stiffness in response to applied stress on the nesprin 1 protein of the LINC complex [94].

Mutations in most of the nuclear LINC proteins, or the lamina complex, are related to a variety of human pathologies such as different laminopathies (congenital muscular dystrophy, mandibuloacral lipoatrophy, cerebral ataxia, dilated cardiomyopathy, and others) [7].

CELLULAR MECHANOTRANSDUCTION MECHANISMS

Internal mechanical forces sensed by cell surface intramembrane receptors (integrins) are responsible for binding cells to the surrounding ECM, and cadherins for cell–cell contact and communication [2] (Fig. 24.3). Mechanical forces applied to cell–cell contact and cell–ECM adhesions affect cellular homeostasis, including single cells as well as surrounding tissues and organs [96]. The complex cell structure allows the detection of alterations in mechanical forces applied from outside or inside the cell, and to converts these signals into a cascade of biochemical events to regulate cell responses known as mechanotransduction [97]. To understand how the body responds to mechanical stimuli, it is critical to study mechanotransduction mechanisms starting from the single-cell level to the more complex levels of tissues and organs, a hierarchy of responses [98]. Cells respond to external forces by regulating the expression of ECM and other downstream effectors inside the cell. The cascade of molecular mechanisms that regulate cell responses to mechanical forces remains under study; however, some of the events are understood and are presented here.

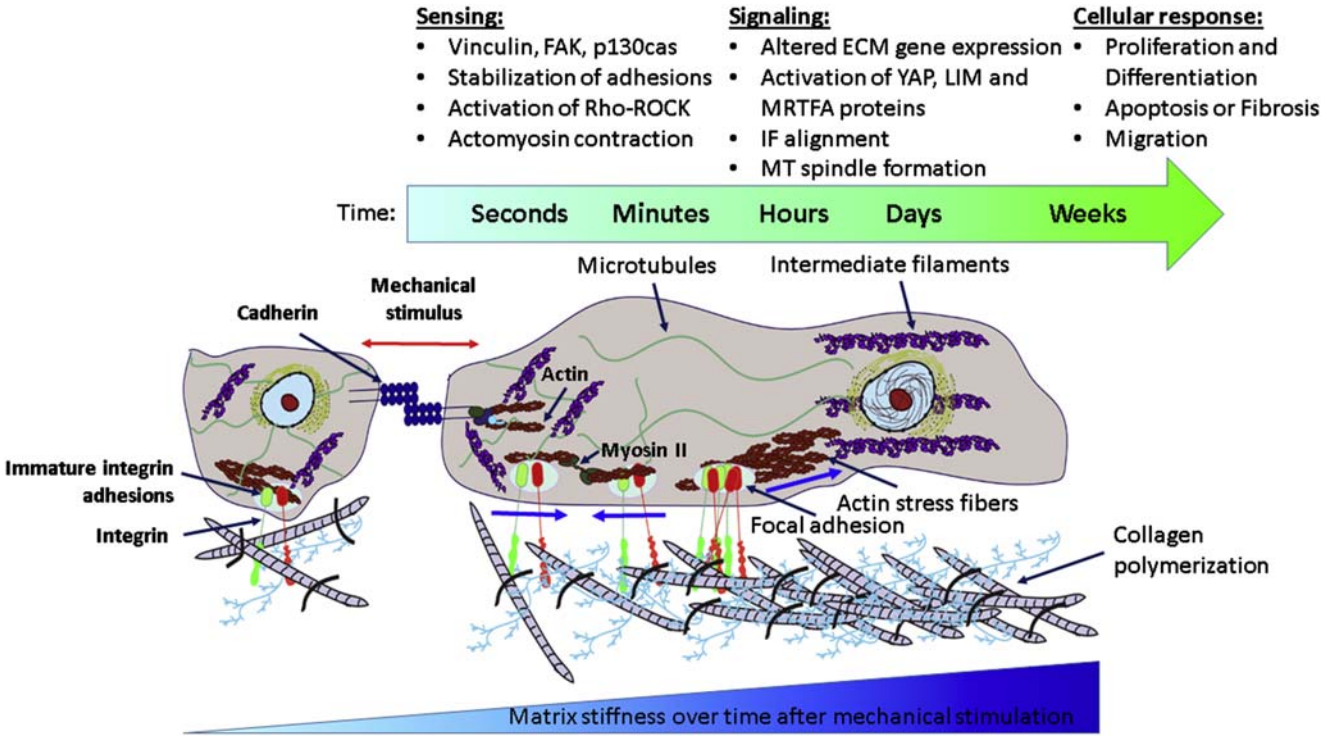

FIGURE 24.3 **Cellular changes over time after mechanical stimulation.** Cell–cell connections sense signals as stretching or shear stress, whereas cell–extracellular matrix (ECM) connections sense matrix rigidity and tension. The signals are converted into a cascade of biochemical reactions that cause cellular responses to the applied stimuli. Immediate changes after stimulation can include actin-myosin filament contraction, stabilization of focal adhesions, and the assembly of protein complexes. During the hours and days after initial signaling, the inputs reach the nucleus and cause changes by regulating major molecular pathways such as Yes associated protein (YAP) and LIM. The final chain of biochemical events can push the cell into division, differentiation, or trigger apoptosis or fibrosis, among other events, depending on the nature of the stimulation. *FAK*, focal adhesion kinase; *IF*, intermediate filament; *MRTFA*, myocardin-related transcription factor A; *MT*, microtubule; *ROCK*, Rho-associated protein kinase.

Mechanotransduction Through Cell—Extracellular Matrix Adhesions

All cells are surrounded by a network of ECM and are connected to this structure at multiple points through integrins of FA sites, to cytoplasmic actin filaments. Over 50 proteins are described in FAs, with integrins as the major component [17]. Integrins consist of two types of homodimers, α and β, which associate with the ECM and various intracellular proteins, such as FA kinase (FAK), talin, vinculin, paxillin, and p130Cas (also known as breast cancer antiestrogen resistance 1) [99]. The associated proteins maintain and regulate the activation of integrins, transduction of mechanical signals, linkage to the actin cytoskeleton, and additional functions. Upon cell attachment to the ECM, integrins bind and initially start to form small focal contacts consisting of integrins and other FA proteins, all of which form a complex FA [100]. Because of the essential role of FAs in regulating mechanotransduction signaling, they are considered to be mechanosensing centers from which the signals are oriented toward the proper organelle or structure to be transduced into a cascade of biochemical reactions [15]. These responses regulate cell adaption toward constantly changing environmental forces. FAs are stress sensitive and constantly alter their conformation under different stress conditions, to protect cells and support survival and stress resistance. These instantaneous changes in FA conformation are regulated by the Rho molecular pathway and its downstream effectors Rho-associated protein kinase (ROCK) and mDia (mammalian Diaphanous) [12,101]. The integrin linker protein talin is also sensitive to stress and undergoes unfolding and stretching in response to stress, revealing its binding site to vinculin to form the talin−vinculin complex. This complex triggers further changes in integrin structure and initiates signal transduction; it is also strongly dependent on myosin II activity. The talin−vinculin complex was shown to have a key role in the cell response to ECM rigidity [13].

FAK is a signaling molecule that has a critical role in regulating mechanotransduction by binding to various proteins such as receptor tyrosine kinase and PI3K, which are responsible for the activation and deactivation of molecular pathways [102,103]. Mitogen-activated protein kinase pathway (MAPK), with its major effectors such as extracellular regulated kinase 1/2 (ERK1/2), p38 MAPKs, and Jun N-terminal kinase (JNK), is upregulated upon FA complex formation [104]. The nucleus receives the signal after ERK1/2 and JNK activation, and via a feedback loop it regulates the expression of critical components of the ECM, such as collagen type I, which is responsible for tissue formation and remodeling [105].

Mechanotransduction Through Cell−Cell Adhesions

Adherent junctions (AJs) and desmosomes are the structures through which cells communicate with each other; and the have a role similar to that of FAs as mechanosensors, or mechanosensing ion channels and mechanotransmitters that include cytoskeleton components, nuclear lamina, and various transmembrane proteins [12,106]. AJs are composed of cadherins, Ca^{2+}-dependent transmembrane adhesion molecules, and intercellular proteins such as α-catenin, β-catenin, and vinculin [74]. Cadherin extracellular domains connect with cadherins of neighboring cells, whereas their cytoplasmic domain is responsible for the recruitment of catenins and other regulatory molecules. Cadherin−catenin complexes are critical in fetal development and in maintaining tissue homeostasis during adulthood [107]. Epithelial cells form a unique feature, TJs, on the apical side of AJs. These features are composed of specific membrane proteins such as occludin and claudin [108]. These TJs are crucial for barrier maintenance and the apical polarity of epithelial cells [109,110]. Several other pathways also regulate signal transduction though cell−cell contact. The Notch pathway regulates cell-fate determination in embryogenesis and tissue homeostasis in the adult state. Upon binding of Notch with its transmembrane ligand Delta, the extracellular domain is cleaved by ADAM (a disintegrin and metalloproteinase) protease, whereas the cytoplasmic domain is cleaved by γ-secretase [111]. The remaining Notch intracellular domain relocates to the nucleus, where it activates and deactivates targeted genes.

Cell−cell contacts share many functional similarities with cell−ECM contacts, such as clustering, recruitment of associated molecules for signal transduction, and trigger signaling cascades that result in activation of Rho family GTPases. Rho family small GTPases are important molecules that regulate cell cytoskeleton remodeling and reassembly in response to changing external forces. There are about 20 members in this family; three were described as regulators of cytoskeleton remodeling: RhoA, Ras-related C3 botulinum toxin substrate 1 (Rac1), and cell division cycle 42 [12]. RhoA protein is activated in response to mechanical stimuli, whereas its inhibition or its downstream effectors, ROCK or mDia, affect cyclic stress-induced cell filaments reorientation. Rac1 has a key role in regulating stress-induced responses in endothelial and other cells [17].

From Cells to Organs: How Mechanobiology Affects Tissue Development and Function

After understanding mechanotransduction mechanisms at the single-cell level, the next step is to understand how these mechanisms affect fetal development and overall tissue homeostasis. Mechanical forces are critical regulators of fertilization and fetal development from the earliest stages [11,12]. Cell motility during fetal development generates mechanical tension that shapes the embryo. Moreover, it significantly affects gene expression and thus cell differentiation [22,71,112]. Therefore, during fetal development there are two processes that play a key role, morphogenesis driven by tissue motility and cell differentiation controlled by gene expression [112].

Fertilization is regulated by mechanical forces, starting from sperm activity that is driven by the ATP-fueled motor protein dynein [12]. Dynein generates tail beats, which allow flagella to move the sperm within the viscous uterine environment toward an egg [113]. Upon sperm penetration inside the egg, a chain of biochemical reactions is triggered that allows the egg membrane to harden through cross-linking of molecular filaments [114].

The early-stage embryo is composed of tightly packed identical cell populations, until actin-driven asymmetrical division splits cells into polar and apolar groups [11,115]. The balance between symmetric and asymmetric cell division during fetal development is regulated by the mitotic spindle located inside the cell, which in turn is controlled by the physical forces generated upon interaction of cytoskeletal microtubules and actin microfilaments [116]. Correlations among cell geometry and the position and orientation of the spindle have been demonstrated [117]. The mechanism that regulates spindle position, and thus cell division, can be explained by the tensegrity model presented earlier [85]. Overall, at the early stages of embryonic development there is little to no ECM present, and thus cell differentiation and embryo development are driven by mechanical forces generated by cellular cytoskeleton proteins or by cell−cell interactions. One of the most well-described models is convergence extension during gastrulation [12,118−120]. Tissue narrowing and lengthening via cell intercalation generate mechanical tension along the embryo, driving morphogenesis. Elongation of the neuroectoderm is a passive process, with mechanical tension arising from the underlying chordamesoderm [121]. Only after the emergence of early epithelial cell layers does the ECM start to assemble, and at this point it is mainly composed of collagen type IV, laminin, and heparan sulfate proteoglycans accumulated at the base of trophectoderm [13,122]. After the ECM assembles, it contributes to the mechanical properties of the fetal microenvironment, and thus regulates cellular differentiation and the control of fetal development by controlling major molecular mechanisms that cause cell differentiation [123]. These features include the Hippo pathway, the conserved signaling pathway that regulates normal organ growth and development in humans and *Drosophila* [124−126].

When the main embryonic axis is formed, predifferentiated cells start to self-assemble into more complex hollow-like and other three-dimensional structures that become future organs. As in early embryonic development, morphogenesis is regulated by mechanical forces generated by cytoskeletal proteins and transmitted through ECM and cell−cell interactions to neighboring cells and tissues [127]. Another critical process contributing to normal tissue development and function is planar cell polarity (PCP) [118,120,128]. PCP regulates cell function in the perpendicular axis of the epithelial layer. Two major molecular mechanisms regulate PCP and are critical at the stage of embryonic morphogenesis: the core PCP and the Fat-Dachsous-Four-jointed modules [11,128]. The major role of these signaling pathways is to control the distribution of transmembrane receptors in opposing cell compartments of various tissues. This process in turn regulates cellular organization, motility, and function, based on the location of the signaling complexes. For instance, PCP regulates cell proliferation during wing development in *Drosophila*, as well as in the skin cracks of crocodiles [128].

Upon the establishment of a morphogenetic body plan, cells trigger differentiation into the organ-specific lineages and self-assemble into more complex structures that become organs [12]. At this stage of embryonic development, mechanical forces may not have a leading role, although they still contribute to organ development and overall body homeostasis. Soluble morphogens have a critical role at later stages of embryonic development, although some of these act by regulating cellular force homeostasis [129−131]. For example, during murine tooth formation, there is a sequence of events [12]. The process starts with increased production of growth factors responsible for cell migration and proliferation, which triggers massive cell migration toward each other, forming a defined condensed mesenchymal cell area [132,133]. The formation of dense tissue in turn triggers the activation of molecular pathways that regulate further tooth development. Finally, the dense mesenchyme initiates the production of collagen type VI containing ECM to harden the organ formed and finalize organ-specific lineage differentiation [11]. Thus, later embryogenesis is controlled by complex mechanochemical mechanisms that together control healthy organ development.

The development of some organs and body systems such as brain [4,134], heart [19,135], bone [136,137], lung [138,139], kidney [140], muscle [141,142], and the hematopoietic system [143−145] are affected by mechanical forces

more than other tissues and organs [20]. The early-stage sensitivity and responsiveness of embryonic stem cells to stretch and stress may still be present upon differentiation toward a defined cell type. For instance, fetal-derived cardiomyocyte progenitors maintain contractility crucial for healthy heart development on substrates with stiffness similar or equal to the native myocardial microenvironment [146,147]. Cytoskeleton formation and assembly of vimentin, filamin, and myosin were sensitive to substrate stiffness [147–149]. Loss-of-function experiments performed with ROCK inhibitors showed restored functions of cardiomyocytes on stiff substrates through the disassembly of stress fibers, which were shown to form in response to mechanical stress, such as stiff substrates [99]. Thus, phenotypic stage–dependent responses of single cells to mechanical stimuli at early stages of embryogenesis are important to the process.

Another example illustrates how the formation of lung buds from epithelial planar layers depends on force balancing in the developing embryo [22]. Cells located in more clustered areas of high turnover regions of cells in the epithelium demonstrate a greater chance of budding outgrowth; in comparison, the regions with higher ECM deposition remained the same size. Moreover, it was shown that budding could be modulated by cytoskeletal tension, causing a loss of differential basement membrane thickness [138,150]. The same budding pattern was observed in capillary sprout growth during angiogenesis [151]. Another example is kidney development, in which flow shear stress contributed to the assembly of glomerular structures, proper function for filtration and liquid flow, and morphogenetic control of nephron formation [152]. It was hypothesized that tissue-specific differentiation was strongly dependent on the properties of the substrate, such as stiffness, ECM composition, and elasticity, rather than mechanical stretching that is critical only during early stages of cell migration and orientation within the embryo.

Mechanical forces significantly affect embryonic development, but also tissue and organ function throughout adult life. Examples include the effect of physical exercise on the musculoskeletal system, blood flow stress on the cardiovascular system, cerebrospinal fluid and blood flow on brain function, and cyclic strain from inspiratory and expiratory forces on the pulmonary system [146]. Thus, normal tissue function and organ homeostasis strongly depend on proper mechanotransduction mechanisms between cell contacts and ECM in the tissue microenvironment. The human skeleton is one systems that can significantly remodel itself in response to physical forces. For instance, physically inactive patients experience osteopenia (bone mass loss) as a result of the lack of mechanical stress on bone and joints [12]. This process leads to increased bone fractures and joint malfunctions [153]. In contrast, an increase in the mechanical loading forces on bone tissue result in tissue hardening and matrix deposition [154]. The muscular system also modulates bone structure and composition via maintenance of tensegrity force homeostasis [155]. Similar to bone tissue remodeling, cardiomyocytes respond to hemodynamic changes in their microenvironment; under increased pressure, cardiomyocytes undergo hypertrophy, which in turn can lead to heart failure [156]. Numerous cardiovascular studies showed various factors contributing to both healthy and maladaptive maintenance of heart function, many of which are mechanosensors or mechanotransducers (stretch-sensitive ion channels, integrins and integrin-associated proteins, sarcomeric proteins, cell surface receptors, and others) [157]. These features support the importance of understanding the principles of mechanobiology. Strict control over tissue and microenvironment remodeling is crucial for organ homeostasis and to prevent devastating life-threatening diseases such as fibrosis and cancers associated with distorted remodeling of the ECM.

CONCLUSIONS

Mechanobiology principles are being applied in all biomedical fields. Mechanical forces have a crucial role in embryonic development and in the homeostasis and function of adult organs. Application of this knowledge in the field of tissue engineering and regenerative medicine will help in designing systems for the growth of artificial organs or tissues. Moreover, the insight and use of the principles of mechanobiology will allow the study of various diseases associated with changes in ECM assembly and misassembly and with cellular responses to mechanical stimuli.

Several microengineered platforms have been developed to recapitulate in vivo–like mechanical environment to decipher the role of mechanical forces in normal and pathological cellular processes [158]. Such platforms include bioreactors that apply tension and compression, microelectromechanical systems–based approaches that combine electrical and mechanical stimulation, and mechanopharmacology approaches that allow the simultaneous investigation of drugs and biomechanics in living systems [159]. However, the underlying mechanisms of how mechanical factors affect stem cell biology remain poorly defined. An understanding of the stem cell “mechano-niche” composed of cellular mechanical properties, the surrounding ECM, and external mechanical cues will enable the lineage-specific differentiation of stem cells for various in vitro and in vivo applications [160].

CHAPTER

25

Morphogenesis, Bone Morphogenetic Proteins, and Regeneration of Bone and Articular Cartilage

A.H. Reddi, Kenjiro Iwasa

University of California, Davis, Sacramento, CA, United States

INTRODUCTION

Morphogenesis is the developmental cascade of pattern formation, establishment of body plan, and the architecture of mirror-image bilateral symmetry of musculoskeletal structures culminating in the adult form. Regenerative medicine is the emerging discipline of the science of the design and manufacture of spare parts for the human body including the skeleton to restore the function of lost parts owing to cancer, diseases and trauma. Regenerative medicine and surgery are based on rational principles of molecular developmental biology and morphogenesis and are further governed by principles of bioengineering and biomechanics. The three key elements for regenerative medicine and surgery are inductive morphogenetic signals, responding stem cells, and the extracellular matrix (ECM) scaffolding [1]. Advances in the molecular cell biology of morphogens will aid in the design principles and architecture for regenerative medicine and surgery. Regeneration recapitulates in part embryonic development and morphogenesis. Among many tissues in the human body, bone has considerable powers for regeneration and therefore is a prototype model for tissue engineering. On the other hand, cartilage is feeble in its prowess for regeneration (Fig. 25.1). Implantation of demineralized bone matrix into subcutaneous sites results in local bone induction. The sequential cascade of bone morphogenesis mimics sequential skeletal morphogenesis in limbs and permits the isolation of bone morphogens. Although it is traditional to study morphogenetic signals in embryos, bone morphogenetic proteins (BMPs), the primordial inductive signals for bone, were isolated from adult demineralized bone matrix. BMPs initiate, promote, and maintain chondrogenesis and osteogenesis and have actions beyond bone. The cartilage-derived morphogenetic proteins (CDMPs) are critical for cartilage and joint morphogenesis. The symbiosis of bone-inductive and conductive strategies is critical for regenerative medicine and is in turn governed by the context and biomechanics. The context in bone is the microenvironment, consisting of ECM scaffolding, and can be duplicated by biomimetic biomaterials such as collagens, hydroxyapatite, proteoglycans, and cell adhesion proteins including fibronectins and laminins. The rules

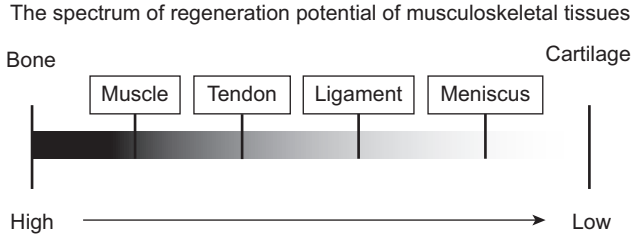

FIGURE 25.1 The spectrum of the regeneration potential of musculoskeletal tissues. Bone has the highest potential, and cartilage the lowest. Tissues with intermediate regenerative potential are muscle, tendons, and ligaments.

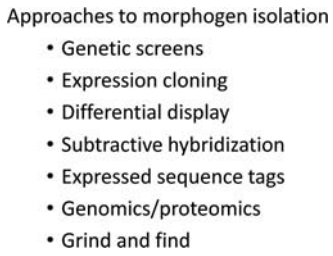

FIGURE 25.2 The various approaches to isolation of morphogens.

of architecture for regenerative medicine and surgery are an imitation and adaptation of the laws of developmental biology and morphogenesis, and thus may be universal for all tissues, including musculoskeletal tissues and a variety of other tissues in the human body.

The traditional approach to identifying and isolating morphogens is first to identify genes in fly and frog embryos by genetic approaches, differential displays, subtractive hybridization, and expression cloning (Fig. 25.2). This information is subsequently extended to mice and humans. An alternative approach is to isolate morphogens from bone with known regenerative potential. The principles gleaned from bone morphogenesis and BMPs can be extended to regeneration of bone and cartilage and other tissues.

BONE MORPHOGENETIC PROTEINS

Bone grafts have been used by orthopedic surgeons for nearly a century to aid in recalcitrant bone repair. Decalcified bone implants have been used to treat patients with osteomyelitis [2]. It was hypothesized that bone might contain a substance, osteogenin, that initiates bone growth [3]. Urist made the key discovery that when implanted intramuscularly, demineralized, lyophilized segments of rabbit bone induced new bone formation [4]. Bone induction is a sequential multistep cascade [5–7]. Important steps in this cascade are chemotaxis, mitosis, and differentiation. Chemotaxis is the directed migration of cells in response to a chemical gradient of signals released from the insoluble demineralized bone matrix. The demineralized bone matrix is predominantly composed of type I insoluble collagen and it binds plasma fibronectin [8]. Fibronectin has domains for binding to collagen, fibrin, and heparin. The responding mesenchymal cells attach to the collagenous matrix and proliferate, as indicated by [^{3}H]thymidine autoradiography and incorporation into acid-precipitable DNA on day 3 [9]. Chondroblast differentiation is evident on day 5, chondrocytes on days 7 and 8, and cartilage hypertrophy on day 9. There is concomitant vascular invasion on day 9 with osteoblast differentiation. On days 10–12, alkaline phosphatase is maximal. Osteocalcin, bone γ-carboxyglutamic acid containing Gla protein (BGP) increases on day 28. Hematopoietic marrow differentiates in the ossicle and is maximal by day 21. This entire sequential bone development cascade is reminiscent of bone and cartilage morphogenesis in the limb bud [7,10]. Hence, it has immense implications for the isolation of inductive signals initiating cartilage and bone morphogenesis. In fact, a systematic investigation was undertaken of the chemical components responsible for bone induction from the demineralized bone matrix.

This account of the demineralized bone matrix–induced bone morphogenesis in extraskeletal sites demonstrated the potential role of morphogens in the ECM. A systematic study of the isolation of putative morphogens from the bone matrix was initiated. A prerequisite for any quest for novel morphogens is to establish a battery of bioassays for new bone formation. The three key steps in bone morphogenesis are chemotaxis of progenitor stem cells, mitosis, and differentiation (Fig. 25.3). A panel of in vitro assays was established for chemotaxis, mitogenesis, and chondrogenesis, and an in vitro bioassay for bone formation. Although the in vitro assays are expedient, we routinely monitored a labor-intensive in vivo bioassay because it is the only bona fide bone induction assay.

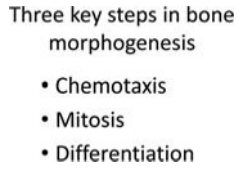

FIGURE 25.3 The three key steps in bone morphogenesis.

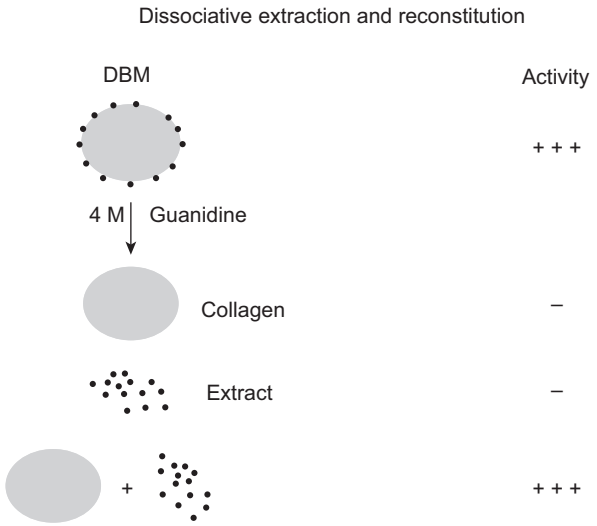

FIGURE 25.4 Dissociative extraction of bone matrix by chaotropic reagents such as 4 M guanidine hydrochloride and reconstitution of the extract with collagenous matrix scaffold. The results indicate that there is a collaboration between the soluble signal in the extract and the insoluble extracellular matrix of bone. *DBM*, demineralized bone matrix.

A major stumbling block in the approach was that the demineralized bone matrix is insoluble and in a solid state. In view of this, dissociative extractants such as 4 M guanidine HCl or 8 M urea as 1% sodium dodecyl sulfate at pH 7.4 were used [11] to solubilize proteins. Approximately 3% of the proteins were solubilized from the demineralized bone matrix; the remaining residue was mainly insoluble type I bone collagen. The extract alone or the residue alone was incapable of new bone induction. However, the addition of the extract to residue (insoluble collagen) and then implantation in a subcutaneous site resulted in bone induction (Fig. 25.4). Therefore, for optimal osteogenic activity it is essential to have a collaboration between the soluble signal in the extract and the insoluble substratum of collagenous ECM [11]. This bioassay was a critical advance in the ultimate purification of BMPs; it led to the determination of limited tryptic peptide sequences and to the eventual cloning of BMPs [12–14]. The dissociative extraction of soluble signals from the demineralized ECM of bone and its subsequent reconstitution with collagen established the cardinal principle of regenerative medicine. The critical principle is that morphogenetic signals stimulate stem cells to differentiate in the optimal scaffold microenvironment (Fig. 25.5). Thus, the triumvirate of signals, stem cells, and scaffolds for regenerative medicine was conceived as a concept.

Although the basic description of bone induction was performed in rats, purification requires a larger and more abundant source of bone. A switch was made to bovine bone. Demineralized bovine bone matrix was not osteoinductive in rats and the results were variable. However, when the guanidine extracts of demineralized bovine bone were fractionated on an S-200 molecular sieve column, fractions less than 50 kD were consistently osteogenic in rats when bioassayed after reconstitution with allogeneic insoluble collagen [15,16]. Thus, protein fractions inducing bone were not species specific and appeared to be homologous in several mammals. It is likely that larger molecular mass fractions and/or the insoluble xenogeneic (bovine and human) collagens were inhibitory or immunogenic. Initial estimates revealed 1 μg of active osteogenic fraction in a kilogram of bone. Hence, over a ton of bovine bone was processed to yield optimal amounts for amino acid sequence determination. The amino acid sequences revealed a homology to transforming growth factor (TGF)-β_1 [16]. The decisive work of Wozney et al.

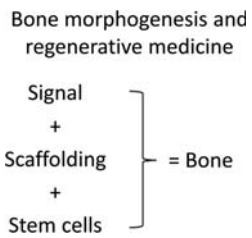

FIGURE 25.5 The key principle of regenerative medicine is that signals stimulate the differentiation of stem cells in the appropriate scaffold.

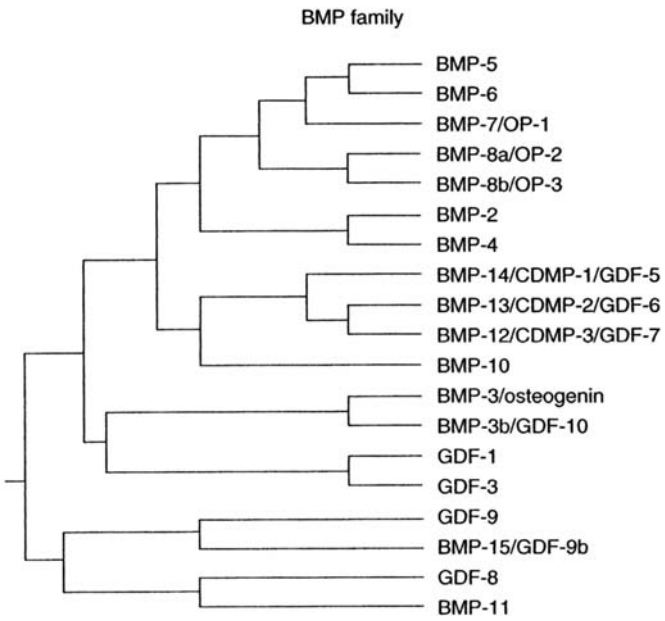

FIGURE 25.6 Members of the bone morphogenetic protein (BMP) family include three main subfamilies: BMP-5, -6, and -7; BMP-2 and -4; BMP-3 and -3b; and growth/differentiation factors (GDF)-5, -6, and -7. *OP*, osteogenic protein.

[12] cloned BMP-2, BMP-2B (now called BMP-4), and BMP-3 (also called osteogenin). Ozkaynak et al. [14] cloned osteogenic proteins 1 and 2 (OP-1 and OP-2). There are several members of this BMP family (Fig. 25.6). Other members of the extended TGF-β/BMP superfamily include inhibins and activins (implicated in follicle-stimulating hormone release from pituitary). Müllerian duct inhibitory substance, growth/differentiation factors (GDFs), nodal, and lefty genes implicated in establishing right and left asymmetry [1,17,18]. BMPs are also involved in embryonic induction [18–21].

BMPs are dimeric molecules, and the conformation is critical for biological actions. Reduction of the single interchain disulfide bond resulted in the loss of biological activity. The mature monomer molecule consists of about 120 amino acids, with seven canonical cysteine residues. There are three intrachain disulfides per monomer and one interchain disulfide bond in the dimer. In the critical core of the BMP monomer is the cysteine knot. The crystal structure of BMP-7 has been determined [22].

Morphogenesis is a sequential multistep cascade. BMPs regulate each of the key steps: chemotaxis, mitosis, and differentiation of cartilage and bone. BMPs initiate chondrogenesis in the limb [23,24]. The apical ectodermal ridge is the source of BMPs in the developing limb bud. The intricate dynamic, reciprocal interactions between the ectodermally derived epithelium and mesoderm-derived mesenchyme sets into motion the train of events culminating in the pattern of the phalanges, radius, ulna, and humerus.

The chemotaxis of human monocytes is optimal at femtomolar concentration [25]. The apparent affinity was 100–200 pM. The mitogenic response was optimal at the 100-pM. range. The initiation of differentiation was in the nanomolar range in solution. However, caution should be exercised because BMPs may be sequestered by ECM components and the local concentration may be higher when BMPs are bounded on the ECM. Thus, BMPs are pleiotropic regulators that act in concentration-dependent thresholds.

It is well-known that ECM components have a critical role in morphogenesis. The structural macromolecules and their supramolecular assembly in the matrix do not explain their role in epithelial–mesenchymal interaction and morphogenesis. This riddle can now be explained by the binding of BMPs to heparan sulfate heparin, and type IV collagen [26–28] of the basement membranes. In fact, this might partly explain the necessity for angiogenesis before osteogenesis during development. In addition, the actions of activin in the development of the frog, in terms of dorsal mesoderm induction, are modified to neutralization by follistatin [29]. Similarly, chordin and noggin from the Spemann organizer induce neutralization by the binding and inactivation of BMP-4. Thus, neural induction is likely to be a default pathway when BMP-4 is nonfunctional [30,31]. This is an emerging principle in development and morphogenesis that binding proteins can terminate a dominant morphogen's action and initiate a default pathway. Finally, the binding of a soluble morphogen to ECM converts it into an insoluble matrix bound morphogen to act locally in the solid state [26].

Although BMPs were isolated and cloned from bone, work with gene knockouts has revealed a plethora of actions beyond bone. Mice with targeted disruption of BMP-2 caused embryonic lethality. The heart development is abnormal, which indicates a need for BMP-2 in heart development [32]. BMP-4 "knockouts" exhibit no mesoderm induction and gastrulation is impaired [33]. Transgenic overexpression of BMPs under the control of keratin 10 promoter leads to psoriasis. The targeted deletion of BMP-7 revealed the critical role of this molecule in kidney and eye development [34–36]. Thus, the BMPs are really true morphogens for such disparate tissues as skin, heart, kidney, and eye. In view of the emerging wider role, BMPs may be called bone morphogenetic proteins (BMPs).

Recombinant human BMP-4 and BMP-7 bind to BMP receptor IA (BMPR-IA) and BMP receptor IB (BMPR-IB) [37]. CDMP-1 also binds to both of the type I BMP receptors. There is a collaboration between type I and II BMP receptors [38]. The type I receptor serine/threonine kinase phosphorylates a signal-transducing protein substrate called Smad 1 or 5 [39]. Smad is a term derived from fusion of Drosophila Mad gene and *Caenorhabditis elegans* (nematode) Sma gene. Smads 1, 5, and 8 signal in partnership with a common co-Smad, Smad 4 (Fig. 25.7). The transcription of BMP-response genes is initiated by Smad 1/Smad 4 heterodimers. Smads are trimeric molecules as gleaned by X-ray crystallography. The phosphorylation of Smads 1 and 5 by type I BMP receptor kinase is inhibited by inhibitory Smad 6 and 7 [40]. Smad interacting protein may interact with Smad 1 and modulate BMP-response gene expression [18,41]. The downstream targets of BMP signaling are likely to be homeobox genes, the cardinal genes for morphogenesis and transcription. BMPs, in turn, may be regulated by members of the hedgehog family of genes such as Sonic and Indian hedgehog [42].

STEM CELLS

It is well-known that embryonic mesoderm-derived mesenchymal cells are progenitors for bone, cartilage, tendons, ligaments, and muscle. However, certain stem cells in adult bone marrow, muscle, and fascia can form bone and cartilage (Fig. 25.8). The identification of stem cells readily sourced from bone marrow may lead to banks of stem cells for cell therapy and perhaps gene therapy with appropriate "homing" characteristics to bone marrow and hence to skeleton. The pioneering work of Friedenstein et al. [43,44], and Owen and Friedenstein [45] identified bone marrow stromal stem cells. These stromal cells are distinct from the hematopoietic stem cell lineage. Bone marrow stromal stem cells consist of inducible and determined osteoprogenitors committed to osteogenesis. Determined osteogenic precursor cells have the propensity to form bone cells with no external cues or signals. On the other hand, inducible osteogenic precursors require an inductive signal such as BMP or demineralized bone matrix. The operational distinction between stromal stem cells and hematopoietic stem cells is becoming increasingly less distinct. The stromal stem cells of Friedenstein and Owen are also called mesenchymal stem cells [46,47], with the potential to form bone, cartilage, adipocytes, and myoblasts in response to cues from the environment and/or intrinsic factors. Mesenchymal stem cells are present in synovium [48], periosteum [49], adipose tissue [50], and blood [51]. There is considerable hope and anticipation that these bone marrow stromal cells may be excellent vehicles for cell and gene therapy [52,53].

From a practical standpoint, these stromal stem cells can be obtained by bone marrow biopsies and expanded rapidly for use in cell therapy after pretreatment with BMPs. Their potential use in both cell and gene therapy is promising. There are continuous improvements in the viral vectors and efficiency of gene therapy [54–57]. For example, it is possible to use BMP genes transfected in stromal stem cells for targeting to bone marrow.

SCAFFOLDS OF EXTRACELLULAR MATRIX AND BIOMIMETIC BIOMATERIALS

The earlier discussion regarding inductive signals (BMPs) and responding stem cells (stromal cells) leads us to the scaffolding (the microenvironment and ECM) for optimal tissue engineering. Natural biomaterials in the composite tissue of bones and joints are collagens, proteoglycans, and glycoproteins of cell adhesion such as fibronectin and the mineral phase. The mineral phase in bone is predominantly hydroxyapatite. In their native state, the associated citrate, fluoride, carbonate, and trace elements constitute physiological hydroxyapatite. The high protein binding capacity makes hydroxyapatite a natural delivery system. Comparison of insoluble bone collagenis an optimal delivery system for BMPs [58]. It is well-known that collagen is an ideal delivery system for growth factors in soft and hard tissue wound repair [59].

During the course of systematic work on hydroxyapatite of two pore sizes (200 or 500 μm) in two geometrical forms (beads and disks), an unexpected observation was made. The geometry of the delivery system is critical

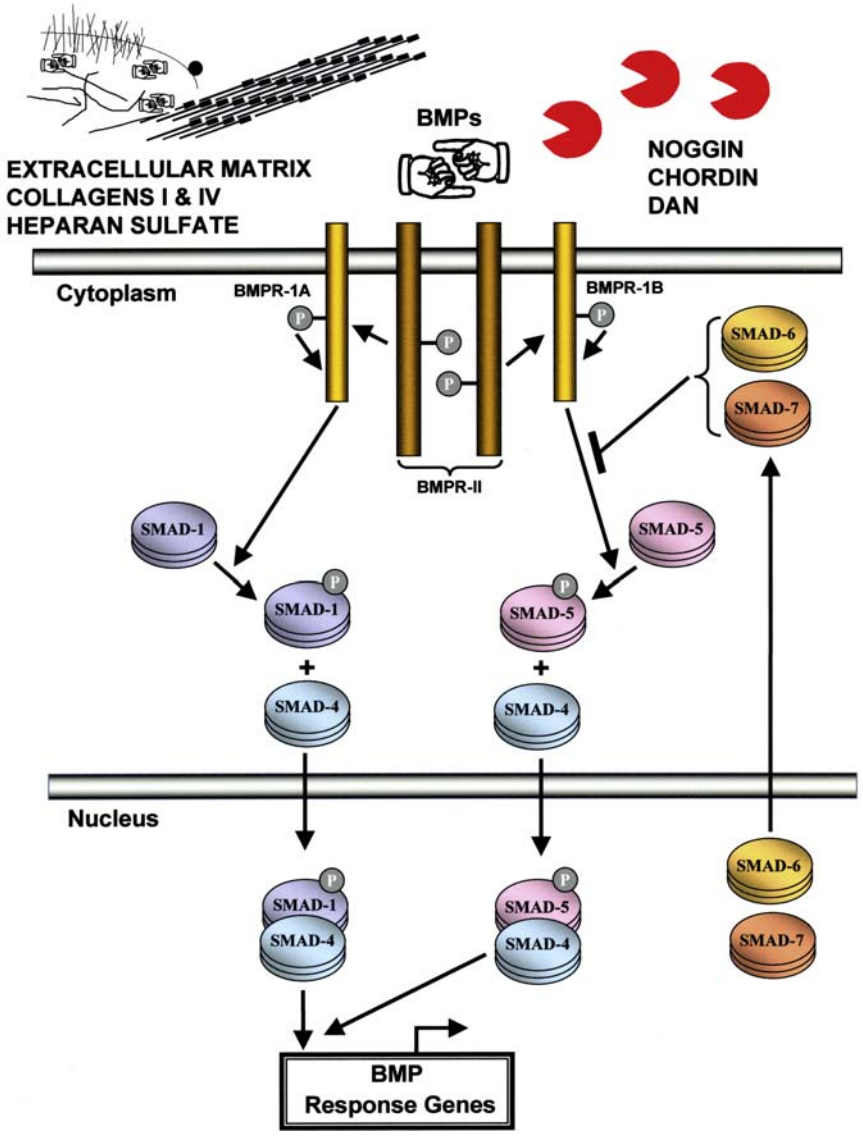

FIGURE 25.7 Bone morphogenetic protein (BMP) receptors (BMPR) and signaling cascades. BMPs are dimeric ligands with a cysteine knot in each monomer fold. Each monomer has two β sheets represented as two pointed fingers. In the functional dimer, the fingers are oriented in opposite directions. BMPs interact with type I and II BMPR. The exact stoichiometry of the receptor complex is being elucidated. BMPR-II phosphorylates the GS domain of BMPR-I. The collaboration between type I and II receptors forms the signal-transducing complex. BMP type I receptor kinase complex phosphorylates the trimeric signaling substrates Smad 1 or Smad 5. This phosphorylation is inhibited and modulated by inhibitory Smads 6 and 7. Phosphorylated Smad 1 or 5 interacts with Smad 4 (functional partner) and enters the nucleus to activate the transcriptional machinery for early BMP response genes. A novel SIP may interact and modulate the binding of heteromeric Smad 1/Smad 4 complexes to the DNA.

for optimal bone induction. The disks were consistently osteoinductive with BMPs in rats, but the beads were inactive [60]. The chemical composition of the two hydroxyapatite configurations was identical. In certain species, the hydroxyapatite alone appears to be "osteoinductive" [61]. In subhuman primates, the hydroxyapatite induces bone, albeit at a much slower rate. One interpretation is that osteoinductive endogenous BMPs in circulation progressively bind to the implanted disk of hydroxyapatite. When an optimal threshold concentration of native BMPs is achieved, the hydroxyapatite becomes osteoinductive. Strictly speaking, most hydroxyapatite substrata are ideal osteoconductive materials. This example in certain species also serves to illustrate how an osteoconductive biomimetic biomaterial may progressively function as an osteoinductive substance by binding to endogenous BMPs. Thus, there is a physiological–physicochemical continuum between the hydroxyapatite alone and progressive

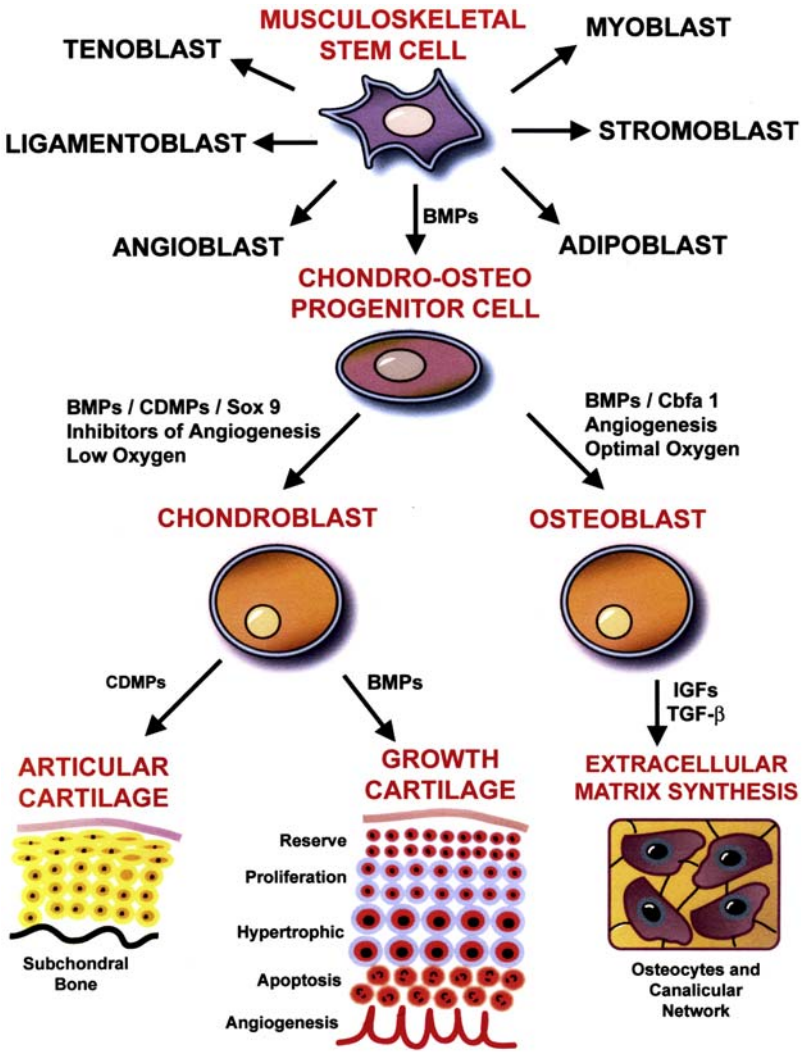

FIGURE 25.8 The lineage of the putative musculoskeletal stem cell. The bone morphogenetic proteins (BMPs) determine the lineage into chondro/osteoprogenitor cells and further specialization into articular chondrocytes growth plate chondrocytes and osteoblast lineage. BMPs are morphogens critical for directing the differentiation of cartilage and bone cells. *Cbfa 1*, core-binding factor α(1); *CDMP*, cartilage-derived morphogenetic proteins; *IGF*, insulin-like growth factor; *TGF-β*, transforming growth factor- *β*.

composites with endogenous BMPs. Recognition of this experimental nuance will save unnecessary arguments among biomaterials scientists about the osteoinductive action of a conductive substratum such as hydroxyapatite.

Complete regeneration of a baboon craniotomy defect was accomplished by recombinant human osteogenic protein (human BMP-7) [62]. Recombinant BMP-2 was delivered by a poly(hydroxy acid) carrier for calvarial regeneration [63]. Copolymer of polylactic and polyglycolic acid was evaluated as a delivery system for BMP 2 in a rabbit ulna nonunion model and the results were satisfactory (Fig. 25.9) [64].

An important problem in the clinical application of biomimetic biomaterials with BMPs and/or other morphogens in regenerative medicine is sterilization. Although gas (ethylene oxide) is used, one should always be concerned about reactive free radicals. Using allogenic demineralized bone matrix with endogenous native BMPs, as long as a low temperature is maintained (4°C or less), the samples tolerate up to 5–7 milliradians of irradiation [65,66]. The standard dose acceptable to the US Food and Drug Administration (FDA) is 2.5 milliradians. This information is useful to biotechnology companies preparing to market recombinant BMP-based osteogenic devices. Perhaps a tissue banking industry with an interest in bone grafts [67] may also use this critical information. Various freeze-dried and demineralized allogeneic bones may be used in the interim as satisfactory carriers for BMPs. The moral of this experiment is that it is not the irradiation dose but the ambient sample temperature during irradiation that is absolutely critical.

FIGURE 25.9 Bone morphogenetic proteins (BMPs) have wide-ranging roles in regenerative medicine and surgery. Their applications include, but are not limited to, orthopedics and plastic and reconstructive surgery, in dentistry and oral surgery. Recombinant BMP-2 has been approved by the US Food and Drug Administration for spine fusion and the nonunion of fractures.

ARTICULAR CARTILAGE REGENERATION AND CARTILAGE MORPHOGENETIC PROTEINS

Morphogenesis of the cartilage is the most important rate-limiting step in the dynamics of bone development. Cartilage is the initial model for the architecture of bones. Bone can form either directly from mesenchyme, as in intramembranous bone formation, or with an intervening cartilage stage, as in endochondral bone development [7]. All BMPs first induce the cascade of chondrogenesis; therefore, they all sense cartilage morphogenetic proteins. The hypertrophic chondrocytes in the epiphyseal growth plate mineralize and serves as a template for appositional bone morphogenesis. Cartilage morphogenesis is critical for both bone and joint morphogenesis. The two lineages of cartilage are clear-cut. The first, at the ends of bone, forms articulating articular cartilage. The second is the growth plate chondrocytes, which under hypertrophy and synthesize cartilage matrix destined to calcify before replacement by bone and are the "organizer" centers of longitudinal and circumferential growth of cartilage, setting into motion the orderly program of endochondral bone formation. The phenotypic stability of articular (permanent) cartilage is at the crux of the problem of osteoarthritis. The "maintenance" factors for articular chondrocytes include TGF-β isoforms and the BMP isoforms [68].

An in vivo chondrogenic bioassay with soluble purified proteins and insoluble collagen scored for chondrogenesis. A concurrent reverse transcription–polymerase chain reaction approach was taken with degenerate oligonucleotide primers. Two novel genes for CDMPs 1 and 2 were identified and cloned [69]. CDMPs 1 and 2 are also called GDF-5 and GDF-6, respectively [70]. CDMPs are related to BMPs (Fig. 25.6). CDMPs are critical for cartilage and joint morphogenesis [71]. CDMPs stimulate proteoglycan synthesis in cartilage. GDF-7 initiates tendon and ligament morphogenesis.

REGENERATIVE MEDICINE AND SURGERY OF ARTICULAR CARTILAGE

Unlike bone, with its considerable prowess for repair and constant regeneration, articular cartilage is recalcitrant. The recalcitrant regeneration in articular cartilage may be due to the relative avascularity of the tissue, the high concentration of protease inhibitors, and perhaps even cytokine inhibitors. The wound debridement phase is not optimal for preparing the cartilage wound bed for best possible regeneration. Although cartilage has been successfully engineered to predetermined shapes [72], true repair of the tissue continues to be a real challenge in part because of hierarchical organization and geometry [73]. The use of autologous culture-expanded human chondrocytes is expanding [74]. Also gaining increasing attention is mosaicplasty for defects in articular cartilage [75]. A continuous challenge in chondrocyte cell therapy is progressive dedifferentiation and loss of a characteristic cartilage phenotype. The redifferentiation and maintenance of chondrocytes for cell therapy can be aided by BMPs, CDMPs, TGF-β isoforms, and insulin growth factors. It is also possible to repair cartilage using muscle-derived mesenchymal stem cells [76]. The possibility of problems posed by cartilage proteoglycans in preventing cell immigration for repair was investigated by chondroitinase ABC and trypsin pretreatment in partial-thickness defects [77] with and without TGF-β. Pretreatment with chondroitinase ABS followed by TGF-β revealed a contiguous layer of cells from the synovial membrane that hinted at the potential source of "repair" cells from synovium. Multiple avenues of cartilage morphogens, cell therapy with chondrocytes, and stem cells from marrow and muscle and a biomaterial scaffolding may lead to optimal tissue-engineered articular cartilage.

REGENERATION OF ARTICULAR CARTILAGE SURFACE AND LUBRICATION

The articular cartilage is a tissue that functions in weight bearing and in friction-free locomotion. Unlike bone, the articular cartilage is recalcitrant to repair and regeneration. The articular cartilage is avascular. Because of this, the innate mechanism of tissue regeneration is feeble and the recruitment of stem and progenitor cells is impaired. In addition, untreated injury to the cartilage progresses to osteoarthritis, with pain and degenerative joint tissue damage [78]. Severe pain is associated with the clinical symptoms of osteoarthritis, and there is a financial burden. In the articular cartilage, regeneration of the superficial zone is critical to maintain joint mobility and reduce wear by optimizing lubrication. The chondrocytes in the superficial zone secrete superficial zone protein (SZP), also known as lubricin and proteoglycan 4, which is encoded by the *prg4* gene. SZP has an important role in lubrication as a boundary lubricant and joint homeostasis. Three key ingredients for the regeneration of the surface of the articular cartilage are signals, stem cells, and scaffolds. SZP secreted by the surface is critical for lubrication. Partial-thickness defects in the articular cartilage do not heal. On the other hand, full-thickness defects penetrating the subchondral bone permit the healing of cartilage. Three important elements for both morphogenesis and regeneration are signals for morphogenesis, stem cells, and scaffolds of ECM. Regeneration is essentially a recapitulation of the sequential cascade of embryonic development and morphogenesis [1].

Normal articular cartilage maintains a functionally optimized lubricated surface with a low coefficient of friction to reduce wear and preserve joint mobility [79]. Cartilage lubrication is critical for joint mobility. Experiments in animals have demonstrated that SZP reduces cartilage degeneration after knee injury [80]. Autologous platelet-rich plasma (PRP) has been used to ameliorate pain, based on the presence of platelet-derived growth factor in the PRP. In an investigation, human PRP significantly stimulated cell proliferation and SZP secretion by surface chondrocytes of the articular cartilage and synoviocytes from the knee joint. In addition, PRP stimulated lubrication in bovine articular cartilage superficial zone in a functional bioassay [79].

It is inevitable during aging most humans will confront the challenges of impaired locomotion owing to wear and tear in bones and joints. Therefore, repair and possibly complete regeneration of the musculoskeletal system and other vital organs such as skin, liver, and kidney may need optimal repair or a spare part for replacement. Can we create spare parts for the human body? There is much reason for optimism that tissue engineering can help patients. We are living in an extraordinary time for biology, medicine, surgery, and computational and related technology. The confluence of advances in developmental biology and inductive signals for morphogenesis of articular cartilage may lead to quantum advances in tissue engineered joints.

The symbiosis of biotechnology and biomaterials has set the stage for systematic advances in tissue engineering [16,81,82]. Advances in enabling platform technology include molecular imprinting [83]. In principle, specific recognition and catalytic sites are imprinted using templates. Applications range from biosensors to catalytic applications, antibody, and receptor recognition sites. For example, the cell-binding RGD site in fibronectin [84] or YIGSR domain in laminin can be imprinted in complementary sites [85].

The rapidly advancing frontiers in morphogenesis with BMPs, hedgehogs, homeobox genes, and a veritable cornucopia of general and specific transcription factor coactivators and repressors will lead to cocrystallization of ligand−receptor complexes, protein−DNA complexes, and other macromolecular interactions. This will lead to peptidomimetic agonists for large proteins, as exemplified by erythropoietin [86]. To such advances one can add new developments in the self-assembly of millimeter-scale structures floating at the interface of perfluorodecalin and water and interacting by capillary forces controlled by the pattern wettability [87]. The final self-assembly is caused by the minimization of free energy in the interface. These are truly incredible advances that will lead to man-made materials that mimic ECM in tissues. Now, superimpose on such chemical progress a biological platform in a bone and joint mold. Let us imagine a head of the femur: a mold is fabricated with computer-assisted design and manufacture. It faithfully reproduces the structural features and may be imprinted with morphogens, inductive signals, and cell adhesion sites. This assembly can be loaded with stem cells and BMPs and other inductive signals with a nutrient medium optimized for optimal number of cell cycles, and then predictably exit into differentiation phase to reproduce a totally new bone femoral head. In fact, such a biological approach with a vascularized muscle flap and BMPs has yielded new bone with a defined shape and has demonstrated the proof of principle for further development and validation [88]. We are indeed entering a brave new world of prefabricated biological spare parts for the human body based on sound architectural rules of inductive signals for bone morphogenesis and responsive stem cell lineage control by BMPs, and with growth and differentiation factors immobilized on a template of biomimetic biomaterials based on ECM.

List of Acronyms and Abbreviations

ECM Extracellular matrix
BMPs Bone morphogenetic proteins
CDMPs Cartilage-derived morphogenetic proteins
BGP Bone gla protein
SDS Sodium dodecyl sulfate
TGF Transforming growth factor
OP-1 and OP-2 Osteogenic proteins 1 and 2
MIS Müllerian duct inhibitory substance
GDFs Growth/differentiation factors
BMPR-IA BMP receptor IA
BMPR-IB BMP receptor IB
SIP Smad interacting protein
rhOP-1 Recombinant human osteogenic protein
FDA Food and Drug Administration
RT-PCR Reverse transcription-polymerase chain reaction
IGFs Insulin growth factors
SZP Superficial zone protein
PRP Platelet-rich plasma
PDGF Platelet-derived growth factor

INTRODUCTION

The goal of tissue engineering and regenerative medicine is to restore or regenerate damaged and degenerate tissues, many of which have explicitly mechanical functions or are regulated by mechanical factors. Indeed, physical stimuli are essential for the proper morphogenesis, maintenance, and repair of numerous tissue types, including bone, cartilage, and blood vessels, all of which are primary targets for tissue engineers. Therefore, being able to describe and understand the role of physical stress and strain mathematically in tissue repair is essential to regenerating functional, mechanically competent tissues.

The role of physical stresses and strains in regulating tissue growth and remodeling has been tremendously interesting to investigators for well over 100 years. Although unfairly to his contemporary colleagues, Julius Wolff is often credited with the concept that tissue structure or form follows from its function (i.e., Wolff's law). At the time, Wolff's law was simply based on the apparent correspondence between anatomical observations of trabecular bone organization and estimations of principal stress directions caused by functional loading conditions. The recognition that adaptation of tissue structure and composition is cell-mediated was not made until later by other investigators. These early observations spawned the interdisciplinary field of mechanobiology, which is focused on identifying mechanisms by which mechanical signals are transduced into cellular activity; it emphasizes the need to consider the effects of physical factors on tissue growth and remodeling as an important part of strategies for tissue regeneration.

Many different cell types from various tissues have been shown to be sensitive to mechanical stimuli in one form or another. The effects of physiological mechanical signals on cells and tissues can be beneficial; they have a central role in maintaining tissue structural integrity via remodeling processes. Alterations in mechanical signals can also contribute to the development of pathological conditions. For example, local shear stresses have a key role in developing and localizing atherosclerotic lesions. Likewise, the progression of osteoarthritis is caused by a vicious cycle of cartilage matrix degradation and increased local stresses. In bone, the mechanical environment also has important clinical implications in the development of osteoporosis, stress fractures, total joint implant loosening, and bone loss during space flight.

Therefore, approaching a tissue-engineering problem from a mechanical perspective involves four steps: (1) describe the native mechanical environment quantitatively, (2) understand the role of mechanical factors in the tissue of interest, (3) manipulate mechanical conditions to enhance function or regeneration, and (4) evaluate the degree of functional restoration of the engineered tissue quantitatively. This chapter will present an overview of the tools and concepts required in each.

DESCRIBE THE MECHANICAL ENVIRONMENT

As mentioned, cells respond and adapt to their local mechanical environment, but to understand this phenomenon, the mechanical environment must be usefully described. This requires an appropriate theoretical framework that can accurately model the salient features of the tissue of interest and describe the local mechanical stimuli experienced by a cell either in situ or in a tissue-engineered construct. The framework must therefore describe the properties and behavior of the tissue or construct, incorporate the loads (boundary conditions) that will be applied, and justify the assumptions made.

It is useful to view tissues as a structural hierarchy through which functional loads are transmitted down to the cellular level (Fig. 26.1). In bone, for example, applied joint and muscle forces result in stresses and strains within the mineralized tissue that can be defined at different scale levels, from the whole-bone level down to submicron mineral crystals embedded within collagen molecules. At each hierarchical level, it is convenient to assume that everything below that level is a continuum (i.e., there is a finite mass density at every point within the material). This simplification allows material properties to be expressed at a given hierarchical level in terms of constitutive equations. As described in the next section, constitutive equations define the relationship between stresses and strains at each level. Cells sense and respond to local stresses or strains produced by forces transmitted from the macrolevel down through the complex structural hierarchy to the cellular level. Cell-mediated adaptational changes in tissue structure and composition subsequently alter the local stresses and strains resulting from functionally applied loads, thus providing a regulatory feedback mechanism. The sensitivity of the cellular response to mechanical stimuli can be altered by a variety of nonmechanical factors such as age and disease, as well as numerous biochemical factors.

Strain and Stress Definitions

Strain

Strain is a normalized measure of deformation. Consider the simple case of a thin rectangular piece of tissue being axially loaded by a force, as shown in Fig. 26.2A. The axial force increases the length of the tissue, but at the same time it decreases its width and thickness. Engineering strain is defined as the change in a dimension of the tissue normalized by its original dimension and is given in the axial direction by:

$$\varepsilon_{11} = \frac{L - L_0}{L_0} \tag{26.1}$$

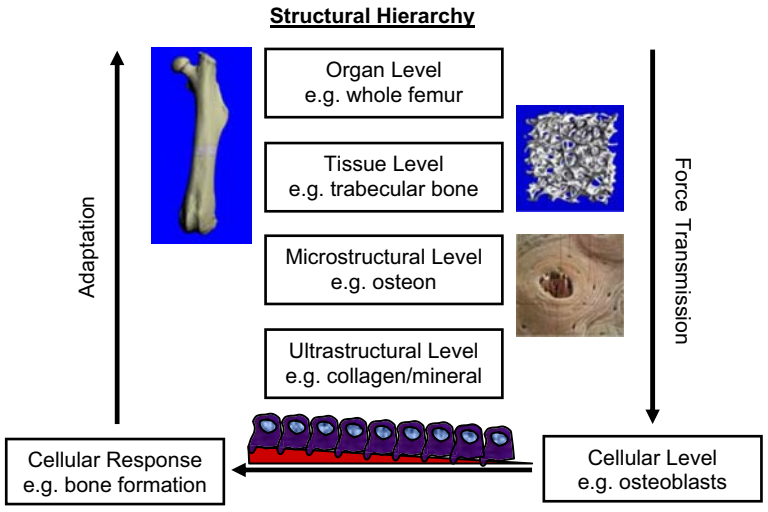

FIGURE 26.1 Force transmission through the structural hierarchy of bone to the cellular level resulting in cell-mediated adaptation of tissue structure and composition.

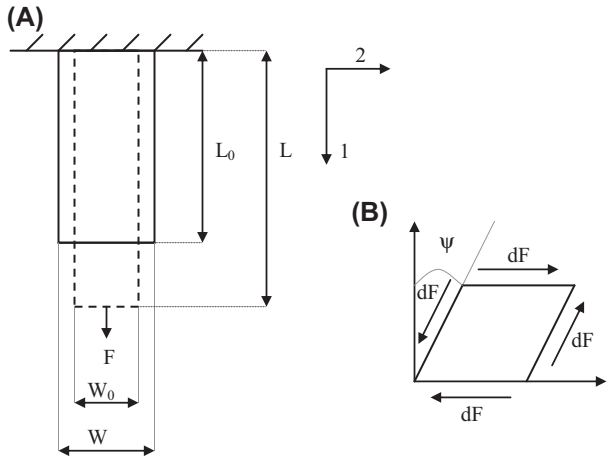

FIGURE 26.2 (A) Axial and transverse strains associated with uniaxial tensile loading. (B) Shear strain associated with torsional or shear loading.

Another important deformation parameter is the Poisson ratio ν, which is defined as the ratio of lateral strain to axial strain and in this case is given by:

$$\nu = -\frac{\varepsilon_{22}}{\varepsilon_{11}} = -\frac{\dfrac{W - W_0}{W_0}}{\dfrac{L - L_0}{L_0}} \tag{26.2}$$

The Poisson ratio is a measure of the tendency for a material body to try to retain its total volume as it is deformed. When $\nu = 0.5$, the material is said to be incompressible (e.g., water) and does not undergo a volume change after deformation. The typical value of ν for tissues is between 0.2 and 0.45. Thus, a tissue subjected to tensile deformation and strain would slightly increase in volume. In contrast to normal strains, shear strains caused by simple shear forces, dF, or from torsional loading, for example, produce a change in shape but not volume, as shown in Fig. 26.2B. Measurement of the angle of shear deformation, γ_{12}, allows calculation of shear strain, as given by:

$$\varepsilon_{12} = \frac{\gamma_{12}}{2} \tag{26.3}$$

The complex deformations created by forces acting in multiple directions necessitate the generalization of deformation to three-dimensional (3-D) space. Deformation in 3-D can be expressed by the deformation gradient tensor, **F**. Consider the body shown in Fig. 26.3A undergoing a deformation from the reference state to a deformed configuration. If one follows the particles P_1 and P_2, they move from position $\mathbf{X}_{P1}$ and $\mathbf{X}_{P2}$ to $\mathbf{x}_{P1}$ and $\mathbf{x}_{P2}$, respectively. There will also be a similar one-to-one mapping of other particles in the reference and deformed configurations. Thus, the deformation of the body can be written as a function relating the current state (lowercase) to the reference state (uppercase):

$$\mathbf{x} = \mathrm{f}(\mathbf{X}) \tag{26.4}$$

In scalar form, this would involve three equations:

$$\begin{aligned} x_1 &= f_1(X_1, X_2, X_3), \\ x_2 &= f_2(X_1, X_2, X_3), \\ x_3 &= f_3(X_1, X_2, X_3), \end{aligned} \tag{26.5}$$

where 1, 2, and 3 correspond to the three directions of the coordinate system.

The displacement vector is given by:

$$\mathbf{u} = \mathbf{x} - \mathbf{X} \tag{26.6}$$

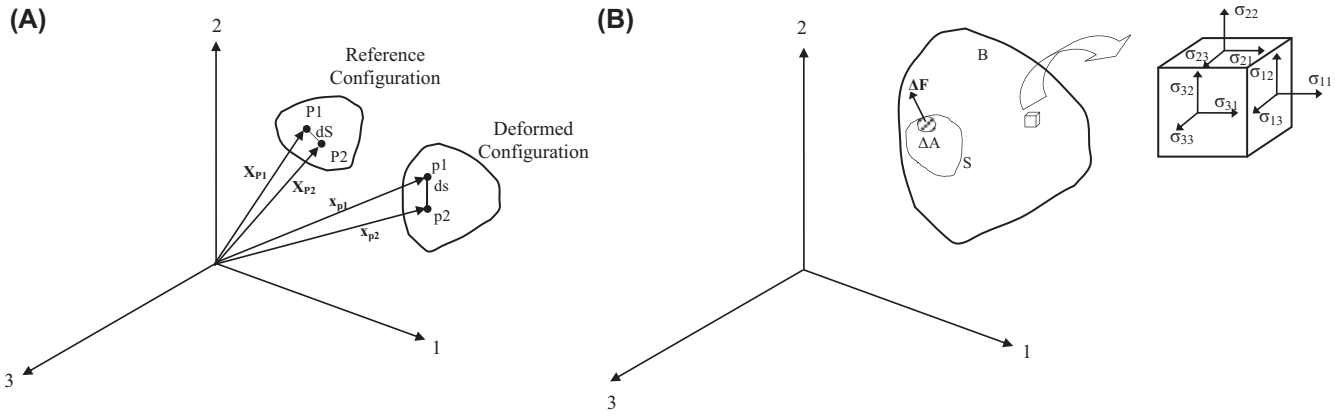

FIGURE 26.3 (A) Deformation of a 3D body from a reference configuration to a deformed configuration. (B) Stress on a surface element, and the nine stress components defining the stress state at a point.

The deformation gradient **F** is then defined as:

$$\mathbf{F} = \frac{\partial \mathbf{x}}{\partial \mathbf{X}} \tag{26.7}$$

In matrix form, the deformation gradient can be written as:

$$[\mathrm{F}] = \begin{bmatrix} \frac{\partial x_1}{\partial X_1} & \frac{\partial x_1}{\partial X_2} & \frac{\partial x_1}{\partial X_3} \\ \frac{\partial x_2}{\partial X_1} & \frac{\partial x_2}{\partial X_2} & \frac{\partial x_2}{\partial X_3} \\ \frac{\partial x_3}{\partial X_1} & \frac{\partial x_3}{\partial X_2} & \frac{\partial x_3}{\partial X_3} \end{bmatrix}, \tag{26.8}$$

and is related to the gradient of displacement by the following expression, in which **I** is the identity tensor:

$$\mathbf{F} = \frac{\partial \mathbf{u}}{\partial \mathbf{X}} + \mathbf{I} \tag{26.9}$$

It is appropriate to use the engineering strains as just defined when the strains in the material are small (typically less than 5%). However, the analysis of large deformations, as frequently observed for soft tissues under functional loading conditions, requires the use of other strain measures. When the deformation is large, a useful measure of deformation is the Green (or Lagrangian) strain, **E**, which is defined as:

$$\mathbf{E} = \frac{1}{2}\left[\mathbf{F}^{\mathrm{T}}\mathbf{F} - \mathbf{I}\right] = \frac{1}{2}\left[\mathbf{D} + \mathbf{D}^{\mathrm{T}} + \mathbf{D}^{\mathrm{T}}\mathbf{D}\right], \tag{26.10}$$

where $\mathbf{D} = \frac{\partial \mathbf{u}}{\partial \mathbf{X}}$ and superscript "T" stands for the transpose of the matrix form of the second-order tensor.

Consider the segment P_1P_2 of length dS that has deformed to p_1p_2 with length ds. In this case, the 1-D Green strain becomes:

$$\mathrm{E} = \frac{1}{2}\left(\frac{ds^2 - dS^2}{dS^2}\right) \tag{26.11}$$

If the deformation under consideration is small, as is typically the case for bone and most structural engineering materials, the quadratic term, $\mathbf{D}^{\mathrm{T}}\mathbf{D}$ in the Green strain can be neglected to give the infinitesimal (engineering) strain tensor, $\boldsymbol{\varepsilon}$:

$$\boldsymbol{\varepsilon} = \frac{1}{2}\left[\mathbf{D} + \mathbf{D}^{\mathrm{T}}\right], \tag{26.12}$$

which in 1-D gives us the familiar expression of engineering strain in a uniaxial test:

$$\varepsilon = \frac{\mathrm{L} - \mathrm{L}_0}{\mathrm{L}_0}. \tag{26.13}$$

To begin to understand the relative values of these strain measures, consider the following example of uniaxial elongation of our rectangular tissue with an original length of 5 cm. In one case, the tissue is stretched to a final length of 5.05 cm (small strain), whereas in the second case, it is elongated to 10 cm (large strain).

	Case I (L = 5.05 cm)	Case II (L = 10 cm)
Green strain $\left(E = \frac{1}{2}\frac{L^2 - L_0^2}{L_0^2}\right)$	0.01005	1.5
Engineering strain $\left(\varepsilon = \frac{L - L_0}{L_0}\right)$	0.01	1.0

Thus, we see that for the small deformations, the different strain definitions give approximately the same value and engineering strain is reasonably accurate, whereas for large deformations, the strain definitions yield different values owing to neglect of the higher-order terms in the engineering strain definition.

Stress

Stress is a measure of the intensity of internal force developed in a material upon application of an external force. Consider force $\Delta\mathbf{F}$ acting on a small surface element of area ΔA in Fig. 26.3B. This element lies on the surface S, which is part of the larger body B. As ΔA tends to zero, the ratio $\frac{\Delta F}{\Delta A}$ tends to a finite limit $\frac{dF}{dA}$, which is defined as the stress on the surface element.
