

# Encyclopedia of **HUMAN DEVELOPMENT**

**Neil J. Salkind, Editor**

**Encyclopedia of  
HUMAN  
DEVELOPMENT**

*These three volumes are dedicated in the hope that the knowledge gained by exploring the topics within these pages can be used to make the world a better, safer, and more peaceful place to live in—and to those lost, from the class of 1964, Weequahic High School, and that interesting and memorable weekend in October of 2004.*

## **ABUSE**

Battered Child Syndrome  
Battered Woman Syndrome  
Child Abuse  
Child Neglect  
Elder Abuse  
Elder Neglect  
Elder Maltreatment  
Incest  
Rape  
Sexual Abuse

## **ADOLESCENCE**

Adolescence  
Dating  
Delinquency  
Gangs  
Juvenile Delinquency  
Storm and Stress  
Teenage Pregnancy

## **AGING AND OLDER DEVELOPMENT**

Activities of Daily Living (ADLs)  
Advance Directives  
Age Discrimination  
Ageism  
Aging  
Aging Parents  
Aging Well  
Assisted Living  
Average Life Expectancy  
Baltimore Longitudinal Study on Aging  
Berkeley/Oakland Longitudinal Studies  
Chronological Age

Dementia  
Elder Abuse  
Elder Maltreatment  
Elder Neglect  
Generation Gap  
Gerontology  
Older Adulthood  
Stroke  
Theories of Aging  
Very Old Age  
Widowhood and Widowerhood  
Wisdom

## **BIOGRAPHIES**

Adler, Alfred  
Ainsworth, Mary Salter  
Ames, Louise  
Apgar, Virginia  
Bandura, Albert  
Barker, Roger

Endocrine Disruptors  
Epilepsy  
Estrogen  
Firearms  
Health Insurance  
Hemophilia  
High Blood Pressure (Hypertension)  
Homicide  
Human Immunodeficiency Virus (HIV)  
Huntington's Chorea  
Hydrocephalus  
Immune System  
Inborn Errors of Metabolism  
Incontinence  
Infectious Diseases  
Ionizing Radiation  
Klinefelter's Syndrome  
Lead Poisoning  
Lesch-Nyhan Syndrome  
Malnutrition  
Methylmercury  
Multiple Sclerosis  
Noise  
Nutrition  
Obesity  
Osteoarthritis  
Osteoporosis  
Polychlorinated Biphenyls (PCB)  
Positron Emission Tomography (PET)  
Preventive Medicine  
Prostate Cancer  
Reflexes  
Rett Syndrome  
Rh Factor  
Rheumatoid Arthritis  
Rubella (German Measles)  
Sexually Transmitted Diseases (STDs)  
Structural and Functional Brain Imaging  
T Cells  
Tay Sachs Disease  
Teratogen  
Testosterone

Thalassemia  
 Thalidomide  
 Tourette's Syndrome  
 Toxoplasmosis  
 Vaccination  
 Vitamin Deficiency  
 Weight  
 Well-Baby Checkup

## **INTELLIGENCE, ABILITY, AND APTITUDE**

Aptitude  
 Aptitude Tests  
 Crystallized Intelligence  
 Developmental Quotient  
 Emotional Intelligence  
 Fluid Intelligence  
 Intellectual Decline  
 Intelligence  
 IQ Tests  
 Mental Age  
 Multiple Intelligences  
 Wechsler Adult Intelligence Scale (WAIS)  
 Wechsler Intelligence Scale for Children (WISC)

## **LANGUAGE AND COMMUNICATIONS**

American Sign Language (ASL)  
 Babbling  
 Baby Talk  
 Bilingualism  
 Echolalia  
 English as a Second Language (ESL)  
 Language Acquisition Device  
 Language Development  
 Mean Length Utterance  
 Phonics  
 Phonological Awareness  
 Private Speech  
 Second Languages  
 Semantic Development  
 Stuttering  
 Universal Grammar  
 Whole Language

## **LAWS AND POLICIES**

Americans with Disabilities Act (ADA)  
 Children with Special Health Care Needs (CSHCN)  
 Children's Rights  
 Courtroom Testimony

Inclusion/Mainstreaming  
 Individuals with Disabilities Education Act (IDEA)  
 Medicare  
 Older Americans Act  
 Public Policy  
 Social Security

## **LEARNING AND MEMORY**

Amnesia  
 Classical Conditioning  
 Dyslexia  
 Extinction  
 False Memories  
 Inhibitory Control  
 Learning  
 Learning Disabilities  
 Long-Term Memory  
 Memory Failure  
 Operant Conditioning  
 Problem Solving  
 Punishment  
 Reinforcement  
 Retention  
 Short-Term Memory

## **MENTAL HEALTH, MENTAL DISORDERS, AND SPECIAL GROUPS**

Anorexia Nervosa  
 Antisocial Behavior  
 Anxiety Disorders  
 Asperger Syndrome  
 Attention Deficit Hyperactivity Disorder (ADHD)  
 Autism  
 Binge Drinking  
 Binge Eating  
 Bulimia Nervosa  
 Cluster Suicide  
 Comorbidity  
 Conduct Disorder  
 Depression  
 Developmental Disabilities  
 Developmental Psychopathology  
 Down Syndrome  
 Eating Disorders  
 Generalized Anxiety Disorder  
 Independent Living  
 Mental Retardation  
 Mood Disorders

Obsessive-Compulsive Disorder  
Oppositional Defiant Disorder (ODD)  
Panic Disorder  
Pervasive Developmental Disorders  
Phobias  
Post Traumatic Stress Disorder (PTSD)  
Postpartum Depression  
Psychopathology  
Ritalin  
Schizophrenia  
Social Anxiety Disorder  
Special Needs Children  
Suicide

### **MIDDLE AND YOUNG ADULTHOOD**

Baby Boomers  
Middle Adulthood  
Young Adulthood

### **OLDER ADULTHOOD AND OLD AGE**

Elderhostel Programs  
Gray Panthers  
Oldest Old Age  
Retirement

### **PERSONALITY**

Anger  
Attribution Theory  
Five-Factor Model of Personality  
Hope  
Identity  
Individual Differences  
Self-Actualization  
Self-Concept  
Shyness  
Temperament

### **PHYSICAL AND BIOLOGICAL DEVELOPMENT**

Activity Theory  
Athletics  
Biological Clock  
BMI (Body Mass Index)  
Brain Development  
Brain Lateralization  
Brain Plasticity  
Breathing Reflex  
Circadian Rhythm

Cochlear Implant  
Crawling  
Electroencephalogram (EEG)  
Exercise  
Fine Motor Control  
Fine Motor Development  
Gross Motor Development  
Hormone Replacement Therapy  
Hormones  
Hot Flashes  
Maturation  
Menarche  
Menopause  
Menstruation  
Motor Skill Mastering  
Myelin  
Myopia  
Neurotransmitters  
Pain  
Physical Development and Growth  
Psychopharmacology  
Puberty  
Sensation Seeking  
Self-Esteem  
Sexual Activity  
Sleep  
Smell  
Taste  
Touch

### **PROFESSIONAL ORGANIZATIONS AND PUBLICATIONS**

American Academy of Pediatrics  
American Association of Retired Persons (AARP)  
American Psychological Association  
American Psychological Society  
Centers for Disease Control  
Gerontological Society of America  
MADD (Mothers Against Drunk Driving)  
National Institute of Child Health and Human  
Development (NICHD)  
*National Vital Statistics Reports*  
Society for Research in Child Development  
World Health Organization

### **RACE, RELIGION, AND ETHNICITY**

African Americans  
Anti-Semitism  
Buddhism

Catholicism  
Ethnic Cleansing  
Ethnic Identity  
Hate Crimes  
Hispanic Americans  
Holocaust  
Immigrants  
Islam  
Judaism  
Native Americans  
Religion

### **SEXUALITY AND SEX**

Bisexuality  
Contraception  
Erectile Dysfunction  
Extramarital Sex  
Heterosexuality  
Homosexuality  
Intimacy  
Kinsey Institute  
Lesbians

### **SOCIAL DEVELOPMENT AND SOCIAL BEHAVIOR**

Aggression  
Altruism  
Androgyny  
Attitude  
Bar/Bat Mitzvah  
Bullying  
Career Development  
Cohabitation  
Conflict  
Cooperative Learning  
Cooperative Play  
Cross-Cultural Development  
Disgust  
Emerging Adulthood  
Empathy  
Friendship  
Gender Differences  
Gender Identity  
Gender Role Development  
Gilligan's Theory of Feminine Morality  
Later Adulthood  
Learned Helplessness  
Locus of Control

Loneliness  
Mentor  
Midlife Crisis  
Moral Reasoning  
Neighborhoods  
Peer Pressure  
Peers  
Pets  
Prosocial Behavior  
Psychosocial Development  
Quinceañera  
Self-Fulfilling Prophecy  
Sex Differences  
Smiling  
Social Class  
Social Development  
Socioeconomic Status  
Strange Situation  
Stress  
Symbolic Play  
Television  
Video Games  
Violence  
Volunteering  
Work

### **STATISTICS, RESEARCH METHODS, AND MEASUREMENT**

Case Study  
Cohort  
Correlation  
Criterion Referenced Tests  
Cross-Sectional Research  
Dependent Variable  
*Diagnostic and Statistical Manual of Mental Disorders*  
Ethical Standards of Research  
Experiment  
Experimental Group  
Experimental Method  
Framingham Study  
Generalizability  
Hypothesis  
Internet  
Longitudinal Research  
Meta-Analysis  
Naturalistic Observation  
New York Longitudinal Study (NYLS)  
Norm-Referenced Tests  
Normal Curve (Bell Curve)  
Norms

Observational Learning  
Qualitative Methods  
Quantitative Methods  
Quasi-Experimental Design  
Reliability  
Sampling  
Scientific Method  
Seattle Longitudinal Study  
Standardized Testing  
Statistical Significance  
Twin Studies  
Validity  
Visual Cliff

**SUBSTANCE ABUSE**

Alcoholics Anonymous  
Alcoholism  
Amphetamines  
Cocaine  
Crack Baby Syndrome  
Drug Abuse  
Drunk Driving  
Gateway Drug  
Marijuana  
Methadone

**THEORIES AND IDEAS  
ABOUT DEVELOPMENT**

Applied Behavior Analysis  
Conscience

Continuity and Discontinuity in Development  
Critical Period  
Deferred Imitation  
Development  
Developmental Direction  
Ecological Theory  
Ego  
Ego Development  
Electra and Oedipal Complexes  
Ethology  
Id  
Imitation  
Imprinting  
Nature–Nurture  
Psychoanalytic Theory  
Reciprocal Determinism  
Self-Efficacy  
Sensitive Period  
Separation Anxiety  
Sociobiology  
Superego  
Tabula Rasa  
Theories of Development  
Utopianism

# About the Editor

---

**Neil J. Salkind** (PhD, University of Maryland, 1973) is a Professor of Psychology and Research in Education at the University of Kansas in Lawrence, Kansas. He completed postdoctoral training as a member of the Bush Child and Family Policy Institute at the University of North Carolina in 1980 and has authored and coauthored more than 125 scholarly papers and books. He is author most recently of

*Theories of Human Development* (2003) and *Statistics for People Who Think They Hate Statistics* (2003), both published by Sage. He was the editor of *Child Development Abstracts and Bibliography*, published by the Society for Research in Child Development (SRCD), from 1988 through 2001 and continues to be active in that organization as a member of various committees.

# Preface

---

The field of human development focuses on the growth and development of the human being, including physical, social, psychological, and emotional development from conception through death. Under the broad umbrella of the term human development are found countless topics, many of which are explored in this encyclopedia. In addition, as our knowledge about development has increased through the use of more sophisticated research techniques and large funding programs, we have seen a growth in the general interest in these areas, hence the proliferation of trade and mass-market books about development that are readily available and accessible to the public.

Although there are hundreds of books about different topics in development, and there are thousands of researchers pursuing more information about the major topics on which specialists in human development focus, there are few comprehensive overviews of these topics and their importance. There are even fewer books that convey this information in a way that is comprehensive, authoritative and informative, and yet not too technical. The purpose of this multivolume *Encyclopedia of Human Development* is to convey this information in that way.

Through approximately 650 entries, experts in each of the areas contained in these pages contribute an overview and an explanation of the major topics in the field of human development.

The underlying rationale for the selection of particular topics and their presentation in this encyclopedia comes from the need to share with the naïve (about human development, that is) but educated reader topics that are rich, diverse, and deserving of closer inspection. Within these pages we provide the overview and the detail that we feel is necessary to become well acquainted with topics that do a good job of representing the field of human development.

As is the case with many encyclopedias, the *Encyclopedia of Human Development* is also organized in alphabetical order, from A through Z. However, particular themes were identified early on that could be used to conceptually organize the information and the entries. These themes or major topic areas constitute the Reader's Guide, which begins on page xv. Categories such as adolescence, education, emotional development, older adulthood, religion, and substance abuse are only a few of the many that help organize the entire set of contributions.

## THE PROCESS

The task of developing a complete and thorough review of the topic of human development started with the identification of entries that the editor and advisory board (see page vii) thought were important to include. We tried to make sure that these entries included topics that would be of interest to a general readership but did not require the use of terms that were too highly technical or too far removed from the interests of the everyday reader. This list was reviewed several times, until we felt that it was a comprehensive set of topics that best fit the vision for the encyclopedia.

As expected, this list was edited and revised as we worked and as authors were recruited to write particular entries. Enthusiastic authors suggested new topics that might have been overlooked and noted topics that might not appeal. All of these changes were taken into consideration as the final list was assembled.

The next step was to assign lengths to particular entries, which ranged from 400 words for bibliographies (such as the one on Charles Darwin) to 5,000 words for articles (such as the one on the human genome). In between, there were articles that were 1,500 and 3,000 words in length. At times, authors asked that the length

be extended because they had so much information they wanted to include, and they felt that the limitation on space was unwarranted. In most cases it was not a problem to allow such an extension.

As for choosing authors, this step took place through a variety of mechanisms, including identifying individuals based on recommendations from the advisory board and the editor's professional and personal experiences, contacting authors of journal articles and books who focused on a particular area directly related to the entry, and asking for referrals from other individuals who are well known in the field.

Once authors were identified and invited, and once they confirmed that they could participate, they were sent detailed instructions and given a deadline for the submission of their entry. The result, after editing, layout, and other production steps, is in your hands.

## HOW TO USE THIS BOOK

Like a good meal, a book is meant to be fully enjoyed, and, while most people believe that encyclopedias are only used for reference purposes, this three-volume encyclopedia is an easy one to sit down with open up, and browse through.

As was mentioned earlier, a primary goal of creating this set of volumes was to open up the broad discipline of human development to a wide and general audience. For this reason, you will find topics that are of particular interest to the general public, such as AIDS, friendship, retirement, and creativity.

Take these books and find a comfortable chair; browse through the topics and read the ones that catch your eye. We are confident that you will continue reading and looking for additional related entries (see the end of many articles for related entries in the set) and, in doing so, learn more about whatever interests you.

Should you want to find a topic within a particular area, consult the Reader's Guide, which organizes entries within this three-volume set into general categories. Using this tool, you can quickly move to an area or a specific topic that you find valuable and of interest.

## ACKNOWLEDGMENTS

Any project as ambitious as this that contains more than 600 entries by more than 650 talented experts has to be the work of many people, and I would like to

acknowledge them all. If this encyclopedia sees success, it is to a very large extent due to the work of these and other fine people.

First, thanks to the advisory board, a group of scholars in many different areas who took the time to review the list of entries and make invaluable suggestions as to what readers might find valuable and how that topic should be approached. These are very busy people who took the time to help the editor develop a list that is broad in scope and represents the most important topics in human development. You can see a complete list of these fine people on page vii.

My editor at Sage Publications, Jim Brace-Thompson, deserves a great deal of thanks for bringing this project to my attention and giving me the chance to make it work. He has been steadfast in his support and advice throughout. I call and he is there to answer my question; I e-mail him and I have an answer in minutes. What else could an editor ask for?

Other Sage people also helped make this task both enjoyable and helped create the useful, informative, and approachable set of volumes you hold in your hands. Among these people are Karen Ehrmann, editorial assistant; Tracy Alpern, project editor; Rolf Janke, Sage References publisher; and Sara Tauber, developmental editor.

My sincere thanks and appreciation go to the managing editors, Kim DeRuyck and Kristin Rasmussen, both advanced graduate students, who managed the submissions from the recruitment of authors to the transmission of the final documents to Sage. Both completed their tasks with enthusiasm, initiative, and perseverance, answering endless questions through thousands of e-mails to hundreds of authors. Thank you sincerely.

And finally, of course, how could anything of this magnitude ever have been done without the timely execution and accurate scholarship of the contributing authors? They understood that the task at hand was to introduce educated readers (such as yourself) to new areas of interest in the broad field of human development, and without exception I think they did a wonderful job. You will see throughout that their writing is clear and informative—just what material like this should be for the intelligent reader. To them, a sincere thank you and a job well done.

## Aging

*First we are children to our parents, then parents to our children, then parents to our parents, then children to our children.*

—Milton Greenblatt

---

## ABECEDARIAN RESEARCH PROJECT

---

The Abecedarian Research Project was an intensive research program designed to study the effect of high-quality educational child care on children from low-income families.

Researchers selected infants from low-income families who were found to be at particularly high risk for educational failure because of low maternal educational levels. The participants received full-time, high-quality educational intervention in a child care setting from their infancy until the age of 5. Each participant was individually prescribed specialized learning games and activities throughout each day that focused on social, emotional, and cognitive areas of development with particular emphasis on language.

Participants' progress was monitored over time with follow-up studies conducted at various ages and with a final study of the original participants at age 21. Findings demonstrated that important, long-lasting benefits were associated with the early childhood program.

The project was initiated in 1972 at the Frank Porter Graham Child Development Center at the University of North Carolina (UNC) in Chapel Hill and was finalized according to plan in the mid-1980s in order to examine the continued effects on participants. The initial project was funded by grants from the

Mental Retardation and Developmental Disabilities Branch of the National Institutes of Child Health and Human Development and from the State of North Carolina. The principal investigator of the original study was Craig Ramey, PhD.

## BACKGROUND

Studies have shown that poverty in early childhood has long-lasting negative consequences for cognitive development and academic outcomes. Children in low-income families tend to lag behind their peers in the earliest school years, suggesting that they enter school at a disadvantage. University-based model programs and research by government organizations have attempted to understand and overcome these negative academic odds.

Most of these endeavors focused on the theory that by providing early intellectual stimulation to at-risk children, cognitive development would be enhanced and allow children to enter school better prepared to learn. This preparation would, in theory, increase the probability of early school success and eventually result in vocational achievement and positive social adaptation in adulthood.

Unfortunately, few early childhood programs were sufficiently well controlled to permit scientists to evaluate the extent to which long-term outcomes were

attributable to the program itself. Researchers were able to assess short-term gains in cognitive development, and they did find improvement in academic performance; however, these gains began to dissipate 3 to 6 years after participants entered school.

The Abecedarian project differed from most other early childhood programs in that (1) it was a carefully controlled study in which half the participants were randomly assigned to receive early intervention in a high-quality child care setting and half were in a non-treated control group; (2) it began in early infancy, whereas other programs began at age 2 or older; and (3) treated children had 5 years of exposure to high-quality early education, whereas most other programs were of shorter duration. This degree of scientific control gave investigators greater confidence that differences between the treated and untreated individuals could be attributed to the intervention itself, rather than to differences among treated and untreated families.

## STUDY DESIGN

Along with principal investigator Dr. Craig Ramey, Margaret Burchinal, PhD, adjunct professor, biostatistics, UNC acted as senior scientist and director of design and statistics. Other investigators included Martie Skinner, PhD, adjunct assistant sociology professor at UNC–Greensboro; Elizabeth P. Pungello, PhD; Barbara Wasik, PhD; and Oscar Barbarin, BA, MA, MS, PhD, Fellow, Preyer Distinguished Fellow for Strengthening Families, psychology, UNC. Joseph Sparling, PhD, and Isabelle Lewis were the codevelopers for the “Learning Games” curriculum.

One hundred eleven healthy infants whose average age was 4.4 months were selected for participation in the Abecedarian Research Project. Fifty-seven infants (the treatment group) were randomly assigned to participate 8 hours a day, 5 days a week, 50 weeks a year with programmed “learning games” designed to focus on cognitive and fine motor skills, language, and gross motor skills. They also received free diapers, food, and transportation and participated in academic, physical, and social enrichment activities. The remaining 54 infants (the control group) experienced either locally available child care or no specialized care.

When the children entered kindergarten, researchers further divided the control and treatment groups. A home and school resource teacher provided academic support to one half of each group, serving as a liaison between families and school officials for the first

3 years of school. Individualized curriculum packets helped parents of the selected families work with their children at home. This portion of the study was designed to determine the different effects of preschool and primary school interventions.

The social and intellectual development of all participants was measured at ages 3, 4, 5, 6½, and 8 years old with the Stanford-Binet and the Wechsler Preschool and Primary Scale of Intelligence tests. Math and reading achievement was measured at ages 8, 12, 15, and 21 using the Woodcock-Johnson Psycho-Educational Battery.

Investigators completed a young-adult follow-up assessment of study participants. At age 21, cognitive functioning, academic skills, educational attainment, employment, parenthood, and social adjustment were measured. One hundred four of the original 111 infants (53 from the intervention group and 51 controls) were assessed.

## FINDINGS

Both the treated and untreated children were initially comparable with respect to scores on infant mental and motor tests. However, from the age of 18 months and through the completion of the child care program, children in the intervention group had significantly higher scores on mental tests than children in the control group. Follow-up cognitive assessments completed at ages 12 and 15 years showed that the intervention group continued to have higher average scores on mental tests. The treated children scored significantly higher on reading and math tests from the primary grades through middle adolescence.

The cognitive and academic benefits from this program are stronger than for most other early childhood programs. Enhanced language development appears to have been instrumental in raising cognitive test scores. As a bonus, mothers whose children participated in the program achieved higher educational and employment status than mothers whose children were not in the program.

## FOLLOW-UP STUDIES

A 15-year follow-up study was carried out. Treated children scored higher on reading and math tests through early adolescence, had a lower rate of grade retention (i.e., flunking or repeating a grade), and were less likely to need special education.

A 21-year follow-up study was performed testing 104 of the original participants. This follow-up study was funded by the Maternal and Child Health Bureau of the Department of Health and Human Services, the Office of Educational Research and Improvement, the Department of Education, and the David and Lucile Packard Foundation. The principal investigator for this study was Frances Campbell, PhD. Relative to their peers in the control group, the participants continued to have a lower rate of grade retention, were less likely to need special education, had higher reading scores, had higher math scores, were more likely to be in school, completed more years of school, were more likely to have attended a 4-year college, were more likely to be engaged in skilled jobs, and were more likely to postpone parenthood.

Young adults who received early educational intervention had significantly higher mental test scores from toddlerhood through age 21 than did untreated controls. Averaged over the age span tested, the mental test score results were considered educationally meaningful. Additional research in 2001 by Reynolds, Temple, Robertson, and Mann indicated a 51% reduction in maltreatment of children who attended the program, suggesting an overall positive effect on treated families.

## IMPLICATIONS

Because poverty in early childhood has long-lasting negative consequences for cognitive development and academic outcomes, low-income children do not always achieve their highest potential. Full-time, year-round preschool child care for low-income families appears to be a positive factor in academic achievement. Thus, quality early childhood education can make a critical difference in the later success of these children and can provide long-term benefits both to the individual and to society.

## FURTHER RESEARCH

Dr. Frances Campbell of the Frank Porter Graham Child Development Center has followed the participants through their adulthood, and as of this writing, has planned an age-30 follow-up report. Leonard Masse and W. Steven Barnett performed a cost-benefit analysis on the project and found that the benefits of the program outweighed the costs by a factor of 4.

And, in order to further appreciation of the results of the study and to disseminate their findings to parents, educators, and policy makers, original

Abecedarian Research Project principal investigator Craig Ramey, PhD, and Sharon Ramey, PhD, completed a 5-year study of 10,000 children from kindergarten through third grade with an aim determining what contributes to a young child's school success. A result of this study is their 1999 book, *Going to School: How to Help Your Child Succeed*, which discusses why the transition to school is such a significant issue and emphasizes the expectations of parents and educators associated with this transition.

## CONCLUSION

The importance of high quality, educational child care from early infancy has been shown to improve the educational experience of disadvantaged children. The Abecedarian Research Project has provided scientific evidence that early childhood education significantly improves the scholastic success and educational attainments of disadvantaged children even into early adulthood.

## ABORTION

---

The technical definition of induced abortion is the removal of products of conception from the uterus of a pregnant woman. Throughout recorded history, there is evidence that women have found the means to limit and space their childbearing through the use of induced abortion. Women of all identities and living in a wide variety of conditions all over the world continue to choose termination as one response to unintended pregnancy. In 2000, an estimated 16 to 21 of every 1,000 women in the United States ages 15 to 44 had induced abortions. The abortion rate has been stable or declining since the 1980s. Another way to express the frequency of abortion is the number of induced abortions compared with the number of live births. In 2000, this ratio was estimated to be 246 per 1,000 births, consistent with a declining trend over the past two decades. These statistics do not include abortions that happen spontaneously, usually called miscarriages.

### WHO HAS ABORTIONS?

Nearly half (48%) of all pregnancies that occur in the United States are not intended, and about the same

proportion (47%) of unintended pregnancies is resolved by abortions. Most women (53%) who have abortions were using some form of birth control during the month they became pregnant, but misused or experienced failure of their contraceptive product or method. By the age of 45, about 43% of women in the United States have experienced at least one abortion. Among the women choosing to have abortions at a given time, most (61%) have already given birth to at least one child, and nearly half (48%) have had at least one previous abortion.

There is not one particular type of woman who is likely to have an abortion. About two thirds of the women having abortions have never been married. Most (56%) are in their 20s, and fewer than 20% are teenagers.

Women of all racial or ethnic, religious, and socioeconomic groups obtain abortions. The largest number (41%) of abortions are performed on non-Hispanic white women, but black women are three times as likely and Latinas or Hispanic women are twice as likely as white women to have an abortion in a given year. Women who identify themselves as Catholic are only slightly less likely to have abortions than other women in the United States. Poor and low-income women are more likely to have abortions than those who are more affluent.

Abortions occur for many reasons, and women tend to have multiple explanations for their decisions to terminate pregnancies. The most common reason, given by three fourths of women having abortions, is that having a baby at that time in their lives would conflict with major commitments such as work, school, or existing family responsibilities. Two thirds of women having abortions give economic reasons for delaying or foregoing parenthood. Half of women choosing abortion do not have the supportive relationship that they would like for becoming a parent—either they do not want to start out as a single mother, or they are having problems in their relationship with a husband or partner. About 13,000 women a year choose abortions to terminate pregnancies resulting from rape or incest.

### WHEN ABORTION WAS ILLEGAL

Major complications from induced abortion are very rare in the United States, occurring in less than 1% of abortions. The risk for death from childbirth, an uncommon event in industrialized countries, is 10 times greater than the mortality risk of abortion. The safety of legal abortion is in stark contrast to the

danger women faced before abortion was decriminalized in the United States in 1973. In the 1950s, for example, there were about 1 million illegal abortions every year, with at least 1,000 associated deaths.

Before legalization, some courageous and qualified providers took considerable personal risks to offer safe procedures to women in need. Women with adequate financial and social resources were sometimes able to seek safe abortions in legal settings outside the United States. Desperation often drove other women to unskilled abortionists working in unsanitary conditions. Women who survived so-called back-alley abortions of this sort or attempts to self-abort sometimes suffered painful chronic illnesses, lost the ability to have children, or experienced trauma that affected their psychological health and well-being.

## JUDICIAL AND LEGISLATIVE RULINGS

On January 22, 1973, the U.S. Supreme Court handed down the *Roe v. Wade* decision, which created a legal, though limited, right to abortion. *Roe v. Wade* concluded that the “right of privacy . . . founded in the Fourteenth Amendment’s concept of personal liberty . . . is broad enough to encompass a woman’s decision whether or not to terminate her pregnancy.” Based on their individual right to privacy, women in consultation with their doctors gained the legal right to choose abortion in the first 3 months (or first trimester) of pregnancy. State laws were permitted to limit second-trimester abortions “only in the interest of the woman’s safety.” In the final 3 months (third trimester) of pregnancy, *Roe v. Wade* allowed states to protect the fetus by restricting abortion unless there is potential danger to the life or health of the pregnant woman.

*Roe v. Wade* granted women the right to early abortion with a physician’s consent, but it did not guarantee financial or medical access to abortion. In 1976, the U.S. Congress passed the Hyde amendment to a federal appropriations bill, eliminating federal reimbursement for induced abortions from Medicaid public insurance coverage for low-income women. As of 2004, Congress had annually reinstated this ban on federal funding of abortion, with narrow exceptions for rape, incest, and threats to the life of the woman if she continued the pregnancy. In 2001–2002, the cost of early surgical abortions was highly variable. On average, women were charged \$364 for procedures in specialized clinics and \$632 in physicians’ offices. The average amount paid by women without insurance coverage for abortion was \$372.

Funding issues have been only one arena of debate in the controversy over women’s right to abortion. Religious and personal beliefs lead some people to reject abortion as an option for themselves. Among those with personal objections to abortion, some advocate for the right of other people to make their own decisions. Others attempt to use the judicial or legislative system to return to the situation that existed before legalization. Attitudes toward sexuality and women’s autonomy, as well as fundamental beliefs about social control over individual decision making, motivate activists on different sides of the abortion issue.

The U.S. Supreme Court heard another major abortion case in July 1992. In *Planned Parenthood v. Casey*, the court reviewed a Pennsylvania statute that required women seeking abortions to receive counseling from physicians in favor of continuing their pregnancies, and then to wait at least 24 hours before obtaining an abortion procedure. Notification of spouses and parents about requests for abortions was also required. Only the provision for spousal notification was considered to impose an undue burden on women by the Supreme Court, and this provision was thus judged unconstitutional. The Court acknowledged the situation of women in abusive relationships, with the potential for violence perceived as part of the burden for women wishing to act independently of their partners. Other provisions of the statute were left intact, although most were seen by the Court as medically unnecessary and burdensome to a lesser extent.

Although *Roe v. Wade* was not overturned by the Supreme Court in the *Planned Parenthood v. Casey* decision, the Court’s strict interpretation of undue burden set a precedent for states to impose numerous restrictions on women exercising their right to abortion. Systematic attacks have eroded women’s access to abortion despite its legal status. As of 2002, 32 states required parental consent or notification for adolescents seeking abortions. In many of these states, it is possible to seek a “judicial by-pass” of parental involvement, but this provision can only be used if a teen has the information and resources to bring a persuasive request to a court. Eighteen states in 2002 mandated delays in accessing abortion pursuant to state-directed counseling. Four states disallowed private insurance coverage of abortion services, and another state required companies to offer alternative policies excluding abortion coverage.

Under the second Bush administration, abortion opponents made significant inroads by labeling a

rarely used procedure “partial-birth” abortion. Most (88%) abortions are performed in the first 12 weeks of pregnancy, and very few occur after 20 weeks. By evoking distorted images of abortion, antiabortion activists succeeded in getting the so-called Partial-Birth Abortion Ban Act of 2003 passed by Congress and signed by President Bush in November 2003. Lawsuits ensued to challenge the constitutionality of the ban and prevent its enforcement, based on the lack of any exceptions to protect the health or life of the woman. As of June 2004, a federal district judge ruled favorably on a lawsuit brought by Planned Parenthood Federation of America (PPFA), and action on other suits was pending.

## ACCESS TO ABORTION

Restrictions on abortion and lack of broad access to abortion services are unique for a legal medical procedure. It is difficult to imagine similar infringements on medical decision making in clinical areas such as heart surgery or cancer treatment. Because of political opposition and associated harassment and violence toward patients and providers, the United States now has a limited number of active abortion providers. In 2000, 87% of U.S. counties (home to more than one third of all women of reproductive age) had no abortion provider. The number of providers declined from 2,042 in 1996 to 1,819 in 2000, with rural areas most seriously underserved.

Most medical residents specializing in obstetrics and gynecology (OB/GYN) are not required to perform first-trimester induced abortions as part of their training. As of 1995, only 12% of OB/GYN residency programs routinely offered abortion training. In 1995, the Accreditation Council for Graduate Medical Education (ACGME) issued a requirement for OB/GYN residencies to provide training for management of spontaneous abortion. In contrast, programs are only required to provide “access to experience” with induced abortion, and residents can opt out of training for elective procedures. A 1998 survey indicated a positive response, with nearly half (46%) of respondents reporting provision of routine training subsequent to the new guidelines. Information on training is incomplete, however, because many programs did not respond to the survey.

The New York City (NYC) chapter of the National Abortion and Reproductive Rights Action League

(NARAL/NY) started its own residency training initiative in response to the provider shortage. In 2002, NYC supported a requirement for all OB/GYN residents working in the city’s public hospitals to receive training in surgical and medical abortion through this program. After implementing the program in New York, NARAL/NY began working to disseminate their training initiative in other states. California has also legislated abortion training for OB/GYN residents in state-sponsored medical schools. The California initiative also has an “opt-out” provision, which allows schools to offer training indirectly through agreements with other institutions. Training in procedures for early abortion is recommended by the Council on Residency Education in Family Practice, yet 71% to 88% of family practice residency programs did not offer such training in 1995.

U.S. Food and Drug Administration (FDA) approval of pharmaceutical agents to induce abortion medically rather than surgically, granted in 2000, could increase the number of U.S. abortion providers. Past experience in several European countries showed mifepristone to be a safe option for inducing abortions without surgery, but acceptance by European women and providers was conditioned by cost and other issues. The early experience with medical abortion in the United States has been promising. Many women prefer the privacy and autonomy of the medical alternative, and acceptance by providers appears to be growing. However, this recently introduced technology requires medical supervision and does not eliminate the need for legal, safe, and accessible surgical procedures. Women’s preferences will continue to be influenced by many practical, physiological, and psychological factors.

## ABSTRACT REASONING

---

Humans must rely on intrinsic cognitive functions for logical conclusions in a variety of situations. Abstract reasoning is a cognitive mechanism for reaching logical conclusions in the absence of physical data, concrete phenomena, or specific instances. Abstract reasoning is essentially a generalization about relationships and attributes as opposed to concrete objects. The capacity for abstract reasoning develops from the initial reasoning about physically present, concrete objects and the subsequent formation of categories and schemas, or cognitive structures that organize and generalize information about specific instances.

In the development of abstract reasoning capacity, cognitive manipulation of objects or data is used to formulate conclusions about relationships. For example, in learning mathematics, one must proceed from understanding the concept of multiple objects in the present visual field to understanding the concept of addition. These new conclusions are successive, just like mathematics themselves. This process is a cognitive transcending of lower-level knowledge to form a new construction, or what Jean Piaget dubbed *reflective abstraction*.

Piaget concluded that the accumulation of knowledge was based partly on this concept of new construction. His hypothesis of schemas application involves two joint mental activities, which he called *assimilation* and *accommodation*. The former involves an integration of new information into previously existing constructs. The latter involves modifying schemas around the new stimulus. Piaget collectively called these operations *equilibration*, in reference to the laborious attempt to maintain homeostasis in cognitive representation. In essence, Piaget suggested that the accumulation of knowledge is a marriage of experience and adaptation.

Piaget thought that children do not form an internal representation of abstract concepts (such as time) on the basis of experience alone. Rather, they form schemas through constant conduction of assimilation and accommodation. Although his original ideas have been elaborated on, Piaget's constructionist view has been embraced for defining universal aspects of cognitive development.

Piaget categorized cognitive development into four maturational stages, and it is in the final stage that abstract reasoning is said to develop. The first stage, the *sensorimotor stage* (birth to 2 years), involves development of goal-oriented interaction and object permanence. The second stage, or *preoperational stage* (2 to 6 years), is characterized by a child's response to visual stimuli. That is, internal representations of the environment are shallow and based only on immediate experience. The child is incapable of projecting relationships within the environment to a higher level. The third stage, or *concrete operational stage* (7 to 12 years), emerges with the development of cognitive reversibility, or the ability to comprehend dynamic states. In the final stage, or *formal operational stage*, (beginning around 12 years), Piaget proposed that relative abstraction skills have been assembled.

Piaget hypothesized that a child at the formal operational level is capable of forming new constructs and make logical deductions in the absence of first-hand experience; that is, the child is able to reason abstractly. The original theory has been evaluated and elaborated on, yet neo-Piagetian theorists maintain the notion that abstract reasoning requires new construction. It is not believed, however, that abstract reasoning peaks at the formal operational level. Research suggests that the development of abstract skills may continue into late adulthood and is contingent on the amount of experience with abstract reasoning.

## ACCOMMODATION

---

According to Piaget's theory of cognitive development, children's thinking occurs as they begin to adapt to their environment in increasingly satisfactory ways. *Schemes* are the techniques that children employ during adaptation. Schemes are patterns of actions that children transfer or generalize by repeating them under similar circumstances or to meet recurring needs. Schemes can be simple or complex patterns of action. An infant, for example, employs a simple eating scheme in turning toward, latching onto, and sucking a nipple that brushes his or her cheek.

An adult follows a much more complicated scheme for eating as he or she sits at a table, spreads a napkin in the lap, and uses a knife and fork to consume food. Schemes are reflexive for infants. As children grow

and acquire additional sensorimotor abilities, their reflexive schemes are enlarged and enhanced. When they encounter a need or a new stimulus in the environment, children inventory their existing schemes to determine which might be used to meet the current need or explore the stimulus. If a match between the need or stimulus and a previously developed scheme is found, adaptation has occurred. If, however, children cannot identify a match, they attempt to achieve adaptation through either *assimilation* or *accommodation*.

During *assimilation*, children achieve adaptation by acting on the environment or objects in the environment to make them fit into existing schemes. Eventually, however, children will encounter a need or a stimulus that cannot be assimilated. They may respond in one of two ways. At the encounter, children may completely ignore or pass by the event without registering it, such as when an adult shows a child a more efficient way to use a tool but the child reverts back to the previous method without attempting what was modeled. A second response may occur when children are dissatisfied with their continued efforts to achieve a match between their existing schemes and an environmental stimulus. Children may use new information from the environment to adjust or modify existing schemes and meet their needs. Adjusting or modifying schemes to meet new needs is called *accommodation*.

For example, a young child may have an established scheme in which he or she calls any large item with wheels a *car*. The child points at a large wheeled item with a box on the back and says "car!" The child's father responds, "No, that's a truck!" The child repeats, "Truck!" and proceeds to identify another similar vehicle in the same way, indicating that he or she has modified or accommodated the scheme based on the new information.

In Piaget's theory, assimilation and accommodation are processes of change. Children change or transform the environment to fit their existing schemes during assimilation, and they change their schemes to accept new environmental information during accommodation. Children and adults use both processes interchangeably and concurrently. Although play is basically assimilation, or the dominance of assimilation over accommodation, accommodation becomes dominant when children imitate another's actions or roles or during periods of intense learning and development.

## ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS)

---

Acquired immune deficiency syndrome (AIDS) is an advanced stage of infection with the human immunodeficiency virus (HIV). AIDS was first identified in 1981 in the United States and was subsequently identified around the world. HIV disease begins by causing the failure of the immune system, the development of any of a set of opportunistic infections (OIs), AIDS, and eventually death. Treatment of HIV disease has improved with the development of new drugs, increasing success at delaying symptoms and reducing mortality rates. However, treatment is not always effective, has significant side effects, is expensive, and is not universally available, especially among the poor and in developing countries.

HIV is a virus that is found most predominantly in body fluids containing white blood cells (e.g., blood, semen, breast milk, and cervical/vaginal secretions). HIV is most often transmitted when one of these body fluids from an infected person enters the blood system of an uninfected person through an opening in the body. HIV transmission most often occurs through sexual intercourse, sharing infected injection equipment involved in illicit drug use, breast-feeding, or transfusion of untested blood products, which does not occur in the developed world. Prevention of HIV infection generally involves modification of behaviors related to these modes of transmission.

### HOW DOES THE IMMUNE SYSTEM FUNCTION?

To understand HIV and AIDS, it is first necessary to understand some rudimentary principles of how the immune system functions. Intact skin is the first component of a functioning immune system. Skin provides a barrier against many infections, including HIV. If an infectious agent such as HIV gets past that first barrier, either through an existing opening, such as a mucosal membrane (e.g., vaginal, anal, urethral tissue) or through a puncture (e.g., injection drug use), the cell-mediated immune system responds to the infection. Generally, the immune system consists of a collection of different types of cells, each of which plays a different role in a sequence of steps that collectively create an immune response. All parts of the immune system are necessary to ensure an unimpaired immune response.

First, a foreign particle such as HIV is introduced into the body. The foreign body is an antigen. The antigen is identified as foreign by immune cells known as *macrophages*. These cells interact with T4 cells (also known as *T helper*, or  $T_H$  cells and as  $CD4^+$  cells), activating the T4 cell. Once activated, the T4 cells secrete lymphokines (e.g., gamma interferon) and begin to divide and replicate. This activity subsequently causes B lymphocytes, or B cells, to multiply and produce antibodies. Antibodies bind to the specific antigen, marking it for destruction. Cytotoxic T lymphocytes (also known as *T8 cells*) eliminate virus-infected cells. After this infection is resolved, T and B memory cells remain to provide a quick immune response in the case of reinfection with the same antigen. In addition, remaining antibodies provide humoral immunity against future reinfection.

### HOW DOES HIV INTERFERE WITH IMMUNE SYSTEM FUNCTIONING?

HIV binds specifically to cells that have the CD4 receptor on their exterior membrane. Therefore, the T4 cell, which is also designated as  $CD4^+$  to indicate the presence of this receptor, is one of the cells that HIV can infect. Once HIV binds to the T4 cell, which also involves binding to the fusin and CC-CKR-5 receptors on the cell membrane, it passes through the cell membrane into the T4 cell. Inside the T4 cell, the virus sheds the protein coat, releasing the viral genetic material, which is RNA, into the cell. Next, the viral RNA is converted into viral DNA by an enzyme

reverse transcriptase. The viral DNA moves into the nucleus of the T4 cell, where it becomes part of the human DNA with the involvement of the enzyme integrase. Subsequently, the merged genetic material begins to manufacture new viral RNA at a high rate. The viral RNA moves out of the nucleus, to the outer cell membrane. Proteins are processed into shorter lengths with the enzyme protease. Immature HIV buds out of the membrane, creating a new HIV virus. This process leaves a pockmark where the HIV viral bud bursts from the T4 cell membrane. The replication of thousands of new HIV cells from the T4 cell eventually kills the T4 cell and releases those thousands of HIV cells to repeat the process with other T4 cells. Through this process, the viral load (number of HIV cells in the blood) increases and the number of T4 cells decreases over time. Because T4 cells play an important role in the sequence of cell-mediated immune functioning, the reduction in T4 cells parallels the decrease in immune function.

### HOW DOES HIV CAUSE HIV DISEASE AND AIDS?

Laboratory tests can monitor T4 cell counts. Normal blood levels are 800 to 1200 per microliter ( $\mu\text{L}$ ) of blood. Over time, HIV replication causes decreases in T4 cell counts. As the level decreases, immune system function also decreases. The impaired immune system fails to respond effectively to other infections, leaving the person more prone to becoming ill from common infections. These infections are OIs because they appear to take advantage of the opportunity of an impaired immune system. Typically, these OIs are significant or life-threatening only in people with impaired immune systems (e.g., newborn babies, elderly people, patients whose immune systems have been impaired by radiation or chemotherapy).

When T4 counts drop below 500, some OIs begin to appear. Below 200, the risk for OI becomes significant. For this reason, a T4 count below 200 in an HIV-positive person is enough to diagnose that person as having AIDS. Alternatively, an HIV-positive person is diagnosed with AIDS when he or she has a T4 cell count higher than 200 and 1 of the 26 defining OIs. The average length of time from infection to development of symptoms of AIDS is about 11 years. This period may be extended with antiviral medications.

The 26 defining OIs are candidiasis of bronchi, trachea, or lungs; candidiasis, esophageal; cervical

cancer, invasive; coccidioidomycosis, disseminated or extrapulmonary; cryptococcosis, extrapulmonary; cryptosporidiosis, chronic intestinal; cytomegalovirus disease; cytomegalovirus retinitis with loss of vision; HIV encephalopathy; herpes simplex (chronic ulcers or bronchitis, pneumonitis, or esophagitis); histoplasmosis, disseminated or extrapulmonary; isosporiasis, chronic intestinal; Kaposi's sarcoma; lymphoma, Burkitt's; lymphoma, immunoblastic; lymphoma, primary in brain; *Mycobacterium avium* complex, disseminated or extrapulmonary; *Mycobacterium kansasii*, disseminated or extrapulmonary; *Mycobacterium tuberculosis*, disseminated or extrapulmonary; *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary; *Pneumocystis carinii* pneumonia; pneumonia, recurrent; progressive multifocal leukoencephalopathy; salmonella septicemia, recurrent; toxoplasmosis of brain; and wasting syndrome due to HIV.

As a person who is infected with HIV continues to lose T4 cells to HIV replication, multiple OIs are likely to develop. Most people with AIDS die of an OI.

### HOW ARE HIV AND AIDS TREATED?

Medical intervention for HIV infection, disease, and AIDS begins with the identification of HIV infection. This is done using a lab test to identify antibodies to HIV present in the blood. Because all viruses, including HIV, are very small, it is easier to identify antibodies to the virus than the virus itself. Therefore, the HIV antibody test is used to identify HIV infection. However, this means that the blood test will only identify infection after antibodies have developed, which can take weeks to months. Many HIV-infected people develop antibodies to the virus within 6 weeks, with almost all developing antibodies within 3 months. Nearly 100% of HIV-positive people develop antibodies within 6 months. The period between actual infection and the development of detectable antibodies is known as the *window period*. Because of this window period, a person who is concerned about possible infection must wait to take an antibody test. If the test is negative, the person is generally encouraged to return in several months for another test to be sure that the result is actually negative. Alternatively, a more sensitive test for the actual virus can be performed, a viral load test. This test is more expensive and therefore is usually reserved to monitor known infection and treatment effectiveness.

Originally, HIV antibody tests were performed on blood samples drawn from the arm, with tests performed at a lab taking several weeks to return results. Therefore, people needed to return for their results. These procedures had several barriers to serving the population. Some people are uncomfortable with blood draws. Many who had initially elected to be tested did not return to receive their results. Newer technology has allowed for home collection of a spot of blood for mail-in testing, needle-free tests performed on cells swabbed from inside the mouth, and most recently, doctor's office testing allowing test results to be given within minutes. Nevertheless, these procedures require initiative on the part of the person to find out his or her HIV status. Currently, most people who are infected with HIV, both in the United States and globally, do not know it.

Once a person is diagnosed as being infected with HIV, or as being HIV positive, medical monitoring and treatment may proceed if available and affordable. Monitoring of health status generally includes T4 cell counts in the blood. In addition, viral load may be monitored using viral load tests. High levels of viral load generally parallel decreases in T4 cell counts, marking immune impairment and predicting risk for developing OIs.

As HIV disease progresses, drug treatment may be implemented, if available and affordable. Drug treatment centers on antiviral medications. Antiviral drugs work by interrupting the processes required for the virus to enter the T4 cell and to use the cell to replicate. There are several different types of antiviral medications used to treat HIV disease. The first type of antiviral developed was a reverse transcriptase inhibitor. These drugs interfere with HIV replication in the T4 cell by inhibiting the enzyme reverse transcriptase and the process of turning viral RNA into DNA. The second type of antiviral drug developed was a protease inhibitor. These drugs interfere with HIV replication by inhibiting the enzyme protease and the process of cutting proteins to the appropriate length for creation of new HIV. Drugs designed to inhibit the integrase enzyme and to block the attachment of HIV to the fusin protein are in development. However, current HIV treatment uses a combination of drugs to inhibit viral replication. This approach, combination therapy, cocktail therapy, or more specifically, highly active antiretroviral treatment (HAART), uses drugs of different types. For example, a common combination includes two reverse transcriptase

inhibitors and one protease inhibitor. This treatment has been found to reduce viral load below detectable levels in many patients. The virus is not eliminated, and interruptions of HAART lead to rebounds in viral load, but with low viral loads, T4 cell counts have been found to increase. With increased T4 cell counts, OIs are naturally reduced. HIV-positive patients on HAART often return to healthy status. AIDS mortality rates in the United States dropped by 50% following the approval of HAART.

Unfortunately, these powerful medications are costly, are not universally or permanently effective, and have significant side effects. In many developing countries, treatment for HIV is unavailable. Some HIV-positive patients find that HAART is not effective because their HIV virus is a drug-resistant strain. Others may find that over time these mutations develop and their own HIV becomes drug resistant, leading to increased viral load, decreased T4 cell counts, development of OIs, and progression of AIDS. Finally, the medications themselves have some very toxic side effects. For example, recent research has reported a twofold to threefold increase in the risk for heart attack among people with HIV taking protease inhibitor medications for 2 to 3 years.

## HOW IS HIV TRANSMITTED?

HIV is transmitted when HIV-positive body fluids that are rich in white blood cells enter the body of an HIV-negative person. Because transmission requires the presence of an HIV-positive person, a spilling of body fluid, and direct entry into an opening of an HIV-negative person, HIV is not transmitted easily or in casual contact. Without direct transmission of body fluids into another person, HIV transmission does not occur. Also, HIV does not live long outside of a human body. HIV transmission is generally associated with four body fluids: blood, semen, cervical-vaginal secretions, and breast milk. For these reasons, caregivers, family members, co-workers, and classmates generally do not need to be concerned about HIV transmission.

Work-site transmission of HIV has only been documented with skin punctures (e.g., needle sticks) or heavy exposure of blood spilled onto mucosal membranes or open wounds (e.g., weeping eczema). Universal precautions, which involve use of protection from exposure to blood and body fluids from all patients, are the standard in health care and prevent HIV transmission.

Transmission of HIV by blood has been mainly associated with untested blood transfusions and sharing of injection equipment by illicit drug users. Donated blood has been universally tested in the United States since 1985. Therefore, HIV transmission by transfusion is largely unknown. HIV is not transmitted to blood donors. Injection drug users (e.g., intravenous heroin users) often share needles and other injection equipment because such equipment is scarce. The reason injection equipment is scarce is that, in efforts to control such drug use, injection equipment has been made available only by prescription (e.g., to diabetics) and is illegal to carry without such a prescription. This means that drug users may share a common set of works or rent the equipment from the drug dealer. In some states, efforts to decrease this mode of HIV transmission have led to more drug treatment, clean needle exchange programs, distribution of bleach and water kits to disinfect injection equipment, and the availability of syringes without prescription in some states.

Transmission of HIV through semen and cervical-vaginal secretions has been the major mode of transmission. Sexual transmission of HIV accounts for most cases of HIV. Historically, the first cases of AIDS identified in the United States were among homosexual men. Globally, however, most cases of AIDS were transmitted through heterosexual contact. In most countries, AIDS cases are equally prevalent among men and women. Prevention of sexual transmission involves abstinence, condom use, and HIV testing and knowledge of status paired with discussion of HIV and prevention with sexual partners.

HIV transmission from mother to child (i.e., vertical transmission) may occur prenatally, at birth, or through breast milk. If a pregnant woman is HIV positive and is not taking antiviral medications, there is a 25% to 30% chance that the baby will be HIV positive. If the mother is treated with even one reverse transcriptase inhibitor, the chance of transmission drops to 8%. Therefore, HIV testing of pregnant women is important in order to initiate antiviral treatment for mother and to protect the fetus. Also, because most babies born to HIV-positive mothers are not HIV positive, transmission through breast milk is an important issue. If a woman is HIV positive and her child is HIV negative, she should not breast-feed. However, in developing countries, formula may be unavailable or too expensive, or the water to mix the formula may not be safe. If a child is born HIV negative to an

HIV-positive mother, the probability of this child eventually being orphaned is also significant.

HIV testing of newborns requires the use of more expensive viral load tests because the child's blood will contain antibodies from the mother, including HIV antibodies, even if the child does not carry the virus itself. Therefore, newborns of HIV-positive mothers must either be tested with viral load tests or treated with antivirals during the 18 months that it can take to clear maternal antibodies and develop detectable HIV antibodies reflective of the child's own HIV status. Also, during that period, breast-feeding would increase the risk for virus transmission to a previously HIV-negative newborn.

## HOW CAN HIV TRANSMISSION BE PREVENTED?

Work on treatment issues parallels work to prevent HIV infection. Vaccines to prevent HIV disease are in clinical trials, but early results have been unsatisfactory. Risk behavior reduction has been the most effective intervention to date. Significant reductions in transmission have been effected with community-wide campaigns to reduce the riskiest behaviors or to modify them to make them safer (e.g., with condoms or with clean injection equipment). Nevertheless, much remains to be done to reduce the rate of growth, much less eradicate the scourge, of HIV and AIDS worldwide.

Prevention of transmission of HIV through blood has focused on testing the transfusion blood supply. With universal testing of blood products, transfusion-related transmission of HIV has been virtually eliminated. Also, modification of illicit drug use behaviors is an important mechanism for preventing blood-to-blood transmission of HIV. Drug treatment to promote abstinence or replacement of injection drugs with prescription oral medications such as methadone is one way to reduce HIV transmission among drug users. Alternatively, approaches known as *harm reduction*, which focus on reducing risks, even if drug use itself is not reduced, have been effective in decreasing HIV transmission. One harm-reduction approach is to distribute bleach and water kits to drug users to allow them to clean equipment between users. The technique is to flush the syringe with bleach twice and then with clean water twice. It is important that drug users also not share other pieces of equipment such as cookers.

Another harm-reduction approach is syringe exchange programs. These are programs in which injection drug users return used, contaminated syringes and are given the same number of clean syringes. Research has countered concerns about this technique. Critics suggested that drug users would use more drugs or would delay seeking treatment. Critics also suggested that the number of drug users would increase. Research has repeatedly countered these concerns by documenting decreased drug use, earlier treatment seeking, and no increase in the number of drug users. Decreases in HIV transmission have been documented. In addition, some states have made syringes available without prescription in order to decrease the need to share needles and subsequently transmit HIV.

Sexual transmission of HIV is the most common form of transmission. Methods of reducing sexual HIV transmission include abstinence, safer sex (condoms, lower risk behavior, fewer partners), and HIV testing and discussion. Abstinence is the only certain method of preventing HIV transmission; however, it is not an acceptable method for many people. For people who do engage in sex and want to reduce their risk for HIV, health education workers have advocated safer sex. Safer sex methods include modifying sexual behavior to avoid high-risk penetrative sex (vaginal or anal) for a lower-risk penetrative (oral) or nonpenetrative (mutual masturbation, frottage) sexual behavior. Penetrative sex can be made safer by using male or female condoms. Also, the odds of encountering an HIV-positive person may be reduced simply by having fewer partners. Another method of reducing sexual HIV transmission is to engage in HIV testing before engaging in sex with a new partner and to discuss HIV status and prevention before having sex. This requires preplanning, interpersonal skills, and the ability to wait for repeat testing after the period of undetectable infection (3 to 6 months) has passed.

In the event of an unintentional exposure to HIV, either through a needle stick in a health care facility, through a sexual assault, or through a voluntary sexual episode, postexposure prophylaxis has been used to reduce the risk of the exposure becoming an active infection. This technique is to administer antiviral medications for 1 month, beginning within 72 hours after the accidental exposure. In theory, any virus that may have entered the body may be prevented from replicating and therefore never establish itself as an infection able to sustain itself. After a month, viral

load testing can evaluate the presence or absence of HIV.

## WHAT IS THE HISTORY OF AIDS IN THE UNITED STATES AND GLOBALLY?

In 1981, AIDS was first identified when a number of patients died soon after presenting with a puzzling set of conditions. Previously healthy young men presented to physicians in San Francisco and New York City with *Pneumocystis carinii* pneumonia (PCP) and Kaposi's sarcoma (KS). PCP is a form of pneumonia usually seen only among newborns, the elderly, and cancer patients whose immune systems have been suppressed by chemotherapy. KS is a cancer of the lining of the blood vessels, appearing as purplish lesions on the skin, which normally appears among elderly men of Mediterranean descent, is usually slow to progress, and is generally not fatal. In 1981, it was reported that 41 young homosexual men had presented with these disorders and that 8 had died within 2 years. The Centers for Disease Control and Prevention in Atlanta released this news in the *Morbidity and Mortality Weekly Report* on June 5, 1981. The *New York Times* was the first to publish this news in the lay press on July 3, 1981.

Until 1983, it was not clear what was causing this syndrome of immunodeficiency-related conditions. In 1983, Dr. Robert Gallo in the United States and Dr. Luc Montagnier in France independently reported that the cause of AIDS was a virus. Gallo called the virus *human T-cell lymphotropic virus type III* (HTLV-III). Montagnier called the virus *lymphadenopathy-associated virus* (LAV). There was a dispute about who had made the discovery first. Nevertheless, the World Health Organization (WHO) renamed the virus the *human immunodeficiency virus* (HIV).

Until 1985, there was no way for persons to know whether they had been infected with the virus. Because there is a lag of years between infection and development of symptoms, many people could be transmitting the virus without knowing that they were infected. In 1985, the U.S. Food and Drug Administration (FDA) approved the HIV antibody test. This development allowed people to determine their HIV status.

Many people did not take the HIV test under the rationale that there was no reason to know because there was no antiviral treatment. At that time, treatment focused on symptomatic OIs in attempts to delay

mortality and improve remaining quality of life. In 1987, the FDA approved the first antiviral for treatment of HIV. This medication was a reverse transcriptase inhibitor, zidovudine (ZDV or AZT), marketed as Retrovir. There were equivocal results in tests of the effectiveness of treatment with this medication. There were questions as to whether it extended life. There was evidence that OIs were delayed, even if death was not delayed. This suggested that the medication could provide better quality of life, if not greater quantity of life.

Several other reverse transcriptase inhibitors were developed in the 1990s, but it was not until 1995 that a significantly new type of antiviral medication was approved by the FDA. In 1995, the protease inhibitor saquinavir mesylate, marketed as Invirase, was approved. Subsequently, other protease inhibitors have been developed and approved. Currently, HAART involves multiple medications, usually two reverse transcriptase inhibitors and one protease inhibitor. Combination therapies were approved in 2000, which showed significant effects at reducing viral load, morbidity (i.e., illness), and mortality. In fact, AIDS mortality in the United States dropped by about 50% with the development of HAART. With future developments of fusin blockers and integrase inhibitors, it may be expected that combination therapies may become even more effective.

## WHAT IS THE GLOBAL IMPACT OF HIV?

In the United States, there have been 886,575 cases of AIDS diagnosed from 1981 through 2002. Of those, 501,669 patients had died by the end of 2002. Globally, there were about 40 million people living with HIV during 2003. Of those, about 5 million were newly infected during 2003. Worldwide, 3 million people died of AIDS in 2003. It is important to note that HIV and AIDS are not evenly distributed around the world. As of 2003, not only are a large number of HIV and AIDS cases found in sub-Saharan Africa (25.0 to 28.2 million infections) and South and Southeast Asia (4.6 to 8.2 million infections), but also the prevalence of HIV and AIDS is disproportionately centered on certain regions in the developing world. Specifically, the adult prevalence rate is highest in sub-Saharan Africa (7.5–8.5%) and the Caribbean (1.9–3.1%), as compared with North America (0.5–0.7%). Similarly, AIDS deaths have been highest in sub-Saharan Africa, with 2.2 to 2.4 million deaths

during 2003. South and Southeast Asia experienced 330,000 to 590,000 deaths in 2003. These were the highest number of deaths, especially as compared with North America (12,000–18,000 deaths) and Australia and New Zealand (less than 100 deaths).

It is important to note that in areas such as sub-Saharan Africa, the high infection, illness, and death rates not only are affecting society as a whole but also are generally concentrated among adults of childbearing age because of the nature of HIV as a sexually transmitted infection. This means that as that cohort is ill and dying, the region is affected by a workforce that is ill and dying and by a generation of parents who are ill and dying, leaving a generation of children orphaned. Workforce productivity, agricultural productivity, and economic vitality are being severely affected by the HIV pandemic.

To respond to the HIV pandemic, these developing nations are significantly limited in their economic ability to provide medical treatment and associated services to people with HIV and AIDS. Therefore, in many of these regions, HIV is left largely untreated, with a morbidity and mortality profile similar to that of HIV in the United States during the 1980s. Specifically, with no antiviral treatment, infection progresses to AIDS unchecked, with a life span of about 2 years after AIDS diagnosis.

## SUMMARY AND CONCLUSION

Not only does the economic status of countries or regions interact with HIV and AIDS, but also specific cultural factors within each region are affected. Specifically, factors that interact with HIV transmission and prevention efforts include levels of education in general, HIV education specifically, poverty and the subsequent influence of injection drug use and prostitution, and the rights of women and their freedom and economic viability to self-determination. All these cultural factors are relevant and must be included in the consideration of prevention and treatment efforts. Overall, it is important to consider the scientific and cultural factors relevant to the prevention and treatment of HIV and AIDS in order to implement effective responses to this pandemic.

## ACTIVITIES OF DAILY LIVING (ADLs)

---

An individual's ability to live independently is often determined by that person's capacity for self-care and ability to engage in various activities of daily living (ADLs). Basic or self-care ADLs include such everyday behaviors as attention to hygiene, bathing, dressing, feeding, and toileting. Complex or *instrumental* activities of daily living (IADLs) include such tasks as cooking and meal preparation, medication administration, financial management, use of communication devices (e.g., telephone), and use of transportation (e.g., driving a vehicle). In older individuals, increasing frailty or declines in cognitive ability are heralded by declines in IADLs followed by declines or disruptions in basic ADLs. Consequently, health care providers routinely evaluate the older individual's level of independence in, versus support needed across, a range of IADLs and ADLs.

ADL functioning may be assessed in three ways: self-report, informant (caregiver) report, or performance of actual ADL tasks. The most common method of ADL assessment is self-report or informant report through informal interview. The individual or primary caregiver (e.g., spouse, adult child) is asked whether the individual requires assistance in any of a range of ADL tasks. Formal self-report questionnaires obtain this information in a standardized way. Lawton and Brody (1969), for example, developed an ADL questionnaire that can be completed either by the individual or by an informant. The questionnaire includes a range of both ADL and IADL behaviors, and the respondent rates each item according to whether he or she is entirely independent in the task (2 points), requires assistance to complete the tasks (1 point), or is entirely dependent on someone else for task completion (0 points). The questionnaire is scored by summing the item responses, with lower scores reflecting greater dependence and need for assistance in IADLs and ADLs. The Older Americans Resources and Services Instrument (OARS), developed for community-based assessment of ADLs in research studies, is similar to the Lawton and Brody measure, although it is an interviewer-administered questionnaire.

Although the self- and interviewer-administered questionnaire method of assessing ADLs is cost-effective and takes little time to administer, the accuracy of this method is dependent on the respondent's honest appraisal or awareness of the individual's true functioning. Research suggests that individuals providing self-report of their own ADL abilities tend to overestimate their functioning, whereas caregivers tend to underestimate their family members' functioning. As such, agreement between self-reports and informant reports may be low, particularly for the more complex IADLs. Disagreements may stem from individuals' overestimates of their own abilities because of lack of awareness of declines or attempts to minimize ADL deficiencies for fear of losing independence. Alternatively, the discrepancies may reflect misestimates by caregivers who have insufficient knowledge of the individual's functioning across the various ADL tasks or from feeling burdened by the care that they already provide to their family members.

Direct performance-based assessment is an alternative method for assessing ADLs that minimizes any biases or inaccuracies in self-report or caregiver report. In this approach, the individual is given a variety of tasks, and his or her performance is rated on

each task based on predetermined criteria. Tasks can include cooking (e.g., making a grilled cheese sandwich, heating up soup), money management (e.g., entering a transaction into a checkbook), and telephone use (e.g., making a phone call and asking for information). Research suggests that performance-based ADL measures are more accurate than self-reports or caregiver reports, and they may be better at determining the individual's level of care needs. The performance-based approach is typically used by occupational therapists in inpatient or rehabilitation settings because these settings provide sufficient time and space to make the detailed observations necessary to plan for the individual's needs. However, few of the performance-based ADL measures used in these settings have been developed for commercial use, and therefore they are not widely available. In addition, this method may be neither suitable nor cost-effective for use in outpatient settings (e.g., a general physician's offices) because of the space (e.g., kitchen setup for cooking tasks) and equipment requirements.

## ACTIVITY THEORY

---

Human actions are the fundamental phenomena that all theories of knowing, learning, and development aspire to explain. However, most theories do not explain concrete individual actions, but provide probabilistic estimates for central tendencies. Most theories also consider actions as expressions and causal consequences of underlying, hidden social or psychological phenomena. Activity theory, on the other hand, is concerned with understanding real, concrete activity in the very settings where it occurs, based on the grounds individual and collective human agents have

for doing what they do. Activity theory therefore aspires to understand and explain each form of action in its concrete material detail, whatever the situation. Because of this orientation, the theory has been in favor with researchers interested in assisting companies and schools in redesigning and changing their everyday work environment. The theory presupposes that structural aspects of a setting mediate activity and that these structures can be understood only by considering their cultural and historical context. A more descriptive name frequently used for the theory is therefore *cultural historical activity theory* or CHAT. Social activities (e.g., fish hatching, teaching, researching), which have arisen as a result of the division of labor in society, are the basic units of analysis in CHAT. The nature of an activity such as *fish hatching* can never be understood by studying it in the abstract, that is, by analyzing the idea of fish hatching; it requires instead the study of the concrete material details of *fish hatching* as a synchronically and diachronically situated system.

### HISTORICAL ORIGINS

Cultural historical activity theory has arisen in response to idealism, which splits concrete human activity from abstract thinking. Grounding their work in the dialectical materialist approach of Karl Marx and Friedrich Engels, Soviet psychologists such as Lev Vygotsky worked to establish a theory that could simultaneously account for knowledge as the result of concrete human actions *and* of sociocultural mediation; this is now known as *first-generation activity theory*. Other Soviet psychologists, including Alexander Luria and Alexei Leont'ev, further elaborated this position by including a dialectical relationship between the individual and collective (culture, society); this is now known as *second-generation activity theory*. Their work constituted the basis for more recent, Western European developments: the Finnish scholar Yrjö Engeström developed a structural perspective on activity systems, whereas the German critical psychologist Klaus Holzkamp worked out a theoretical and methodological framework that focuses on a subject-centered perspective of human activity. *Third-generation activity theory* is concerned with understanding and modeling networks of activity systems.

## POWER TO ACT, AGENCY

Fundamental to CHAT is the human ability to act or agency. Individual knowledge can be thought of in terms of the action possibilities (room to maneuver) individuals have in concrete situations; an increase in action possibilities constitutes learning and development. Culture and cultural knowledge can then be theorized as the generalized action possibilities, which exist at the collective level—any action, even the most atrocious war crimes, are then concrete realizations of possibilities for which the culture as a whole is responsible. Importantly, existing culture is reproduced and new culture produced in the concrete actions of individuals. These actions always arise from the (dialectic) relation of the social and material (i.e., sociomaterial) structures in concrete settings, on the one hand, and the internal, mental structures (schemas) that enable perception of these external structures, on the other.

Agency and structure are dialectically related; they presuppose one another. Structure exists both as social and material resources and as schemas. The resources and schemas are dialectically related: schemas develop as the newborn individual engages with the world, but the perception of the world requires schemas. New schemas are therefore coextensive with new lifeworld elements available to the individual consciousness. Because of this dialectical relationship, individual development is both highly idiosyncratic, leading to differences in the schema developed, but also highly constrained, given that all individuals interact with the same material structures and cultural practices.

Agency also means that the human subjects of an activity system are not mere responders to fixed external conditions; they are endowed with the power to act and thereby change their conditions. Thus, to take a concrete example, fish culturists and hatchery managers are not merely cultural dopes reacting to external conditions or blindly following rules. Rather, hatchery workers actively contribute to reproducing fish hatching as concrete activity, and they produce fish hatching in new ways and therefore contribute to individual and collective learning and development. However, agency and therefore control over the context are not unlimited. Objectively experienced structures in the hatchery and higher organizational levels constrain what any hatchery employee can do. There are always social and material constraints on actions. Thus, the agency of hatchery employees is dialectical: both subjectively determining and objectively

determined by their life conditions. CHAT articulates human learning and development in terms of the *expanding* control over the conditions.

## HIERARCHICAL LEVELS WITHIN ACTIVITY

In CHAT, *actions* play a special role because this is what human individuals bring about and what researchers observe. In many situations, feeding fish, uttering a request for more fish feed, or (mentally) adding the number of feed bags to find the total amount of feed distributed in a day are typical actions because they realize conscious goals articulated by individual hatchery workers. An action implies both physical (bodily) involvement—even mental arithmetic requires a human body—and participation in social *activity* (fish hatching). Actions also imply acting subjects and objects acted on. Actions, however, do not constitute the smallest element in the analysis because they are realized by unconsciously produced elements, *operations*. To understand or theorize any moment of human activity, three concurrent levels of events need to be distinguished: activities, actions, and operations.

## Activities, Actions, Operations

Activities are directed toward objects, always formulated and realized by collective entities (community, society). Fish hatching is an activity; fish culturists can earn a salary, which they use to satisfy their basic and other needs, because fish hatching contributes to the maintenance of society as a whole. Actions are directed toward goals, framed by subjects (individuals, groups); feeding fish constitutes an action because at any time during the day, fish culturists make conscious decisions (form the goal) to go to the ponds and throw food. Operations are unconscious, oriented toward the current conditions: for example, the current state of the action and its relation to the sociomaterial structures of the setting. Experienced fish culturists do not have to form the goal, “flick the hand to spread the food as widely as possible,” but their arms and hands produce the required movements, making adjustments to the amount of food currently on the scoop, wind, distribution of fish in the pond, or weight of the scoop.

It is apparent that in the course of individual and collective development, particular phenomena change levels. For example, at some time in the cultural historical evolution, human individuals who needed

some tool decided to make it—even chimpanzees fashion branches to “fish” termites from their mounds. Later, as part of the division of labor, tool making became an activity in its own right. For example, one hatchery worker fashioned a mechanical feeder from scratch, including a leaf blower. If a company were formed to build such mechanical feeders in large numbers, a new activity system would have formed. A movement in the opposite direction is observed when newcomers to the hatchery learn to feed fish. Initially, the feed thrown with a scoop tends to clump, leading to feed falling to the bottom of the pond, both wasting feed and giving rise to dangerous bacterial growth. The newcomer consciously focuses on flicking the hand holding the scoop to spread the feed as widely as possible—here flicking the hand is an action. But with time, the newcomer no longer needs to consciously focus on flicking the hand, which now has become an operation contributing to realizing feeding fish.

### Sense, Reference, Meaning

Activities and actions are dialectically related: actions concretely realize activities, one action at a time, but they are oriented toward the realization of an activity. That is, activities presuppose the actions that realize them, but actions presuppose the activities that they realize. It is in its relation to the activity that an action obtains its *sense*: the sense of feeding fish in a hatchery differs from feeding fish in a home aquarium or feeding fish at the Vancouver Aquarium Marine Science Center. Actions and operations also mutually constitute and therefore presuppose one another: operations concretely realize specific actions, thereby presupposing the former, but actions are the context in response to which operations emerge. Actions therefore constitute the *referents* in response to which operations emerge. The hatchery workers’ hand flick operations presuppose fish feeding, but fish feeding only exists in the material details of operations such as filling the scoop, extending the arm, and flicking the hand. It is only in the dual orientation of actions to activities (sense) and operations (reference) that we can talk of *meaning*. An action is grounded both in the body that produces it and in the culture that gives it its sense. Communicative actions (including sentences, words, and other symbols) are meaningful only in their simultaneous relation to collective activity and embodied operations (e.g., unconscious production of words and gestures).

## NATURE OF HUMAN ACTIVITIES

### Subject and Object

Cultural historical activity theory presupposes human activity (e.g., fish hatching) as its basic unit of analysis. This unit is dialectical in the sense that however we partition it, each part can be understood only in its relation to all other parts. The most fundamental partition that can be made is that between the acting subject and object. For example, to understand the concrete activity of *fish hatching*, we can ask “Who is doing the work?” “What are they working on?” and “What is the result?” The answer to the first question gives us the subject, individual or group (hatchery personnel); the answer to the second question gives us the object, the raw materials involved in hatchery operations, eggs, milt, and the continuously developing young fish. The result to the third question gives us the outcomes of the activity, for example, “a well stocked river.” To understand *fish hatching*, subject and object cannot be understood independently of one another: fish culturists are defined by what they are working on as much as the things being worked on are defined by the fish culturists. Most importantly, activity theory conceives of subject and object as appearing twice: as concrete structures and schemas. To understand a concrete activity (or action), one needs to know how the raw materials appear to the acting subject and what its visions are for the future outcomes.

### Motive, Emotion, Motivation

Motivation and emotion are tied to the motive of activity. They do not exist independently from cognition, impinging somehow from the outside. Rather, they are integral to its constitution. Fish culturists identifying with the hatchery, and therefore pursuing its central motive, are also highly motivated in their everyday work. They “go the extra mile.” Because of this identification, everything they learn contributes to the development of the hatchery community: every benefit to the collective becomes a learning opportunity for others. Their attunements to the hatchery and to themselves as participants become indistinguishable. Fish culturists who do not identify with the hatchery have as their object (motive) the earning of a salary. Their motive is therefore different, no longer coinciding with the production of fish. These individuals may be disgruntled, work to rule, and dissociate themselves from the collective motive.

**Figure 1** The structure of an activity system, using a hatchery as a specific example.

## Identity

In acting toward the object, subjects of activity not only produce outcomes but also reproduce themselves and their community. When hatchery workers feed fish, they reproduce the cultural practice of fish feeding; in the same action of fish feeding, however, they also constitute themselves as members of the hatchery. Identity—who the subject is with respect to others in the relevant community—emerges as the outcome of engagement with the object; that is, as the result of real concrete activity.

## STRUCTURE AND HISTORY OF HUMAN ACTIVITIES

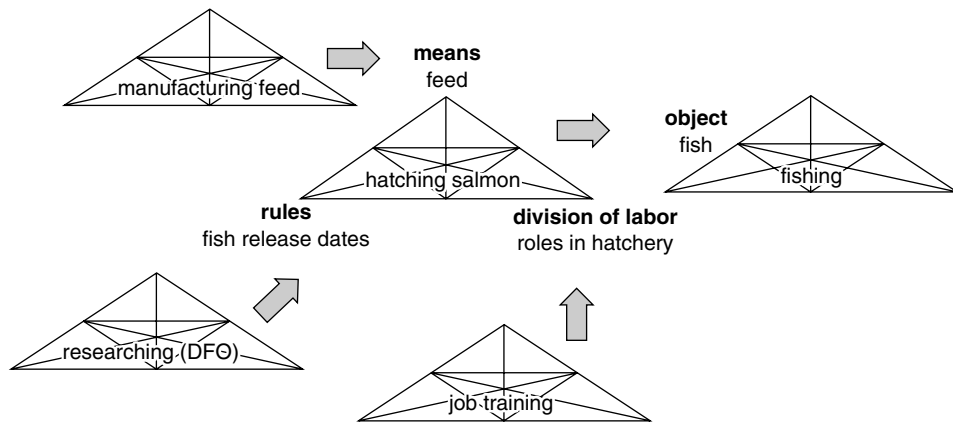

### Structure of Activity

To study a concrete activity such as fish hatching, researchers begin by articulating the activity and then ask what its constituent structures might be. One commonly used heuristic includes six basic conceptual entities (Figure 1): subject (individuals or groups), object (artifact, motive), means of production (including instruments, artifacts, and language), community, division of labor, and rules. Two points are important. First, none of these six entities can be studied in isolation because in a particular concrete activity, the subject (which schemas are brought to bear) and the relevant object (which material structures are currently relevant) presuppose one another. The scoop for throwing feed is used in ways characteristic of fish hatching practices, which is different from the ways in which scoops are used in other

activities. Second, the diagram only presents the system at single point in time. But CHAT has a second focus in the cultural and historical nature of activity; that is, the diachronic aspect of human activity. This aspect is poorly represented in the commonly used heuristic. The activity system as a whole and each of its constitutive parts require an understanding of the cultural historical context.

### Analyzing Activity

To understand any particular action observed, for example, *fish feeding*, requires an analysis of the tools that are used (scoop and bucket versus mechanical food spreader), the division of labor (permanently employed fish culturist versus temporary worker), and the nature of the object (different salmon require different amounts of food, different rates of weight increase, different target weights before release). To understand why one fish culturist uses hydrogen peroxide and another one plain salt as a disinfectant, or why one fish culturist uses a product called “MS-222” whereas another uses carbon dioxide as an anesthetic, researchers need to investigate the individual and collective development of these fish culturists and this hatchery. To understand why two fish culturists change the grain size of the feed that they distribute to fish at different moments in time, one needs to understand where they are with respect to their own professional and developmental trajectories (identities). One of them may have learned, for example, to perceive fish spitting out or nibbling feed of inappropriate hardness, size, or composition.

**Figure 2** Human society consists of many mutually dependent and constitutive activity systems. This interrelation provides for choices because participation in any of the systems contributes to the collective determination of life, which in turn secures the individual.

## Historical Contingency

Whatever happens in the hatchery requires understanding the historical evolution of the hatchery and its larger cultural context, the Salmonid Enhancement Program of the Canadian Department of Fisheries and Oceans. This department has itself undergone changes, such as increased and decreased levels of funding that have mediated the events in the hatchery, and thereby shaped any of its constituent parts, including individual learning and employees' identities. To understand the relative freedom of individual fish culturists to make decisions in their ongoing work of raising fish and their noninvolvement in the decision about when fish are to be released requires careful historical and structural analyses of management-worker relationships and transitions in management over time.

## Division of Labor: Society as a Network of Activities

In the same way that an activity cannot be understood apart from its historical context, it cannot be understood apart from its cultural (societal) context. Historically, different forms of activity have evolved through division of labor, which has allowed some people, at some point in history, to hunt or farm and others to produce hunting and farming tools. Through *exchange* (Figure 1), which in early history took place in the form of bartering, game, grains, and tools were exchanged, providing for the needs of all members of a society, who *consume* the fruits of their labor literally and metaphorically. Through such exchanges,

economic, cultural, and symbolic capital comes to be *distributed* unevenly both within and between activity systems and between individual (worker, millionaire) and collective subjects (social classes). Today, society consists of complex networks of activity systems. Thus, a fish hatchery is connected to many other activity systems, independent of which the events inside the hatchery cannot be understood—a typical articulation of third-generation CHAT (Figure 2). An increased number of salmon in the local river, estuary, and nearby ocean provides the resources on which commercial fishery depend. It also provides resources for sports fishery, which creates a tourist industry, on which hotels, restaurants, or angling and other shops depend. The participants in the different activity systems can then exchange their earnings for food and shelter, the products of yet other activity systems. That is, participation in fish hatching secures hatchery workers with opportunities to fulfill their needs without having to fish, hunt, gather, or farm. That is, participation in fish hatching frees individual hatchery workers from depending on the conditions in an adverse world and allows them to control their own conditions by participating in the collective control of life conditions.

## CONTRADICTIONS

Contradictions are important to CHAT because they are starting points for thinking about and enacting change, which leads to learning and development. Contradictions can be identified within an element, between pairs of elements, between the objects of the

system in its current and more advanced forms, and between neighboring systems. Identifying contradictions within activity systems and how they arise and function generally requires critical analysis. There are two forms of contradictions: *inner contradictions* are those that arise from the unit of activity as a whole, whereas differences, inconsistencies, antinomies, breakdowns, and logical (external) contradictions are expressions of deeper inner contradictions. *External contradictions* mediate (impede) with the activity, but fixing them is equivalent to treating symptoms rather than causes (inner contradictions). Two examples may illustrate the nature of these contradictions. First, verbal utterance “You have to flick your hand like this” and the gesticulations that accompany it express the *same* idea (unit); the difference between utterance and gesticulations is an external expression of an inner contradiction of communication in general. Because utterance and gesticulations are different, they may also express different things. Thus, during human development, words and corresponding gestures may express different ideas, or utterances may lag with respect to the corresponding gestures, giving rise to additional contradictions. Second, graphs used in the hatchery and their corresponding verbal descriptions by a fish culturist express the same ideas but do so in very different ways (material, form). The inner contradiction lies in the fact that each representation is an expression of something without actually being the something (idea).

In workplace and information technology design studies, the identification of contradictions has become an important tool for understanding activity systems, redesigning and changing them, or introducing new tools. All these actions contribute to change and development of and within the system. Contradictions therefore are opportunities for orienting change processes, a reason for the popularity of CHAT in praxis-oriented communities (design, teaching, counseling). But the presence of contradictions is not a sufficient condition for change. Thus, although there were evident contradictions between the fish culturists’ and their manager’s assessments of fish release dates, these were reproduced year after year without leading to any noticeable change in the decision-making practices. True inner contradictions, however, push the activity continuously ahead. Thus, in his classic study, Karl Marx showed how the inner contradiction of a commodity, externally expressed in the antinomy of use-and-exchange value, was the driving force that made a barter-based society evolve into a capitalist society.

## KNOWLEDGE, LEARNING, AND DEVELOPMENT

### Knowledge

In CHAT, knowledge cannot be talked about in the abstract. Knowledge does not exist as something out there or beyond the world of appearances. It is better thought of in terms of knowledgeableability, always exhibited in the concrete details of practical action. Because of the commitment to activity as unit of analysis, the assessment of what hatchery workers know depends on the context. If hatchery workers are asked to do paper-and-pencil problems, for example, about graphs in general, they no longer participate in their normal everyday activity system but in the researcher’s, which focuses on the production of completed problem sheets. Because tools (paper and pencil), object of activity, community, rules, and division of labor differ, the kinds and levels of knowledgeableability expressed in the respective actions also differ. If researchers study how the fish culturists use graphs to track the average weight of fish as part of their daily work, they will notice deep understanding and integration of graphs into the work processes. How well the fish culturists do on paper-and-pencil graphing tasks does not predict how well they use graphs at work—results that reflect those that have been observed among research scientists.

The distinction between what is inside and outside an individual’s head is no longer useful because actions inherently constitute the interface between inside and outside. Whenever a person does something, it happens both in the world, available to other participants in the activity, and inside, as neuronal event. It may be objected that “thinking,” such as mental arithmetic involved in adding 12 and 15 bags of feed, is internal. Vygotsky already pointed to the empirical fact that thinking is inner speech. The underlying processes that eventually allow the person to pronounce the result 27 bags of feed therefore require the same inner processes that previously have been associated with adding numbers aloud in the presence of an elementary school teacher.

### Subjectivity and Intersubjectivity

Subjectivity and intersubjectivity are dialectically related. At the very moment that humans utter sentences, they presuppose that others already understand.

The same is true for actions. Humans always have grounds for their actions and attribute similar intentionality to the actions of others. When fish culturists on stand-by report that “5,000 fish died,” they presuppose the intelligibility to the recipient of the report. However, what one person knows (that 5,000 fish are dead or that the fish tank was overheating) may not be known to another. These differences arise from the material difference between the subjects and their subjectivities, each of which nevertheless concretely realizes generalized, cultural possibilities (intersubjectivity). That is, although the intelligibility of the news exists at the general level, the specific news (knowledge) is concretely realized in different material bodies, which are therefore forced to communicate to ascertain that they are aligned with respect to their understandings of the current state.

### Expansive and Defensive Learning

An increase in individual or collective action possibilities constitutes learning. Increases in possibilities constitute greater control over situations and therefore are inherently motivating—this is expansive learning. There are many instances, however, when individuals learn not because it provides them with desirable increases in their room to maneuver but because they want to avoid punishment—this is defensive learning. For example, fish culturists might take an online course because the managers require it but for which they do not see much use. They would study for the exams only to forget what they studied a short time after. Here, the fear of getting low grades, which might affect not only their career but also future job prospects and other aspects of life, would encourage them to study and (reasonably) do well. They might study but lack inherent motivation.

### Individual and Collective Development

Vygotsky introduced the (asymmetrical) notion of *zone of proximal development* to theorize activity and learning when less able individuals achieve at a higher level while working with more able individuals. The zone of proximal development is then the distance between unaided and aided actions. The notion is asymmetrical because it focuses on the learning of one individual rather than on co-theorizing the additional possibilities available to all individuals who participate in collective activity. In CHAT, centrally

concerned with the relation between individual and collective, the zone of proximal development is understood as the distance between the everyday actions of individuals and the historically new and culturally more advanced actions within a collective.

In a fish hatchery, there are many jobs that individuals could do on their own, such as capturing a female salmon in a holding tank, killing it, and taking the eggs. However, two or three fish culturists working together are more efficient at doing the job, not just because there are two or three times as many hands for the same actions but also because working collectively, a whole range of new actions become possible. Thus, working alone, an individual would have to attempt to catch a fish with a dip net, a truly difficult task. Working collectively, one fish culturist can use a dip net as a barrier or can step into the holding tank (dressed in a wet suit) and use the body as an additional form of barrier, while the other is “chasing” the fish in the manner a fish culturist would do working alone. Neither action is observed when there is only one person. An expansion of action possibilities constitutes development of the entire activity system. That is, approaching tasks collectively results in situations that provide *new* action possibilities exceeding the sum of individual possibilities. Because the action possibilities have expanded, there are now new possibilities for individual learning, because in the concrete realization of some new action, the individual subject acquires new competencies and thereby expands collective possibilities. To continue with the previous example, fish culturists can now learn how to use their bodies together with dip nets for crowding fish, something they cannot learn when working on their own. That is, because individual and collective stand in a dialectical relationship, individual and collective developments are linked. Each action produces resources that change the totality of resources available to the individual *and* the collective. New resources mean new possibilities to act and therefore are coextensive with development of the collective.

### SUMMARY

Cultural historical activity theory is concerned with understanding and explaining real, everyday, situated activity in its concrete, material detail. Its purpose is to provide accounts for the particulars of each action rather than probabilistic description that may not be applicable to any single action or activity. It achieves

this purpose by including all relevant and salient detail. CHAT arrives at a comprehensive picture of human culture by constructing a tight link between individual and collective. However, CHAT is not a master theory, a theory of everything, because it understands itself as the outcome of an activity system: at any moment it is the current provisional and contingent product of a continuously evolving historical process of theorizing practical activity.

## ACUPUNCTURE

---

Acupuncture is the medical practice of inserting needles into specific *acupoints* for the purpose of treating disease. Acupuncture is part of a larger body of eastern health care that includes herbal pharmacy, moxibustion, electrostimulation, massage, fitness exercises including Tai Qi and Qi Gong, meditation, and dietary habits. Each of these features of eastern health care can be employed in both the treatment and prevention of disease. The intentional combining of these eastern health care strategies is designed to promote and maintain healthy development.

The first written record of acupuncture comes from 3000-year-old Shang Dynasty hieroglyphic inscriptions on bones and tortoise shells in China. It is commonly believed that development of this medicine in China existed in the Stone Age more than 10,000 years ago. Acupuncture and other medical practices developed in China and spread to Japan, Korea, Vietnam, other Asian countries, and eventually Europe and the Americas. Today, acupuncture and Chinese medicine are successfully employed worldwide in the prevention and treatment of a wide range of diseases.

Acupoints can be found on defined *meridian pathways* in the body. Twelve of these meridians are connected to 12 individual bodily organs. Eight other meridians run defined paths vertically on the front and back midlines and horizontally at the girdle in five other trajectories that do not connect to a particular organ. Through these pathways run currents of energy, referred to as *Qi* in Asian medicine, which well up at particular *points* along the meridian. The acupuncturist can press or massage, heat, charge, needle, or otherwise stimulate a point, which then affects the meridian and organ or region targeted. A needle placed between the second and third lumbar vertebrae for specific acute lumbago (low back pain) is an example of treatment of a particular point. Using leg points on the stomach meridian for rehabilitation after knee surgery is an example of treating the meridian. Needling stomach meridian points and adding moxibustion (heat therapy) for indigestion and stomachache is an example of treating the associated organ. All are

treated by using acupoints found on meridian pathways running through our bodies.

Acupuncture and Asian medicine have historically been used to treat disorders of the day and the place. In the Warring States period in China, the medicine was crafted to address trauma. In the North of China, cold-induced disorders were addressed, whereas in the South, feverish diseases were treated. As time passed, the medicine was adapted to treat such modern issues as radiation sickness and related cancer in post-World War II Japan, and more recently AIDS, hepatitis, and modern viral plagues worldwide. The 21st century has been called the Age of Shen—spirit disorders such as depression, anxiety, and other mental illnesses.

In Asia, traditional Chinese and modern allopathic medicines are routinely combined in hospitals and clinics. This is the future of medicine in the Western world as Asian medicine moves from “alternative to complementary to integrative” status in our prevention and treatment of disease in all of its manifestations.

## **ADAPTATION**

---

Adaptation takes place simultaneously, and in many ways, it is a complementary process to organization. Like organization, adaptation is a process that has its theoretical roots in biology, which also reflects Piaget’s early training as a biologist. Adaptation is the individual’s adjustment to the environment.

The plant and animal kingdom abound with examples of adaptation (also called *adaption*). For example, the female cardinal is colored a dull brown (whereas the male is bright red), so she is minimally conspicuous and in less danger of being killed (a threat to the survival of the species). The beautiful colors of spring and summer flowers attract insects that are part of the reproductive process that takes place through pollination.

Adaptation is a very complex process that involves the modification of the individual or the environment

to fit the needs of the individual, and the process of adaptation can be broken down into two complementary processes: accommodation and assimilation. Assimilation is the modification of external experiences to fit existing mental schemas or structures, whereas accommodation is the modification of existing mental structures or schemas to meet new experiences. Assimilation and accommodation are complementary, and both operate simultaneously, yet one can take precedence over the other depending on the demands of the environment or the developmental level of the individual.

## **ADDICTION**

---

An agreed upon definition of addiction does not exist among medical and psychological theorists and researchers. The term *addiction* has taken on new meanings as knowledge about the misuse of alcohol and other drugs has progressed and as cultural conceptions of excessive or inappropriate drug usage and behavior have evolved. The concept—not necessarily the term—was first invoked in the description of alcohol problems but has since been applied to other classes of drugs, such as opioids and stimulants, as well as to potentially problematic and “addictive” behaviors that do not involve ingestion of psychoactive substances (e.g., gambling, eating, sex).

In Colonial times, the excessive use of alcohol was viewed as a choice made for pleasure, and repetitive drunkenness earned one the label of drunkard. Heavy drinking was very common, and in fact per capita alcohol consumption in the United States reached its highest levels to date in the mid-1800s. As the Temperance Movement of the 19th century developed

into an abstinence movement that eventually spawned the Prohibition Era (1920–1933), the idea that alcohol use can become compulsive and beyond one's control firmly took root. This emphasis on loss of control and the progression of drinking behavior to harmful levels are essential tenets of the disease model of alcoholism and, by extension, of other addictions as well. The disease model of addiction promotes education about drugs and the addictive process and total abstinence as the treatment goal, and has been the prevailing view embodied by most alcohol and drug rehabilitation agencies for several decades. In addition, Alcoholics Anonymous and the American Medical Association endorse this concept and have been instrumental in developing and promoting this view, although not without challenges from those who think of problematic alcohol and drug use and their treatment as more behavioral and psychological, rather than biological and medical, in nature.

Specific definitions of *addiction* vary in length, specificity, and emphasis. For example, the term has been defined generally as an overwhelming preoccupation with obtaining and using one or more drugs and a tendency to resume use after stopping. Other components of the many definitions available include the notion that usage is clearly nonrecreational and may occur at inappropriate times (e.g., morning drinking) and places (e.g., at work), and that its negative consequences are severe in several domains of functioning and may be felt almost immediately (e.g., hangover) or long term (e.g., liver disease). Traditionally, addiction has meant the most severe form of drug abuse that includes an intense desire or craving (a biopsychological phenomenon) for the drug, physiological tolerance resulting in a need to take more of the drug to achieve the desired effect, and physiological withdrawal symptoms that occur when use of particular drugs is stopped or decreased.

Current conceptions of addiction and problem drug use give more prominence to psychosocial variables and consequences. For example, the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV)* describes criteria for substance use disorders, the most serious of which is labeled *substance dependence*. Criteria for a diagnosis of substance dependence (e.g., alcohol dependence, cocaine dependence, opioid dependence) are met if a person experiences clinically significant impairment or distress, and at least three of the following are present within the same 12 months:

(1) tolerance; (2) withdrawal syndrome for a particular substance; (3) substance often taken in larger amounts or over a longer period than intended; (4) persistent desire or unsuccessful efforts to cut down or control substance use; (5) great deal of time spent in activities necessary to obtain, use, or recover from the substance's effects; (6) important social, occupational, or recreational activities are given up or reduced because of the substance; (7) and the substance use is continued despite knowledge of having a recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance. These criteria apply to both licit and illicit substances. Additionally, the diagnosis may be specified further by indicating whether the substance disorder is accompanied by physiologic dependence (evidence of tolerance or withdrawal) or does not include symptoms of physiologic dependence (no evidence of tolerance and withdrawal). Note that the word "addiction" does not appear in these criteria or in any portion of the *DSM-IV* because of the ambiguity and disagreement that the term invokes from researchers, clinicians, and theorists in the field. Some also point out that to describe someone as addicted, or to label them as an "addict," may lead to stigmatization and dehumanization, or refusal on the part of the person to acknowledge the problem and seek help for it. Another area of current controversy involves the question of whether the addiction term and concept should extend to potentially addictive behaviors that do not involve drug ingestion. Does "addiction" to the internet, shopping, gambling, sex, work, exercise, or eating exist? Clearly, negative consequences and personal distress may be associated with these often compulsive behaviors, yet should the cultural popularity and ubiquity of the term compromise behavioral science standards and nomenclature?

Although the "substance dependence" criterion in the *DSM-IV* perhaps most closely captures what is usually meant by addiction, other terms and phrases that signify problems with alcohol or other drugs are commonly used. Terms like *drug (or alcohol) abuse*, *drug misuse*, *substance abuse*, *substance use and misuse*, *alcoholism*, *polysubstance abuse* or *dependence*, and *chemical dependency* may add to the confusion sometimes experienced by both professionals and laypeople when attempting to describe problems of this type in a shorthand manner. To clarify, it is helpful to view any use of substances as falling on a continuum from nonproblematic usage to combined psychological

## USAGE CONTINUUM

Substance use	Substance misuse	Psychological dependence	Psychological and physical dependence
---------------	------------------	--------------------------	---------------------------------------

## CONSEQUENCES

Benign	Some negative consequences	Chronic negative consequences and high risk for irreversible physiologic impairment or premature death
--------	----------------------------	--

## SUBSTANCE USE PATTERN

Low frequency, duration, and quantity	Increased frequency, duration, and quantity	Continuous or near continuous consumption in high quantities
---------------------------------------	---	--

**Figure 1**      A Continuum of Substance Abuse

and physical dependence (Figure 1). Other continua that are functionally related to these descriptors characterize levels of harmful consequences and consumption patterns. *Substance use* encompasses ingestion of over-the-counter and prescribed medications and legal drugs such as alcohol. *Substance misuse* includes the unintentional or inappropriate use of medications as well as use of licit or illicit substances for the purpose of getting high or realizing other intended effects. For instance, taking more than the prescribed dose of Percocet, an opioid pain reliever, in hopes of achieving more effective pain relief, is an inappropriate use of a medication. Taking it occasionally only for its euphoric effects would likewise constitute misuse (often the term *abuse* is used in this context, but inanimate objects are said to be *misused* rather than abused). Note that any use of tobacco products or illicit drugs such as cocaine is usually thought of as being misused, regardless of the frequency or quantity used.

*Psychological dependence* implies a preoccupation with substance use, at least some evidence of uncontrollable desires or urges to use a substance, and an explicit or implicit goal of changing or controlling one's emotions, cognitions, or perceptions through use of the substance. Continuous or heavy periodic (binge) consumption, and significant, negative consequences of using alcohol or other drugs usually characterize those who can be described as psychologically dependent. Harmful consequences may be

thought of as being psychological (e.g., depression, anxiety, memory impairment), interpersonal (e.g., conflicts with family), social (e.g., absence of leisure time; withdrawal from normal activities), occupational (e.g., job loss), educational (e.g., academic failures and absenteeism), legal (e.g., criminal arrests; driving while intoxicated), or physical (e.g., liver, lung disease) in nature. As the duration of problematic substance use increases, the negative consequences associated with it tend to become chronic, especially if the disorder is untreated. Seeking and anticipating drug-induced euphoria or other intended consequences is central to the drug-taking experience initially, but may later fade and be replaced by a perceived need to use drugs to feel "normal." *Physical dependence* symptoms, combined with the aforementioned characteristics of psychological dependence, constitute the most severe end of the substance use continuum. Although the presence of tolerance and withdrawal are not necessary or sufficient criteria of substance use problems, they should be considered primary indicators of problem severity because of the medical complications that may occur. For example, seizures, hallucinations, and even death may be associated with alcohol withdrawal syndrome. High levels of tolerance may also result in death from unintentional overdose. Moreover, fear of aversive withdrawal symptoms often drives physically dependent people to maintain their habit, and they are immediately rewarded when drug ingestion prevents these unpleasant effects.

Finally, it should be noted that physical dependence might occur without psychological dependence or the presence of harmful consequences, as is the case with pain patients taking opioid medications.

In summary, the concept of addiction is multifaceted and not easily defined, possibly because of the entanglement of both willful and compulsive behavioral patterns. Perhaps the most pragmatic way to view substance use problems, and other potentially addictive behaviors, is to assess the extent to which impairment in biopsychosocial functioning occurs. Fortunately, a range of moderately effective treatments is available to those struggling with minimal or more severe substance use disorders.

## ADLER, ALFRED (1870–1937)

---

Alfred Adler was a physician and psychologist who created the Individual Psychology movement. Adler wrote 19 books and many articles and papers. He gave numerous lectures and demonstrations internationally. He was born in Rudolfsheim, Austria, and he had rickets as a young child. In his later description of the development of personality, physiologic and environmental conditions that increased a young child's felt inferiority were seen as pivotal. He also had an older, healthy, and competitive brother, Sigmund, with whom he experienced intense rivalry for their parents' attention. This struggle sensitized him to the significance of family constellation for the child's developing style of life, which is one of the basic tenets of Individual Psychology. His difficulties with math during his early schooling helped him to understand that teachers

should focus on children's assets rather than their deficits. Adler believed that parents should create a democratic and encouraging atmosphere for children in which neither generation nor gender is used to create statuses of above or below. Adler was the first psychologist to acknowledge the significance of power in both parent-child and marital relations. He thought that males and females, as well as adults and children, should be seen as social equals. Children then could be educated to find active and constructive ways to strive for mastery and to develop social interest. Social interest requires a tendency toward cooperation rather than competition and a focus on contribution to others rather than the status of self. He saw all behavior as purposive and believed that behaviors seen as problematic or symptomatic often were mistaken attempts to compensate for felt inferiority and powerlessness. Motives for such behaviors usually remain outside of the awareness of the individual. Adler's most enduring contributions to child development have been in the areas of parent education, teacher training, and psychotherapy. One of the most widely utilized programs for parent education, Systematic Training for Effective Parenting, is based on the principles of Individual Psychology. He believed that "anyone can learn anything" and developed teacher training approaches to provide the understandings and skills needed by educators to create classroom environments that were democratic and encouraged children's self-confidence. He moved psychotherapy with children from an approach of working with the individual child to one that involved working with both with the child and parents. His founding of child guidance centers had international impact and greatly influenced contemporary approaches in both the training and practice of psychotherapists.

## ADOLESCENCE

---

Adolescence is the transitional period of growth, development, and maturation that begins at the end of childhood (about 10 years of age). The onset of puberty can begin as early as age 8 or as late as age 15 in girls and as early as age 9.5 years and as late as age 15 in boys. It is the defining marker of the start of adolescence. The end of adolescence generally occurs between the ages of 17 and 21 years and is marked by the individual reaching full physical and developmental maturity or young adulthood. This developmental phase involves significant physical, hormonal, cognitive, emotional, and social changes. A neurodevelopmental perspective of adolescence holds that most changes occur in three overlapping stages: early, middle, and late. Early adolescence marks the onset of puberty, middle adolescence is characterized by peak growth and physical maturation, and late adolescence marks the end of puberty and the integration of all functional skills. The concept of adolescence is primarily a product of Western culture where youth are viewed as needing a time to mature from being children to taking on the responsibilities, values, and norms exhibited by the adults in their culture.

### DEVELOPMENTAL PROCESS

A neurodevelopmental view of adolescent development involves examining how the human grows and matures with respect to the component skills necessary to perform various age-appropriate tasks. Those components are referred to as the *functional domains*. The developmental or maturational process of youth occurs across several distinct functional domains, is not always even, but is sequential; however, there is individual variation in the manifestation of that process. The skills learned and mastered are commonly divided into several functional domains: physical, motor, visual, auditory, perceptual, language, cognitive, psychosocial, and specific integrative-adaptive. All basic skills in these domains are mastered by the end of childhood in the normally developing individual.

Physical and psychological trauma, as well as deficits in any of the functional domains, can impede normal development.

### Physical Growth and Development

The physical growth of young adolescents involves significant changes in the height, weight, and brain development that are exceeded only during two other time periods: when the fetus is in utero and between the ages of 1 and 3 years. Although 75% of brain growth (in weight) has developed by age 2, the process of central nervous system maturation takes place over a lifetime.

### Motor Skills Development

The motor skills domain includes all fine and gross motor skills. Fine motor skills include precise, specific, and fine neuromotor responses such as pincer grasp and the ability to write legibly, cut paper designs with scissors, button, fasten, sew, draw match-to-sample designs, and control motor responses (i.e., tics, tremors, fidgeting, jerky motions, uncontrolled motions). Gross motor skills usually refer to whole body movement, including coordination of skeletal muscles, postural control, balance, coordination of motor planning, agility, muscular strength, and endurance (examples of such skills include the ability to hop, skip, jump, walk, run, crawl, walk a balance beam, walk a straight line toe to toe—forwards and backwards—throw, catch, and hit an object with another object).

### Visual Skills Development

Visual skills include visual acuity, the ability to make discriminations between visual stimuli, the ability to track moving or still objects, color vision, extraocular muscle control, which includes resting balance of the eyes, control of eye movement, and visuomotor coordination (looking in different directions and seeing).

### Communication Skills Development

#### *Auditory Skills Development*

The auditory domain refers to an individual's ability to have "normal" hearing acuity, the ability to

process what one hears, and the ability to employ selective discrimination of sounds and auditory cues.

### ***Language Skills Development***

The language domain skills (or the ability to communicate) involve two major areas: receptive and expressive language skills. Receptive language is the ability to understand spoken, signed, or written language and the ability to discriminate meanings and understand semantics and syntax. Expressive language refers to the ability to communicate effectively through spoken, signed, or written language.

The resultant neurobiological changes in childhood and adolescence are immense. For example, changes in the brain dealing with speech and language skills accelerate and peak in early adolescence; acquisition skills for a second language diminish after that.

### **Cognitive Skills Development**

Cognitive skills refer to multiple facets of brain function including (1) the ability to pay and sustain attention that is required to focus selectively and generally on events, actions, and information in the environment; (2) the ability to be alert, which involves mental processing speed, and the ability to respond effectively to environmental cues and stimuli that cause or allow appropriate behavioral adaptation, which facilitates optimal positive outcomes and minimizes negative outcomes; (3) the ability to employ memory skills that include acquiring, storing, and recalling information; (4) the ability to use thinking skills, which means that the individual has knowledge of specifics (store, recall, retrieve), is able to comprehend information (oral, written, and through all senses), and can apply, analyze, synthesize, and evaluate that information; (5) the ability to solve problems and make decisions; and (6) the ability to perform multiple cognitive and functional tasks simultaneously.

### **Perceptual Motor Skills Development**

Perceptual motor skills refer to the ability of the individual to experience a stimulus, process that information in the brain, and employ specific cognitive skills to determine the correct response and then execute the response. Such action requires the integration of stimulus-specific responses from the functional

domains, such as visuospatial discrimination, which includes (1) eye–hand coordination, (2) stereognosis, (3) judgment of speed, (4) discrimination of the direction of the movement of people or their body parts or objects, and (5) spatial orientation of moving objects. Additional perceptual motor skills include temporal sequencing (the awareness of sequential ordering; awareness of time and sequence of events), proprioceptive sense, kinesthetic sense, and reaction time (time elapsed between stimulus perception and initial neuromotor response). Successful maturation of this domain means that the individual is able to synthesize all the other domains (physical, cognitive, visual, language domains), which results in the adolescent having the ability to perceive, interpret, plan, and execute an appropriate neuromotor response to stimuli in the environment, and includes coordination, balance, agility, reaction time, and visuomotor responses. Because the perceptual and motor systems are mutually calibrated, any actions by the adolescent are constantly being fine tuned. The ability to see, hear, think, and move are important but are significantly affected by a person's level of perceptual motor development. This ability begins at birth—children begin to learn to coordinate and integrate their physical, cognitive, visual, auditory, and language skills from birth. Being able to perform the basic motor skills but not being able to plan complex motor functions and not having a well-developed visual skill of tracking can result in awkward or clumsy behavior.

### **Psychosocial Skills Development**

Psychosocial skills include the emotional and social functional skills required to allow an adolescent to cope with others and how he or she perceives the world emotionally. Emotional skills include the adolescent's ability to exhibit emotions appropriate to situation or circumstances, the ability to monitor emotion, and the ability to regulate emotions. Social skills include the ability to initiate, develop, and sustain friendships; the ability to develop healthy interpersonal relationships with others; the ability to establish and maintain mutually beneficial intimate relationships; the ability to be empathetic; and the ability to be altruistic. Social skills also include the adolescent's ability to adopt the moral values of his or her culture and of the greater society. Youth who are moral can use appropriate judgment to discriminate right from wrong and develop a sense of morality.

## Integrative and Adaptive Skills Development

The final functional domain is the task-specific integrative and adaptive skills development domain. This domain involves the ability to coordinate, integrate, and adapt various domains to meet the specific demands of a given task or situation.

## DEVELOPMENTAL STAGES OF ADOLESCENCE

### Rational for this Perspective

Addressing adolescent development from a neurodevelopmental perspective helps one to understand the complexities of the maturational process of normal growth and development. Although this section is geared toward normal development, it is easier to realize how deficits in one functional domain can affect the function of other domains. During the first 10 years of life, most of the changes in the developing human evolve around physical, visual, motor, and language development; skills acquisition is the primary focus. During adolescence, new skills are acquired, but the focus shifts to refinement and expansion.

Adolescents who experience normal development will be able to integrate all functions of each domain and use those skills to successfully adapt to the demands of the environment in which they live. Youth who experience the complex process of maturation and growth normally achieve mastery and integration of these processes by late adolescence (ages 17–21 years).

### Early Adolescence (Ages 10–14 Years)

With the onset of puberty, most adolescents begin to experience a physical growth spurt and begin sexual maturation resulting in significant changes across all domains of function. Some youth experience a “disconnect” between what they are experiencing developmentally and where they are placed in the school setting. There are often major differences across all domains between the abilities of a 10 year old and those of a 14 year old; additionally, because these youth are experiencing other transitions (e.g., going from elementary to middle to high school), they have to adjust to these environmental issues at the same time they are adjusting to biologic and physiologic changes.

## Physical Growth and Development

The onset of puberty causes the adolescent to gain 25% of his or her final adult height (up to 10 cm per year), gain 50% of the ideal adult body weight; experience the doubling of major organs, maturation of facial bones, decrease in lymphoid tissue, genital maturation, primary and secondary sex characteristics, and central nervous system (CNS) maturation, triggering a rise in sex hormones including adrenal hormones, estrogen (female hormone), and testosterone (male hormone). The most significant physical changes of puberty involve a sequential increase in the genital system and secondary characteristics. These changes occur over a 2- to 4-year period resulting in height velocity peak and growth of pubic hair. Females begin to develop breasts (thelarche), grow axillary hair, and menstruate. Males experience growth of pubic hair (pubarche), early testicular and penile growth, nocturnal emissions, marked voice changes, facial hair growth, and muscle development. It is not uncommon for girls to be taller and heavier than boys of the same age during early adolescence.

## Brain Growth and Development

In addition to physical growth, the young adolescent undergoes CNS maturation without increase in brain size. The developing brain consists of billions of cells that are in place (by late fetal life). Neurological insults in early adolescence can have a major adverse impact on later development exposure to infections and toxins. Additionally, effects of these insults to the brain can be observed in young adolescents who were exposed to infections and toxins that damaged their brains in utero.

Other threats from the environment that can cause considerable brain injury result from violence exposure, malnutrition, poverty, and the adverse effects of chronic stress. Some experts hold that the developmental period of early adolescence offers a window of opportunity to repair damage or deficits in brain functioning or neurocortical connections. They offer that the brains of adolescents at this stage of development are repairable and say that because of the *plasticity* of brain tissue, brain cells have an astonishing capacity to adapt to changes and challenges that occur throughout life. Interventions designed to stimulate various functions of the brain may improve or influence the interconnectedness of brain cells or brain circuitry. Such environmental stimulation is also important

because the young adolescent is undergoing profound CNS changes. Therefore, there are still enough redundant functions to allow for retraining of the brain to develop skills using previously unused portions of the brain in adolescents who may have suffered some types of brain injury.

### ***Motor, Visual, and Auditory Development***

All basic gross motor skills are developed by this stage. Youth are better able to maneuver their fine motor skills. Visual acuity, discrimination, tracking, color vision, and extraocular muscle control are all fully developed as youth enter this stage of development.

### ***Auditory Development***

The ability to hear is present at birth but is refined and fully developed by the end of this developmental stage. Components that contribute to this refinement are acuity, the ability to selectively process and discriminate between sounds, and the selective discrimination of written language.

### ***Perceptual Motor Development***

Basic perceptual motor skills such as those that allow for integrated stimulus-specific fine motor and gross motor responses, visuospatial discrimination, eye-hand coordination, and stereognosis are developed at a basic level by age 10 or during childhood. Maturation results in refinement of those skills and improved judgment of speed, direction, and spatial orientation of moving objects.

### ***Language Development***

All basic receptive and expressive language functions are in place. Further development, practice, exposure, and training result in improved language and communication skills.

### ***Cognitive Skills***

These youth are beginning the cognitive refinement process. Although most young adolescents still engage in “concrete” thinking (“here and now,” “right or wrong,” “black or white”), their ability to perform more complex mental tasks (thinking skills and

problem-solving skills) is increasing. They have a clear sense of justice, know right from wrong, and may have an awakening sense of morality and altruism. However, they cannot project future outcomes nor always see abstract relationships between their behavior and potential risks. They have improved mental processing speed and alertness, longer attention spans, and better judgment. They are beginning to understand the purpose of the rules they learned earlier. They understand and can apply factual knowledge to familiar situations but may not be able to apply that knowledge to unique or different situations. They can understand and answer more complex questions as their vocabulary increases and their ability to distinguish between the similarities and differences improves; they can complete simple analogies and are beginning to develop inductive and deductive reasoning abilities. They are able to adopt another person’s spatial perspective with ease and can describe the arrangement of objects from another person’s point of view. They are developing prepositional logic in which they can think about thinking itself. These adolescents are also able to enjoy and take pride in increasingly complex accomplishments, which positively contributes to developing and strengthening a healthy self-image. Their difficulty with futuristic thinking affects their ability to think about the consequences of their behavior before they act. They often engage in “magical thinking” or the belief that they have unique powers that will protect them from harm. Therefore, they are at increased risk for accident-related morbidity and mortality.

### ***Psychosocial Development***

Emotionally, because they are preoccupied with the rapid physiological changes of puberty, these young adolescents may experience feelings of confusion and worry about what is happening to them. They may seem forgetful, distracted, moody, and hypochondriacal, often complaining about body aches or pains. They generally know it is not okay to make fun of others in public. They can control their anger or hurt feelings when they cannot get their own way, are teased by siblings or peers, or are rejected by others. Many adolescents begin to experience emotional distress and conflict when they are trying to decide whether to follow the values of their peers or their families. However, the approval and support from family (especially parents) remains a crucial feature

of their healthy development and resilience. Socially, they have a clear sense of their own body image and social standing with their peers; they can accurately discriminate between peers who are popular or “smart” and those who are not. Although most young adolescents do not engage in unhealthy behaviors, too many do. The outcome of such experimentation can result in a significant level of morbidity and mortality.

Socially, developing and maintaining peer relationships and cognitive skills to cope with emotions and social situations are crucial during this stage of maturation. Friendships tend to be one at a time or with unisexual cliques; peer acceptance is of increasing importance and influence. Because they are keenly aware of their own body image and are sensitive to the criticism of others, the high incidence of bullying and teasing that occurs at this age can have a significant impact on how the young adolescent feels about himself or herself and responds to his or her environment.

### ***Parent-Adolescent Relationships***

Parents may frequently be perplexed by their adolescent’s rapid mood changes, secretiveness, challenging, telling lies, or refusal to give straight answers. Because the young adolescent is experiencing so many simultaneous changes (physical, hormonal, biological, emotional, and social), it is essential that parents, teachers, and other care providers be patient and help guide them through techniques to manage their emotions, helping them expand their critical thinking and problem-solving skills. In this manner, these youth can learn conflict resolution and self-soothing skills that will allow them to manage their distress and family conflict while improving their self-confidence.

### **Middle Adolescence (Ages 14–17 Years)**

The middle stage of adolescence spans ages 14 to 17 and encompasses the middle school (8th grade) and high school years.

#### ***Physical Development***

Most adolescents experience continued increases in specialization of gross motor skills, muscle mass, strength, and cardiopulmonary endurance. Some adolescents may find it difficult to adjust to the somatic growth spurt, which may result in temporary clumsiness or awkwardness. Some youth may become very concerned about their normal increases in body weight and

size. This may result in excessive dieting and exercise, purging, or other pathogenic weight control measures.

#### ***Motor, Visual, and Auditory Development***

All skills in these domains are fully developed at the end of middle adolescence, with the exception of the pincer grasp, which continues to develop in late adolescence. As with other domains of function, however, practice and training can further refine these skills.

#### ***Language Development***

By the end of middle adolescence, youth have mature language skills and can improve on their language abilities with training and practice.

#### ***Cognitive Development***

Cognitively, these youth can independently weigh consequences of their decisions before taking action; they can engage in fantasy, develop theories about life, and think about what they would like to do when they become adults. Their ability to engage in inductive and deductive reasoning is expanding.

#### ***Perceptual Motor Development***

All perceptual motor skills are fully developed by the end of this stage. Practice and training can help further refine such abilities.

#### ***Psychosocial Development***

Although most adolescents move through this developmental stage with minimal distress and problems, some struggle with fluctuating moods and emotions, the impact of which ranges from transient to debilitating. Some youth begin to develop unhealthy behaviors related to weight control practices, eating disorders, substance or alcohol use or abuse, questions about their sexual identity, or sexual activity.

Although these youth have the language skills and cognitive skills to solve problems, rationalize, and understand what is happening to them, they do not have the life experiences to know that their distress is temporary and transitional. This lack of experiential knowledge and coping skills could result in the adolescent running away from home, attempting suicide, engaging in self-mutilation, failing school,

or engaging in other high-risk behaviors.

These adolescents may know and understand the consequences of risk-taking behaviors, but their caution may be overridden by their stronger need for popularity and peer recognition. Such negative adaptations may present significant problems for some adolescents. They may become preoccupied with comparing their physical characteristics with peers', and thinking about sexual relationships may occupy much of their time. As adolescents consistently experience success, they tend to develop a positive self-image and increased confidence. Because of their limited life experiences, adolescents may remain highly sensitive to negative comments from others, peer rejection, bullying, and traumatic personal experiences. As these youth begin to date and have increased sexual desires, they may have sexual fantasies. Some youth will fantasize about same-sex peers and become very disturbed over these events. They may need reassurance that this does not denote sexual orientation. Other youth are beginning to clearly know their sexual orientation. Youth who realize they are gay, lesbian, bisexual, or transgendered may begin to experience mental distress in reaction to fears of being discovered and rejected by their family and peers. Youth who are older or younger than their grade peers may experience psychosocial and emotional problems. Violence and substance use or abuse may become prominent parts of the lives of some youth, increasing their risk for pregnancy, substance abuse, academic failure, injury, or even death (Table 1).

### ***Parent-Adolescent Relationships***

During middle adolescence, youth continue to develop their independence from parents and authority figures. Adolescents now begin to rely more and more on peers as their frames of reference. They use peer feedback to set personal goals and rules of conduct. They are capable of multiple relationships. Their

**Table 1** Behaviors That Increase the Risk for Morbidity and Mortality

#### **Characteristics**

Being male (especially 15–19 years old)  
 Being a minority (except for suicide and sports injuries)  
 Being obese  
 Having a chronic or physical illness  
 Being older or younger than peers

#### **Behaviors**

Not wearing a helmet when riding on a motorcycle or bicycle, skateboard, etc.  
 Riding with a driver who had been drinking alcohol  
 Driving after drinking alcohol  
 Spending increased amounts of time with peers and strangers  
 Dating (which may result in being forced to engage in sexual activities or being physically abused)  
 Using tobacco (i.e., cigarettes, cigars, smokeless tobacco)  
 Using or abusing substances (e.g., marijuana, cocaine, inhalants, injected drugs, steroids)  
 Engaging in dieting behaviors to lose or control weight (i.e., restricted caloric intake, bingeing, purging, excessive exercise)  
 Engaging in sexual activity (including oral, anal, or vaginal sex), which can result in sexually transmitted diseases, pregnancy, or early parenthood  
 Being bullied or a bully  
 Physical fighting  
 Carrying a weapon  
 Attempting suicide  
 Committing homicide  
 Engaging in criminal activities  
 Belonging to a gang

feelings are often very intense and may increase their tendency to engage in risky behavior, argue, or challenge authority.

### ***Emancipation***

Adolescents at this stage of development have the requisite skills to recognize and understand the demands of a particular academic activity, field of study, social endeavor, or sport and can decide whether they want to engage in the necessary behaviors to meet those requirements. Exposure to multiple exploratory activities that are healthy will improve the adolescent's opportunities to be successful and understand personal needs, desires, and limitations (Table 2). Issues related to sexuality, substance use, and healthy lifestyle need to be clearly and directly addressed by parents. It is important that parents remember that they retain considerable influence over their adolescents so that they do not give up on their children.

**Table 2** Promoting Characteristics to Develop Resilient Youth

Youth who seem to resist peer pressure, violence, drugs, and juvenile delinquency share the following characteristics:

#### Individual Characteristics

These youth are:

- Socially competent
- Responsive
- Capable of caring attitudes
- Flexible

These youth have the following well-developed cognitive skills:

- Abstract thinking
- Conceptual and intellectual thinking
- Communication
- Planning and goal setting
- Problem solving

Emotionally, these youth have a positive attitude and a good sense of:

- Humor
- Autonomy and independence

These youth also have the following attributes:

- Impulse control
- Hope
- A future orientation
- High self-esteem

#### Environmental Conditions

Strong support systems

Consistent living and educational conditions

### Late Adolescence (Ages 17–21 Years)

During this stage of development, adolescents are facing high school graduation, placement tests, and often college or career selection activities. They are expected to make major decisions about the rest of their lives. By the end of late adolescence, most youth reach full physical, cognitive, social, and emotional maturity, and most issues of emancipation are essentially resolved.

#### *Physical Development*

Specialization of gross motor skills, gains in strength, and aerobic capacity are fully developed; however, some adolescents may continue to develop speed and increase in size; these changes occur at a slower rate compared with during middle adolescence, and females continue to accumulate fat mass. Their vision is fully developed.

#### *Cognitive Motor Development*

These youth engage in more complex cognitive skills. Abstract thought has been established, empathy skills are well developed, and personal values are clearer and well defined. Youth are able to process and make adult decisions, are future oriented, and perceive, set, and react on long-range options and goals. They have the cognitive ability to understand and remember strategies for most academic, sports, and life endeavors.

#### *Psychosocial Development*

These youth are continuing the process of emancipation and their significant symbolic movement away from home. Some adolescents seek employment, move away from home, and become financially independent. Others go to college and only temporarily move from their parents' home and continue to be financially and emotionally dependent on their parents. Other youth may choose some combination of these two scenarios. Adolescents in the late stages of development are beginning to resolve conflicts between themselves and their parents. At this stage, youth should have developed an acceptable body image and gender role. They continue to develop their ability to function independently and are less influenced by peers; now they can think independently and use their own judgment for setting personal rules. They are more actively participating in sexual experimentation, are able to be altruistic, and can initiate, develop, and sustain intimate relationships. Their relationships with romantic partners are less narcissistic and more geared toward mutual respect and gratification. They prefer the association with groups and couples and prefer intimacy versus isolation. Most adolescents at this stage of maturation have developed a strong sense of personal identity.

#### SUMMARY

A neurodevelopmental perspective of adolescence holds that it is a transitional period of growth, development, and maturation that begins at the end of

childhood and ends with entry into adulthood (about between the ages of 10 and 21 years). The onset of puberty signals the start of adolescence. The end of adolescence is marked by the individual reaching full physical and developmental maturity or young adulthood. As adolescents matriculate through this phase of life, they experience significant physical, hormonal, cognitive, emotional, and social changes. These changes occur in three overlapping stages: early, middle, and late adolescence. Early adolescence marks the onset of puberty, middle adolescence is characterized by peak growth and physical maturation, and late adolescence marks the end of puberty and the integration of all functional skills. Youth who experience normal growth and development phase through these stages with minimal problems and emerge a fully functioning member of society.

## ADOPTION

---

Adoption is a complex family form that touches the lives of many. In a national survey of adoption attitudes conducted by the Evan B. Donaldson Adoption Institute, 64% of respondents indicated that a family member or close friend had either been adopted, had adopted, or had placed a child for adoption. Despite the large numbers of people who have a connection with adoption, there is no current attempt to collect one comprehensive national data set that includes information about public, private agency, and independent adoption. The Adoption and Foster Care Analysis and Reporting System (AFCARS) tracks children adopted from foster care, and the State Department tracks international adoptions through the record of orphan visas issued each year. The most comprehensive figure for the number of total adoptions in the United States is provided by the 2000

Census, which for the first time included the category “adopted son or daughter” and places the number of adopted children under the age of 18 at 2.5% of the population. This number is a broad estimate because it encompasses a wide range of adoptions, including adoption of stepchildren, biologically related and unrelated children, and domestic, international, independent, and informal adoptions. The lack of a comprehensive system for collecting reliable adoption data hinders the accurate reporting of adoption statistics.

## BECOMING ADOPTIVE PARENTS

Prospective adoptive parents encounter experiences unique to adoption. David Brodzinsky and Ellen Pinderhughes delineate five tasks associated with becoming an adoptive parent. First, adoptive parents require the approval of others to become parents. An in-depth evaluation called a *home study* is a legal requirement to adopt in every state. This process requires prospective adoptive parents to open themselves to the scrutiny of social work professionals as to their adequacy for parenting. Despite the educational and supportive intent of the home study, it can feel evaluative in nature, producing anxiety that one may not be found adequate. Second, there is the period of time during which consent for the adoption is given, parental rights of the birth parents are terminated, and adoption finalization occurs.

Third, adoption is characterized by an uncertain timeline for achieving parenthood. The process can take from a few months to a year or longer. Waiting for their child to join the family can be a frustrating experience for prospective adoptive parents. Fourth, although favorable opinions about adoption are increasing, adoption is still characterized by social stigma. Although adoptive parents are satisfied with their decision to adopt, they and their children must cope with the negative attitudes of some that adoption is a “second best” route to parenthood. Families formed across racial or national lines may encounter additional prejudices. Finally, adoptive parents have fewer adoptive parent role models to turn to for advice, especially advice related to the unique challenges of raising adopted children.

## TYPES OF ADOPTION

There is no one description that can characterize adoption. Adoption is no longer limited to a married

couple adopting a same-race infant whereby confidentiality between birth and adoptive families is paramount. Adoptive families reflect the diversity of family forms found in society. Kinship adoption (adoption by a nonparent relative or stepparent) is a prevalent way of forming adoptive families. Although there is lack of precision in available data, the National Adoption Information Clearinghouse reports that kinship adoptions are the slight majority of adoptions in the United States. Despite the preference for married couples by adoption agency staff, birth parents, or both for nonrelative adoptions, single-parent adoption has increased in prevalence. Single parents have a greater likelihood of adopting special needs children for whom finding a permanent placement may be more difficult. There are also a small but growing number of adoptions by gay and lesbian couples. Controversy surrounds this practice, with some states banning gay and lesbian adoption, whereas the Child Welfare League of America asserts that gay and lesbian couples should be assessed the same as any other adoptive applicant.

Permanency planning for children in the child welfare system for whom reunification with a biological relative is not possible has increased the number of adoptions from foster care. Most recent estimates for fiscal year 2001 indicate that 18% of children who exited from foster care were adopted, up from 14% in 1998. There is a higher proportion of children adopted from foster care with physical, behavioral, or emotional disabilities, and as such, financial subsidies are available to adoptive families to provide medical, maintenance, and special services to their children. International adoption has continued to rise, with more than 21,000 children adopted from other countries in fiscal year 2003. During this period, the largest number of children were adopted from China (6,859), followed by Russia (5,209), Guatemala (2,328), and South Korea (1,790). *Transracial adoption*, defined as racial or ethnic minority children adopted by white parents, can be further differentiated into domestic and international transracial adoption. In general, research indicates that both domestic and international transracial adoptees are psychologically well adjusted and engage in active exploration of their racial and cultural identities.

## DEVELOPMENTAL ISSUES RELATED TO ADOPTION

Two important developmental issues related to adoption are attachment and the development of an

adoptive identity. A common assumption is that since an adopted child's first attachment is not to the adoptive mother, the mother–infant attachment in adoptive families is less secure. The research support for this assumption is equivocal. Some feel that early attachment disruptions can prolong the initial adoptive mother–infant attachment process, yet others view attachment as a developmental process that allows relationships to stabilize and change over time, thus allowing secure adoptive–parent attachments to occur.

Adopted adolescents have an additional layer of complexity related to the development of a personal identity. They must incorporate how being adopted influences how they view themselves. Adopted adolescents do think about their adoptive status, as evidenced by the responses of adopted teens in a national survey conducted by the Search Institute: 27% endorsed the statement “adoption is a big part of how I think about myself,” and 41% said they thought about adoption at least two or three times per month. Integrating adoptive status into their identity is crucial because it allows for the construction of a narrative that explains, accounts for, or justifies their adoptive status.

## OPENNESS IN ADOPTION

Openness in adoption describes the amount of contact between adoptive and birth families. It can be placed on a continuum with confidential adoption at one end and fully disclosed at the other. Mediated adoption is midway on the continuum. Fully disclosed adoption describes direct, ongoing communication between birth and adoptive families, which can include face-to-face meetings. Confidential adoption is characterized by the absence of communication between adoptive and birth families, with information shared at placement being nonidentifying. Mediated adoption is characterized by the communication of nonidentifying information through an intermediary, often the adoption agency. There has been movement toward greater openness in adoption in response to birth mothers' desire for continued contact, the need for adopted people to understand their past, older children who know and remember their birth parents being adopted, and the adoption of sibling groups. In response, most adoption agencies currently incorporate openness into their adoption practice. After placement, changes in openness can be influenced by the desires of the adopted person, by adoptive and birth

family dynamics, and by the amount of available information. Most adoptive families will at different points consider whether more contact is desired. In general, openness is a dynamic process that can work in both infant and older child placements when adoptive parents, birth parents, and adoptees work together to communicate in a manner that meets the information and relationship needs of all involved.

## Search and Reunion

For those adopted people who do not have direct contact with their birth families, curiosity about one's adoption may lead them to search for members of their birth family, particularly their birth mothers. Not all adopted people desire to initiate a search, but many do. Thinking about searching can begin in adolescence when approaching adulthood makes searching legally possible. Gretchen Wrobel, Harold Grotevant, and Ruth McRoy studied a group of 93 adolescents with varied amounts of openness, and found that satisfaction with the amount of adoptive openness was negatively associated with adolescent search intentions and that those with more information about their birth parents had a higher desire to search or had actually done so. Adult searchers are most likely to be women, 25 to 35 years old, white, married, and placed in their adoptive families earlier than nonsearchers. Most of those adults who reported contact with their birth mother after a search describe the experience as positive, resulting in satisfaction with information received and a better sense of self. Currently, in contrast to earlier perspectives, search intentions and actions for both adults and adolescents are not viewed as resulting from problematic relationships in the adoptive family.

## CONCLUSION

Our understanding of adoption has changed considerably in the past 20 years. Adoptive families are complex, reflecting the many family forms found in society. Children join their adoptive families from a variety of backgrounds: they may have been born in another country, have experienced foster care, be of a different race or ethnicity than their adoptive parents, or already have ties in the kinship system. Adoptions also vary by the amount of contact and communication between birth and adoptive families. The multifaceted nature of adoption requires that the adopted

person be understood within the unique context of his or her own adoption. As adoption practice and policy continue to evolve, so will our understanding of adoption.

—Gretchen Miller Wrobel

## ADVANCE DIRECTIVES

Advance directive is the general term used to describe statements given in advance of incapacitating illness regarding how individuals want medical decisions made for them if they become too ill to speak for themselves.

Advance directives come in two basic forms. *Proxy advance directives* (e.g., a durable power of attorney for health care) designate a surrogate decision maker (usually a spouse or other close family member) to make decisions for the patient when he or she is no longer able. Proxy directives convey the legal right to make treatment decisions for an incapacitated individual, but do not necessarily contain any explicit guidance regarding what those decisions should be. *Instructional advance directives*, often referred to as *living wills*, include instructions of some kind about the type of care the individual would like to receive.

The concept of advance directives emerged as modern medical technology made it increasingly possible to prolong the lives of seriously ill individuals. In 1969, attorney Luis Kutner suggested that individuals too ill to make decisions for themselves could maintain their ability to influence the use of life-sustaining medical treatments such as cardiopulmonary resuscitation and artificial nutrition and hydration by documenting treatment wishes before incapacitation in what he termed a "living will." The crucial legal decision supporting the use of advance directives was a 1990 U.S. Supreme Court case involving a 24-year-old woman named Nancy Cruzan. Ms. Cruzan's parents sought legal action to remove her from life support after a car accident left her in a persistent vegetative state with no hope for recovery. The U.S. Supreme Court upheld a decision made by the Missouri Supreme Court stating that Cruzan's parents had the right to terminate treatment for their daughter only if there was "clear and convincing evidence" that this was consistent with Nancy's prior wishes. An advance directive would meet this legal standard of clear and convincing evidence.

Unlike the more controversial issue of physician-assisted suicide, the use of advance directives to refuse unwanted medical treatment near the end of life is endorsed widely by medical associations and supported by U.S. state and federal law. Advance directives have achieved similar levels of acceptance in a number of European countries, although the issue has

understandably received little attention in developing countries where medical technology is less available and in many Asian countries where cultural values are less supportive of individual autonomy as an ethical priority in medical decision making.

Although individuals can create their own advance directives without using a previously prepared form, most U.S. states have standard forms (conforming to specific state statutes), as do many organizations interested in the rights of the dying. Some advance directive forms are very specific, recording an individual's preferences for receiving specific medical treatments in specific medical scenarios. Others are quite general, focusing on documenting general values (e.g., religious) or goals (e.g., maximizing quality rather than quantity of life) that individuals wish to guide their end-of-life care. Verbal statements can also serve as legal advance directives, particularly if the statement is formally recorded by a health care professional (e.g., a do-not-resuscitate, or DNR, order noted on a patient's hospital chart).

Despite the proliferation of policy and law encouraging the use of advance directives, psychological research has raised significant questions about their ability to improve end-of-life care. Issues in particular need of future research are the stability of preferences for life-sustaining treatment across changes in an individual's psychological and medical condition, the effectiveness of advance directives in improving the accuracy of surrogate decision making, and cultural, ethnic, and racial differences in the use of advance directives and attitudes toward end-of-life care.

## AFRICAN AMERICANS

---

Historically, African Americans have been studied and explained as compared with the values and characteristics of Europeans. The term *African American* is an Afrocentric word adopted as a label for people who live in the United States and are descendants of slaves and who share the legacy of bondage, segregation, and legal discrimination. Their ancestors came from sub-Saharan Africa. The Afrocentric view holds that African Americans (people of African descent, African people) and their interests must be viewed as actors and agents in human history, rather than as marginal to the European historical experience.

The second Africans in North America (1528) came as indentured servants or as part of a ship's crew; the second wave of immigrants were captured in Africa and sold into bondage for the slave trade in the United States. Some of these individuals lived as free men and women, and others earned their freedom. By 1600, most African Americans were forced to come to this country as slaves on ships and under the most extreme and horrid conditions; many perished in the journey. The forced migration of people from sub-Saharan Africa occurred as a result of the growth of the tobacco and cotton industries and a need for a free and renewable labor force. Africa became a major source of the labor force that made the United States prosperous. Slavery remained legal for 200 years. About 500,000 Africans were forced into slavery in the United States; legalized slave trading was abolished in 1808.

Before the 19th century, other terms were commonly used to refer to African Americans, including words such as "colored," "Negro," and "black." The term "colored" was used during the 1800s as a means of including individuals who were the product of miscegenation (children who were born of parents who were either of European/white, American/Native American or a combination of both, and African/black). Other terms were used simultaneously during the 1890 census (e.g., black, mulatto, quadroon and octoroon, depending upon the degree of white blood in their ancestry).

The political correctness of what to call African descendants changed again during the 20th century. As a result of the Civil Rights movement of the 1970s, African Americans demanded that they be referred to as “Negro” versus “colored.” During the 1970s, the Black Power movement brought about the term “black” as the appropriate reference term, followed by the term African American in the 1990s. Forms used during the 2000 Census allowed citizens to self-identify as African American/black, making the terms interchangeable. By 2003, almost half of blacks preferred to be called African American.

The label African American remains a controversial and ambiguous term for several reasons. First, not all people of African descent were descendants of slaves born in the United States. Changes in the federal immigration law in the 1960s resulted in an influx of people from sub-Saharan Africa and Latin America. These people were descendants of Africans but were not born in the United States and did not share the legacy of slavery. Their presence caused a major demographic shift in the African American population. During the 1990s, the numbers of immigrants to the United States from Africa nearly tripled; the number from the Caribbean grew by more than 60%. The number of foreign-born people of African descent was estimated to be 2.0 million in 1999, and this number represents 8% of the foreign-born population in the United States. Additionally, individuals of African descent who continue to reside in their native countries (Caribbean, Haiti, Dominican Republic, Puerto Rico, South America, and Canada) are also African Americans because of their ancestors and the fact that they reside in the Americas; none of these individuals considers himself or herself as African American, nor do governmental officials. For instance, individuals of mixed ethnicities of African and Hispanic descent are labeled on census forms as Hispanic. Others are separated as being black of Hispanic origin. Another example is people from Haiti who consider themselves Haitian, not African Americans. These individuals are classified as African American/black, resulting in a 14% (more than 4.4 million) increase in the population of African Americans, whereas the total U.S. population grew by only 10%.

Second, not all people of sub-Saharan African descent are “black.” One interesting issue came to light during the 2004 presidential campaign. Historically, individuals who come from the continent

of Africa are automatically thought to be black. However, a number of individuals of Euro-Caucasian and Asian-Indian descent had children who were born African. When these individuals grow up and immigrate to America, they too are technically African Americans. The same label also applies to black Africans who immigrate to the United States.

Third, the commonly identified ways of recognizing African Americans involve skin color, hair texture, and facial features. Not all African Americans have dark skin, kinky hair, broad noses, or thick lips. These characteristics often exist in other racial groups and ethnicities. There are many examples of people who self-identify as African Americans who fit the stereotypical physical features of Europeans (pale or light skin, straight hair, long thin noses, and thin lips). Historically, in the United States, any descendant of a slave, regardless of physical features, was called colored or Negro. To maintain the slave status of African descendants, any person who had a mother who was a slave was identified as a slave. Not only does the one-drop rule apply to no other group than American blacks, but apparently the rule is unique in that it is found only in the United States and not in any other nation in the world. In fact, definitions of who is black vary quite sharply from country to country, and for this reason, people in other countries often express consternation about the American definition. The one-drop rule was done to ensure the steady supply of slave labor: 4 million slave laborers for the tobacco, cotton, and agricultural industries.

## ORIGINS OF AFRICAN AMERICANS

Most African Americans came to the United States in bondage. Although slavery is an institution as old as civilization (it has existed in some form among peoples of all ethnic groups), the industry changed radically with the introduction of Europeans into Africa in the 15th century. The first Africans captured and sold into bondage were exported to Central and South America to work in Portuguese and Spanish Colonies and on the sugar plantations of the Caribbean islands. As cotton, tobacco, and other agricultural needs in the colonies of North America increased, so did the demand for a cheap labor source; this demand was met with the importation of Africans. Unfortunately, the inhuman conditions of their transport resulted in 30% to 50% of Africans dying before they reached their destination.

The first documented African to come to this country was Estebanico (also known as *Estevan*, or Stephen). He arrived as a part of an expedition of 400 people from Cuba. Estevan was a slave who came to this country in February of 1528 in search of the Rio Grande River. He was killed as a part of that venture in May of 1539. The second group of Africans to arrive in North America came 100 years before the Mayflower, before what is commonly reported to be the arrival of Africans in the American colonies (Jamestown, 1619). Twenty Africans worked as indentured servants. Like other indentured servants, their servitude expired after a certain period, at which time they were freed and given a small sum of money and land to start a new life. Other Africans were also brought by Europeans: English, Dutch, French, and Spanish settlers in 1626 to New Amsterdam (later New York), and in 1636 to Salem.

As the demand for a cheap labor source grew, plantation owners found that European indentured servants and indigenous Indians were becoming scarce, and many died under the harsh working conditions. The Indian slaves, because of their knowledge of the land, were able to run away and avoid recapture. Africans represented a renewable or replaceable resource when they died and did not run away as easily because they were in a foreign land. Additionally, their physical features made them easy to identify and recapture.

Another factor that perpetuated the slave conditions of the Africans in America was the passage of laws and the acceptance of the view that they were not human beings and therefore could be treated as beasts of the field. Before 1667, most colonists believed that if a person became a Christian, he or she could not be held in slavery. The laws held that no Christians could be a slave for life; therefore, those Africans who became Christians could work their way out of slavery as indentured servants. However, in 1640, the standards for Africans were legally changed to state that only white Christians could not be enslaved for life.

In 1641, Massachusetts adopted a regulation making slavery an institution. Other colonies followed suit. That regulation held that all children born in the colonies should be defined by the race of the mother—making race an inherited condition. Religious and political philosophies were also adopted that made slavery morally correct. Slaves were defined as outsiders and were dehumanized, thus making their enslavement acceptable to the “good” Christians of the colonies. The substandard conditions of slaves were further legalized

in the Declaration of Independence. The document that treasured the right to freedom of Europeans gave them the right to own slaves and pass that ownership down to their progeny; slaves could be defined as property. Slaves were property that could lawfully be bred, sold, housed in conditions less than those of European settlers, maimed, and even killed. American forefathers further perpetuated these conditions in the Constitution by not outlawing slavery and by counting slaves in the Census as three fifths of a man.

In 1807, the importation of slaves from Africa and slave trade were abolished. Unfortunately, this action only created a need for slave owners to find ways of maintaining a cheap and renewable labor force to continue their prosperity. One effective method of controlling slaves was to separate them from fellow tribesmen and their families, to prohibit them from speaking their native languages, and to strip them of any identity they may have held onto from their country of origin. Traces of these attitudes toward African Americans continue to exist in contemporary American society. The legal condition of slavery ended with the end of the Civil War and the Emancipation Proclamation.

## EQUALITY AND FREEDOM FOR AFRICAN AMERICANS

In 1954, the Supreme Court of the United States passed a momentous decision when it ruled in *Brown v. the Board of Education of Topeka, Kansas*, and overturned the legalization of segregation “separate but equal” (1896, *Plessy v. Ferguson*), which set the stage for the 1964 Civil Rights Act. This act led to further legislated desegregation and to specifically and inclusively define all of the areas in which society must desegregate itself. This led to the passage of the Voting Rights Act of 1965, which mandated that African Americans be allowed to vote. The 1990 Civil Rights Bill outlawed discrimination in the workplace. However, economic oppression among African Americans persists.

## DEMOGRAPHIC CHARACTERISTICS

### Population

Census data for 2000 showed that non-Hispanic Euro-Americans made up 69% of the U.S. population;

**Table 1** Selected Sample Population of African Americans

<i>Year of Census</i>	<i>African Americans/Total U.S. Population</i>	<i>Percentage</i>
1860	4,441,790/31,443,790	14.1
1870	4,880,009/39,818,449	12.7
1880	6,580,793/50,155,783	13.1
1890	7,488,676/62,947,714	11.9
1900	8,833,994/75,994,575	11.6
1910	9,827,763/93,402,151	10.7
1920	10,463,131/105,710,620	9.9
1999	34,658,190/281,421,906	12.3
2003	38,749,034/290,809,777	13.3

African Americans accounted for 12%; Hispanic Americans represented 13% (Hispanic, any race); Asian and Pacific Islanders accounted for 4%; and American Indian/Eskimo/Aleut made up 1%. The proportion of African Americans in the U.S. population has remained relatively stable since 1860, about 11% to 12% (Table 1).

### Geographic Location

In 1870, nearly 95% of all African Americans lived in the South, and by 1960, that number had dropped to 60%. Fifty-five percent of African Americans lived in the South in 2000. Nearly 40% of all African Americans lived in suburban areas; 18% lived in the Northeast, 18% in the Midwest, and 9% in the West. In comparison, 33% of non-Hispanic Euro-Americans lived in the South, 27% in the Midwest, 21% in the Northeast, and 19% in the West.

Like the rest of Americans, African Americans primarily live in large metropolitan areas; however, unlike non-Hispanic Euro-Americans, African Americans live in the central cities of those areas.

### Age Distribution

The age distribution of African Americans in the United States is skewed toward individuals over the age of 25 (Table 2). Most African Americans are older than 18 years but younger than 64 years; the largest

group within this category is between the ages of 25 and 44 years. The next largest group of individuals is between the ages of 45 and 64 years, followed by youth between the ages of 14 and 17 years.

### Education

Most African Americans ages 25 and older in 2002 had obtained a high school diploma (Table 3); 17% had earned a bachelor's degree, and 17.8% had 4 years or more of college. Unfortunately, the rate of graduation in 2002 for this population had dropped by 7.8%. Additionally, rates still are lower than for non-Hispanic Euro-Americans.

### Income

In 1950, African Americans averaged only 54% of the income of Euro-Americans. That average is currently at 55%. In 2002, the median annual income for African Americans was \$29,177, which was 62% of Euro-American families' income. Young African American males, at all educational levels, continue to experience unemployment rates (1999) more than twice those of young Euro-American males.

### Employment

In 2002, slightly more than one fourth of African Americans were employed laborers, whereas equal

**Table 2** Age Distribution Data from the U.S. Census Bureau, February 25, 2002\*

<i>Age Range</i>	<i>Percentage of African American Population</i>	<i>Percentage of Total Population</i>
<18 years	31.4	25.7
<1 year	1.5	1.4
1–4 years	1.6	5.5
5–13 years	6.5	13.2
14–17 years	16.5	5.7
18–64 years	60.4	61.9
18–24 years	11.0	9.6
25–44 years	30.9	30.2
45–64 years	18.6	22.0
65 years and older	8.1	12.4

\*Columns do not add up to 100%.

**Table 3** Selected Educational Statistics for African Americans, 2002

	<i>African Americans</i>	<i>Non-Hispanic Euro-Americans</i>
High school diploma (2002)	79% ages 25 and older 87% ages 25–29	89.0%
Completed high school (2000)	86.8%	94.0%
Bachelors degree or higher (2002)	17% ages 25 and older	29.0%
Advanced degrees (e.g., master's, PhD, MD, or JD) (2002)	1.1 million ages 25 and older	
Four or more years of college (2000)	17.8%	34.0%

numbers were employed in white collar jobs (Table 4); most individuals were employed in white collar jobs (56%). African American females continue to have more employment opportunities than African American males.

Of the 74.3 million families with money income in 2001, 8.8 million were African American, and 53.6 million were non-Hispanic Euro-Americans (Table 5).

## Poverty

In 2001, 6.8 million families in the United States had incomes below the poverty level. Of these families, 1.8 million were African American and 3.1 million were non-Hispanic Euro-American. However, a greater percentage of African American families than of non-Hispanic Euro-American families were poor:

21% compared with 6%. A larger proportion of African American married-couple families (8%) than of non-Hispanic Euro-American families (3%) were poor. Families with one parent as head of household and especially those maintained by women with no spouse present have higher poverty rates overall. These rates are highest for African American heads of household. About 30.2% of all black children younger than 18 years lived in poverty in 2001.

## FAMILY CHARACTERISTICS

The common view of African American families is that they are poor, are inferior to Euro-American families, represent a monolithic institution, live in urban areas, and are wrought with pathology. More contemporary Afrocentric views offer that the nuclear

**Table 4** Various Employment Statistics for African Americans in 2002

<i>Occupation</i>	<i>Males</i>	<i>Females</i>

	33% families	57% families
≥ \$75,000	27% married couples	40% married couples
	16% families	35% families

SOURCE: McKinnon, 2003.

family is very functional rather than dysfunctional, that is, not pathological (abnormal) in terms of African heritage and kinship networks. The cultural differences that exist between African American and Euro-American families are based on the African Americans' African heritage combined with the reality of racial oppression, past and present. Previous studies of African American families did not respect African American culture, included interviews of African American fathers, and only focused on the very poorest families. Subsequent findings were then erroneously generalized to all African American families. Finally, researchers used theoretical models limited to Western cultural lifestyles.

For instance, in the European view, fathers should be head of household; therefore, the stereotypes of African American families as matriarchal led them to attribute pathology to this culture. However, recent research supports that African American families at all socioeconomic levels are equalitarian, characterized by complementarity and flexibility in family roles, in contrast to the normative pattern of white families

with the more traditional patriarchal authority structure. These families are strong and tend to encourage their children to develop the skills, abilities, and behaviors necessary to survive as competent adults in a racially oppressive society. In general, black families are reported to be strong, functional, and flexible. They provide a home environment that is culturally different from that of Euro-American families in a number of ways.

The numbers of babies born to unmarried African American mothers is almost two times that of Euro-Americans, and the number of single parents and divorces is also higher for this group but is reflective of national trends.

## CULTURE

The Human Genome Project made the issue of race moot. Researchers found that humans were more than 99% the same regardless of physical characteristics. The variation that is observed is not significant enough to warrant racial labels. Therefore, African

Americans simply represent ethnic group variations. Those anthropological and biological differences that result in physical trait differences between groups are frequently found in the range of variation within each group. For instance, there are African Americans who have fair skin, blue eyes, and blond hair; conversely, there are Euro-Americans who have dark skin, brown eyes, and dark, kinky hair.

African Americans represent the only Americans whose initial migration was a forced migration. They represent an incredibly wide-ranging and diverse group of people. The cultural aspects of African American life represent a combination of all ethnic groups in the Americas. What sets African Americans apart is how they have retained vestiges of their African heritage while incorporating aspects of Latin, European, Middle Eastern, Asian, and Native American cultures to create music, art, food, clothing, and linguistic styles that have influenced people from around the world. Contemporary examples include the influences of African American Rap music and Jazz on popular Euro-American culture. These influences can be seen in other countries around the world.

When Africans were forbidden to use their native languages and to communicate with people who looked like them but did not share their language, they created distinctive patterns of language. They also displayed ingenuity in incorporating the misspoken language of English when used by Italians, Irishmen, Native Americans, and others with whom they were forced to interact. The development of shortened forms of words and grammatical structures (pidgins) was another excellent example of the adaptability and intellect of the descendants of African immigrants. These adaptations can still be observed in the language of many people, including the Gullah on the Sea Islands of South Carolina and Georgia, and as a part of African American Vernacular English (AAVE), black English, or Ebonics. The usage of this type of English is often considered a legitimate form of a dialect of English spoken by some African Americans.

Although certain foods are historically said to be associated with the African American culture, a review of the conditions of poor people of all ethnic groups will show that they also used many of the same agricultural products in very similar manners, and the differences are often regional as opposed to ethnic. Foods and agricultural products commonly associated with African American culture include yams, peanuts, rice, okra, grits, indigo dyes, ham hocks, pig intestines (chitterlings), fried

chicken, boiled greens, gumbo, “hoppin’ John” (black-eyed peas and rice), and cotton. What does stand out is how creative Africans and their descendants became in making use of the products they found in their new land. Because they were often forced to use foods thought undesirable and discarded by their slave owners, their tenacious nature prevailed. The make-do foods were lovingly prepared and became known as *soul food*. Such foods are now recognized and labeled as cuisine.

## RELIGION

African Americans come from people who embraced spiritualism; that basic belief system was transformed in the New World to Christianity for most individuals. Christianity was used as a means to help quell the unhappiness of slaves and the guilt of slave owners. Slaves were told they would receive their reward in heaven and that the protestant ethics of hard work and suffering were valued. Although Euro-Americans promoted Christianity for slaves, they kept their worship separate. This is still seen in religion today. Sunday Morning worship time has often been referred to as the most segregated time in America. Even in the time of slavery, African American churches were the seat of religious, social, and political leadership and change. The first nationwide church for African Americans was established in 1816 by Richard Allen in Philadelphia and was called the African Methodist Episcopal Church. This was followed by Baptists founding the National Baptist Convention in 1895. This is currently the largest African American religious denomination. Other religions have significant representation among African Americans. The most prominent Black Muslims organization in the United States was founded in 1935.

## HOLIDAYS AND SPECIAL CELEBRATIONS

African Americans and other ethnic groups have worked tirelessly to gain legal recognition of African Americans in this country. Successful ventures include the Black History Month (first recognized as Negro History Week in 1926 and extended to become Black History Month in 1976). A national holiday was enacted in 1983 by the U.S. Congress to honor slain civil rights leader Martin Luther King, Jr., which is observed in January, the month of Dr. King’s birthday. African Americans also embrace most American holidays and celebration. They also recognize such

holidays and celebrations connected to their other ethnic and religious heritages. A more recent recognition of African American culture is the 1966 advent of the festival of Kwanzaa. This celebration was designed to affirm the African heritage of African Americans and is celebrated December 26 through January 1. Each of these celebrations carries on the tradition of adaptation, flexibility, and inclusion as consistently demonstrated by the African descendants. The purpose of each celebration is to affirm the African heritage of its people and their struggles and triumphs.

## CONCLUSION

The contributions of African Americans to the American culture are too numerous to cite in this article. Readers are directed to resources below to identify the scientific, cultural, religious, sports, musical, media, and other contributions of the African Americans.

## AFTER-SCHOOL PROGRAMS

---

After-school programs (ASPs) are those programs available to children 6 to 18 years of age that are characterized by structure, adult supervision, and an emphasis on skill building. ASPs tend to be voluntary, hold regular and scheduled meetings, and emphasize developmentally based expectations and rules for the participants. In most cases, ASPs are organized around developing particular skills and achieving goals. The challenge and complexity of the program activities increase with the participants' developing abilities.

The range of ASPs available to children and adolescents in the United States is substantial. In general, ASPs can be viewed at one of three levels: (1) nationally sponsored youth organizations and federally funded programs (e.g., Boys and Girls Clubs of America, YMCA, YWCA, 21st-Century Community Learning Centers, 4-H, Boy Scouts and Girl Scouts of America, Camp Fire); (2) community, school, and local sponsorship, including grassroots youth developmental organizations, faith-based youth organizations, and public sector institutions (e.g., school-sponsored extracurricular activities, museums, libraries, youth centers, youth sports organizations, and community service programs); and (3) individual activities or types of activities (e.g., sports, music, hobby clubs, social clubs, religious and service activities), which can be differentiated on the basis of specific goals, atmosphere, and content.

Because school-age children in the United States and other Western nations spend about half of their waking hours in discretionary activities outside of school, there has been a growing interest in understanding how ASP participation may influence the development of young people. Indeed, several reports have been published that underscore the critical role of after-school time for young people (e.g., the

Packard Foundation's 1999 report, "When School Is Out"; the National Research Council's 2002 report, "Community Programs to Promote Youth Development"; the Public/Private Ventures 2002 report, "Multiple Choices After School"; the 2003 National Research Council's report, "Working Families and Growing Kids: Caring for Children and Adolescents"; the 2003 Nellie Mae Foundation report, "Critical Hours"; and the forthcoming volume, "Organized Activities as Contexts of Development"). The opportunities and risks associated with after-school time are detailed in these reports.

In the light of a rapid historical increase in maternal employment, perhaps the most basic opportunity provided by ASPs is the provision of a safe and supervised context for young people while their parents are working. However, such programs are frequently implemented with a range of additional goals indicating the increased interest in viewing after-school time as an opportunity for young people to develop competencies that complement learning experiences in the school classroom. These include (1) reducing the risks associated with unsupervised and unstructured leisure time; (2) promoting social-emotional competence, school attachment, civic engagement, and educational attainment; (3) addressing racial or ethnic and income disparity in school achievement and social adjustment; and (4) preparing young people for the transition to adulthood, higher education, and employment. In other words, ASPs allow young people to capitalize on their personal interests, abilities, and environmental resources to both reduce risks for developing problem behaviors and build competencies that increase the likelihood for healthy adjustment in the future.

The foregoing discussion implies that participation in organized after-school programs may promote positive development. But, does the available research support this assertion? The next section summarizes findings from several studies that have examined the link between ASP participation and adjustment in young people. The focus is on two types of ASPs: formal programs for school-age children, and extracurricular activities and after-school community programs for adolescents.

### **AFTER-SCHOOL PROGRAMS FOR SCHOOL-AGE CHILDREN**

Owing in large part to increases in maternal employment, ASPs now provide child care and adult

supervision for more than 8 million American children with working parents. These programs are oriented to children in the elementary and middle school years.

Several studies of after-school program participation and child adjustment have found both academic and social benefits for participating children compared with nonparticipants, or compared with children in alternative after-school arrangements such as self-care or relative care. Benefits are most apparent for disadvantaged children and for at-risk students whose parents are not native English speakers. Positive changes in school bonding, parent involvement, and school attendance appear to mediate the program-related growth in social-academic competence. However, the benefits of ASPs for children may be limited to quality programs that are regularly attended by students.

### **AFTER-SCHOOL PROGRAMS FOR ADOLESCENTS**

Involvement in ASPs such as sports teams, lessons, and clubs is relatively common during adolescence. For example, among youth ages 12 to 17 from the 1997 National Survey of Families, 57% participated on a sports team, 29% participated in lessons, and 60% participated in clubs or organizations after school or on weekends during the last year. Recent reviews support the conclusion that participation in ASPs helps promote several forms of competence during adolescence and beyond.

#### **Increased Educational Attainment and Achievement**

Participation in extracurricular activities and after-school community programs is associated with increased education attainment. This includes low rates of school failure and dropout, high rates of postsecondary school education, and good school achievement. Increases in school engagement and attendance, better academic performance and interpersonal competence, and higher aspirations for the future partly explain the long-term educational benefits.

#### **Reduced Problem Behaviors**

Several studies have found that participation in adolescent ASPs is associated with reduced behavior problems. This includes an associated reduction in

developing problems with alcohol and drugs, aggression, antisocial behavior and crime, or becoming a teenage parent. Activity-related affiliations with nondeviant peers, mentoring from adult activity leaders, and conventional time use are the main explanations why organized activities protect against problem behaviors.

### Heightened Psychosocial Competencies

ASP participation is positively associated with psychosocial adjustment in a number of areas. For instance, participation is related to low levels of negative emotions, such as depressed mood and anxiety during adolescence, and to high levels of self-esteem. Moreover, ASP participation appears to promote initiative, which involves the application of extended effort to reach long-term goals and fosters civic identity development. The unique combination of psychological features and opportunities for positive social relationships and belonging in ASPs are salient factors thought to affect these psychosocial processes.

### PROMISING AND PROBLEMATIC PRACTICES

With reference to ASPs, scholars appointed by the National Research Council and Institute of Medicine recently evaluated the features of developmental contexts that promote positive outcomes for young people. The committee derived the following list of eight key features that facilitate positive development: physical and psychological safety, appropriate structure, supportive relationships, opportunities for belonging, positive social norms, support for efficacy and mattering, opportunities for skill building, and integration of family, school, and community. The research on ASP participation indicates that programs incorporating these features do confer benefits for the participants. However, we do not yet know which features are most important or which combination of features may be optimal to promote positive adjustment for different young people.

To be sure, not all ASPs have been shown to benefit participants, and some are organized in ways that do not facilitate positive development and may be harmful. An example involves participation in youth recreation centers that provide relatively low structure, provide limited adult guidance, and lack skill-building aims. Regular involvement in these settings

appears to facilitate deviant peer relationships during adolescence and leads to persistent criminal behavior into adulthood. Mentoring programs provide a second example. Volunteer mentors are often a valuable resource in providing adult guidance for adolescents and can facilitate perceived self-esteem and school achievement. However, the programs may pose a risk if the mentoring relationship is short lived or fails.

### SUMMARY

ASPs are important contexts that help young people build competencies and successfully negotiate important developmental tasks of childhood and adolescence. Participation tends to be associated with academic success, mental health, positive social relationships and behaviors, identity development, and civic engagement. These benefits, in turn, pave the way for long-term educational success and help prepare young people for the transition to adulthood. Although the research findings are generally positive, variations across the types of programs and the participants suggest the need for researchers to differentiate the features of programs that facilitate development and the conditions under which the benefits is most likely to occur. Accordingly, current and future research must continue to examine what types of programs best serve the needs of different young people in the short and long terms.

## AGE DISCRIMINATION

---

Robert Butler is credited with originating the term *ageism* in 1968. Ageism involves negative attitudes and discriminatory practices against individuals based on age. Such attitudes and practices often result in age discrimination, specifically against older individuals. Ageism has been evidenced in our media's excessive emphasis on youth, in our medical and mental health fields, and in employment settings.

Ageism and age discrimination are based on negative attitudes fueled by stereotypes about older people. These stereotypes contain the following incorrect assumptions: that all aging people are ailing physically and are frail and disabled; that older individuals are impaired cognitively and lack mental acuity; and that older people are perpetually depressed, gloomy, or hostile. These stereotypes involving the physical, cognitive, and emotional functioning of older people converge to produce common assumptions that older individuals lack vitality, productivity, sexuality, and the ability to learn new things—all of which contribute to age discrimination toward older individuals.

## CROSS-CULTURAL VIEWS OF AGING

Ageism does not exist across all cultures. Unlike many Western nations, countries such as Japan, China, and Korea associate age with positive rather than negative features. Generally, these countries see the elderly as wise, respected, strong authority figures who advise the family. A long-standing, traditional Japanese ritual, the *Kankrei*, releases the elderly

person from middle age responsibilities, so that he or she can have the freedom to achieve whatever he or she wishes. A national holiday in Japan, known as *Respect the Aged Day*, celebrates older people. In comparison, within the United States and other Western nations, the elderly are not considered a vital and integral part of the culture. Attitudes toward the older generation are much more negative, including the perspective that older individuals are far less productive and do not have much to offer society. Such attitudes contribute to age discrimination.

## AGE DISCRIMINATION IN THE WORKPLACE

Two trends are shifting the composition of the U.S. workforce to an older one. First, there are growing numbers of people 55 years and older remaining in the workforce. In 2000, 13% of the workforce was older than 55 years, and by 2020, this number is projected to increase to 39%. In 2005, the actual number of workers 55 years or older is 22 million. Why do people continue to work longer? The reasons are varied and include increased life expectancy with good health combined with fewer physically demanding jobs, the need to financially support dependents, and increased medical and health care costs with less coverage by health care benefits and pensions. Retirement of the “baby boomers” is the second trend affecting the workforce. As the baby boomer population continues to retire throughout this decade, there will be increasingly more jobs available than workers to fill them. The result of these trends is a substantial increase and reliance on older workers.

Perhaps the most well-documented environment in which older individuals encounter age discrimination is the workplace. The older worker may face age discrimination in seeking employment and may also face discrimination on the job. Despite evidence that older employees are generally as flexible, easy to train, and cost-effective as younger workers, older job candidates may be less successful in finding employment than younger individuals. Several important factors, including contextual and situational variables, have been shown to influence age discrimination in the selection of employees. The more obvious variable that can result in age discrimination is the strength of the bias against older workers held by the individuals making the hiring decisions. Strength of such bias varies widely across people. For this reason, organizations such as the American Association of Retired Persons (AARP) and

industrial gerontologists have recommended training those who do the hiring in recognizing and counteracting potential bias against older people. A second variable, age-typing of the job involved, also is related to age discrimination. Older individuals are more at risk for being passed over in hiring processes if the job is perceived as a “younger person’s job.” Positive age stereotypes in relation to older workers can also exist. In such cases, older workers have the advantage because they are seen as more appropriate or qualified for an “older-person’s job.” Finally, empirical support exists for the idea that negative stereotypes are far more likely to inadvertently creep into hiring decisions if such decisions are conducted hastily or while the evaluator is cognitively distracted by other tasks. For this reason, employers are encouraged to avoid making decisions quickly or while they are mentally preoccupied with other work issues. Instead, such individuals need to be trained to make thoughtful and informed decisions in which they carefully evaluate all available information about the specific job candidate, while keeping aware of the potential for bias.

Older workers may also encounter age discrimination on the job in the form of poorer job performance appraisals. Age has not been found to be a good predictor of productivity, and existing research in general does not support the idea that job performance declines with age. To prevent age discrimination in job performance appraisals by supervisors, organizations are encouraged to have well-designed performance appraisal systems that are reasonable, relevant to the job, and applied consistently by different evaluators across employees and over time.

Because of concern about age discrimination in the workplace, an amendment was passed to the Fair Labor Standards in 1967. This act, known as the *Age Discrimination in Employment Act (ADEA)*, was placed under the jurisdiction of the Equal Employment Opportunity Commission, a federal agency. Under ADEA, it is illegal to discriminate against older workers by basing any employment-related decision on age, age-related stereotypes, or assumptions about an individual’s abilities and performance. Instead, employers must make decisions based on the specific capabilities of the individual rather than on age. The spirit of ADEA is to promote fair and equitable hiring, compensation, and treatment of older people in the workplace. ADEA and subsequent related rulings (1978, 1986) place individuals who are 40 years of age and older into a protected class and specifically prohibit

discrimination against these individuals on the basis of age unless age is a “bona fide occupational qualification.” *Western Air Lines v. Criswell, 1985*, established that in order for age to be considered a bona fide occupational qualification (BFOQ), the employer must be able to demonstrate that a particular age is “reasonably necessary to the normal operations of the particular business . . . all or nearly all employees above an age lack the qualifications for it.” BFOQs are rare and include occupations such as airline pilot. A primary function of ADEA is the prohibiting of financially strained companies from specifically targeting and laying off their older employees. The EEOC has ruled, however, that employees can waive their rights to sue under this law in exchange for improved retirement benefits packages. Under the Older Workers Benefit Protection Act (1990), a worker has 45 days to decide whether to agree to such a waiver and then an additional 7 days after signing a waiver to revoke the decision. Such packages have been referred to colloquially as “the golden handshake,” and their use is on the rise. Since the passage of ADEA, there has also been a solid trend in increasing numbers of age discrimination cases filed with the EEOC annually, with almost 20,000 age-based cases filed in 2003.

## AGE DISCRIMINATION IN HEALTH AND MEDICAL PROFESSIONS

Age discrimination is not limited to the workplace; it has been found in the health and medical services provided to older individuals as well. Research suggests that medical and mental health professionals are more likely to rate older patients as less appropriate for services, treat them less aggressively, and provide them with a less positive prognosis. To date, less empirical research has been conducted in relation to ageism in environments other than employment settings, and this is an area in need of further study. However, it is theorized that *healthism*, or the inclination by medical and mental health professionals to feel more negatively about their patients with chronic health problems compared with physically and mentally healthy patients, is a stronger influence than pure age on such practices in the health arena.

## IMPACT OF AGE DISCRIMINATION

On a psychological level, age discrimination can affect the self-esteem, life satisfaction, and

psychological well-being of members who experience or perceive it the strongest, and therefore can directly influence the well-being of older adults. In the workplace, age discrimination prevents qualified workers from being hired and, once the older worker is hired, can result in obstacles to advancement and premature ending of employment in the position. On a medical level, ageism can result in less compassionate and less aggressive treatment in both inpatient and outpatient situations. However, it should also be noted that contrary to ageist stereotypes, older individuals as a group are, in general, as emotionally healthy as other age groups; however, being the target of ageism is a risk factor for them. Social support from same-aged peers can serve as a protective factor against ageism because it may promote positive identity despite the social stigma of aging. The United States and other Western nations could learn much from those countries in which the older person is respected and valued and is perceived as an important and contributing member of society.

## AGEISM

Robert N. Butler first introduced the term *ageism* to refer to prejudice and discrimination against older people based on the belief that aging makes people less attractive, intelligent, sexual, and productive. Ageism comprises three distinguishable yet interconnected aspects: (1) prejudicial attitudes toward older adults, old age, and the aging process; (2) discriminatory practices that focus on behaviors against older people; and (3) institutional practices and policies that perpetuate stereotypes about older adults, reduce their opportunity for life satisfaction, and undermine their personal dignity.

With medical improvement and scientific advances, the population is aging at an unprecedented rate. The proportion of U.S. residents older than 65 years rose from 9.2% in 1960 to 12.6% in 1990 and is predicted to reach 17.7% in 2020. Most developed countries in Western society show similar trends. The population structure change leads to concern about the resources necessary to support elders. This concern has resulted in continual debate among legislators and in the media on aging-related issues, such as federal debt, social security, health care, and housing. The theme of such debate focuses on whether there are ageism practices in the corresponding area and how to protect elders from age-related discrimination. Overall, a trend has been expected that older individuals would wield considerably more political power, be more active in the workplace and education, and have a much greater stake in the world's economic output.

There are legislative acts providing broad protections against ageism, such as the 1967 Age Discrimination in Employment Act (ADEA) and the amended Older Workers' Benefit Protection Act. The former was designed to protect employees older than 40 years from differential treatment in all phases of the employment process. The latter act was designed to ensure that early retirement packages and other incentives that require workers to waive their right to sue for age discrimination are offered in a way that does not unduly harm the worker. However, a recent Supreme Court ruling implies that elders do not deserve special protections against ageism because they do not constitute a group with a history of discrimination. Consistent with this, mandatory retirement and increasing insurance costs on the basis of age alone, rather than competence or demonstrated health risks, are still legal.

Although the ADEA legislation has allowed many older workers to continue employment, there are still other manifestations of ageism in the workplace. First, hiring and firing practices are age differentiated. Qualified older workers are less likely to be hired for positions than same qualified young workers. When forced to downsize, organizations are likely to target early retirement and layoffs at older workers. These observed patterns of employment that favor young workers over older workers may be due to the stereotypical beliefs about physical and mental declines of older individuals. Second, organizations are often reluctant to train older workers. Accumulated evidence suggests that strongly held societal beliefs are responsible, such as older people are unwilling to change, not worth training because they will not be around long, learn too slowly, do poorly in the classroom, and are computer illiterate. Third, declining earnings by older workers have been related to ageism. Stereotypes about older workers as being unable to perform and produce at levels that are required by the workplace are common. They lead to age differences in wages, after controlling for worker background, education, training, experience, job characteristics, and labor market conditions.

In summary, ageism is a form of discrimination based on age alone. Because of the changing demographics in Western society, it becomes increasingly important to protect the elderly from ageism in all aspects of their lives.

---

## AGGRESSION

---

Aggressive behavior often poses problems in humans across the life span, both as initiators and recipients of aggression. The study of the causes of and methods to reduce aggression is vital, especially with regard to the psychological development of children and adolescents.

### DEFINITIONS

Aggression is a verbal or physical behavior that involves delivery of a noxious stimulus (e.g., an insult, a punch) to another person with the *intent to harm* that person. Aggression is not assertiveness, such as standing up for oneself, and it is not accidental. Violence is extreme aggression that usually results in severe injury to the recipient. There are four main types of aggression: (1) *impulsive*, which occurs without thought and usually when the person is uncomfortable (e.g., feels hot); (2) *retaliatory*, which occurs in response to provocation (such as a slap from another person); (3) *instrumental*, which is when a person aggresses to attain another goal, such as hitting in order to get a desired toy; and (4) *angry*, which is when the person experiences anger while aggressing.

### CAUSES OF AGGRESSION

#### Situational Factors

Four of the most heavily studied situational causes of aggression are when a person (1) is verbally or physically attacked, (2) perceives that he or she is being blocked from obtaining a goal and feels frustrated, (3) feels physically uncomfortable or in pain, and (4) is exposed to violent media. Insults and physical attacks from others are, of course, a main cause of retaliatory aggression. Research has clearly shown that situations that evoke frustration, such as when a person cannot solve a jigsaw puzzle or when the car in front of a person fails to move after the traffic light turns green, often result in increased aggression. Frustration effects on aggression are exacerbated when coupled with a provocation (e.g., an insult).

Similarly, uncomfortable environments, such as those that are hot, painful, or noisy or that cause sleep deprivation, also often result in enhanced irritability and aggression. For example, many archival studies of

the relation between heat and violent crime (i.e., murder, rape, assault) have found that hot days, months, years, and locations are associated with higher violent crime rates than are comfortably cool days, months, years, and locations. Aggression is less likely to occur in uncomfortable situations if the individual thinks that he or she can control the cause of the discomfort. For example, when participants are given opportunities to turn off a loud noise, they act less aggressively than participants exposed to noise that they cannot turn off. Often, the aggression that results when a person is uncomfortable is impulsive; the person “lashes out” at another person without provocation.

Watching violent television and movies, playing violent video games, and listening to music with violent lyrics have all been shown to increase aggressive thoughts and feelings and sometimes result in aggressive behavior. Early research on media violence revealed significant positive correlations between watching violent television and aggressive behavior, but these findings were criticized because the correlational nature of the data did not allow for conclusions to be drawn about the causal role of violent television. That is, these studies found that people (mostly school-age children) who watched a lot of violent television were reported as acting more aggressively by peers, parents, teachers, and even the children themselves, than those who watched less or no violent television programs. However, the higher aggression in those who watched violent television could be explained by many other causes, such as that people with aggressive personalities tend to aggress more (and also tend to watch violent television).

Media violence research over the past three decades has been more methodologically sophisticated and has included experimental designs that control for all other potential causes of aggression and test exclusively the effects of viewing media violence. The conclusion from these studies is clear: exposure to violent media (e.g., television shows, movies, music lyrics, video games) increases aggressive thoughts and angry feelings and may increase aggressive behavior. Young children are especially susceptible to these effects because they are highly likely to imitate aggressive (especially same-sex) models and because they cannot easily discern fantasy from reality. Imitation effects of violent video games are particularly problematic because of the active physical and psychological engagement with the games as well as personal identification with the characters. New

research has found that even video games rated “for everyone” (as well as those labeled “for mature audiences only”) have been associated with increased aggressive behavior.

## Person Factors

Many researchers who have studied and theorized about aggression are social psychologists who focus on the roles of situational factors and underestimate the effects of factors about the person such as aggressive personalities and biological and genetic predispositions. Therefore, early theories of aggression mostly assumed that aggressive behavior is not consistently expressed across the life span; rather, it is evoked by some external stimulus.

The assumption that aggressiveness is not a stable disposition across the life span changed when Olweus published a review of several longitudinal studies that measured aggressive behavior of children of different ages across time. Several studies found that 3-year-old children differ in aggressiveness and that the intensity and frequency of their aggressive acts at age 3 were similar to the intensity and frequency of aggression 12 to 18 months later. Aggressive children between the ages of 8 and 9 aggressed at similar rates 10 to 14 years later. Olweus also found that 12- and 13-year-olds aggressed at a similar rate and in similar ways for 1 to 5 years. These findings, however, should not be interpreted as meaning that certain people are aggressive most of the time. Alternatively, Olweus suggested that aggressive dispositions (or personalities) interact with both situational factors and the person’s interpretation of the situation to predict (and produce) aggressive behavior.

Boys and girls have been found to differ in the type of aggression that they display, and these sex differences are attenuated by age. Several studies have found that boys tend to engage in more “direct” physical or verbal aggression against a target. Girls have been found to engage in more “indirect” aggression, which involves manipulations of social networks to isolate or otherwise psychologically harm the target. Sex differences in indirect aggression have been found in 8 year olds and more so in 11 year olds, when social skills are more developed. Sex differences in adult aggression are less pronounced, but the same pattern of the direct and indirect types of aggression have been demonstrated. Studies on the intensity of displayed aggression have revealed that males tend to act more

aggressively than females when they are not provoked by another person, but when provoked, women are as aggressive as men. Women are also as aggressive as men when the aggression is displayed in written or verbal forms (rather than in physical behavior).

Testosterone levels have also been shown to positively relate to expression of aggressive behavior in both men and women. Decreases in estrogen and progesterone, which occur in the premenstrual phase of the menstrual cycle, are similarly associated with an increase in aggressive behavior. Some genetic factors have been found to relate to aggression, such as the high proportion of males incarcerated in prison for committing violent crimes who have an additional Y chromosome (i.e., they have an XYY genetic chromosomal makeup).

The way that people cognitively interpret potentially provoking situations has further been shown to predict aggression. Child and adolescent bullies tend to be less capable than nonbullies at correctly understanding other people's intentions in social situations. Bullies often assume that others are threatening them when they are not and respond "in kind" by aggressing. This tendency has been labeled a *hostile attribution bias* because such individuals tend to falsely attribute hostile intent to other people's actions.

Men and women have also been found to differ in their interpretations of their own aggressive behaviors. Men tend to view aggression as an effective way to control other people in order to attain interpersonal or other goals and often report the aggression as satisfying. Alternatively, women tend to view their own aggression as uncontrolled emotional behavior and feel guilty and remorseful for their inability to suppress the emotional outburst.

## Summary

Main situational causes of aggression are verbal and physical provocation, frustration, physical discomfort, and violent media exposure. Person causal factors include an aggressive personality, which is often consistent across the life span, and genetic and biological factors such as testosterone levels and presence of an extra Y chromosome. Males tend to engage in direct aggression and females in indirect (or manipulative) aggression, and when women are provoked, they may be as aggressive as men. Finally, cognitive interpretations of potential threats affect whether or not individuals respond aggressively.

## THEORIES OF AGGRESSION

### Frustration-Aggression Theory

One of the earliest theories of aggression is the frustration-aggression theory, which states that frustration always causes aggression and that aggression is always caused by frustration. Research has since clarified that this theory is too restrictive; although frustration is a main cause of aggression, it does not *always* precipitate aggression, and frustration is not necessary for the expression of aggression.

### Social Learning Theory

Social learning theory, a meta-theory of psychology that provides an elegant explanation of learning processes, was first applied to describe why children repeat the aggressive behavior that they witness. Children often imitate aggressive behavior that has been *modeled* by another person (particularly if that model is of the same sex as the child and if the model is rewarded for aggressing, called *vicarious reinforcement*). Children are less likely to engage in aggression when they observe a model receive negative consequences for aggressing (*vicarious punishment*).

### Cognitive-Neoassociationism Theory

The cognitive-neoassociationism theory posits that thoughts, feelings, and behavioral tendencies are stored together in memory networks analogous to spider webs. Exposure to an aggressive stimulus (such as a picture of a weapon or a provocation) can automatically bring to mind hostile thoughts and angry feelings and can increase the likelihood of an aggressive response.

### Excitation Transfer Theory of Arousal

According to the excitation transfer theory of arousal, people are more likely to act aggressively when they are physiologically aroused, especially when an aggressive stimulus is present (e.g., during or after exercise, or following ingestion of a drug that enhances central nervous system activity). For example, if a person is insulted after exercising, then their physiological arousal can be "misattributed" to anger toward the insulter rather than to the exercise, and the person may feel more intense anger and aggression propensity than would a nonaroused individual.

## General Aggression Model

The general aggression model (GAM) is one of the most comprehensive theories of aggression in that it consolidates the components of each of the previously described theories with the effects of person variables that have been correlated with aggressive behavior. The GAM posits that both situational (e.g., frustrating events or viewing of weapons) and person (e.g., attitudes endorsing violence) factors can independently or jointly cause an increase in aggressive thoughts, feelings, and physiological arousal. According to the GAM, when aggressive thoughts, feelings, or arousal are enhanced, the person then either engages in a rapid, immediate appraisal of the situation (e.g., “she shoved me, and I am going to shove her back”) or in a more deliberate, thoughtful appraisal of the situation, in which they think about potential causes of the aggressive stimulus (e.g., “perhaps she shoved me by accident”) and about the potential costs or rewards associated with aggressing.

If the person does not have the time or motivation to think about the causes of the aggressive stimulus or the potential negative consequences of aggression, then the person is likely to engage in impulsive aggression, often very quickly. If the person does think about the causes and possible consequences of their actions, then they are more likely to engage in thoughtful deliberative behavior that may or may not be aggressive. The “target” person in the social interaction who “receives” the aggressive or nonaggressive response then will respond in some way, which influences the other person’s beliefs and may serve as yet another situational stimulus (e.g., a provocation) that can again initiate the cycle described.

## Summary

Five theories of aggression are presented: frustration-aggression, social learning, cognitive-neoassociationism, excitation transfer theory of arousal, and the GAM. The first four theories focus on different causal mechanisms, namely frustration, imitation, priming of aggressive thoughts, and misattributing physiological arousal to a feeling of anger. The GAM incorporates the tenets of each of these theories and provides a comprehensive framework for understanding how situational and person factors affect aggressive thoughts and feelings that result in impulsive or deliberative aggression (or refraining from aggression).

## AGGRESSION AND CHILD-REARING PRACTICES

Early life experiences and the environment in which children are raised can influence and inhibit aggressive responses. Studies of child-rearing practices have shown that positive parent-child relationships, reasonable discipline, appropriate supervision, open communication, and modeling prosocial family values and behaviors all contribute to protecting children from acquiring aggressive and problematic behaviors.

### Parent-Child Relationships

Researchers of early childhood development generally agree that the responsiveness of caretakers and their relationships with children in their care are important predictors of children’s social competence, coping skills, and ability to form close friendships and intimate, nonaggressive relationships. Securely attached children have protective factors that act as social and emotional buffers against many risk factors correlated with aggression. Preschoolers and young children from stable and emotionally supportive caregivers possess higher levels of self-esteem, demonstrate higher levels of appropriate self-reliance and reality testing, respond more empathetically to others, and are more socially adept and accepted by others. Additionally, social scientists have shown that adolescents and young adults from nurturing parental figures form caring and healthy friendships with both sexes and experience intimate relationships in which both positive and negative affective states are explored and expressed nonaggressively.

Conversely, preschoolers and young children with hostile or rejecting parental figures tend to respond aggressively and with anger to younger siblings and peers, and later in life relationships. Children who experienced unpredictable and insensitive parents were shown to become anxiously needy and angry, characteristics highly correlated with aggressive behavior, such as jealousy, competitiveness, and possessiveness.

Child-rearing practices in which parental figures are both abusive and neglectful create a high probability that these children will view the world as dangerous, rejecting, unpredictable, and unavailable to meet their needs. Feelings of anger and fear have also been shown to predict aggressive dysfunctional

coping strategies in children (i.e., controlling through bullying, threatening, and other forms of aggression). Additionally, mental health problems such as depression, anxiety, and conduct disorders have been positively correlated with abusive and neglectful parenting practices.

## **Discipline**

Child rearing also involves setting boundaries, providing adequate supervision, and disciplining children. Parental characteristics such as age, socioeconomic conditions, marital status, and larger family size relate to parental discipline styles. To establish desirable nonaggressive behavior, researchers have demonstrated the importance of reinforcing targeted nonaggressive behaviors. Some forms of punishment can engender feelings of anger and shame and arouse a desire for revenge, highly connected with aggression and violent behavior.

Corporal punishment has been demonstrated to have both short- and long-term negative effects on children, including the development of antisocial behaviors. An important longitudinal study found that children were more likely to engage in aggressive behaviors if subjected to severe physical discipline, particularly when other early social and emotional needs were not met. Although corporal punishment remains a parental right, the practice has largely been abandoned by educational institutions and is illegal in a little more than half of the states in the United States. Adult corporal punishment of children is legally considered a form of child abuse in several countries around the world.

## **Summary**

Child-rearing practices that promote nonaggressive behaviors include positive parent-child relationships, modeling healthy and nonviolent responses to conflict and stress, monitoring children's behaviors, establishing boundaries and expectations for children, and communicating prosocial family and community values.

## **ROLE OF PEER RELATIONSHIPS AND AGGRESSION**

It is long established that peer relationships of children, along with family context, are critical factors in evaluating the developmental trajectories of aggression in children. Researchers have been interested in several types of social peer interactions, specifically

friendships, mutual antipathies, rejection by peers, and bullying and peer victimization.

## **Friendships**

Friendships are based on reciprocal liking and equality. Beginning at an early age, peer relationships establish a model for future adult relationships while providing social and cognitive developmental skills. Friendships provide a multitude of benefits, including resource sharing, collaboration of ideas, mutual trust, feedback, feelings of belonging, and entertainment. It is not clear whether well-adjusted children are more likeable or if friendships contribute to helping children become socially competent. Nevertheless, friendships and social affiliation are positively associated with nonaggressive behaviors in children and are predictive of future relationships.

Friends also exhibit aggressive behaviors such as verbal or physical fights. However, this form of aggression is characteristically not as forceful; the parties reunite after fighting, and the role of aggressor alternates. Some researchers suggest the ability to make and maintain friendships is the best predictor for healthy adult adaptation.

## **Relationships Involving Rejection and Mutual Dislike**

Children experience rejection by peers as well as relationships involving mutual dislike. Studies show both types of relationships are common. However, research in this area of peer relationships is sparse, and the outcomes from studies are mixed. Children who experience rejection when other factors place them at risk (such as violent neighborhoods and poor family relations) may turn to aggressive outlets. Further, inimical peer relationships may place children at greater risk for exhibiting aggressive behaviors because conflicts and confrontation may lead to violent expression. However, socially adept children experience rejection and have antipathies without harmful effects or signs of aggressive responses. In fact, in both male and female relationships, enemies may inhibit aggressive behavior. The findings are not conclusive, and future studies of relationships between enemies will likely examine such factors as communication patterns, relationship importance, the circumstances and dynamics surrounding animosity, and the emotional consequences of rejection and conflict in peer relationships.

## Bullying and Peer Victimization

As a result of an increase in violence in primary, secondary, and high schools worldwide, peer relationships characterized by bullying and peer victimization have received international attention. Bullying, generally carried out in small groups, consists of verbal humiliation, physical assaults (including sexual assaults), and social ostracism. Researchers generally agree the primary motivator for bullying is power and a strong desire to achieve some material or social reward. Studies have found bullying behaviors (without intervention) persist into adulthood and may be a source of depression, physical illnesses, anxiety, substance abuse, and academic failure.

Peer relationships involving bullying behavior, once believed to be a male phenomenon, appear to be common to both sexes. Although males tend to use more direct forms of aggression such as hitting and biting, even against females, older children and females generally employ indirect relational aggression such as spreading rumors and encouraging others to exclude peer victims. These types of behaviors, evident during early childhood, appear stable over time. Although researchers are uncertain whether male or female tactics are more severe, most victims of bullying do score lower on measures of self-esteem and higher on emotional problems. It is anticipated that exploration of personality development, environmental factors, family relationships, attitude formation, and cognitive development in bullies and victims will contribute to programs implemented in schools to prevent these negative peer relationship patterns.

## Summary

Peers exhibit aggressive behaviors in their relationships. Some aggression is normal and part of the socialization process, whereas other behaviors are injurious and developmentally harmful for children.

## ANGER AND ANGER MANAGEMENT PROGRAMS

### Anger

Anger is a natural human emotion with the potential for both constructive and destructive consequences. When channeled constructively, it has been credited

with motivating positive life changes, asserting personal and collective rights, and even providing the impetus for creativity. Although some scholars assert anger is never a constructive emotion, almost all would agree that suppressed or explosive anger is destructive and can lead to acts of violence, physical ailments including heart disease and other stress-related illnesses, and psychological symptoms associated with anxiety, depression, and substance abuse. Additionally, suppressed anger has been associated with passive-aggressive behavior, sarcasm, cynicism, and verbal hostility. It is estimated that most people experience anger several times a week. Although most people generally express their anger verbally, about 10% respond with physical aggression.

## Anger Management Programs

Programs designed to reduce the expression of anger in unhealthy and violent ways have become a lucrative industry in the United States and around the globe. Legal and educational systems, business enterprises, government agencies, and many other institutions have directed individuals into anger management classes designed to teach participants inner and interpersonal problem-solving and peacemaking skills.

Anger management programs are diverse in course content, format, number of sessions, and theoretical orientations. Although studies have substantiated the value and usefulness of the skills acquired in these workshops, anger management programs are by no means an educational or treatment panacea for every type of anger or every type of angry person. In fact, they are not reliably predictive of outcomes for participants. Ongoing research has identified several important factors currently under investigation, including gender, ethnicity, and cultural differences; environmental factors; readiness and expectations about the program itself; the setting in which the program is delivered; the personal goals of the participants; and the individual's level of personality trait anger.

Most anger management programs are based on sound psychological principles and instructed by mental health professionals. Although there is a proliferation of anger management programs worldwide, the science lags behind the industry. The American Psychological Association has credited anger management programs as helpful for some participants, whereas the American Psychiatric Association has not made such an endorsement, largely because no

diagnostic category for anger exists in the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV-TR)*. Researchers are trying to establish whether there is a separate set of criteria for such a diagnosis or whether anger is in fact a constellation of many different clinical disorders. Most academic scholars do agree that anger remains one of the most understudied emotions to date.

### Anger Management Curriculum

Some anger management programs teach participants to punch pillows, hit punching bags, or otherwise discharge anger in a physically aggressive manner. This practice is predicated on application of the Freudian theory of “catharsis,” which posits that acting aggressively should reduce aggressive impulses by “getting it out of the person’s system.” Paradoxically, research studies have clearly demonstrated that these practices tend to escalate the intensity of anger and fail to decrease aggressive behavior. Acting aggressively toward inanimate objects also strongly associates angry feelings with aggressive responses (i.e., conditioning).

Today, most anger management programs provide instruction in the art of relaxation, problem-solving skills, and cognitive-behavioral strategies focused on changing thoughts and maladaptive behavioral responses. Some programs incorporate conflict resolution techniques, communication training, forgiveness, self-monitoring, and even humor. Although it is fair to say that most anger management programs are psychoeducational in nature, a minority of them are more firmly rooted in traditional therapeutic approaches such as insight-oriented exercises, personality assessments, and self-exploration and family-of-origin exploration, especially for individuals with histories of violence. It is anticipated that future programs will be able to tailor anger management programs for each participant rather than providing a generic program. Toward that end, researchers are investigating whether one-on-one training programs are more effective than group sessions.

### Summary

Definitions and conceptualizations of anger have been debated in the psychological literature, whereas the need for consensus in understanding of the etiology

and control of anger is great, both nationally and internationally. Effective anger management programs teach participants to identify angry feelings and divert them into nonaggressive and constructive channels of expression.

### PREVENTION OF AGGRESSION

Because environmental and intrapersonal characteristics factor into the equation of aggression and violence, prevention involves a multidimensional and multidisciplinary approach that begins early in the child’s life. The following types of programs contain key prevention factors that have been identified as important deterrents in developing or expressing aggression in violent ways:

1. Early childhood school programs that include *early identification* of mental health problems, learning disabilities, and behavioral, emotional, or cognitive developmental delays contribute to preventing hostile and aggressive behavior in children (found in longitudinal studies of children in day care and early childhood programs)
2. Programs to help parents develop *positive parent-child relationships*, adequate supervision, consistent and reasonable discipline, and prosocial family values
3. Programs designed to assist parents (and other significant adult influences) to become *nonaggressive role models* for children (including domestic violence prevention programs)
4. Programs designed to *deter alcohol and drug use* in parents and children (because of the strong correlation between drug and alcohol use and aggression)
5. Multicultural and gender diversity training programs that provide *cooperative work with people who differ*, particularly in terms of racial and ethnic background, gender, religion, sexual orientation, and physical abilities
6. Educational and employment-related programs designed to help individuals *establish economic stability* (and parity) because communities with economic hardship are at higher risk for violence
7. Programs designed to *reduce undesirable amounts of exposure to violent media* such as television, movies, music, and video games
8. Programs designed to reduce gun availability

## CONCLUSION

Aggression is influenced by situational factors, such as frustrating events and the provocation of others; person factors, such as one's personality and gender; and the individual's cognitive interpretation of the situation. Theoretical models of both the causes and methods to prevent aggression reflect these factors. Parental and peer engagement in or abstention from aggression is often imitated by children (and adults) and influence subsequent aggression. Parenting that develops emotionally secure relationships with children fosters less development of pugnacious tendencies in children. Intervention and prevention programs that focus on reducing exposure to aggressive stimuli, such as weapons, violent video games, highly aggressive peers and drugs associated with aggression, and on helping individuals interpret stimuli nonaggressively and not experience enhanced anger, perhaps through the use of relaxation techniques, have been posited as useful in reducing aggression.

## AGING

---

Aging is inevitable. Although the average life expectancy has increased dramatically in recent years, we have yet to discover the proverbial fountain of youth. As such, our body gradually succumbs to the aging process. This process is so powerful that it inundates every aspect of life, from changes in appearance and limited physical mobility to cognitive impairments that may rob us of our very essence. These age-related changes are resultant of both pathological and normal aging processes. Although age-related diseases such as Alzheimer's and Parkinson's can be traced to pathological aberrations, "normal" aging surely contributes to the downward progression of these disorders as well. Despite what could be perceived as a bleak prognosis, there is striking individual variability in how aging influences our everyday life both between and within demographic groups. Consider the range in physical abilities and the disparity of cognitive abilities in an aged population. For instance, although aging generally leads to a reduction in muscle strength, the actual rate of decline can be affected by lifestyle variables such as activity level, diet, basal metabolic rate, and a host of other contributing factors. Indeed, older athletes who continue to train can maintain high levels of athletic competence. It seems unrealistic to believe that we can forever thwart the "beast" of age. Yet, through a better understanding of how the aging process interacts with biological, cognitive, and social aspects of our lives, we hope to glean insight into how we might age successfully.

## NEUROANATOMICAL CORRELATES OF AGING

It comes as no surprise that our brain ages in a manner much similar to other bodily organs. These changes are evident using techniques that range from the molecular to the psychological, and everything between. Age-related changes in function are associated

with structural brain changes that can have profound psychological consequences. For example, visual impairment is one of the first symptoms of aging, with the average 85-year-old demonstrating about 80% less visual acuity than that of a 40-year-old. Fortunately, from an aging brain perspective, retinal degeneration appears to be the major cause of this change because the brain areas involved in visual processing appear to remain generally unaffected. Although this observation may not be cause for celebration, it does suggest that brain circuitry remains relatively intact with advanced age, dispelling a common misconception about how the brain ages: the idea that age-related neuron loss is ubiquitous. Technological advances have been instrumental in debunking this belief, with evidence accumulating that the brain does not atrophy in a nonspecific, passive manner akin to that of a muscle with misuse. In contrast, brain atrophy appears to be limited in extent, selective in regional expression, and subject to considerable individual variability. For example, early research suggested that widespread, senescence-associated cell loss occurred throughout the hippocampus, an area of the brain heavily implicated in the formation of many types of new memories. Consistent with this notion are the observations that the types of memories processed by the hippocampus are frequently compromised in older adults. Yet, recent studies using improved microscopic techniques indicate that hippocampal cell loss is relatively minimal and restricted to specific hippocampal subfields. These regional and discrete observations parallel those of memory decline seen in old age; not all aspects of memory function are impaired; rather, only specific modes are influenced by the aging process. In particular, hippocampal function is strongly correlated with the ability to form durable memory traces, with older adults showing greater declines in memory for newly acquired information dependent on this ability, relative to well-established, long-standing memories that are more readily retrieved by older adults. Other areas of the brain yield similar observations. Consider, for example, the cerebellum—a brain region that plays a major role in orchestrating directed movement. Impaired motor coordination and balance are common complaints in old age, which could suggest impaired cerebellar function. In part, this is true because there is significant age-associated neuron loss in the anterior lobe of this structure, yet the entire cerebellum is not equally affected.

Despite the evidence that widespread cell loss is not a recurrent theme in the aging brain, some brain regions are particularly susceptible to the deleterious effects of aging. The cerebral cortex has been the focus of a great deal of research because it is highly developed in evolutionarily advanced animals—humans included. Moreover, the cortex is organized in a highly conserved, laminar pattern that greatly facilitates identifying cell layers (and the subsequent input and output pathways) and subregions of the cortex itself. In regard to aging, one area in particular in the cortical region has been the focus of intense research scrutiny—the prefrontal cortex. The prefrontal cortex is a brain region involved in controlling an array of functions, all generally related to the ability to regulate and organize behavior. At a cellular level, dendritic arborization in superficial cortical layers of this region is diminished with advanced age, whereas deeper cortical layers are relatively unaffected. On a more global level, the prefrontal cortex appears to be particularly susceptible to the effects of age because this area experiences a greater overall volumetric loss than is experienced in other cortical regions. These structural observations also have functional correlates, with reduced prefrontal activation during performance of cognitive tasks. Behaviorally, these changes manifest as declines in the ability to engage strategic memory processing (i.e., the coordinating, interpreting, and elaborating of information that occurs during memory encoding to place it in its appropriate context and facilitate its later retrieval). It is this specific strategic use of memory that appears to show the greatest decline in old age, with the largest decrements seen in free recall, whereby strategic memory processing must be engaged in order for successful retrieval to occur.

An age-associated reduction in dendritic arborization of supragranular neurons is also seen in the parietal region of cortex, specifically in Wernicke's area in the parietal lobe (a cortical region involved in language comprehension). In fact, these effects, as well as those previously mentioned for prefrontal cortex, appear to reflect their developmental progression. Specifically, dendrites in supragranular cortical layers continue to expand well into adulthood, whereas dendrites in deep cortical layers are relatively stable much earlier in life. Consistent with these observations, the distal sectors of the dendritic arbor appear also to be more responsive to experiential effects. Ironically, this property of enduring brain plasticity in these distal

regions across the life span may ultimately predispose this region to age-related deterioration.

At the cellular level, dendritic spines (the site of most excitatory synaptic contacts between neurons), neurotransmitter levels (the chemicals used by neurons to communicate with each other), and even cellular receptors (the site at which neurotransmitters have their primary effect) have been shown to be quite responsive to differential experience. Considering these parallels between developmental and experiential plasticity, and the seeming increased susceptibility during aging, it is not surprising that there is an age-associated reduction in spine and receptor density in selective brain regions and that the physiological properties of neurons are dramatically affected by such changes.

## NONNEURONAL BRAIN CHANGES

Although most attention has traditionally emphasized the role of neurons in brain function, the contributions of glia (historically viewed as support cells; involved in processes such as neuronal insulation and phagocytic activity) and dynamic changes in vasculature are becoming rapidly appreciated. Like that for neurons, there are glia-specific changes in response to behavioral experiences and both regional and cell-specific modifications. Similar to neurons, the types of glia and their functions are differentially modified in senescence. For example, age-related alterations in myelination (the insulation of nerve fibers) have been reported, an observation that parallels changes in cognitive abilities. Specifically, small-diameter fibers appear particularly vulnerable to age-related degeneration, with a loss of about 10% per decade. Conversely, astrocytic activity (typically associated with repair and restorative functions) has been reported elevated in several brain areas of aged subjects.

Much like that for neurons and glia, the cerebral vasculature has been shown to be quite responsive to altered demands. Changes in brain vasculature are reflected most obviously by the increased incidence of stroke in aged individuals. Unfortunately, by the time a stroke is overtly diagnosable, a series of smaller such episodes have already occurred. Our inability to detect these smaller strokes is limited, in large, by the spatial resolution of modern neuroimaging of the cerebrovasculature. By analogy, vascular blockage of the heart must be quite severe to be detected. As such, impaired cardiovascular health oftentimes is

undiagnosed for many years. Surely, similar effects also occur in the brain. If so, the loss of a significant number of these small-diameter vessels would likely go undetected for a great period of time using current imaging techniques. We know that the cerebral vasculature, like that for neurons and glia, is responsive to differential experience—creating more vessels in response to neuronal demand. This robust plasticity of the cerebral vasculature suggests that blood flow, or the lack thereof, may play a key role in the cognitive decline frequently observed with normal aging. Congruent with this notion, it has been shown that poor cardiovascular health is linked to greater incidence of Alzheimer's disease.

## Theoretical View of the Influences on Brain Aging

Taken together, the previously mentioned observations suggest that the very mechanisms that enable our brain to change in response to experiences earlier in life may be implicated for the decrements observed later in life. Yet, as previously discussed, there are striking interindividual differences in behavioral outcomes. Moreover, a great deal of variability exists in the underlying anatomy and physiology. Are some individuals prone to cognitive impairments with advanced age and others somehow relatively immune to such declines? That is, why do some individuals succumb to the deleterious cognitive effects of age early in senescence while others appear to be relatively unaffected well into advanced age? It has been suggested that a decline in synaptic density may “set the stage” for age-related changes in cognition for both normal aging and pathological conditions. The underlying anatomy is influenced by both genetic and experiential factors. Yet, to date, we have been unable to identify the source of such anatomical differences and, as such, cannot completely account for individual differences.

It is here that a theoretical approach to these processes is of particular value. One such theory is the canalization model of development proposed by C. H. Waddington (see Grossman et al., 2003). Although originally conceived to address developmental progression, this model can be readily modified to incorporate both genetic and nongenetic factors linked to age-related declines in cognition as well. In this model, envision a sloped canal with early life events depicted at the top of the canal. An individual is

represented by a “ball” that travels along the canal surface, “downward” as life progresses. The slope of the canal is defined by genetic influences and serves to guide the developmental progression of an individual in a normalizing manner, along the bottom of the canal. In the model, genetic and experiential events are encountered along the walls of the canal and can serve to promote normal development (the ball rolls toward the middle of the canal), or push development up the slope toward a threshold that defines abnormal behavior (in this case, age-related deficiencies). In regard to aging, this model incorporates a host of factors such as a progressive loss of neurons or spines, individual differences such as genetic predispositions and congenital perturbations, and environmental influences such as toxic assaults (all leading to reduced synapse numbers and altered neuronal function). Such factors would serve to push an individual toward, and possibly to surpass, an individually defined threshold of overt behavioral deficits. Likewise, the model captures the influence of canalizing experiences that serve to normalize or restore function. Indeed, evidence is accumulating that advanced education, physical exercise, continued cognitive challenges, and genetic differences all lead to maintained synapse numbers and robust, healthy neuronal function. Together, these interventions may, to some extent, “immunize” the brain to progressive pathology later in life. All told, these findings point to the conclusion that although neuronal cell loss occurs with advancing age, the brain can be protected to some extent by differential experiences, explaining why some individuals face impairments in mental function in old age, whereas others appear to be relatively impervious to such effects. Moreover, these general findings suggest that neural vitality (and by parallel—behavioral) is best maintained through a philosophy of “use it or lose it,” dispelling another misconception: that eventual “wear and tear” is the underlying cause for such deficits. Increasing amounts of data from a number of longitudinal studies support these claims: education and intellectually engaging activities buffer against cognitive decline in old age.

### **PSYCHOSOCIAL INFLUENCES ON BRAIN-BEHAVIOR RELATIONSHIPS**

Although the above discussion suggests that changes in brain structure and function, at both the neuronal and nonneuronal levels, are strongly linked

to cognitive-behavioral decrements in the older adult, these decrements are neither inevitable nor irreversible. The real story is much more complicated because cognitive function in old age is characterized by growth, decline, and stability. Strategic memory processing, for example, which has been described as being particularly problematic in old age, is an important aspect of one type of memory that has been linked to reliable age differences—declarative memory. Declarative memory generally refers to the conscious experience of remembering, usually tested through recall or recognition measures, and can be thought of in terms of “knowing that.” Examples of these types of memories include remembering the state capital, the name of a spouse, or the rules of a game. This type of memory can be dissociated from nondeclarative memory, usually measured indirectly by observing changes in performance that result from prior experience, without any conscious recollection or reference to that experience. Nondeclarative memory encompasses many different forms, supported by distinct neural pathways, and generally shows little, if any, appreciable decline with advancing age. This type of memory can be thought of in terms of “knowing how.” Some examples of nondeclarative memory function include skill learning and repetition priming (facilitated processing of previously encountered stimuli, i.e., a change in the speed, accuracy, or bias towards old stimuli, relative to baseline or novel stimuli). Regarding skill learning, research indicates that the old adage “You can’t teach an old dog new tricks” is not universally true. Both simple and complex skills can be acquired well into old age. Two important caveats are worth noting, however. First, the acquisition rate of new skills, and colloquially, new memories, proceeds much more slowly in older adults than it does in young adults. The major implication here is that older adults require more extensive practice than younger adults before skill mastery occurs. Second, even though new skills can be acquired by older adults, a growing amount of research indicates that to the extent that the skill relies on declarative memory or motoric function, age differences in skill performance will be present. This is an important observation because it maps onto a key distinction in the skill acquisition process—the distinction between early and late stages of learning. Each stage relies on different supporting cortical regions, some of which experience more changes with advancing age than others, so that age differences in skill acquisition and

performance may actually represent learning stage differences, and not memory decrements, *per se*. To illustrate, during the early stage of learning, strategic processes are heavily involved in the monitoring and regulation of the many cognitive processes that become engaged to attain the final goal of successful skill performance. Some of these processes include breaking up the skill into its individual steps, using feedback about performance to make adjustments, and planning the next sequence of actions. With practice and training, these initial steps in skill acquisition become more proceduralized and automated, so that strategic processing becomes less necessary in skill performance. The early stage of learning has been linked to brain activity in the prefrontal cortex, an area that shows significant anatomical changes with advancing age. Once tasks have become proceduralized and less strategic in terms of the cognitive processes involved, however, there is a shift in brain activation from the prefrontal cortex to posterior cortical regions. These latter areas do not experience the same magnitude of change with advancing age as the prefrontal cortex. Such findings indicate that age differences in skill acquisition are stage dependent: age differences are larger during the early stage of learning than during the later stage. This conclusion is supported by the observation that for skills acquired early in life, for which presumably a high level of expertise has been afforded and performance is likely automated, age differences are greatly attenuated, and in some cases even eliminated. Well-learned skills, then, tend to be immune to the effects of aging, whereas newly learned skills may not be expected to be resistant to aging effects.

A number of arguments exist as to why expertise reduces age differences in skilled performance. One argument has been that older experts develop a compensatory mechanism that allows them to offset the negative effects of aging by relying on relevant domain-specific knowledge to enable them to perform at levels comparable to that of young adults. For example, in studies examining older and younger pilots versus nonpilots, age differences in the performance of tasks related to pilot communication activities were present only in the nonpilots. Older pilots compensated for potential age differences in task performance by relying on their knowledge about pilot communication to readily perform the task. Similar types of compensation have been observed in older chess experts, typists, pianists, and bridge experts. These

mechanisms are believed to develop unconsciously over time as the aging individual strives to maintain performance levels in the face of decline. Although the compensatory effects of expertise tend to be domain specific (i.e., they have larger buffering effects within areas of expertise than in other areas), arguments have been made that expert performance is supported by a long-term working memory system (see, for example, Horn & Masunaga, 2000). This system is characterized by its ability to hold and manipulate large amounts of information over extended periods of time so that it can be quickly accessed during task performance. This type of memory appears to emerge over time, as expertise develops to allow for superior performance. The evidence from older experts indicates that long-term working memory may be resistant to the effects of aging, although additional research investigating this claim is needed.

Beyond skilled performance, other areas of cognitive function also demonstrate growth or stability in old age. These areas include verbal comprehension, logical reasoning, induction, and concept formation. Collectively, these abilities represent an aspect of mental ability known as *crystallized intelligence* and represent experiential, or culturally valued, knowledge. They generally reflect the development of everyday judgment, understanding, and thinking—skills that mature over time. These abilities are often contrasted with fluid intelligence abilities, those mental abilities that are not acquired through experience or culture. Some examples of fluid abilities are spatial reasoning and perceptual processing speed. Arguments have been made that these abilities reflect central nervous system integrity, so that, consequently, they reveal a pattern of decline in old age. As is the case regarding memory function, with age-related performance dissociations existing between declarative and nondeclarative memory, general intellectual ability also shows age-related performance dissociations, providing additional support for our argument that aging does not produce universal declines in function.

In addition to the issues just described, a growing corpus of research indicates that psychosocial factors such as education, environmental complexity (e.g., community dwelling versus institutionalized living), physical activity, sense of control, and self-efficacy may strongly influence cognitive function to attenuate age differences. For example, older adults with strong perceived control over memory function outperform older adults with weaker perceived control. Similarly,

modifying one's sense of control or self-efficacy regarding memory function (i.e., adopting a more positive perspective) can lead to improvements in memory performance. Combined, these findings indicate that although changes in brain function alter older adults' cognitive abilities, psychosocial and environmental factors can help maintain cognitive competencies—the situational use of cognitive abilities—in old age. Despite the losses to cognitive abilities (with memory loss being the most notable of these changes), cognitive competency, particularly in occupational and daily living activities, can increase across the life span.

Finally, one additional factor that has been shown to provide buffering effects against cognitive decline in old age is the social environment of older adults. Recent large-scale longitudinal studies reveal that greater levels of social engagement (i.e., more contact with friends and family and greater involvement in group activities), as well as greater levels of emotional support from friends and family, can provide some protective effects against cognitive decline in old age. These effects appear to be independent of other factors that might predict cognitive decline, so that social isolation in and of itself has a tremendous impact on the cognitive function of older adults.

## SUMMARY

Aging is a complex and often misunderstood process. Although the aging process itself is inevitable, aging does not always produce decline and impairments in function. Gains and losses are both part of the aging process, so that aging can take many different paths. We have focused our discussion on brain changes and their consequent effects on cognitive and mental abilities because these aspects of human behavior have strong ties to an individual's psyche, such that within some individuals, these changes can preclude the development of mood disorders, mental illness, or even dementia. However, most individuals experience these changes without significant deleterious effects in their everyday lives, illustrating a key factor related to successful aging: aging varies across individuals. Although some general conclusions about the effects of biological aging can be made, individuals can play an active role in determining the course and eventual outcome of these changes to minimize decline, maintain stability, and achieve growth, at any age.

## AGING PARENTS

---

Throughout our life span, the family is one of the most stable and reliable relationships we experience. Aging parents in America are thriving within the context of their families. Despite the empirical support for this statement, negative stereotypes about older families persist. It is not uncommon to hear about the threats accruing to aging parents as a function of geographic mobility, family breakdown, and social isolation. Concomitantly, older adults may be characterized as “greedy geezers,” placing huge burdens on both the family and society.

Decades of empirical study, however, reveal a picture of families in which aging parents play a key role. Most of this research has been guided by the solidarity model proposed by Bengtson and Schrader in 1982. This model examines intergenerational relations in terms of normative solidarity, affectional solidarity, consensual solidarity, associational solidarity, functional solidarity, and structural solidarity.

Normative solidarity refers to perceptions that one is experiencing usual or typical life events. Indeed, the phenomenon of aging parents is normative. Most older Americans are parents, with 75% to 80% having at least one living child. This, coupled with increased longevity, increase the likelihood of living in a four-or five-generation family. Moreover, this trend is expected to continue; by the year 2020, 60% of women age 50 and older are expected to have at least one living parent. Thus, one can simultaneously *have* aging parents and *be* an aging parent.

Affectional solidarity refers to shared feelings of esteem and affection. The parent-child bond is the strongest familial bond (outside of marriage) and continues to be important to both children and aging parents. However, there is some evidence that these relations may be more important to aging parents, giving rise to the “intergenerational stake” hypothesis. This states that relative to their children, aging parents report higher levels of affection and a stronger desire to maintain contact with other generations. This trend extends to the middle generation, who value their relationships with their own children more highly than they value their relationships with their parents.

Consensual solidarity refers to the degree to which generations agree about fundamental social, cultural, and political views. We know that attitudes and expectations are in flux, making it difficult to adequately gauge the effects of consensual solidarity. Some research suggests that this aspect of intergenerational solidarity is especially important for immigrants and first-generation families.

Associational solidarity is indexed by the frequency of contact between the generations. Associational solidarity is high, with 80% of older parents having some contact with an adult child at least once a week. Not surprisingly, there are gender differences in the frequency of such interactions, with aging mothers reporting higher levels of contact than aging fathers.

Functional solidarity, the exchange of goods and services, flows bidirectionally across contiguous generations. Aging parents may provide child care, financial assistance, and advice; adult children may provide help with household chores, home repairs, and personal care. In late life, parents tend to receive more than they give. When aging parents require assistance, it is family members who provide the bulk of that care.

Structural solidarity focuses on living arrangements. Throughout American history, and continuing

today, separate but proximate households are the norm. Only about 20% of the noninstitutionalized elderly reside in households in which two or more generations are present. Gender, age, and race affect the likelihood of multigenerational coresidence. Women are more likely to coreside with nonspouse family members, both as a widowed mother and as an aging daughter or daughter-in-law. As one might expect, the percentage of older adults coresiding with a younger generation increases dramatically with advanced age, with nearly half of adults older than 90 years who live in the community sharing a residence with at least one younger generation. African Americans are more likely than Euro-Americans to live in multigenerational homes.

### AGING PARENTS AS CAREGIVERS

Although most parents look forward to launching their sons and daughters into an independent adulthood, some adult children are not able to live independently. Parents of adults with chronic disabilities may experience extended parenting in which the roles they enacted during early childhood continue into that child’s adulthood. When sons and daughters experience such lifelong disabilities, it is often aging parents who provide assistance. Two types of chronic disabilities are associated with this extended parenting: developmental disabilities, including mental retardation; and chronic mental illness, such as schizophrenia. In addition, aging parents are often viewed as the “front-line” child care providers when the middle generation requires assistance raising their own offspring.

Providing continued parental assistance to an adult son or daughter with a chronic disability is associated with a host of satisfactions and burdens for aging parents, especially aging mothers. Mothers of adults with chronic mental illness report particularly high levels of caregiving burden, even when they do not reside with their son or daughter. Even in these situations, however, the parent-child relationship is characterized by high levels of affectional and functional solidarity. As in other aging families, the flow of assistance between aging parents and adult children with disabilities is often bidirectional. In fact, most older mothers of adults with serious mental illness receive at least some help from their adult offspring.

A second area in which aging parents provide substantial assistance to younger generations is that of child care. About 22% of adults ages 65 to 74 years

provide child care to family members. In many cases, the older adult resides with the young child. More than 1 in 10 U.S. grandparents raise a grandchild for at least 6 months, with most providing care for 3 years or more. Nearly 5 million U.S. children currently live with grandparents.

The custodial grandparenting role occurs under difficult family crises related to the middle generation, including death, incarceration, divorce, substance abuse, teenage pregnancy, abuse of the child, and abandonment. In a comparison of the effects of various caregiving constellations, custodial grandparents profile as more distressed by their caregiving demands than caregivers to older patients with chronic illnesses.

### SANDWICH GENERATION: AGING PARENTS AS CARE RECIPIENTS

The pattern of care shifts within a family such that aging parents begin to receive more assistance than they provide. Whereas 35% of adults ages 65 to 74 provide personal care to someone else, only 12% of those ages 85 and older provide such care. Mothers, old parents, parents in need of support, and parents without a partner receive relatively more support from their adult offspring. Reciprocity, however, continues to characterize relations with aging parents. Even when aging parents are receiving assistance from their adult children, older parents may continue to provide a range of support, including emotional and tangible support (e.g., child care, household tasks).

Middle-aged individuals are sometimes referred to as the “sandwich generation.” This term has two levels of meanings. Structurally, it refers to middle-generation cohorts sandwiched between older and younger cohorts in the population. Individually, it refers to people in middle adulthood who simultaneously have relations with their adult children, as they enter and adjust to adulthood, and their aging parents, as they deal with issues of later life. Members of this sandwich generation are presumed to face potential stresses from the combined and competing demands of their intergenerational roles as parents and children.

Despite the attention that this construct has drawn in the popular press, the notion of a sandwich generation may be misleading. First, many of the conflicts middle-aged adults report are due to competing roles in general, not competing generations. Second, conflicting obligations or “sandwiching” can be experienced by anyone who assumes the caregiving role.

Research in this area must be viewed in the larger context of generational reciprocity across the life span. It is only in later life, after age 85, that older adults begin to receive more support than they provide. However, even though relatively few middle-aged adults are actively involved in assisting their children and parents, either individually or in combination, at any particular time, there may be substantial burdens for those who are.

In summary, aging parents continue to exert positive influence in society. Families maintain frequent and fulfilling contact across generations. The assistance that is provided within families flows in a bidirectional manner, with the balance shifting toward aging parents as recipients of care in very late life.

## AGING WELL

---

Most adults want to live long, in good health, and with an overall sense of well being. *Aging well* describes this goal by promoting positive images and approaches to human aging. Aging well, as opposed to a difficult old age, is the outcome of personal lifestyle choices and behaviors in interaction with supportive physical, social, and cultural environments. Aging

well results from exercising the choices that create a successful, healthy, and productive life. It is a dynamic process that involves the individual in interaction with his or her environment, and is affected by historical events of the time and cultural influences. In many ways, aging well is affected by the resiliency and adaptability of the aging individual. The individual and the environment are interactive, and the positive outcomes associated with aging well are a direct result of personal adaptations and negotiations that take place within this context.

As increasing numbers of people worldwide are living longer and are more active throughout the adult years, archaic views of old age as a time of burden, decay, and decline are quickly being replaced by more positive ideas that focus on active and engaged lifestyles that include choices as we age. Attaining a good old age, or aging well, is an important social goal for countries that are experiencing rapid increases in the percentage of older people in their population. The myths and negative stereotypes about older people that were so dominant during the 20th century are challenged by newer views that convey successful aging, active aging, productive aging, healthy aging, and aging well. These contemporary ideas are aimed at replacing past images of old people as burdens on society with views that focus on positive aging. It is important, however, to be realistic in the images of aging that are presented in the media and ideas that are reflected in social policies and programs because it is an equal disservice to older people to create exaggerated images. Aging well, as both a process and an outcome of personal behaviors coupled with positive environments, may be instrumental to creating a productive adjustment within communities to the enlarging older adult segment of the population.

As a dynamic process, aging well cannot be presented as a single description or prescription of how to live. People age differently within their personal life contexts according to individual characteristics and histories that they bring to older adulthood. A hallmark of the aging population is a great degree of both heterogeneity and diversity. *Heterogeneity* refers to variability within the individual as he or she ages, and *diversity* refers to the position of different groups in relation to one another within society. The two terms are often confused with one another when understanding issues related to the aging population, and both terms are relevant, particularly in reference to aging well. Even though aging is intensely personal, it

is still of great public concern and responsibility. To facilitate and promote aging well among adults in different societies around the world, public commitment is needed for providing policies and environments that enhance lifestyle choices for successful, active, productive, and healthy aging, which collectively represent the ideal conditions for aging well.

Aging well is a contemporary idea and perspective that is intended to counteract negative views and practices. Unfortunately, some social policies and programs that were developed to help older people also contributed to the pervasive negative images held of older people. Programs that created voluntary or involuntary retirement, for example, all too often have promoted a sense of role loss, diminished status, and dependence. Early research in gerontology also promoted negative stereotypes of older people. For example, a biomedical approach to aging often conveys growing older as a medical problem in which illness and diseases are the main foci of attention. This perspective encourages society to think of aging in pathological terms and is accompanied by policies and services that target the care needs of helpless, hopeless, and infirm elders. More recent research provides evidence for a different reality, one in which there has been a decline in health problems and disease rates among the older population, such that more positive images of the aging process might suggest a different outlook. As a more positive view of old age, aging well emphasizes the idea that people can adapt and maintain satisfying lives as they age even when, for some individuals, the circumstances are less than optimal.

Considerable work has been completed in recent years to develop the concept and provide research evidence to support aging well. The intention behind the aging well concept is to propose a continuum for studying heterogeneity among people; this continuum is represented by optimal well-being on the positive end and a difficult old age at the other end. Such a conceptual framework will allow the discovery of determinants and causes on a more integrated level of thinking, one that embraces the physical, social, mental, daily life activity, and material well-being of the individual. Aging well is intended to imply not a dichotomy, but rather a continuum that is flexible across cultures, individuals, and circumstances.

The study of aging has a rich and diverse history, representing varied perspectives on what it means to grow old. This history reflects much of the ideology of the times and cultures in which it was developed and presented in the literature. To say the least, how human

aging is currently understood is quite different and clearly evolving from earlier theories of social gerontology. More recently, considerable interest has been aimed at the generation of paradigms and theoretical premises that promote ideas such as successful aging, productive aging, healthy aging, active aging, and aging well; however, much controversy has also arisen around the potential lack of robustness of these concepts to explain a good old age for older people worldwide.

As population aging and globalization continue to affect the lives and lifestyles of older adults, how aging is understood and experienced can be expected to evolve. A single explanation of aging is unlikely and probably not desirable; however, the study of important propositions and social factors that provide foundational explanations of well-being in old age lies at the heart of current conversations about human development across the life span. It is in this context that the concept of aging well has emerged in a broadening range of literature and social action plans, including recent publications of the Second World Assembly on Aging held in Madrid, Spain, in 2002.

In summary, aging well is a person-centered process in which the promotion and protection of physical, cognitive, social, economic, and daily life activities are paramount for achieving a sense of satisfaction and well-being in old age. Aging well is a concept that is recognized as applicable in shaping the public's image of the adult life course. Aging well is both proactive and interactive behavior in response to the circumstances in which adults live—individually and collectively. The test of aging well is directly related to one's outlook and to one's ability to select positive opportunities that will result in a personally satisfying life, as well as social and physical environments that are structured to support aging well versus creating the conditions for a difficult old age. Aging well encourages individuals and societies to envision a desirable future and create a proactive social response that is designed to ensure that future.

## AINSWORTH, MARY SALTER (1913–1999)

---

Mary Dinsmore Salter was born on December 1, 1913, in Glendale, Ohio, but grew up in Toronto, Canada. As a psychology student at the University of Toronto, she became drawn to William Blatz's "security theory," which inspired her dissertation, completed in 1939.

After a stint as instructor at the University of Toronto, Mary entered the Canadian Women's Army Corps in 1942, gaining substantial clinical and diagnostic skills. She returned to the University of Toronto in 1946 and married Leonard Ainsworth, a WWII veteran and graduate student in 1950.

Serendipitously, Leonard's decision to complete his doctoral studies in London led to Mary's collaboration with John Bowlby at the Tavistock Institute for Human Relations, where she was exposed to Bowlby's emerging ideas about the evolutionary foundation of infant–mother attachment. She also admired the naturalistic observations of mother–child separation conducted by Bowlby's research assistant, James Robertson. In 1953, when Leonard accepted a post-doctoral position at the East African Institute for Social Research in Kampala, Uganda, Mary was able to undertake a short-term longitudinal study of mother–infant attachment interactions in Ganda villages. This made her the first researcher to apply and

extend the insights of attachment theory, but her book, *Infancy in Uganda*, was not published until 1967.

After the Ainsworths' move to Baltimore in 1954, Mary performed diagnostic work at a psychiatric hospital and lectured at the Johns Hopkins University, where she was offered a professorship in developmental psychology in 1958. Shortly thereafter, she and Leonard divorced.

In 1963, Mary Ainsworth launched the Baltimore Project, modeled on her work in Uganda. Monthly home visits of 26 families began after a child's birth and ended at 12 months. Detailed narratives captured mother–infant interaction quality during feeding, contact, play, and distress episodes. The final observation, at 12 months, consisted of a mother–infant separation and reunion procedure now known as the “strange situation.” Patterns of infant behavior during this laboratory procedure were predicted by maternal sensitivity and harmonious interaction qualities at home. Journal articles and a book, *Patterns of Attachment*, based on the findings were published over the next decade and inspired major longitudinal attachment studies in the United States, Germany, and Israel.

At Johns Hopkins, Ainsworth attracted many graduate students, whose work expanded her findings. This continued at the University of Virginia, where she became Commonwealth Professor in 1975. In 1978, Ainsworth was elected president of the Society for Research in Child Development. Despite mandatory retirement in 1984, she remained professionally active until 1992, when her health began to fail. Among her many honors was the American Psychological Association's Gold Medal Award for Life Achievement in the Science of Psychology in 1998, a few months before her death on March 21, 1999, in Charlottesville, Virginia. Her conceptual contributions and empirical findings have revolutionized how psychologists think not only about infant–caregiver attachment but about close human relationships at all ages.

—Inge Bretherton

## ALCOHOLICS ANONYMOUS

---

Founded in 1935, Alcoholics Anonymous (AA) is a mutual-help organization for alcoholics, with about 2 million members and 99,000 groups in more than 140 countries. Among individuals who seek help for an alcohol problem in the United States, more than half go to AA—substantially more than those who choose formal treatment.

The structure and function of AA are guided by the Twelve Steps (structuring the therapeutic process) and the Twelve Traditions (governing AA's operation as an organization). Members are encouraged to attend meetings and “work” the steps, often with support from a senior “sponsor.” Working the steps requires that members (1) admit powerlessness over their drinking, (2) accept that only a power greater than themselves can relieve them of alcohol dependence, (3) surrender to a higher power, (4) admit to their defects and ask for their removal, (5) acknowledge how they have hurt others and make amends where possible, and (6) help others become acquainted with AA and carry out God's will generally. AA has a spiritual emphasis, but it is noncreedal. AA draws from many traditions, encouraging individuals to interpret “God” as they deem fit.

The Twelve Traditions were developed to preserve AA as an organization dedicated to helping individuals live life free of alcohol. In accordance with these traditions, groups are self-starting and self-governing. No franchise system allots territories or populations to groups, and groups are autonomous and financially independent. Meetings are led by temporary leaders instructed to “serve but never govern.” Except for the copyrights on its publications, AA owns no property,

and AA forbids external affiliations and endorsements. AA does not solicit members through promotional activity and receives income only from voluntary contributions.

Ample research suggests that AA is effective in helping individuals remain abstinent from alcohol. Studies of Veterans' Administration (VA) inpatients have reported abstinence rates twice as high among men reporting AA (vs. no AA) attendance. Likewise, Project MATCH, a rigorous clinical trial of individuals seeking treatment for alcohol problems, found that AA attendance predicted higher rates of abstinence during treatment and through the 1-year follow-up. These and similar studies of AA's effectiveness have been challenged on grounds that individuals who choose to attend AA have higher motivation than those who decline involvement, or differ in other ways that could account for the relationship between AA and outcomes. Those concerns have been somewhat mitigated by consistent findings that AA affiliates display *higher* initial problem severity than nonaffiliates. Some evidence suggests that AA is ineffective when involvement is coerced, although naturalistic studies have also found good outcomes under coercion.

AA's approach differs substantially from usual psychotherapeutic practice. There is no professional therapist in attendance at AA meetings. Members are of equal status and help each other, in part by listening, telling their stories, doing service (e.g., setting up chairs and making coffee), and sponsoring others. Further, AA's claim to authority is not based on scientific knowledge, but on tradition, experience, and spiritual beliefs. Nevertheless, many treatment programs now incorporate clinicians with experience in 12-step groups, and some are explicitly modeled on 12-step principles (e.g., the "Minnesota model" approach). Further, most treatment centers now encourage or mandate 12-step attendance.

AA has helped spawn countless 12-step groups for the addictions and other lifestyle problems (e.g., Narcotics Anonymous, Cocaine Anonymous, Overeaters Anonymous, and Obsessive Compulsive Anonymous) and contributed to the formation of various secular alternatives, such as Rational Recovery Systems (founded in 1986), Secular Organizations for Sobriety (founded in 1986), and Women for Sobriety (founded in 1976). Associated groups include Al-Anon (for family members of alcoholics), Alateen (for their teenage children), and Adult Children of Alcoholics.

---

## ALCOHOLISM

---

### WHAT IS ALCOHOLISM? WHO IS AN ALCOHOLIC?

Alcoholism, as lay people generally know it, is the fondness, desire, or even need for alcohol in an extreme sense to the point of addiction. Alcohol is the most widely used legal drug worldwide that also predisposes people to dependence or abuse (addiction) in certain parts of the world. Different cultures have varied features of the extent of alcoholism in their societies, especially with different levels of accessibility, rules, and norms of drinking. For instance, some countries have higher levels of alcoholism (e.g., about 10% of the U.S. population), accompanied by higher levels of people's tolerance for alcohol, and then may consider alcoholism as normal and not deviant. Some others, such as many countries in the Middle East and Asia, have laws and religious prescriptions that encourage the prohibition of the import and sale of alcohol, where society's alcoholism levels, and at times distress levels, are extremely low. On the other hand, there are also some other countries, like France and Italy, where drinking alcohol is acceptable and not regulated, and still addiction to alcohol is low. Moreover, different cultures relate to alcoholism differently. Some cultures deny the existence of alcohol addiction and consider talking about any degree of alcoholism or its consequences as taboo. Other countries minimize alcoholism as an issue or concern that warrants any kind of societal or community attention. Still other societies recognize alcoholism as a mental health issue and spend a substantial portion of their resources in abating the problem. In the United States, the direct and indirect costs of alcoholism

(i.e., money spent for the prevention, detoxification, and rehabilitation of alcoholism and amount spent because of absenteeism, loss of productivity, and medical claims) amount to an exorbitant \$148 billion each year.

Psychologists, especially those who work with alcoholics (i.e., therapists and counselors), use the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV-TR)* as a standard reference in defining mental health disorders such as alcoholism. According to the *DSM-IV-TR*, alcoholism is defined by increased tolerance, increased withdrawal symptoms, persistent and compulsive alcohol intake, and distressing consequences in social, occupational, and familial functioning. Increased tolerance is manifested by ever-increasing consumption of alcohol with lessened psychophysiological effects (not getting drunk easily, inhibitions lessened only slowly, personality change not as dramatic) on the drinker. In short, increased tolerance means a greater capacity for alcohol each time to obtain the desired effects. When the alcoholic experiences a period of time without alcohol, he or she exhibits withdrawal symptoms, including shaking, perspiration, and yearning for alcohol. These symptoms are aversive and make it extremely challenging to go without alcohol. With alcohol abuse or dependence, there are inevitable consequences on the person's functioning that may include being unable to go to work regularly; being unable to concentrate in academic work; having conflicted, chaotic, or distant relationships; or being unable to fulfill one's responsibilities of being a father or mother. *DSM-IV-TR* classifies alcoholism on two levels, substance abuse and substance dependence, with regard to its severity and frequency. Substance abuse is the pattern of alcohol use that leads to distress for a period of 12 months, whereas substance dependence is the maladaptive pattern of substance use that leads to greater and more extreme impairment for a period of 12 months. Substance dependence is the persistent addiction to alcohol despite greater and more difficult consequences to alcohol intake. Alcohol is the most common drug of abuse and dependence and has a high likelihood of being mixed with other drugs in polysubstance use.

### WHAT ARE THE TREATMENTS OF ALCOHOLISM AS A MENTAL HEALTH DISORDER?

As a mental health concern, there have been many attempts, some more effective and efficacious than

others, to treat alcohol abuse or dependence. Among them are medical treatment, psychotherapy, lifestyle change, and community interventions. Individual psychotherapy, usually consisting of cognitive-behavioral orientation and techniques, is one of the treatments used when there is availability of psychotherapy and financial resources. The cognitive orientation in therapy taps into modifying the alcoholic's irrational or self-defeating beliefs that fuel the addiction. Psychotherapy using the behavioral orientation aims at providing reward or reinforcement for acceptable behavior and establishing healthy alternative associations that retard the drinking behavior. Group therapy is another form of treatment, whereby a group of six to eight people struggling with alcohol abuse or dependence meets regularly with one or two therapists. Group therapy has proved effective because of the valuable resource each group member is to the other. Moreover, the group lends itself to the value of universality; enables identifying with each other; allows for sharing and encouraging change, information, ideas, and ways of coping; and extends hope and courage among each other. Over the years, community treatments have proved not only cost-efficient but also effective, even to the substance-dependent person. It is for this reason that halfway houses, outpatient groups, and Alcoholics Anonymous have been successful. Alcoholics Anonymous, because its vision is rooted in the quest for spiritual meaning and its essence relies heavily on modeling and companionship, has proved very popular and effective for substance abusers and substance-dependent people. In these forms of treatment, a necessary feature is relapse prevention. Because alcohol abuse and dependence are very challenging to treat, preventing relapse, preparing for relapse, having alternative behaviors, coaching on how to deal with relapse, and planning for this have been essential in treatment. In any form of treatment, a great deal of weight and credibility is accorded to the therapist working with substance use disorders; the therapist is especially effective and trusted when he or she has recovered from alcoholism.

### WHAT ARE THE COSTS AND CONSEQUENCES OF ALCOHOLISM?

A great number of consequences to alcoholism have been identified. It is especially obvious to someone living with an alcoholic or loving someone with substance dependence that the costs are huge, the

expenses endless, and the consequences in relationships exorbitant. Alcohol abuse and dependence affect one's ability to be productive at work—attendance at work usually drops with increasing occasions of hangover. The alcoholic's concentration, initiative, and motivation for work are usually jeopardized with addiction to alcohol. There is disruption or loss of a sense of vocation and urgency for a career, and there is indifference about not having a regular source of income. In terms of relationships, alcoholism not only creates distance from strangers (e.g., because of behavior when intoxicated) but also creates estrangement, fear, and threat to relationships that are supposedly important and endearing to the alcoholic. It is unfortunate that the most vulnerable to the relationships fostered with alcoholics are their children, spouses, parents, siblings, friends, and co-workers. These relationships may be characterized by distance, indifference, conflict, anger, chaos, and unpredictability. Because of the alcoholism and changes in the alcoholic's personality and functioning, these relationships are likened to being on an emotional rollercoaster. Psychophysiological changes in alcoholism differ among alcoholics—some people become more extroverted, others more introverted, and still others more expressive of anger or affection; some become impulsive or bolder and exhibit risky behavior. Whatever the changes, however, they all affect the alcoholic's relationships and perceptions of other people, as well as other people's attitude towards the alcoholic. Because inhibitions are depressed by alcoholism, these relationship changes may reinforce the psychophysiological changes. Finally, the most obvious and easily apparent consequence is economic or financial. Although alcohol as a substance may be relatively inexpensive, its abuse or dependence has economic impact in the context of an already impoverished household or when the vocational, social, medical, and intrapersonal consequences have financial repercussions. For instance, an alcoholic father who is laid off from work because of irregular attendance and the lack of productivity is then unable to provide for food, shelter, and health care for his family. Or, for instance, a mother's substance dependence can no longer be tolerated by her husband, who divorces or abandons her without many resources or even takes the children away from her. Continuous and persistent intake of alcohol also presents risks for diseases such as cirrhosis, high blood pressure, stroke, hepatitis, and cancer, which

can almost always be very costly, financially and psychoemotionally.

## HOW DOES ALCOHOLISM DEVELOP?

It is acknowledged that enumerating the causes of alcoholism may put this discussion at the risk for degrading or blaming the victim. It is thereby the hope that this list of causes conveys the respect for the struggle and predicament of people with alcoholism. Developmentally, drinking alcohol is often first experienced in adolescence. Certain familial, genetic, behavioral, and cultural norms (availability, encouragement of family, prices, accessibility, media and advertisement) and the individual's predisposition all interact to determine whether the adolescent continues to drink in early adulthood and whether the individual pursues abusive drinking into adulthood.

The genetic cause of alcoholism has been confirmed by research; people with parents who are abusers or dependents usually have higher tolerance for alcohol and a higher predisposing risk for addiction. Behaviorally, alcoholism may have been established as a person's way of coping with problems, hardship, or emotional emptiness and depression. Drinking alcohol can also be due to a strong pressure from one's peers and one's community. Relying on alcohol for relaxation and relief from life's challenges can also be learned and may then be passed on to the next generation. Moreover, the psychophysiological effects of drinking may be reinforcing; that is, because the personality and bodily changes to the drinker are perceived as favorable, these effects may be rewarding, and the drinking is reinforced as well, which eventually may lead to abuse and then dependence. Relationally and usually more common in collectivistic cultures, behavioral and emotional patterns are learned in response to the alcoholic. In families with an alcoholic, these patterns may eventually allow the alcoholic to continue with the dependence. For instance, qualitative studies focusing on the spouses and children of alcoholics report that the way of coping with the alcoholic member, which is to survive and cope emotionally and financially by themselves, eventually "allows" the alcoholic to continue with the dependence. A vicious cycle then develops in which the worse the alcoholism becomes, the more the family tries to cope without the help and presence of the alcoholic, and then the more the alcoholic continues with

the dependence, with seemingly no detrimental consequences.

## SUMMARY

Alcoholism is defined by people as their experiences and lives witness the addiction in their own or in their loved ones' lives. Psychologists generally use the *DSM-IV-TR* as the standard definition for substance abuse and substance dependence. This definition is used to more effectively treat alcoholism as a mental health disorder. Because alcoholism has been a long-standing concern in most cultures, many forms of treatments have been used. The consequences of alcoholism are costly, not just to the individual (career, intrapersonal, social, personality, economic), but also to the individual's loved ones (relationships, commitments, and responsibilities). As with any addiction, societies have been spending a lot of financial, personnel, and psychological resources in the treatment of alcoholism, especially acknowledging the many causes of alcoholism. It is the soul of changing an addiction in that the desire and intentionality of the alcoholic person are most imperative. In essence, ceasing alcoholism is highly probable only when the alcoholic has set his or her heart on changing.

## ALLELES

Alleles are variant forms of a particular gene. Each person carries two copies of each gene (one from their mother and one from their father). They may have two exact copies of a particular gene, or their two copies may vary from each other. The varied forms of a particular gene are called *alleles*. Sometimes alleles are called *polymorphisms* (many forms).

At the molecular level, alleles differ from each other in their DNA sequence. Thus, alleles may vary in the exact sequence of nucleotides, the length of the sequence of nucleotides, or the level of expression of the sequence of nucleotides. The interaction, or lack thereof, of the gene products of the different alleles will determine the phenotype of the individual with regard to that gene pair. Some alleles are dominant over other alleles, such that they determine the phenotype. An example of this is ABO blood types, whereby a person with one A allele and one O allele has type A blood. Recessive (or masked) alleles only show effects in the phenotype when no dominant allele is present. Thus, in blood types, the only way a person can have type O blood is to have two O alleles. Some alleles can interact with each other to produce an intermediate or blended phenotype, or in some cases, both phenotypes are present. An example of this is AB type blood, which results when an individual carries both A and B alleles for this gene pair.

Different alleles may have wide-ranging effects on the trait they influence. Some alleles have very small or mild effects, whereas others have large or even lethal effects on the individual. Some alleles are called

*mutant alleles* because their expression (alone or with another mutant) results in a mutant phenotype (trait). For example, one form of dwarfism, achondroplasia, is the result of a single dominant mutant allele of the *FGFR3* gene. On the other hand, cystic fibrosis results only when two recessive mutant alleles of the *CFTR* gene are present in an individual.

One particular type of allele that is receiving much attention is the single nucleotide polymorphism (SNP), in which there is a single nucleotide difference between the two alleles. Some of these changes can drastically alter the function of the gene, whereas some have no effect. There is a concerted effort by geneticists to catalog all of the human SNPs and figure out which of them have important phenotypic effects. Because many of these small differences affect how individuals respond to drugs, cataloging these particular differences may revolutionize the way that physicians treat patients. It is hoped that treatments can be tailored to the individual person with less risk for adverse side effects.

## ALLERGY

---

Allergies affect millions of people in the United States and include environmental allergies to pollen, animals, foods, different chemicals, and certain man-made substances. Allergic responses occur when the body reacts to normally innocuous substances in the environment as it would to toxins. The body reads the allergen as an intruder, and the immune system is activated. Responses to allergens often depend on the substance. Airborne allergens most often cause respiratory responses that can range from upper airway reactions such as sneezing and nasal congestion to lower airway reactions such as wheezing and bronchial constriction. Some allergens can cause rashes, itching, or hives, often by contact with the

affected area. Food allergens can cause gastrointestinal responses such as nausea, vomiting, abdominal cramping, or diarrhea. In some instances, allergens can enter the circulatory system, either immediately by injection of medicine, for example, or more slowly through digestion or inhalation, and anaphylaxis can occur. Anaphylaxis is rare but serious and involves several body systems, leading to death in some cases.

### ALLERGIC RESPONSE

The body's allergic response takes place in three stages: sensitization, mast cell activation, and prolonged immune activation. In the first stage, the allergen first encounters the immune system; although no reaction is produced at this stage, the body is primed for future encounters with the allergen. Immune system cells degrade the allergen and present its fragments to T cells. Antibodies are then created for that particular substance. These antibodies are then distributed to other immune cells in the body. In the second stage, the allergen encounters the body again. The body recognizes the allergen as an intruder, and chemicals are released to combat the allergy, including substances such as histamine and leukotrienes. These chemicals cause the symptoms recognized as an allergy attack. In the third stage, prolonged immune activation, mast cells continue to release the chemical substances and attract other cells to the area. The other cells become involved in fighting the allergen, and the increased production of chemicals can cause cell damage.

### AIRBORNE ALLERGENS

Airborne, environmental allergies are the most common type of allergy. These include allergic rhinitis, commonly known as *hay fever*, which is a seasonal allergic reaction caused primarily by pollen from trees and flowers in the spring, grasses in the summer, and weeds in autumn. Symptoms include sneezing, congestion, and watery or itchy eyes. Allergic rhinitis is diagnosed primarily by history of seasonal reactions. Perennial rhinitis with allergic triggers is a year-round condition caused by household allergens like dust, mold, and animals kept as pets. Symptoms and treatment are the same as for allergic rhinitis, but sometimes an allergy test is needed to determine the triggers.

Treatment for rhinitis includes over-the-counter or prescription medication such as antihistamines and decongestants. Antihistamines are generally available

over the counter and can relieve symptoms such as sneezing and watery eyes by blocking the histamines that are released by immune cells. These antihistamines tend to cause drowsiness. For this reason, antihistamines are sometimes combined with decongestants, which have stimulating side effects that counteract the drowsiness. However, decongestants can cause nervousness, restlessness, or insomnia, even while they relieve nasal congestion. Newer forms of antihistamines perform the same tasks as earlier ones, but do so without any sedating effects. These relatively new antihistamines are generally available by prescription and cost significantly more than earlier medications that are available over the counter. Recently, some new forms have become available over the counter as well. Intranasal corticosteroids may be used and cause fewer side effects than earlier antihistamines, but are less effective at treating watery and itchy eyes. Oral corticosteroids may be used on a limited basis (3 to 7 days) for more severe and treatment-resistant allergy symptoms. Allergen immunotherapy, or “allergy shots,” can be used in people who have yearly, recurrent, seasonal symptoms of long duration, or perennial symptoms. Allergy shots are not recommended for preschool-age children or the elderly because anaphylaxis can occur. Treatment is also not recommended for longer than 3 to 5 years.

When treating children for allergic rhinitis, non-pharmacological approaches, such as removing the allergen from the environment, are preferred. When this is not feasible, oral antihistamines and non-steroidal intranasal treatments are the first-line therapy. The sedating effects of some antihistamines are sometimes beneficial for children, allowing them to sleep comfortably. Many later antihistamine medications have not been approved for use with children. Intranasal corticosteroids are effective in children, but some may have a temporary stunting effect on growth, and dosages should be small and monitored routinely.

With adults, precautions should be taken when using allergy medication with the elderly and those with high blood pressure. In the elderly, allergic symptoms are sometimes attributable to drug interactions or side effects of antihypertensive medication. Newer antihistamines that do not cause sedation or performance impairment should be considered. People with high blood pressure should be careful about using antihistamines and use only those medications approved for them.

## SKIN REACTIONS

In another form of allergy, there are two kinds of contact dermatitis: irritant and allergic. Both allergic and irritant contact dermatitis can vary in presentation from mild redness, itching, and chapping of skin to severe blistering and ulceration. Only a thorough history and skin patch testing can diagnose allergic contact dermatitis. Patch tests include strips of hypoallergenic tape to which allergens have been applied to the patient’s back and are removed after 48 hours. These test sites are evaluated for any reactions. Blood samples can also be used to check for antibody levels, but are not considered as accurate as patch testing. Blood testing is sometimes used in the case of allergic responses that are too severe to risk further exposure to the allergen.

Treatment of allergic contact dermatitis includes avoidance of the allergen as well as a course of prednisone, a steroid, for severe reactions. Prednisone is usually given as a higher initial dose and then tapered off over a period of time. Lower initial doses and more rapid tapering can lead to dramatic rebound of symptoms.

## FOOD ALLERGENS

Food allergy is a reaction to something in a food or ingredient in a food, usually a protein. The eight most common food allergens—milk, eggs, peanuts, tree nuts, soy, wheat, fish, and shellfish—are thought to cause more than 90% of all allergic reactions to foods. Other foods have been found to be allergenic for individuals, but are less common. The National Institutes of Health estimated that 5% to 8% of children and 1% to 2% of adults have a true food allergy. Symptoms of food allergy vary from person to person and can also vary in the same person on different exposures. Symptoms can range from skin irritations such as rashes, hives, and eczema, to respiratory symptoms like runny nose, sneezing, and shortness of breath. In more severe cases, anaphylactic shock can occur. Symptoms of anaphylaxis usually appear rapidly and can include swelling of the throat, difficulty breathing, lowering blood pressure, and unconsciousness. Standard emergency care includes an injection of epinephrine and immediate medical attention for further evaluation.

Not all adverse reactions to foods are true food allergies; instead, they are food intolerances or food idiosyncrasies, which are generally localized and

temporary and rarely lifelong. Food intolerance is an adverse reaction to a food or additive that involves digestion or metabolism but does not involve the immune system. An example is lactose intolerance, whereby a person lacks an enzyme needed to digest milk sugar. Food idiosyncrasy is an abnormal response to a food or food substance, but also does not involve the immune system. Sulfite sensitivity is an example.

At this point, the only way to treat food allergy is to avoid the food that causes the reaction. If a reaction occurs, then a person has several options of treatment, depending on the severity. Severe food allergy requires that the allergic person carry an epinephrine injection at all times in case of accidental ingestion or exposure. For less severe reactions, antihistamines or asthma inhalers are sometimes used to treat symptoms. Initial trials of vaccines to combat against allergic responses to certain foods are being conducted.

## ALLERGIES AND ASTHMA

Although asthma and allergies do not always occur together, an estimated 70% to 75% of people with asthma have allergic triggers for their asthma. Asthma can be triggered by a host of different allergens and can trigger airway constriction, coughing, and wheezing.

## PSYCHOLOGICAL IMPACT

It is currently unclear what, if any, psychological impact having allergies has on the average person. Many people who suffer from allergies treat their symptoms as needed and go on with their lives. Some people with severe, life-threatening allergies may experience extra stress because of their allergies and may suffer from increased anxiety. The phenomenon has been most studied in children, in whom there is some evidence of an increased association between allergies and some anxiety disorders, such as panic disorder. This evidence is in line with research showing that asthma is sometimes associated with an increased risk for anxiety disorders. As with any chronic illness, someone who is experiencing stress related to their illness may be helped by treating symptoms of anxiety.

## ALTRUISM

---

Philosophers throughout the ages have debated whether humans actually intend to perform altruistic actions, actions that are beneficial to others and costly to the actor, without any clear resolution. In recent decades, psychologists have addressed the long-standing philosophical debate over the existence of altruism, usually defined as unselfish concern for the welfare of others, with empirical studies. Categorizing an action as altruistic often implies that the decision to perform the action was not influenced by consideration for the self or the possible benefits to the self that may accrue from performing the action.

## PSYCHOLOGICAL RESEARCH ON HELPING

Psychologists have studied helping behavior from a variety of perspectives. For example, Latane and Darley have developed a five-step cognitive model of bystander intervention. These steps consist of: (a) noticing the event, (b) interpreting the event as requiring help, (c) assuming personal responsibility, (d) choosing a way to help, and (e) implementing the decision. This model has been shown to be applicable to both emergencies and nonemergency situations. Behaviorists have demonstrated that helping behaviors can be increased by direct reinforcement and modeling, and social psychologists have shown that helping is more likely to occur when the rewards of helping outweigh the costs. Psychologists have also uncovered characteristics of the target that increase the chances of helping, such as attraction based on attractive physical appearance, friendly behavior or personal qualities, and similar racial characteristics.

## RECENT PSYCHOLOGICAL RESEARCH ON ALTRUISM

Batson and colleagues' empathy-altruism hypothesis proposes that a truly altruistic motivation can be evoked by empathic concern toward another person for whom the benefit is directed. Actions based solely on the motivation to benefit another are proposed to result from a series of cognitive events. In the enabling stage, the observer takes the perspective of the needy target, which may be stimulated by perceived similarity between oneself and the other, by instructions to take the other's perspective, or by an attachment such as kinship, friendship, or prior contact. This leads to an emotional response of empathic concern, including feelings of sympathy, warmth, tenderness, and compassion, resulting in a desire to improve the other's welfare, rather than one's own welfare.

Although altruist advocates admit that human motivation is frequently for self-benefit, they see the need for a pluralistic explanation of helping behaviors that includes both altruism and egoism. Studies supporting the empathy-altruism hypothesis have systematically varied on whether individuals can only obtain egoistic goals by helping, or whether they can escape from the situation and obtain the egoistic goals without helping. These studies purportedly demonstrate that at least some people have helping intentions that are not explained by egoistic motivations, such as the relief of personal distress (as proposed by Aquinas and Hobbes), escaping public shame for not helping, the relief of sadness, and the desire to make oneself happy.

Other researchers assume psychological egoism, the thesis that people always try to act in ways that benefit themselves. Cialdini and associates have proposed that it is the sense of self-other overlap, or "oneness," between the helper and the individual in need that motivates helping, rather than empathy. Helping others with whom one feels commonality would not be selfless because it leads to a more favorable mental state. Egoist advocates suggest that empathic concern is an emotional signal of oneness and that empathy per se at best leads to superficial helping.

Studies examining whether the effect of empathic concern can be eliminated when the sense of oneness with the target, or self-other overlap, is accounted for have produced contradictory results. One philosophical objection to the egoist argument is that seeing the other as part of the self is in itself altruistic. The

perceived overlap implies that the self and other share a common fate, so that resources and other assistance may be shared to maximize outcomes for more than just the individual.

## UNDERSTANDING ALTRUISM IN AN EVOLUTIONARY FRAMEWORK

Integrating concepts from evolutionary theory enhances the psychological framework for understanding altruistic helping intentions. An evolutionary approach promotes the understanding of affect, cognition, motivation, and behavior as expressions of functional, adaptive processes that evolved through natural and sexual selection to solve problems in our ancestral environments. The altruism debate may be clarified by disentangling proximate motivations and ultimate selection pressures. An evolutionary framework acknowledges the possibility of both altruistic and egoistic motivations from the perspective of the individual. From an evolutionary perspective, subjective experiences underlying an adaptation can vary, as long as they reliably lead to adaptive behaviors. The underlying motive or subjective experience of the individual is less important than the consequences of their actions. This allows for the possibility of behaviors that are altruistic in terms of costs and benefits to the donor, although egoistic in terms of the benefit to the genes shared by the individuals.

William Hamilton's inclusive fitness theory explained that by assisting in a time of need, one could help his or her relative become an ancestor of offspring with similar genes. Kin selection, a genetically influenced tendency to differentially help relatives, is likely to spread across a population when the cost in reproductive fitness to the donor is less than the product of the fitness benefit to the recipient and the proportion of genes that the donor and recipient share. Nepotistic acts encouraged by kin selection include the altruism advocates' example of a mother rushing to help her injured child.

Consistent with evolutionary theory, the experience of oneness or empathy could arise as a consequence of attachment-related cues (kinship, friendship, familiarity) that signaled the potential for relatively high genetic commonality in our ancestral environment. The psychological states provoked by these cues could increase the chances of the needy individuals receiving assistance, enhancing the survival and replication

of genes influencing the psychological capacities for oneness and empathy. A number of studies have found support for predictions derived from kin selection in psychological mechanisms influencing helping, behavioral intentions to help, and actual helping behaviors.

Kin selection is not the only recognized evolutionary pathway for altruistic actions. Trivers' theory of reciprocal altruism predicts that altruistic behaviors will also be a function of beliefs about the recipient's likelihood of reciprocating. The exchange of resources and support in times of need is adaptive owing to benefits conferred to the viability of the group as a whole. Solitary altruistic actions will occur because the donors may some day find themselves in need and could expect to benefit from help. As long as this occurs, altruistic actions benefiting nonrelatives will occur. The social environment in the ancestral environment encouraged the development of reciprocal altruism because the relative social isolation increased the chances that other altruists would benefit from others' altruistic behavior. One recent study found that cognitive mechanisms facilitating reciprocal altruism accounted for the greatest portion of the variance helping intentions, more than all other effects combined.

The mental events facilitating reciprocity are usually depicted as cognitive mechanisms evaluating the likelihood that the target would provide help if conditions in the situation were reversed. In recent years, this cognitive perspective has been supplemented by the recognition of emotional pathways that are consistent with the adaptive framework of evolutionary psychology. Emotional bonding with others promotes commitment to helpful actions that are performed for the benefit of the other individual, rather than for an expected favor in return. Over time, individuals may benefit from having maintained these relationships, rather than severing ties if helping actions are not immediately reciprocated. Those individuals who eventually find themselves in need will gain from the more elastic form of reciprocal altruism facilitated by emotional commitments. Of course, repeated violations of the norm of reciprocity may attenuate emotional commitment with another.

Altruistic actions performed for "the good of the species" are usually rejected because natural selection operates more effectively within breeding populations than between them. Since the 1960s, arguments for group-selecting altruistic arguments have been discounted by most evolutionary biologists. Assuming that the tendency to sacrifice oneself for the sake of

one's group varies among individuals within groups, those with more selfish tendencies will survive better than their more altruistic neighbors. This would lead the group to eventually become more selfish in nature. In recent years, more sophisticated arguments for group selection have revived this debate. However, the newer group selection models mirror those of individual level selection; therefore, they can be mathematically transformed into each other. It is also possible that genuine group-selecting altruistic actions have been generated from cultural influences and that groups benefiting from these actions are more successful than other groups, although this has not resulted in novel genetic adaptations for helping behaviors.

## CONCLUSION

In conclusion, actions that are altruistic from the perspective of the proximate mental motivation of individuals are consistent with evolutionary adaptation. Proximally altruistic mechanisms may operate within a genetically selfish system. Actions that are genetically altruistic, those that reduce one's inclusive genetic fitness, will be extremely rare. Studies have indicated that psychologically altruistic and egoistic pathways for helping behaviors may operate simultaneously.

## ALZHEIMER'S DISEASE

---

Alzheimer's disease (AD) is a progressive, neurodegenerative disease that accounts for 50% to 75% of all dementias affecting older adults. AD affects 5% to 10% of all adults older than 65 years, and this proportion doubles every 5 years over 65; consequently, it is a major health concern in the United States. About 4.5 million people had the disease in 2004, and this number will rise to about 11 million by 2025. Considering that most individuals with AD spend at least some time in a full-care facility, health care costs associated with the disease are high. Costs associated with AD in 2004 approached \$1 billion per year, and these will continue to increase as the population ages. The high incidence of institutionalization stems from the cognitive effects of the disease. People with AD gradually become unable to accomplish everyday tasks like driving and cooking; their abilities to communicate and manage their own grooming and self-care deteriorate, and eventually control of bodily functions and motor abilities is lost. However, the most devastating effect, particularly for family members, is the gradual deterioration of personality: Affected individuals lose interest in hobbies and outside events, fail to recognize family members, and eventually cease to interact with the world around. Thus, the disease is devastating on both societal-economic and personal-familial levels. Intense research continues to investigate etiological factors, cognitive sequelae, and treatments for this debilitating illness.

### BIOLOGICAL AND GENETIC CHARACTERISTICS

The characteristic histological markers of AD are intercellular neuritic plaques and intracellular

neurofibrillary tangles. Plaques occur in the spaces between neurons and comprise a beta-amyloid ( $\beta$ -amyloid) protein core surrounded by a cluster of dead and dying neurons. Neurofibrillary tangles consist of the tau protein fibers that normally organize and give shape to a cell but that have become deformed, possibly as a result of interaction with  $\beta$ -amyloid. The tau protein aggregates into intracellular tangles that block the normal flow of nutrients and information within the neuron. Consequently, the number of synapses the cell can maintain with other cells diminishes, and eventually the cell dies.

Amyloid proteins transport cholesterol throughout the body and brain so that it can be used for cellular repair.  $\beta$ -Amyloid is one of three common variants of the amyloid protein, and unlike other variants, none of the enzymes normally produced by the body can break it down. Moreover, the  $\beta$ -amyloid protein is particularly sticky and has been associated with the deposition of fatty cholesterol deposits in blood vessels as well as with neuritic plaques in AD. Consequently, the individual who has this version of the amyloid protein is at risk for cardiovascular disease in addition to AD.  $\beta$ -Amyloid protein is encoded by a particular gene on chromosome 19, known as the *apolipoprotein  $\epsilon 4$*  (*ApoE4*) gene. This gene variant cuts the amyloid precursor protein in a different place than normal, yielding the insoluble  $\beta$ -amyloid. Like all genes, individuals have two copies of the *ApoE* gene. People carrying one copy of *ApoE4* (about 25% of the population) have a higher risk for AD than individuals with other variants of the *ApoE* gene; individuals who carry two copies of the *ApoE4* gene (about 2% of the population) have a much higher risk for developing AD at a younger age than those with only one copy of the gene. In fact, the *ApoE4* gene variant accounts for about 50% of all cases of *late-onset AD*, that is, AD diagnosed after age 60. Furthermore, compared with noncarriers, carriers of the *ApoE4* gene show metabolic differences in their brain in the same areas that are affected by AD as early as age 30; however, cognitive differences are minimal or absent between noncarriers and carriers of the *ApoE4* gene from age 30 to 55. *Early-onset AD* refers to the 1% of AD cases that are diagnosed in people in their 40s and 50s, caused by mutations to genes other than *ApoE*. In addition to genetics, other risk factors for AD include increasing age, family history of AD, previous head trauma or stroke, and lower education and verbal ability.

AD preferentially targets brain centers that control higher cognitive abilities. The hippocampal region in

the medial temporal lobe is affected first, hampering the ability to encode new memories, followed by the posterior cingulate, which is instrumental in making and evaluating decisions. Subsequently, the multimodal association cortices in the temporal and parietal lobes show signs of the disease, leading to difficulties with language use and spatial-temporal orientation. Later, the prefrontal cortex shows signs of the disease, which is reflected in attentional and behavioral deficits, as discussed subsequently.

## DIAGNOSIS

Physicians suspect AD might be present when individuals show a decline in memory ability and at least one other cognitive domain (e.g., language, orientation in time and space, or executive functions) that affects their daily occupational and social activities. Furthermore, this decline must have a gradual onset and must continue over time. To make a clinical diagnosis of AD, the doctor must exclude a number of other possible causes for this decline. Physicians use in-depth interviews, blood tests, and brain imaging (usually computed tomography scans or magnetic resonance imaging) to rule out depression, drug interactions, endocrine disorders, nutritional deficiencies, head trauma, brain tumor, and stroke as causes of decline before making a diagnosis of probable AD. It is still not possible to make a positive diagnosis of AD until autopsy; however, imaging techniques that highlight amyloid deposition in the brain have been developed recently that may allow in vivo diagnosis of AD in the near future.

## COGNITIVE CHARACTERISTICS

AD has profound effects on cognition, speech, and overall behavior that vary individually, depending on the sequence in which different parts of the brain are affected. By the time individuals are diagnosed with AD, usually at the very mild or mild stage of the disease, damage to hippocampus and posterior cingulate is typically already relatively severe, leading to deficits in learning new information, short-term memory, autobiographical memory, and judgment. Consequently, people with AD often repeat questions and stories and make poor decisions because they cannot assimilate new information. Additionally, these individuals often have word-finding problems and difficulty expressing themselves, and their attentional

and spatial impairments make driving hazardous. Even at this mild stage of the disease, individuals have severe difficulty with organizing, planning, problem solving, and abstract reasoning. Typically, individuals are aware of their deficits and are often depressed and irritable. As the disease progresses, this awareness diminishes while memory and language problems increase.

At the moderate stage of the disease, typical, daily activities become increasingly difficult: the individual cannot prepare meals, use tools, or even take telephone messages. Although automatized tasks like self-grooming may be preserved, concerns about personal hygiene and appearance often suffer. Speech becomes vague and usually includes an overabundance of pronouns replacing more specific nouns, whereas the ability to comprehend complex sentences and discourse deteriorates. At this stage of the disease, many people with AD feel a profound restlessness and may begin to wander away from home. Because they become easily lost and often cannot remember their address or phone number, wandering can be a serious problem. Sleep difficulties, hallucinations, and personality changes are also common at this stage of the disease.

At the severe stage of AD, individuals slowly lose interest in their surroundings. Their ability to communicate relevantly declines and eventually disappears, as they lapse into mutism. They can no longer groom themselves and become incontinent. Additionally, they may not recognize common items, including food, and may have difficulty swallowing, which can lead to resistance to eating and drinking and subsequent malnutrition. They become agitated over changes in routine, and the loss of personality is profound. Eventually, they become bedridden and unresponsive; death, however, is usually due to infection or other complications.

## TREATMENT

Current treatments for AD are based on the fact that AD affects the brain's ability to produce many of the neurotransmitters crucial for memory and cognition. The primary drugs used in early AD, tacrine and donepezil, are acetylcholinesterase inhibitors, which prevent the breakdown of acetylcholine, a neurotransmitter necessary for memory function. In about 50% of individuals with early AD, these drugs minimize or slow the deterioration of cognitive abilities and help control behavioral problems, such as depression,

agitation, and insomnia. Research to develop a vaccine that would prevent the accumulation of  $\beta$ -amyloid in the brain is in progress, but to date has been unsuccessful.

Maintaining communication with the individual with AD can help mitigate the burden the disease places on caregivers. Certain strategies can facilitate this communication, such as minimizing environmental distractions, limiting the use of pronouns and complex grammar, maintaining eye contact, and repeating or paraphrasing important information. Caregivers should also be encouraged to take advantage of home health care and adult day care services where available, as well as support groups, because the constant demands of caregiving can be debilitating both physically and emotionally.

In summary, AD is a devastating disease with enormous human and economic costs that will continue to increase as the population ages. However, research continues to identify ways to treat the disease and to improve quality of life for individuals with the disease and their caregivers.

## AMERICAN ACADEMY OF PEDIATRICS

---

The American Academy of Pediatrics (AAP) was founded in 1930 at Harper Hospital in Detroit. A group of 34 physicians who specialized in children's health convened in the hospital's library to set forth the future of America's children, acknowledging the differences between adult and child health care. They settled on the name *American Academy of Pediatrics* because it best represented the commitment to all children and the pediatric specialty.

Today, the AAP is a not-for-profit, 501(c)(3) Illinois corporation organized for scientific and educational purposes, with a strong presence in the United States and overseas. The organization has a membership of 60,000 pediatricians; pediatric medical subspecialists, including neonatologists, allergists, and cardiologists; and pediatric surgical specialists. The AAP employs more than 350 people, who work at AAP headquarters in Elk Grove Village, Illinois, and in Washington, DC, where legislative and federal activities are managed.

### MISSION AND ORGANIZATIONAL STRUCTURE

The mission of the American Academy of Pediatrics is to attain optimal physical, mental, and social health and well-being for all infants, children, adolescents, and young adults. The AAP's mission is carried out in a number of ways. The organization is governed by a 13-member board of directors who maintains the integrity of the AAP mission by following a set of organizational bylaws. The board comprises an executive committee and directors. These pediatric health practitioners are elected by AAP members and serve as chairs representing 10 geographic districts.

Internally, staff in the Office of the Executive Director handles Board Administration, Development/Fundraising, Communications, International and Interprofessional Affairs, Human Resources, and the Customer Service Center. Other staffed areas within the AAP include separate departments according to specialty. These areas are the Departments of Chapter and State Affairs; Community and Specialty Pediatrics; Practice; Research; Education; Finance and Administrative Services; Information Technology; Marketing and Publications; Membership; and Federal Affairs (based in Washington, DC).

Another important facet of the AAP is a grassroots network of 59 chapters in the United States and 7 in Canada. Each state and local chapter is individually incorporated, has its own bylaws, and is managed by local pediatricians. Most have a staff executive director. Chapter leaders strive to fulfill the AAP mission on the state and local level and work to implement other local priorities on behalf of children and adolescents.

### EDUCATION AND ADVOCACY

The AAP receives funding from a variety of sources, including membership dues, individual contributions, and unrestricted educational grants from foundations,

corporations, and government entities. These valuable resources help support more than 200 AAP-sponsored programs every year.

Programs cover a broad range of issues, such as neonatal resuscitation, obesity, childhood immunization, breast-feeding, car-seat safety, media literacy, prevention, and health promotion. Patient and family brochures on these and other topics are available to the public and health professionals, and a series of child care books written by AAP members is featured in the AAP bookstore.

The AAP sponsors ongoing continuing medical education (CME) courses and is considered the premier source of CME for pediatricians. These courses help advance the professional education of AAP members and are held in hospitals, universities, and other settings around the United States as well as through Internet-based learning environments.

More than 30 AAP national committees, covering issues ranging from adoption and infectious diseases to violence and poison prevention, are responsible for creating the organization's policy statements. These statements appear in *Pediatrics*, the AAP's monthly scientific journal and are used as recommendations in pediatric care.

Additionally, the AAP has more than 50 sections consisting of more than 30,000 members with interests in specialized areas of pediatrics, such as surgery, ophthalmology, breast-feeding, critical care, endocrinology, and pediatric dentistry. Section members present current research and practical knowledge in their respective subspecialties during various scientific meetings throughout the year, including the AAP's National Conference and Exhibition (NCE).

Federal advocacy initiatives have been handled by staff at the AAP's Department of Federal Affairs, based in Washington, DC, for more than 30 years. Pediatricians active in child advocacy collaborate with lawmakers to help ensure that the health needs and concerns of all children are covered as legislation and public policy are developed. An annual legislative conference in Washington, DC, brings together pediatricians, lawmakers, and other concerned individuals to address current issues and public policy.

On the state level, AAP staff provides technical assistance to chapters on a variety of issues, including Medicaid, child safety, and immunizations. Chapter leaders maintain relationships with local and state lawmakers, working with them on advocacy, policy, and other legislative initiatives.

## ACADEMY SUCCESSES AND MILESTONES

During the past 75 years, the AAP has earned a proud place in the advancement of child and adolescent health, serving as pioneers in a variety of areas. Among the most notable are the following:

- The AAP Task Force on Infant Sleep Position focused on sudden infant death syndrome (SIDS.) The task force developed a landmark 1992 AAP policy statement that urged parents and guardians to put infants to sleep on their backs to prevent SIDS. As a result of this effort, dubbed "The Back to Sleep Campaign," more than 10,000 infants are alive today.

- The Academy's immunization initiatives have increased immunization rates among children and adolescents and lowered the incidence of infectious childhood diseases such as polio, measles, chicken pox, and pneumonia. This was accomplished through an organized grassroots effort facilitated by local pediatricians and the AAP chapter network.

- More than 1 million pediatricians and other health care professionals in the United States and overseas have been trained in the AAP's Neonatal Resuscitation Program (NRP.) The NRP, launched in 1987, has become the standard of care for treatment of newborns at birth. Additionally, NRP materials have been translated into 22 languages and introduced in 71 countries.

—Deborah M. Bullwinkel

## AMERICAN ASSOCIATION OF RETIRED PERSONS (AARP)

---

### BEGINNINGS OF AARP

The American Association of Retired Persons (AARP) is a nonprofit, nonpartisan membership

organization for people age 50 years and older with more than 35 million members. According to its literature, AARP is dedicated to “enhancing quality of life for all as we age,” and the organization also provides a range of benefits and services. Despite its name, anyone older than 50 may join, retired or not. Its mission is to inform members and the public of issues important to Americans older than age 50; advocate on legislative, consumer, and legal issues; promote community service; and offer specialized products and services to members.

AARP was founded in 1958 by Dr. Ethel Percy Andrus, a retired high school principal, and was modeled after the organization also found by Andrus in 1947, the National Retired Teachers Association (NRTA). Part of the impetus to create the NRTA was to assist older Americans in their efforts to obtain health insurance, usually unavailable at that time. Once Andrus realized how significant this need was, the AARP was formed and opened to all older people, not just teachers.

## AARP MISSION

AARP focuses a significant part of its resources on education and in doing so publishes the bimonthly *AARP Magazine*, which covers a broad range of topics related to aging such as health, finance, and leisure. Members of AARP also receive the *AARP Bulletin*, published 11 times a year, which includes information regarding relevant federal and state legislation. In addition, *Segunda Juventud*, a quarterly Spanish-English newspaper, is published as well. In addition to offering these publications, AARP uses its Public Policy Institute to conduct and publish research on aging issues.

## AARP PROGRAMS

AARP offers several types of programs to meet the needs of its members and to address some of the at-large policy issues that aging Americans face.

The AARP Independent Living/Long-Term Care/End-of-Life Issues program addresses issues of prevention and examines options in services and financing. The physical activity initiative is targeted at increasing the number of people who make physical activity a regular part of their lives. Finally, the predatory lending campaign is aimed at reducing the incidence of fraud against older homeowners.

With older Americans finding it increasingly challenging to drive safely as they age, the AARP driver safety program is an 8-hour classroom refresher course designed for drivers age 50 and older. It covers rules of the road, defensive driving tips, and normal physical changes that accompany aging and ways to compensate for them.

The AARP grief and loss programs offers resources and information to AARP members and their families who have experienced the loss of a loved one. The program develops and offers bereavement outreach services, support groups, and educational programs for bereaved individuals.

AARP Tax-Aide, administered through the AARP Foundation, is a free tax counseling and preparation service for all taxpayers with middle and low incomes, with special attention to those age 60 and older. Trained and certified volunteers serve almost 2 million taxpayers.

Finally, AARP Senior Community Service Employment Program (SCSEP) is a work-training program for low-income people age 55 and older.

## AMERICAN PSYCHOLOGICAL ASSOCIATION

---

The American Psychological Association (APA) formed over a century ago to promote the exploration of psychology through research and clinical practice. This impressive association is the largest and most influential psychological organization today.

## HISTORY AND MISSION

The APA was formed in 1892 at Clark University in Worcester, Massachusetts. Originally comprised of 26 members, its current membership has expanded to more than 150,000. The APA continues to use its size and power to aid psychological practice and research.

An excerpt of the APA's mission, found in its bylaws, is as follows:

The objects of the American Psychological Association shall be to advance psychology as a science and profession and as a means of promoting health, education, and human welfare by: the encouragement of psychology in all its branches . . . the promotion of research in psychology. . . the improvement of the qualifications and usefulness of psychologists . . . the increase and diffusion of psychological knowledge . . . the promotion of health, education, and the public welfare.

## STRUCTURE AND LEADERSHIP

The APA's bylaws supersede all other internal rules of the APA and can only be changed by vote of the entire membership. These bylaws establish the leadership structure of the APA, which includes a council of representatives, a board of directors including the APA officers, and a central office. The APA's council of representatives, selected from the divisions and state and provincial psychological associations (SPPAs), votes in six board members and has control over its budget. The board of directors heads the organization in all business aspects and is comprised of these six members appointed by the council of representatives and six APA officers elected by the APA membership. These officers include the APA president, past president, president elect, treasurer, secretary, and chief executive officer.

The APA generates more than \$71 million through membership dues, investments, publications, and real estate. There are 53 professional divisions in the APA, which reflect specialties and interest areas (such as the Society for the Teaching of Psychology, Society of Clinical Psychology, Society for Industrial and Organizational Psychology, and American Psychology-Law Society, among others.)

The APA promotes education in psychology, research and scientific affairs in psychology, the clinical practice of psychology, and the dissemination of psychological information. Serving as the accrediting board for advanced degree programs in psychology, the APA currently accredits more than 355 doctoral psychology programs, 469 doctoral internships, and 15 postdoctoral residency programs. The APA also approves organizations to be continuing education providers to maintain and advance the skills and competency of its licensed practitioners.

In the area of research and scientific affairs, the APA provides advanced training institutes (ATIs), which instruct psychologists on up-to-date methods and techniques in research. The APA also promotes research by annually funding graduate students through dissertation research awards. The APA's science policy staff endeavors to ensure that psychological research and knowledge are used in legislative policy decision making, and its Amicus Briefs on relevant, psychological issues also promote the use of relevant psychological knowledge within the legal system. The APA also strives to more generally disseminate psychological knowledge through its journals, books, and electronic databases such as PsychINFO, PsychARTICLES, and the APA Web site. The 49 APA journals are the premiere journals in psychology, publishing no less than 1,798 empirical and conceptual articles in 2002.

The APA supports its clinical practitioners and the consumers of psychological services, for example, by providing strong legislative advocacy for managed care reform in the mental health area. The APA's *Ethical Principles of Psychologists and Code of Conduct* guides practitioners, teachers, and researchers of psychology to ensure the integrity of the profession and welfare of its clients.

## SUMMARY

The APA is a large, influential organization that focuses on psychology, its development, its impact, and clinical practice through its varying publications and 53 divisions.

---

## AMERICAN PSYCHOLOGICAL SOCIETY

---

The American Psychological Society (APS) is the leading national organization devoted solely to scientific psychology. Its mission is to promote, protect, and advance the interests of scientifically oriented psychology in research, application, and improvement of human welfare.

Established in 1988, the APS was instantly embraced by psychology's scientific community, and its membership grew rapidly. By the end of its first year, APS opened an office in Washington, DC, and now has about 15,000 members from around the world. Members are engaged in scientific research or the application of scientifically grounded research spanning all areas of psychology. There are also student affiliates and institutional members. Distinguished contributions are recognized by fellow status.

### FORMATION

The APS was created out of recognition that (a) the needs and interests of scientific and academic psychologists were distinct from those of members of the professional community primarily engaged in clinical practice and (b) there was a strong need for a society that would advance the interests of the discipline in ways that more specialized organizations were not intended to do. An interim group, the Assembly for Scientific and Applied Psychology (ASAP), had sought to reform the American Psychological Association from within, but their efforts were rejected by an APA membership-wide vote. The APS then became the official embodiment of the ASAP reform effort, and the new organization was launched on August 12, 1988.

### PUBLICATIONS

The APS publishes three journals: (a) *Psychological Science* publishes authoritative articles of interest across all of scientific psychology's subdisciplines; (b) *Current Directions in Psychological Science* offers concise, invited reviews spanning all of scientific psychology and its applications; and (c) *Psychological Science in the Public Interest* provides definitive assessments by panels of distinguished researchers on topics on which psychological science has the potential to inform and improve the well-being of society. The APS also publishes the monthly *Observer*, featuring news and opinion pieces; a *Current Directions Readers* series in conjunction with Prentice Hall; a *Festschrift* series in conjunction with LEA Press; and self-published books on the teaching of psychology.

### ANNUAL CONVENTION

The APS holds a meeting in late spring each year to showcase the best of scientific psychology. The program features presentations by the field's most distinguished researchers and educators in a variety of formats, including invited addresses and symposia, submitted symposia, "hot topic" talks, and posters. The convention also includes workshops on specialized topics.

### APS FUND FOR THE TEACHING AND PUBLIC UNDERSTANDING OF PSYCHOLOGICAL SCIENCE

In 2004, the David and Carol Myers Foundation pledged \$1 million to the APS for the creation of an endowed fund that aims "to enhance the teaching and public understanding of psychological science for students and the lay public, in the United States, Canada, and worldwide."

### ACHIEVEMENT AWARDS

The APS recognizes exceptional contributions to scientific psychology with two annual awards: (a) the APS William James Fellow Award for significant intellectual contributions to the basic science of psychology and (b) the James McKeen Cattell Fellow Award for outstanding contributions to the area of applied psychological research.

## APS STUDENT CAUCUS

Students are an important and active component of APS. The APS Student Caucus (APSSC) is the representative body of the society's student affiliates. The APSSC organizes research competitions, convention programs, and a variety of membership activities aimed at professional development and enhanced education in psychological science.

## ADVOCACY

The APS is widely recognized as an active and effective leader in advancing the interests of basic and applied psychological, behavioral, and social science research in the legislative arena and in the federal agencies that support these areas of research.

—Robert. W. Levenson and Sarah Brookhart

## AMERICAN SIGN LANGUAGE (ASL)

---

American Sign Language (ASL) is the principal language of the signing community in the United States. There are estimated to be as many as 500,000 ASL signers, making it one of the most frequently used languages in North America. ASL, however, is only one of many sign languages used by deaf people around the world; deaf people in most countries have their own distinct sign language.

ASL has not always enjoyed such widespread popularity. Educational opportunities for deaf children were practically nonexistent in postcolonial America, and Thomas Hopkins Gallaudet (1787–1851) sought to remedy this situation. Nearly 200 years ago, Gallaudet set out to learn how Europeans taught deaf children. He was impressed by a school for deaf students in Paris, an institution that included instruction in sign in its educational program. Gallaudet persuaded a deaf teacher at this Paris school, Laurent Clerc, to return with him to America. In 1817, Gallaudet and Clerc helped found the first U.S. public school for deaf students. Clerc relied on his fluency in French Sign Language for both teaching and program development—which probably accounts for the

considerable similarity between American and French Sign Language signs. (According to recent linguistic analyses, 60% of ASL signs are clearly related to corresponding signs in the French system.) Signs from some of the indigenous sign communication systems that were present in America also contributed to the emerging ASL lexicon. And, inasmuch as ASL is a living language, it continues to add new vocabulary items.

Until recently, linguists did not consider ASL a *true* language. Largely because of the pioneering research of William Stokoe (1919–2000), there has been a dramatic turnaround. Stokoe demonstrated that ASL signs have a distinct linguistic structure. More specifically, he identified three formational aspects that differentiated one ASL sign from another: *handshape* (the configuration and orientation of one or both hands); *location* (where on or near the body the sign is made); and *movement* (changes in hand and arm position needed to form the sign). He also observed that the various sign handshapes, locations, and movements functioned in a manner similar to that of phonemes in spoken languages. Today, most language experts recognize ASL to be a genuine language with a rich vocabulary and a rule-governed grammar.

Unlike many spoken languages that rely on word inflection, intonation, and order to generate variations in meaning, ASL uses changes in sign size, speed, repetition, and spatial location to help convey meaning. With some ASL verbs, for example, the direction of a sign's movement determines who does what to whom and where the action takes place. Signers also take advantage of eye movements, facial expressions, and body postures to transmit meaning. By making optimal use of both gestural and visual modes, ASL signers can communicate complex ideas quickly and with the same precision as those who speak.

ASL also differs from spoken languages in how it is transmitted. For those deaf children with deaf parents, ASL is acquired from their parents in much the same way hearing children learn to speak—through spontaneous communication at home. For the more than 90% of deaf children who have hearing parents, however, language acquisition often takes a different form. Historically, these deaf youngsters typically learned to sign and to refine their sign skills through interaction with ASL-using peers while at residential schools for deaf students. But this process appears to be changing: fewer deaf children today are attending residential schools, and more hearing parents and teachers are learning to sign. Finally, regardless of how it is acquired, it should be evident

that in learning ASL, children are mastering a rich language capable of conveying a wide variety of meanings quickly and accurately.

—John D. Bonvillian

## AMERICANS WITH DISABILITIES ACT

---

The Americans with Disabilities Act (ADA) was enacted in 1990 and became effective in 1992. Expanding the protection afforded by the Vocational Rehabilitation Act of 1973, the ADA represents the most inclusive and far reaching of the nondiscrimination laws since the landmark Civil Rights Act of 1964. The ADA protects otherwise qualified individuals from discrimination based on their disability and guarantees equal treatment in employment, public services, public accommodations, and telecommunications (Titles I, II, III, and IV respectively), as well as covering miscellaneous issues (Title V) (ADA of 1990, Pub. L. 101–336, 1990).

ADA defines a person with a disability as an individual with (a) a physical or mental impairment that (b) substantially limits one or more major life activities (e.g., seeing, hearing, speaking, walking, breathing, performing manual tasks, learning, caring for oneself, or working), or (c) has a record of such an impairment (e.g., a person recovered from cancer or mental illness), or (d) is regarded as having such an impairment (e.g., severe physical disfigurement) (ADA of 1990, Pub. L. 101–336, Sec. 12102 [2], 1990). Individuals with minor or short-duration conditions are not covered (e.g., broken leg).

### EMPLOYMENT

Title I prohibits discrimination against a qualified applicant or employee because of his or her disability in any employment practice or related activity, including

recruitment, job application procedures, selection, termination (layoff or firing), promotions, compensation, leaves, training, and other terms, conditions, and privileges of employment. All private employers, state and local governments, employment agencies, and labor unions with 15 or more employees are covered. The ADA does not impose any affirmative action obligations, and employers have the right to hire any qualified candidates.

A key concept in the ADA is that of “otherwise qualified.” Otherwise qualified individuals possess the knowledge, skills, abilities, and other characteristics or requirements (e.g., legitimate experience or education) and can perform the essential functions of the job successfully *with or without* a reasonable accommodation. Job modifications (e.g., exchanging job tasks with co-workers, flexible work hours omitting nonessential tasks), environmental changes (e.g., ramps, larger stalls and grab bars in restrooms, automatic door openers, improved lighting), or auxiliary aids (e.g., speakerphones or headsets, adjustable workstations, wrist or arm supports, magnification aids for reading) that allow a qualified applicant or employee with a disability to perform the essential functions of the job and do not create *undue hardship* for the employer are considered *reasonable accommodations*. Reasonable accommodations may involve modifying workplaces, equipment, or jobs; modifying work schedules; providing qualified readers or interpreters; or appropriately modifying examinations, training, or other programs. These accommodations should be evaluated and made on a case-by-case basis. Employers are not expected or required by law to lower employment standards, provide personal-use items (e.g., glasses or hearing aids), or identify individuals to receive accommodations. People with disabilities must self-identify, provide evidence of their disability, request needed accommodations, and flexibly interact with the employer. Undue hardship is also determined on a case-by-case basis and occurs when the requested accommodation involves excessive financial cost or effort that exceeds employer resources.

People with disabilities who feel that they have been discriminated against can seek legal remedies. Like Title VII of the Civil Rights Act, some cases will involve adverse impact or disparate treatment. Additional ADA cases concern the employer's refusal or failure to accommodate. Litigation will determine whether the individual's disability interferes with work efficiency or poses a risk or hazard to others

(e.g., person's disability is an infectious disease) or if an accommodation creates undue hardship for the organization.

## PUBLIC SERVICES

Title II protects qualified individuals from discrimination on the basis of disability in services, programs, benefits, or activities of a public entity (e.g., a state, an agency, political subdivision, any commuter authority). Each service, program, or activity must be operated such that it is readily accessible to and usable by individuals with disabilities unless it would result in a fundamental alteration in the nature of a service, program, or activity or an undue financial and administrative burden. Title II also requires the accessibility of new construction and covers the modification of existing buildings when other methods are not effective in achieving accessibility. Public transportation (e.g., buses, subways, trains) is also covered and must be accessible. Exceptions for providing services in situations where safety and health are jeopardized are also included when they are based on objective criteria and not the result of stereotypes or generalizations.

## PUBLIC ACCOMMODATIONS

Title III covers private organizations that provide goods, services, and programs. These organizations, including restaurants, hotels, banks, theaters, doctors' offices, pharmacies, retailers, museums, libraries, parks, schools, and day care centers, cannot deny access on the basis of a person's disability and must make facilities accessible. Title III requires all new construction of places of public accommodation be accessible and requires reasonable modifications to existing facilities.

## TELECOMMUNICATIONS

Title IV makes available telecommunications (telephone and television) devices and services for hearing- and speech-impaired users. It requires local and long distance telephone carriers to establish relay services for callers with hearing and speech disabilities who use telecommunications devices (e.g., telecommunications devices for the deaf [TDDs] or teletypewriters [TTYs]) or third-party communications assistants. It ensures confidentiality of these transmissions and sets standards for service. Title IV also

requires closed captioning of federally funded public service announcements.

## MISCELLANEOUS

Title V deals with a wide range of issues, including retaliation, insurance coverage, construction, state immunity, attorney fees, illegal drug use, exclusions from the definition of disability, and instructions to federal agencies (Equal Employment Opportunity Commission [EEOC] and Department of Justice [DOJ]) for enforcement of the statute. The key protection in this provision is the prohibition of (a) coercing or threatening, or (b) retaliating against the disabled or those attempting to aid a disabled person who files a charge or opposes a discriminatory practice under the ADA.

## IMPACT

General acceptance of the law and its mandates is reported in all areas. The old adage "the more things change, the more they remain the same" applies to the effectiveness of this act. Although advancements in accessibility to employment, commerce, technology, telecommunications services, housing, and public services, facilities, and programs have been achieved, the vision of full participation has not materialized, and substantial obstacles remain. The EEOC and DOJ, through enforcement efforts, have obtained substantial monetary settlements and nonmonetary benefits (e.g., reasonable accommodation, policy changes, training and education, job referrals, union membership) for individual workers. The National Council on Disability (NCD) details steady improvement in the efficiency and procedural consistency of enforcement activities. However, large differences between disabled and nondisabled populations are reported in employment, graduation rates, income, home ownership, use of computers, access to transportation and Internet, health care, participation in a range of activities including entertainment, socializing, attendance at religious services, and political participation. Clearly, significant advances need to be made to improve the quality of life for more than 54 million Americans living with a disability.

## AMES, LOUISE (1908–1996)

---

Noted child psychologist Louise Bates Ames, PhD, was instrumental in the field of child and human development. Both her undergraduate (1930) and master's (1933) degrees in psychology were received from the University of Maine. Her doctoral degree in experimental psychology was granted by Yale University in 1936. Working with Arnold Gesell, in her doctoral dissertation, Ames examined the development of creeping and crawling in infants, otherwise known as the development of “prone progression.” This, along with her collaboration with Gesell, soon developed into the theme that followed her life's work—the appearance of relatively clear-cut stages of human development that follow each other in a defined and predictable pattern. This work led to numerous honorary degrees and awards. Among them are two doctor of science degrees, awarded in 1957 from the

University of Maine and in 1967 from Wheaton College. In 1974, Ames was the recipient of University of Maine's Alumni Career Award, described as the highest and most distinguished alumni award offered by the university.

Upon the completion of her doctoral degree, Ames worked with Gesell in the Yale Child Studies Clinic. In 1950, Ames, Frances L. Ilg, and Janet Learned (Rodell) cofounded the Gesell Institute of Child Development in Gesell's honor to continue his work. There, Ames served as director of research, associate director, and director and following her retirement, as president of the board.

Her publication list (ranging from 1953 to the early 1990s) is extensive. She authored and coauthored many books and articles and appeared on several television and radio shows. Some of her best-known books are also listed as her favorites, including *Don't Push Your Preschooler*, which she coauthored with her daughter, Joan Ames Chase. *He Hit Me First, Your One Year Old*, and *Your Seven Year Old*, coauthored with her granddaughter, Carol Chase Harber, are also among her most popular. In addition to her publications, Ames began a daily newspaper column, “Questions Parents Ask,” in 1952 that lasted for 25 years and was carried by 65 newspapers across the country. “We had more papers than Ann Landers when we began. And we started first,” she often noted with pride. One year later, she brought her knowledge and expertise about children and parenting to television stations in major cities.

Ames died on October 31, 1996. Her work is carried on today by the Gesell Institute of Human Development in New Haven, Connecticut.

## AMNESIA

---

Slight lapses in memory, such as forgetting to return a call from a friend or to pick up milk at the grocery store, are normal and to be expected in healthy individuals. Amnesia is *not* a normal lapse of memory; rather, it is memory loss due to brain

damage or psychological trauma. Amnesias caused by surgery, an accident, drugs, or disease are called *organic amnesias*. Organic amnesia can devastate one's ability to learn new information, to remember information from the past, or both. Amnesia differs from dementias (such as Alzheimer's disease), which involve more than simple memory loss. Amnesic patients do *not* have deficits in immediate recall (e.g., repeating a string of numbers immediately after hearing them) and have preserved overall intelligence, whereas patients with dementia exhibit continuous deterioration of memory ability along with other cognitive skills. Further, dementias progress as a result of ongoing neuronal loss, whereas amnesia has an abrupt onset.

*Anterograde amnesia* refers to the inability to learn and remember new information. It is often seen in individuals who have suffered a stroke, although a wide variety of medical problems that inflict damage on the medial temporal lobe of the brain can cause anterograde amnesia. Usually, these amnesics have difficulty learning all varieties of new information, although it is possible to have problems learning specific varieties of information (e.g., amnesia may be limited to learning spatial locations). The most famous anterograde amnesic is a patient known as H. M., who underwent radical surgery that removed tissue from his medial temporal lobe in order to help control his life-threatening seizures. From the time he awoke following surgery until the present (more than 50 years), H. M. has been unable to learn and remember any new information, including what year it is, where he now lives, and who his caregivers are.

An inability to remember information that was previously known is called *retrograde amnesia*. This can result from damage to the cortex, with the extent of brain damage strongly related to the density of the resulting amnesia. Even in cases of severe retrograde amnesia, there may be "islands" of intact memory for salient events. Generally, retrograde amnesia occurs only for a brief period of time preceding the injury. For example, if a person in a car crash sustains brain damage, he or she might be brought to the hospital unconscious and awaken a few hours later. Although the patient may be able to understand and remember that he or she is now in the hospital, the last thing the patient might remember is leaving the house that morning. Interestingly, most cases of anterograde amnesia are accompanied by some degree of retrograde memory loss, although the severity of the

anterograde and retrograde deficits is not always strongly correlated.

*Psychological amnesia* is sometimes also called functional, psychogenic, traumatic, or dissociative amnesia. Psychological amnesia can result when an individual is under extreme stress or experiences a traumatic event (in the absence of brain injury). The amnesic individual may report lapses in memory for information related to a traumatic or stressful event or period in his or her life. Memory loss can last anywhere from an hour to a period of years. Memories may be recalled after being triggered by stimuli related to the trauma. Psychological amnesia sometimes occurs in individuals involved in combat or victims of childhood abuse. A rare subtype of psychological amnesia is dissociative fugue, in which an individual completely forgets who he or she is and often creates a new identity. Dissociative fugue can last anywhere from a few hours to years, and patients emerging from the fugue state often regain their true identity but have amnesia for events from the fugue period.

## AMPHETAMINES

---

Currently, amphetamines (AMP) and methamphetamines (MA) are among the most widely abused illicit drugs in the world, second only to marijuana. More than 35 million individuals worldwide use and abuse

AMP or MA on a regular basis (as compared with cocaine, which is used by about 15 million people, and heroin, used by fewer than 10 million). As a specific compound in the larger amphetamine family of powerful psychoactive stimulants, MA has become the most popular drug because of its high potency, relative low cost, and ease of manufacture.

Amphetamines were introduced into medical use in the United States in the early 1930s as a nasal spray for the treatment of asthma. By the mid-1960s, the U.S. Food and Drug Administration (FDA) placed the entire class of drugs under regulatory control because of growing concern over its misuse and overuse. Terms to describe the effects of AMP use and users such as “speed freaks” and “speed kills” are an enduring legacy to the phenomena. In the 1970s, regulatory controls on lawfully made AMP were progressively tightened. The Controlled Substances Act, which sorts all regulated substances into one of five schedules based on the substance’s medicinal value, harmfulness, and potential for abuse or addiction, includes AMP and MA in Schedule II (Control Level). These drugs are considered to have a high abuse potential with severe psychic or physical dependence liability.

Methamphetamine is known by a large variety of slang names, including “crystal,” “meth,” or “speed.” It can be injected, smoked, snorted, or taken by mouth. The intensity and duration of the “rush” experienced after use is a result of the release of high levels of dopamine into the brain and depends in part on the method of administration. This rush is almost instantaneous when MA is smoked or injected, but takes about 5 minutes after snorting or 20 minutes after oral ingestion. The half-life of MA is 12 hours, giving a duration of effect ranging from 8 to 24 hours (in contrast to the 1-hour half-life of cocaine, giving a high of only 20 to 30 minutes). The use and misuse of MA result from its subjective effects, including euphoria, reduced fatigue, reduced hunger, increased energy, increased sex drive, and increased self-confidence. Although AMP and MA initially produce positive effects, the user is typically unaware of negative consequences to many of the body’s systems. Short-term and long-term cardiovascular, respiratory, neurological, cognitive, dermatological, dental, and psychiatric damage may occur in many individuals.

The immediate physiological effects of MA use are like those produced by the fight-or-flight response. As the body prepares for the simulated emergency of the fight-or-flight response, increased blood pressure and

heart rate, constricted blood vessels, dilated bronchioles (breathing tubes), and increased blood sugar levels can cause irreversible damage to blood vessels in the brain, producing stroke, respiratory problems, irregular heart-beat, extreme anorexia, cardiovascular collapse, and death. Other negative physical and medical side effects include stomach cramps, shaking, high body temperature, stroke, and cardiac arrhythmia.

Abnormal movements and facial gestures are hallmarks of chronic stimulant abuse, and both acute and chronic use of AMPH and MA may result in coordination problems, shaking, involuntary facial and mouth movements, stereotyped movements, and tics. Abnormal, involuntary movements associated with stimulant use may decrease or end when drug use stops; however, chronic AMP and MA addicts may demonstrate long-lasting movement disorders that may persist for several years after drug withdrawal. Other negative consequences of use include cognitive deficits in memory, attention, concentration, and problem solving. Although some of these deficits may improve over time, enduring deficits may occur in some individuals.

Short-term and long-term AMP or MA use may result in psychological effects such as increased anxiety, insomnia, aggressive tendencies, paranoia, and hallucinations. Of great concern is a psychotic state that may be indistinguishable from paranoid schizophrenia. Paranoid delusions and transient auditory and visual hallucinations are frequent with MA use and its associated psychoses, with as many as two thirds of chronic MA users experiencing delusional psychoses. The delusions may be brief, although it is common for episodes to last several days to months. Of much concern is the violence that often accompanies AMP and MA use, especially in instances of use by parents of young children.

Importantly, the route of administration affects the potential for adverse reactions and associated medical disorders. Intravenous use may result in illnesses associated with the use or sharing of contaminated drug paraphernalia, including human immunodeficiency virus (HIV), hepatitis, tuberculosis, lung infections, pneumonia, bacterial or viral endocarditis, cellulites, wound abscesses, sepsis, thrombosis, renal infarction, and thrombophlebitis. Nasal insufflation (snorting) is associated with sinusitis, loss of sense of smell, congestion, atrophy of nasal mucosa, nose-bleeds, perforation or necrosis of the nasal septum, hoarseness, problems with swallowing, throat ailments, and a persistent cough.

Continued use of MA may result in tolerance, and increased use at higher dosage levels may lead to dependence. Investigations of the long-term consequences of MA use in animals indicate that as much as 50% of the dopamine-producing cells in the brain can be damaged even after low levels of MA use, and serotonin-containing nerve cells may be damaged even more extensively. Withdrawal effects from discontinuing use of MA often include depression, irritability, fatigue, anergia, anhedonia, and some types of cognitive impairment that last from 2 days to several months.

## ANDROGYNY

---

Feminine traits, those characteristically associated with women, include helpfulness to others, gentleness, warmth, and emotionality. Masculine traits, stereotypically associated with men, include assertiveness, self-reliance, achievement orientation, and independence. Traditionally, psychologists viewed femininity and masculinity as opposite roles of a single bipolar continuum: the more feminine a person was, the less masculine that person could be.

In the 1970s, Sandra Bem and other psychologists, such as Janet Spence and her colleagues, began to challenge the bipolarity assumption. They conceptualized femininity and masculinity as two independent dimensions, rather than as one dimension in which masculinity and femininity were mutually exclusive. According to this view, individuals can show any combination of female-stereotypic and male-stereotypic

characteristics. A high degree of one does not imply a low degree of the other.

Individuals, female or male, who exhibit high levels of both feminine and masculine personality traits are said to demonstrate *androgyny*. People who have many masculine traits but few feminine ones are termed *masculine*; those with many feminine but few masculine characteristics are labeled *feminine*. Individuals who show few feminine and few masculine traits are designated as *undifferentiated*.

A number of tests have been constructed to measure femininity and masculinity. The two most widely used instruments are the Bem Sex Role Inventory (BSRI), developed by Sandra Bem, and the Personal Attributes Questionnaire (PAQ), developed by Janet Taylor Spence and her colleagues. These instruments, both published in 1974, ask participants to indicate the extent to which various personality traits apply to them. The traits used in these tests are virtually all positive. Each of these tests yields both a femininity score and a masculinity score.

Bem has hypothesized that androgynous individuals are more flexible and adaptable than others, able and willing to engage in either feminine or masculine behaviors as the situation requires. For example, the androgynous woman or man could successfully close a tough business deal at work and also be a nurturing spouse and parent at home. Furthermore, because androgynous individuals can summon a wider range of behaviors to meet the challenges of life, they should enjoy advantages in mental health and psychological adjustment.

There is a good deal of evidence that androgynous children, adolescents, and adults are better adjusted than are masculine, feminine, or undifferentiated peers. For example, androgynous adolescents, compared with other adolescents, have better social relations and greater self-esteem, and they are more likely to have resolved identity crises.

Some research, however, has found little or no difference between androgynous and masculine individuals. Several studies, for example, have found that androgynous and masculine individuals are equally high in self-esteem. Apparently, it is high masculinity and not the specific combination of high masculinity and high femininity that is strongly related to well-being and self-esteem. What might account for the positive relationship between masculinity and psychological adjustment? One possible reason is that masculine characteristics have broader adaptive significance

for an individual than do feminine characteristics. Another related hypothesis is that masculine traits are more highly valued in Western society than are feminine traits. Thus, people with masculine traits may feel more positive about their ability to function effectively.

The contribution of femininity to overall adjustment is less clear than that of masculinity. Femininity appears to have little or no effect on the adjustment of women. However, highly feminine men appear more poorly adjusted than highly masculine men. This may result from the greater cultural pressure placed on men than women to conform to their socially expected role. A more recent notion about the contributions of femininity and masculinity to adjustment is the differentiated androgyny model. According to this view, the context of the situation or behavior is critical in determining the relative importance of femininity and masculinity to an individual's self-esteem. For example, high femininity can be an asset to both women and men in social interactions and in some occupations such as nursing and special education.

The past three decades have witnessed major changes in the incidence of masculinity and androgyny among college students. During the 1970s, female college students were more likely than their male peers to score high on femininity, and males were more likely to get high scores on masculinity. About one third of females and males were rated androgynous. In recent years, there has been a noticeable increase in masculinity and androgyny among women and a slight increase among men. Moreover, women and men no longer differ on several traits previously classified as masculine, such as being assertive, ambitious, active, independent, or self-reliant; defending one's beliefs; and acting as a leader. These changes most likely are a result of societal shifts in women's roles and status in the past few decades. Opportunities for girls to develop masculine-typed traits have expanded significantly in the spheres of sports, education, and employment. Although women have been encouraged to become agentic, men have not been as encouraged to become communal. Such findings bring into question the validity of the masculine and feminine dimensions of instruments such as the BSRI and PAQ, which were developed 30 years ago. We also cannot assume that findings based on undergraduate college students are generalizable to other segments of society.

When the psychological measurement of androgyny was introduced in the 1970s, it was received

enthusiastically by feminist scholars. It replaced the notion that psychological health required that females be feminine and that males be masculine. By embodying socially desirable traits for both females and males, androgyny seemed to imply the absence of gender stereotyping. Moreover, by incorporating both feminine and masculine behaviors, androgyny appeared to broaden the scope of behaviors that can be used to handle different situations and thus lead to more flexible and adaptive behaviors.

Although androgyny continues to be viewed by feminist scholars as more positive than restrictions to either femininity or masculinity, several criticisms have been leveled against this concept. One criticism is that the instruments used are too narrow to be considered comprehensive measures of femininity and masculinity. For example, some researchers note that only socially desirable agentic and communal traits are measured. Others have noted that the concepts of femininity and masculinity may mean different things to women and men. In addition, white and African American women do not define femininity in the same way. Thus, instruments such as the BSRI and PAQ, at best, measure only one component of whatever ways masculinity and femininity are defined in different populations.

Another criticism is that the notion of androgyny, similar to the bipolar differentiation of femininity and masculinity, is based on the division of gender into female-stereotypic and male-stereotypic characteristics. Rather than making traits gender neutral, androgyny involves the combination of gender-specific orientations. Some theorists have suggested that androgyny should be viewed as a transcendence of gender roles, rather than emphasizing some balance between feminine and masculine traits.

An additional concern is that androgyny might be erecting unrealistic goals for individuals by requiring that people be competent in both the communal and agentic domains. In a sense, such expectations restrict, rather than expand, the range and flexibility of individuals' behavioral choices.

A further criticism of androgyny is that the concept does not deal with masculinity and femininity in their unequal cultural context. It neither acknowledges nor attempts to eliminate the greater cultural value placed on male activities. A related concern is that androgyny will not lead to the elimination of gender inequality, a goal that requires societal rather than personal change. That is, the mere existence of individuals with both

feminine and masculine traits does not alter the patriarchal power structure in society.

---

## ANEMIA

---

Anemia is a condition in which the oxygen-carrying capacity of the red blood cells is reduced. The red blood cells, or erythrocytes, contain molecules called *hemoglobin* that bind oxygen. Oxygen is picked up from the lungs on the hemoglobin molecules and transported through the blood throughout the body to tissues as required.

There are many causes of anemia. Anemia may result from deficiencies of substances needed to produce red blood cells: iron, vitamin B<sub>12</sub> (cobalamin), or folate (folic acid). Those at risk have inadequate dietary intake or absorption of these substances or increased requirements. Iron deficiency is the most common cause of anemia. According to one national survey, 3% to 5% of females between 16 and 49 years

of age and 3% of children between 1 and 2 years of age have anemia due to iron deficiency. Iron requirements increase during rapid periods of growth in young children and adolescence and during pregnancy. In addition, dietary iron ingestion may not be enough to counter blood loss in menstruating women. Strict vegetarians are at risk for developing iron and vitamin B<sub>12</sub> deficiencies, whereas folate deficiency is more common among alcoholics and others with poor diets. Folate is destroyed by heat, putting those who eat primarily overcooked or canned foods at risk for deficiency. In addition to poor intake, some individuals may be unable to absorb iron, vitamin B<sub>12</sub>, or folate because of specific disorders (e.g., pernicious anemia, sprue) or prior gastrointestinal surgeries (e.g., gastrectomy). Some medications can impair the body's ability to use folate properly. Blood loss or destruction of red blood cells within the body due to exposure to specific toxins (e.g., naphthalene in mothballs, fava beans) may also cause anemia. Anemia is also associated with chronic infections and diseases such as renal failure, cancer, and arthritis.

There are many symptoms of anemia, but most are vague. Patients with anemia may complain of fatigue, coldness, weakness, dizziness, or sore tongues. Pale skin and fingernail beds may be noted. In more pronounced anemic states, the heart rate may be increased and chest pain or shortness of breath may be reported. Infants and young children with anemia are at risk for developmental delays and behavioral disturbances. In addition, patients with vitamin B<sub>12</sub> or folate deficiency anemia may have neurological symptoms such as irritability, changes in memory, and tingling or numbness of the extremities.

The diagnosis of anemia is dependent on documentation of low hemoglobin and hematocrit levels in the blood. The normal values are higher in adult men than in adult women and also change from infancy through childhood. Other laboratory abnormalities depend on the cause of the anemia itself. For example, the mean corpuscular volume (MCV), the size of the red blood cell, will be low if the anemia is due to iron deficiency, but high if due to vitamin B<sub>12</sub> or folate deficiency. A careful dietary and medical history should be accompanied by measurement of serum iron, vitamin B<sub>12</sub>, and folate concentrations to establish the cause of the anemia.

The treatment of the anemia is dictated by the cause. Patients with iron deficiency are commonly give a several-month course of ferrous sulfate or other

iron salt until hemoglobin levels return to normal and iron stores are repleted. Vitamin B<sub>12</sub> is available as oral tablets and may also be given as monthly intramuscular injections for those with medical conditions that affect absorption. Folate is generally given orally once daily. Patients with acute blood loss or dramatically low hemoglobin levels may also be given blood transfusions to correct the anemia immediately. Treatment of underlying causes (e.g., cancer, chronic infections) will also improve anemia. Patients with anemia due to kidney disease often receive injections of drugs that increase the production of red blood cells by the bone marrow. The development of anemia may be prevented by the use of folate, vitamin B<sub>12</sub>, and iron supplements in pregnant women and others at risk for deficiency.

## ANGER

---

Emotions are often written all over children's faces. They are unique qualities that develop over time, distinguish each individual child from others, and significantly influence our personalities over the course of our life spans. Anger is one of the most talked about yet least understood emotion. It has been an important field of study in many disciplines. Anger is a powerful emotion, and rational solving can quickly give way to emotional and reflexive reactions.

Parents, educators, and counselors spend a great deal of time helping children learn how to deal with anger and aggression because problems arising from such behavior account for most referrals to mental health services. The cost borne by educational, health, criminal justice, and mental health systems that deal with youngsters and adults who are aggressive and have conduct problems are staggering, making aggression and antisocial behavior the most costly mental health problem in North America.

### WHAT IS ANGER?

*Anger* is the internal experience of a private, subjective event (i.e., emotion) that has cognitive (e.g., thoughts, self-statements, private speech, attributions) and physiological (e.g., shifts in heart rate, muscle tension) components. *Aggression*, which may be verbal (e.g., taunting, threatening, name calling) or physical (e.g., hitting, fighting), involves behavioral acts that inflict bodily or mental harm on others. Aggressive behavior may be proactive (threatening, bullying) or reactive (retaliatory). Aggression causes less serious harm than *violence*, wherein the aggressive acts cause serious harm (e.g., aggravated assault, rape, robbery, homicide).

### THEORIES OF ANGER AND AGGRESSION

Given that anger and aggressive behavior are frequent among children, it is logical to ask why children behave this way. What causes a child to hit another, to verbally abuse another, or to shove another child aside to take a toy? Over the years, several theories of aggression have been proposed. Some suggest that to behave aggressively is an instinct, part and parcel of the human condition. For instance, Freud's psychoanalytical theory suggests that we all have a death drive that leads us to act aggressively toward others as we turn our inward hostility outward. Ethologists contend that a fighting instinct, stemming from primitive urges to preserve territory, maintain a steady supply of food, and weed out weaker animals, is innately imbedded in our makeup. Sociobiologists often take an evolutionary point of view in considering the biological roots of social behavior by arguing that aggression facilitates the goal of strengthening the species and its gene pool as a whole, according to the "survival of the fittest" doctrine. Male testosterone and other biological factors may underlie aggressive behavior and, in part,

explain why males are more likely aggressive than females. Such instinctual explanations, however, fail to account for the increasingly sophisticated cognitive ability that humans develop as they grow older and fail in determining when and how individuals will behave aggressively. Social learning theories have emphasized how social and environmental conditions teach individuals to behave aggressively. Cognitive approaches suggest that the key element in understanding anger is to examine one's interpretations of other's behavior and of the environmental context in which the behavior occurs. For example, developmental psychologists note that some children are more prone to assume actions are aggressively motivated, have difficulties in paying attention to the appropriate cues in a situation, and are unable to interpret the behaviors in a given situation accurately. Instead, they assume, often erroneously, that what is happening is related to other's hostility. They become physiologically aroused and subsequently experience anger. In deciding how to respond, they base their behavior on inaccurate interpretations of other's behavior and behave aggressively in response to a situation that may never, in fact, have existed. Aggressive individuals are often more impulsive and deficient in problem-solving capabilities. Thus, angry and aggressive children and adults manifest a developmental lag and deficits in specific social-cognitive and affect-labeling processes. Environmental theories contend that family forces can foster high levels of aggression in children and involve inconsistent parental discipline, rejection of the child, harsh punishment, and lack of supervision.

## DEVELOPMENTAL PROGRESSION OF ANGER AND AGGRESSION

As children grow and learn, they exhibit anger and aggression in generally consistent stages. Beginning shortly after birth, if not before, a child's individuality is manifested primarily in temperament, which is the groundwork for the early-emerging, stable individuality in a person's behavior. *Temperament* has been viewed as constitutionally based individual differences in behavioral characteristics that are relatively consistent across situations and over time—dominant mood, adaptability, activity level, persistence, and threshold for distress. These constitute the foundations of personality growth and are closely related to emotions that shape our experience with the world and exercise a pervasive influence throughout the life

span. Emotional experience changes considerably with development and involves complex feelings that far surpass the range of temperamental variability. In infancy, the extremes of emotional arousal from intense anger or crying to exuberant delight may oftentimes appear unregulated by the child and uncontrollable. Between the ages of 2½ and 5, temper tantrums appear, often when children are frustrated, are told “no,” or do not get their way. Preschoolers commonly struggle over toys and control of space. In fact, oppositional, defiant, aggressive behaviors are so common in preschoolers that it takes a very high level or severity of such things to be considered pathological. As verbal skills improve, however, there is a shift from more overt physical aggression toward greater use of verbal aggression. As this trend continues in middle childhood, aggression occurs mostly during social play. *Instrumental aggression* appears as a way or an instrument to reach goals. *Hostile aggression*, action intended to hurt another person, increases during early childhood and then declines. After the age of 6 or 7, most children become less aggressive as they become more cooperative, less egocentric, and more empathetic. They can understand another person's perspective and begin to understand more positive ways of dealing with others. They become more reflective and strategic about their emotional lives and can be managed better through cognitive means as well as behavioral strategies.

However, some children do not learn to regulate their anger and become increasingly destructive and interact with others in an angry, threatening fashion. Such aggression not only is a reaction to problems in a child's life but also causes major problems by making other children and adults dislike a child. *Relational aggression* (e.g., ostracizing, verbal insults, gossiping) emerges as a way of psychologically harming others. When angry, such behavior is more likely exhibited by girls because boys remain more confrontational in interpersonal interactions. At every age, however, boys show more aggression, assertiveness, and dominance. In adolescence, emotional swings appear to reemerge; adolescents are acutely sensitive to emotion in themselves and peers. There appear to be two unique pathways in the development of aggression and related equivalent problems over the life span. Some children, in life-course-persistent (LCP) path, display aggressive behavior at an early age and continue to do so into adulthood. The adolescent-limited (AL) path involves youths whose aggressive,

antisocial behavior begins at about puberty and continues into adolescence but then drops off in their early to middle 20s. Children with severe anger and conduct problems often do not “grow out of it” but experience difficulties as adults and have problems with the law, related psychiatric problems, employment difficulties, and poor parenting of their own children.

Overall, emotional development continues into adulthood because adults often seek to create personal lifestyles that are emotionally satisfying, predictable, and manageable through various activities. Thus, learning to deal with anger is an important task of early childhood but, for some, is never really mastered and continues to adversely affect their development.

## TREATMENT OF ANGER AND AGGRESSION

Treatments must be sensitive to where a child is in this developmental trajectory. More specifically, methods and goals need to differ not only for preschoolers, school-age children, and adolescents but also according to the type and severity of the individual's acting out problems. In general, the further along a child is in the progression of aggressive, antisocial behavior, the greater is the need for intensive interventions. Three treatment approaches with proven success have included parent management training, cognitive-behavioral problem-solving skills, and multisystemic treatment. Parent management training teaches parents to change their child's behavior at home by changing the way they interact with their children. Cognitive-behavioral problem-solving skills training focuses on the cognitive deficiencies and distortions displayed by children and adolescents with anger problems; they are taught to be better problem solvers in dealing with life's frustrating situations. Multisystemic treatment is a family systems approach that emphasizes interacting social influences and views children with aggressive conduct problems as reflecting dysfunctional family relations. In striving to empower caregivers, it views the child with such problems as functioning within a network of social systems, including the family, school, neighborhood, and court and juvenile services.

## SUMMARY

Anger is one of the basic emotions in the human experience. It is an internal subjective reaction to

external problems or “triggers” and is influenced by cognitive and physiological components. Aggression involves behavioral acts that can take several forms—instrumental (way to reach goals), hostile (inflicting bodily or mental harm on others), or relational (gossiping, ostracizing). Although children and adolescents learn to regulate their anger as they develop, some continue to manifest significant social-cognitive deficits in managing such emotions. During childhood, aggressive behavior and related conduct problems are about 3 to 4 times more common in boys than girls, although this difference decreases by middle adolescence, mainly owing to an increase in covert antisocial behavior in girls. There is a general progression of antisocial behavior from difficult early temperament and hyperactivity, to oppositional and aggressive behavior, to social difficulties, to school problems, to delinquent behavior in adolescents, to criminal behavior in adulthood.

Future research directions need to further elucidate developmental factors in anger and aggression. Various personal characteristics and environmental conditions that either place individuals at risk for problematic aggressive behavior or protect them from the effects of risk need to be further identified. Finally, intervention programs need to be evaluated to establish better “best practices” procedures.

## ANOREXIA NERVOSA

---

Anorexia nervosa (AN) is characterized by a severe disturbance in eating behavior as well as an underlying psychological profile that is as important to the disorder as the disturbed eating behavior. Individuals with AN are underweight yet fear gaining weight and also exhibit disturbances in the perception of the shape and size of their bodies. In addition, they exhibit psychological characteristics such as identity disturbance, perfectionism, and low self-esteem despite their often exceptionally high levels of performance in various spheres. A variety of physical, psychological, and psychosocial complications can arise as a result of this disorder. Several treatment options are available to individuals with AN, including interpersonal, cognitive-behavioral, group, and family therapies, as well as pharmacological treatments.

### CHARACTERISTICS AND SYMPTOMS

In order to be diagnosed with AN, individuals must exhibit each of the following:

- Severely reduced weight (e.g., weight less than 85% of expected weight for age and height)
- Intense fears of gaining weight
- Disturbed experience of body weight or shape, or denial of the seriousness of the current low body weight
- For women, the absence of at least three menstrual cycles (amenorrhea)

There are two subtypes of AN: binge-eating and purging type, and restricting type. Individuals with AN binge-eating and purging type regularly engage in binge-eating or purging behavior. In contrast, individuals with AN restricting type do not regularly engage in binge-eating or purging behavior. Binge-eating

involves feeling out of control while eating a large amount of food in a discrete period of time, and purging behavior includes self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

### PHYSICAL AND MEDICAL COMPLICATIONS

Many of the physical and medical complications associated with AN arise as a result of the semistarvation state that characterizes this disorder. These complications include emaciation, cold intolerance, osteoporosis, anemia, low blood pressure (hypotension), slow heart rate (bradycardia), and the development of a fine, downy body hair (lanugo). Erosion of dental enamel and other dental problems may also occur in individuals who use vomiting as a means of weight control.

### PSYCHOLOGICAL CONSEQUENCES

Many individuals with AN exhibit depressed mood, social withdrawal, insomnia, and other depressive symptoms. These symptoms may be the result of being in a semistarvation state; hence, mood disturbances may disappear after weight gain, although those that were present before weight loss often persist. Obsessive thoughts and compulsive behaviors concerning food are common and also may be associated with a lack of proper nutrition (although obsessive-compulsive features unrelated to food, body shape, or weight also may occur).

Irritability, loss of sexual libido, and reduced concentration are other features that may occur in individuals with AN. These psychological consequences, in addition to the physical and medical complications associated with AN, negatively affect the quality of life of individuals with AN.

### PREVALENCE

For females, the lifetime prevalence of AN is about 0.5%. AN occurs about 10 times more frequently in females than in males. The onset of AN typically occurs during middle to late adolescence (14 to 18 years). AN seems to be more prevalent in industrialized societies in which food is abundant, including the United States, Canada, Europe, Australia, Japan, and South Africa. The incidence of AN has increased over the past several decades; however, it is not clear whether this merely reflects an increased awareness of AN or whether the true incidence of this disorder is increasing.

## DEVELOPMENT OF ANOREXIA NERVOSA

A biopsychosocial perspective has been employed to describe the factors that may contribute to the development of AN. This perspective implicates cultural, familial, biological, social, cognitive, and other factors in the development and maintenance of AN. These factors are outlined below.

### Sociocultural Factors

The idealization of thinness that exists in Western society is thought to contribute to the development of AN. The “thin ideal” tends to exist in cultures in which there is an abundance of food. Furthermore, the idealization of thinness is targeted more at females than males.

### Familial Influences

Compared with the families of individuals with no eating disorders, the families of anorexic individuals are more rigid in their organization and typically avoid discussing disagreements between parents and children. However, it could be that these factors are a consequence of having a family member with AN, rather than a cause of the disorder itself.

There is also evidence that suggests eating disorders occur more often among the first-degree relatives of individuals with AN, as compared with the relatives of individuals without eating disorders. This may reflect genetic or environmental transmission of AN.

### Individual Risk Factors

#### *Personality and Trait Characteristics*

Individuals with AN tend to be perfectionistic and have low self-esteem. Hilde Bruch, an influential contributor to the literature on etiology and psychotherapy for AN, suggested that individuals with AN are struggling for autonomy, control, and self-respect and that the changes in eating behaviors that occur with AN represent attempts to overcome this struggle. The use of weight and shape as a means of self-evaluation, identity formation, and control appears to be a key factor in the development and maintenance of AN.

#### *Body Dissatisfaction*

Body dissatisfaction in and of itself is unlikely to lead to the development of AN. However, if an individual

with high body dissatisfaction seizes upon weight and shape as a means of self-control, extreme dieting behaviors may ensue, which in turn may contribute to the development of AN in susceptible individuals (who also have the personality and familial risk factors).

### *Biological Factors*

Neuroendocrine functioning is altered in individuals with AN. Serotonin imbalance has been implicated as a cause of AN, although it remains unclear whether this imbalance is present before the development of AN, or whether it may be a consequence of the disorder.

### *Adverse Events*

Negative interpersonal experiences, including trauma and abuse, have also been implicated in the development of AN. It may be that individuals who experience these stressful life events develop AN as a coping mechanism in order to attempt to regain emotional control and overcome identity problems.

## TREATMENT

People with AN often fail to recognize or admit that they are ill. As a result, they may resist treatment. Many individuals with AN present for treatment in order to satisfy their loved ones who pressure them to seek treatment out of concern. Once in treatment, AN patients may fail to comply with treatment requirements and may be uncooperative with clinicians.

Because of the complexity and severity of the disorder, individuals with AN require a comprehensive treatment plan, including medical care, psychosocial interventions, nutritional counseling, and, when indicated, medication management. When a clinician diagnoses an individual with AN, the clinician must determine whether the person is in immediate physical danger and thus requires hospitalization. Treatment of AN typically involves three main components: (1) restoring weight to a minimally healthy level; (2) treating psychological disturbances such as body shape or weight distortion, low self-esteem, and interpersonal conflicts; and (3) relapse prevention (maintaining treatment gains).

### Hospitalization

Patients with AN may require hospitalization for the purpose of medical management or active treatment

of the eating disorder. Severity of weight loss is the major criterion used to indicate that admission is required. When weight is at or below 75% of what is expected for the person's age and height, hospitalization is usually recommended. Inpatient programs typically involve several elements, including nutritional and medical rehabilitation and psychotherapy. Patients are encouraged or required to eat regular meals. In addition to these meals, patients may be required to take nutritional supplements. There is considerable controversy as to the appropriateness of feeding patients against their wishes. Admissions for involuntary feeding are considered to be an emergency measure. Patients admitted under these circumstances are not considered to be actively pursuing treatment. AN patients may also receive individual or group therapy addressing their psychological disturbances. Inpatients with AN progress to outpatient treatment when it is considered safe for them to do so.

## Psychotherapy

Unfortunately, limited psychotherapy outcome data exist for the treatment of AN. The data that are available fail to indicate which type of treatment is best. However, several types of psychotherapy are available:

- Cognitive-behavioral therapy includes behavioral elements (including the normalization of eating) with a focus on identifying and altering dysfunctional thought patterns, attitudes, and beliefs, which may trigger and perpetuate restrictive eating and binge-eating and purging behavior. Self-monitoring of food intake and symptoms is also important, as is identifying triggers and developing alternative reactions to them.
- Interpersonal psychotherapy focuses on relationship difficulties, self-esteem, assertiveness, social skills, and coping strategies.
- There is no one unified form of family therapy. The goal of family therapy is to help members of the family change behaviors that may have contributed to the development and maintenance of the eating disorder.
- Group psychotherapy can be very helpful because it provides people with AN with the opportunity to share their experiences and to give feedback to each

other, and it may enhance self-esteem through helping others. Groups are usually led by one or two facilitators.

## Medication

No specific medications have been shown to treat AN effectively. However, some medications may be helpful in speeding up recovery or in treating associated problems such as anxiety and depression. Antidepressant medications may help in reducing depressive feelings, as well as controlling obsessive thoughts about food and weight.

## Course and Prognosis

The mortality rate among people with AN is estimated at 0.59% per year, which is about three times higher than for other psychiatric illness. The most common causes of death are complications of the disorder, such as cardiac arrest or electrolyte imbalance, and suicide. The course and outcome of AN vary. Of those individuals who survive, about 46% fully recover, 33% experience some improvement, and 20% remain chronically ill. A number of individuals with AN later develop other eating disorders, particularly bulimia nervosa. One study found that 16.8% of AN patients went on to meet diagnostic criteria for bulimia over the course of a 6-year follow-up period.

## ANTI-SEMITISM

---

Anti-Semitism, or prejudice against the Jews or Jewish culture, has plagued the world for almost 2,000 years. The Jews were scapegoats first in the ancient and medieval Christian world and then in the modern world. Anti-Semitism is one of the greatest examples throughout the course of human history of man's inhumanity to his fellow man.

The history of the Jews has been marked with triumph, but also great tragedy. Nearly 2,000 years ago in ancient Rome, the Jews were forcibly expelled from their homeland, and the diaspora took them to various parts of the Middle East, North Africa, and Europe. The birth of anti-Semitism can be traced directly to Christian anti-Jewish attitudes. The early Christians were frustrated that the Jews did not convert to the new religion, and the anti-Jewish hostility can be found in the New Testament in the Gospel of John and letters of Paul. Many Christians believed that Jews were responsible for the death of Jesus of Nazareth, and the term "Christ-killer" was applied to the Jews throughout the Middle Ages.

From the 4th century onward, Christians shunned the Jews and forced them to live in ghettos. Jews had to wear distinct medieval costumes and in many parts of Europe a yellow badge to signify that they were Jewish and to warn the Gentile population. As the centuries progressed, the animosity that Christianity had toward its sister religion gradually escalated into homicide. In 1095, Christians slaughtered hundreds of thousands of Jews and Muslims during the Crusades. In 1347, the Black Death swept across Europe, taking the lives of nearly half of the population. Christians eventually accused the Jews of poisoning the wells, thereby bringing about the plague. The Christians slaughtered thousands of Jews in retaliation. The violence continued in the 15th century as Europeans accused Jews of ritually murdering Christian children. The blood libel myth lasted until well into the 20th century and led to extraordinary violence against the Jews. Anti-Semitism continued in the late 1400s in the

aftermath of the Spanish Inquisition as hundreds of thousands of Jews were expelled from Spain in 1492. The Protestant Reformation of the 16th century offered a glimmer of hope for the Jews as the religion of Christianity effectively divided in half between Roman Catholicism and Protestantism. The Jews of Europe anticipated tolerance from the Protestants, but unfortunately that was not to be, as Martin Luther penned the most anti-Semitic document ever written in 1543 entitled, "On the Jews and their Lies." The relationship between Jews and Christians remained tense for centuries to follow.

At the start of the modern era, Jews residing in Western Europe had reason for optimism. In the mid-18th century, the enlightened despot Frederick the Great allowed for some Jews to live outside of the restrictive ghettos in historic Prussia. The movement toward emancipation continued in the early 20th century as Napoleon Bonaparte destroyed the remaining ghettos in Western Europe. Jewish Emancipation appeared to be a distinct possibility but unfortunately failed to materialize as a new form of anti-Semitism developed focusing on Jewish control of the economic and social aspects of European life. In the capitalist nations of Western Europe, Jews proved to be a convenient scapegoat for all the shortcomings of European society. As nationalism increased in Western Europe, so too did anti-Semitism. Germany was the birthplace of modern anti-Semitism, as pseudoscientists like Wilhelm Marr, Georg von Schönerer, and Herman Ahlwardt and the composer Richard Wagner blamed the Jews for all of Germany's problems. France also experienced a rise in anti-Semitism in the late 19th century. Edouard Drumont's anti-Jewish newspaper, *La Libre Parole*, experienced widespread circulation. In the late 1890s, the nation was bitterly divided during the Dreyfus Affair, a scandal that centered on a Jewish captain in the French Army who was accused of selling military secrets to the Germans. Captain Dreyfus was innocent but was convicted solely on the fact that he was Jewish.

In 19th century Eastern Europe, the Jews faced an even more dangerous situation. The Czarist Government of Russia forced the Jews to live in the Pale Settlement, and the Jewish population was subject to frequent attack. By the 1880s, homicidal anti-Semitic attacks were so frequent that a new word, *pogrom*, was ushered into the Russian vocabulary. In 1881, Alexander III became the new czar of Russia and immediately adopted measures to keep Jews from owning land.

He also slashed Jewish university enrollment by 90%. The May Laws of 1882 placed further restrictions on the Jews, stripping them of the most fundamental of human rights. Because of these harsh restrictions, many Russian Jews left the nation permanently, settling in Western Europe, South Africa, and the United States. Pogroms intensified in Russia over the next 25 years as Russian mobs slaughtered thousands of Jews and destroyed or confiscated large amounts of Jewish property in the Pale Settlement. Not only did massive Jewish emigration occur in late 19th-century Russia, the Jews also began to search for a Jewish nation in what was more commonly known as *Zionism*.

Zionism had its origins in the Pale Settlement in Russia in the 1880s and was a direct response to European anti-Semitism. The objective was to establish a Jewish state somewhere in the world as a way to provide a safe haven for the Jews. In 1896, Theodor Herzl took control of the Zionist movement. Herzl was born in Vienna, Austria, and was raised in a fully assimilated Jewish family. After witnessing the anti-Semitism of the Dreyfus Affair, the journalist Herzl became an avowed Zionist. In the Zionist Congresses in Switzerland, Jewish delegates discussed various locations for a Jewish nation, including Argentina, Uganda, and Palestine. Unfortunately, a Jewish state did not come into existence by the early 20th century, and the movement suffered another setback with the untimely death of Herzl in 1904.

As the early 20th century progressed, many Jews attempted to leave the European continent and settle in Palestine or the United States. By 1930, the Jewish population in the United States was the largest in the world. Although anti-Semitism in America paled in comparison to Europe, it was nevertheless prominent in the 1920s and 1930s. Before the Great Migration (1881–1921), anti-Semitism in America was virtually nonexistent. However, as large numbers of Russian Jews began arriving in the United States in the late 19th century, American public opinion pressured Congress to restrict the numbers of Jews and other undesirables entering the nation. Congress responded by effectively sealing the nation's borders in 1924. The United States had been a Protestant nation for Protestant people, and now Americans faced a sizable Jewish population and a large Catholic population. The Ku Klux Klan experienced resurgence in the 1920s in response to these unwanted newcomers. African

Americans, Jews, and Catholics were all targets of the Klan as membership in the organization soared. Universities across the nation imposed a quota system to limit the amount of Jews who could enroll in medical, law, or graduate school. Many Americans considered Jews to be communists or subversive elements who could inflict considerable harm on the nation. The automobile manufacturer Henry Ford reprinted the Protocols of the Elders of Zion in his newspaper, *The Dearborn Independent*. The Protocols, a proven forgery by 1921, alleged an international Jewish conspiracy that sought to control the world. Anti-Semitism reached its apex in the United States in the 1930s during the Great Depression. A Roman Catholic priest, Fr. Charles Coughlan, led his own crusade against Jewish Americans, despite the fact that his own Detroit parish had been victimized by frequent cross burnings of the Ku Klux Klan. The "radio priest," as he was called, railed against the evils of New Deal legislation and Jewish influence in the nation. Charles Lindbergh, a Nazi apologist and sympathizer, also espoused anti-Semitic remarks at various rallies in the United States throughout the late 1930s and early 1940s. Anti-Semitism was a significant problem in the United States in the first half of the 20th century, but it never reached the levels of Europe. In the second half of the 20th century, anti-Semitic attitudes in the United States began a steady decline.

In the aftermath of World War I, many Germans blamed the Jews for Germany's defeat in the war. More than 400 anti-Semitic organizations formed in Germany in the 1920s, despite the fact that the Jews amounted to less than 1% of the population. The Nazi Party, one of the more prominent of the new German political parties, tied together extreme nationalism and anti-Semitism. Adolf Hitler, the leader of the Nazi Party, accused the Jews of stabbing Germany in the back and conspiring to ruin the nation. When Hitler became Chancellor in 1933, he put his German nation on the road to genocide. Anti-Semitism reached its most horrific chapter during the holocaust as a supposedly civilized and cultured nation participated or stood idly by as nearly 6 million European Jews were murdered through systematic execution and starvation. The holocaust took the lives of nearly 70% of the Jewish population in Europe and more than 50% of the Jewish population in the world.

In 1948, the nation of Israel came into existence, fulfilling the Zionist dream of the 19th century.

Anti-Semitism, while declining slightly in Europe, increased significantly in the Middle East in the second half of the 20th century. Although the nation of Israel was established, a Palestinian state failed to materialize. The violence between Jews and Arabs was all too predictable. The Arab-Israeli conflict is still unresolved in the present day, and there is little reason for optimism in the near future.

Anti-Semitism has affected the world for almost 2000 years. The irrational hatred of the Jewish people stands as testimony to the dangers of intolerance. For as the great holocaust historian Raul Hilberg warns, “as long as a group of people are not fully assimilated into a society they walk a tightrope between acceptance and annihilation.”

## ANTISOCIAL BEHAVIOR

---

### DEFINITION

The term *antisocial behavior* was originally defined as recurring violations of socially prescribed norms across a range of contexts (e.g., school, home, and community). Antisocial behaviors include verbal and physical aggression toward others, disregard for authority figures, readiness to break rules, and a breach of society’s social norms and mores. In the school setting, antisocial behaviors are manifested in the form of noncompliance, defiance, bullying, truancy, stealing, aggression, and eventually, school dropout. Aggression—physical, verbal, and gestural—is the hallmark characteristic of antisocial behavior. Although aggression provides these youngsters with short-term rewards, aggressive behavior is aversive to others and leads to rejection. By definition, antisocial is the opposite of prosocial, which

is characterized by positive, cooperative social interaction patterns.

Researchers and practitioners often conceptualize problem behaviors as being either externalizing or internalizing problems. Externalizing behaviors refer to behavior problems that are outer directed or undercontrolled (e.g., aggression and disruption.). In contrast, internalizing behaviors refer to behavior problems that are inner directed or overcontrolled (e.g., somatic complaints, anxiety, and depression). Antisocial behavior can be viewed as a subclass of externalizing behaviors and the foundation for conduct disorder (CD), a psychiatric diagnosis. This is particularly disturbing given that conduct disorder is viewed as a chronic, lifelong condition that is often not responsive to adult-controlled tactics and is very resistant to intervention efforts.

Antisocial behavior, which is viewed as a precursor to delinquency and criminality, is an all too common form of psychopathology among today’s youth. It is the most frequently cited reason children are referred for mental health services. In fact, almost half of all referrals are due to antisocial behaviors. Without intervention, students with antisocial behavior are at risk for a host of short-term and long-term negative consequences.

### COMORBIDITY

Comorbidity refers to the co-occurrence of disorders. Comorbidity is a concern given that having more than one disorder may produce a highly negative “multiplier effect.” Youths with antisocial behavior are often comorbid with learning disabilities, depression, and hyperactivity. Youngsters with antisocial behaviors often have learning disabilities and academic underachievement in general. Some evidence suggests that these academic deficits actually broaden over time, whereas other evidence suggests that the deficits maintain over time. Youths with antisocial behavior and depression are also at heightened risk for pejorative outcomes such as suicide. The combination of antisocial behavior and problems of hyperactivity-impulsivity-inattention (HIA) also leads to heightened risk for destructive outcomes (e.g., impaired relationships with teachers and peers, academic failure) as well as the clinical diagnosis of conduct disorders. Some suggest that the co-occurrence of conduct problems and HIA is a precursor to criminality and other serious forms of psychopathology.

Unfortunately, high-risk populations are often vulnerable to multiple-risk disorders, having a strong negative impact on their development. Consequently, it is important that screening and assessment procedures attend to multiple problems and disorders evidenced by this population. It is particularly important to address aggression early on because aggression is highly stable over time, with the consequences of aggression increasing in magnitude as children develop.

### **IMPACT ON CHILDREN AND FAMILIES**

Antisocial behaviors can be devastating to the individual, the family, the school, and the community as a whole. Antisocial behavior can occur either early in a child's development or later during adolescence. Outcomes are much worse for those youth with early-onset antisocial behavior. Antisocial behavior evident early in a child's educational career is actually the single best predictor of delinquency during adolescence. In fact, 70% of youths with antisocial behavior have been arrested at least once within 3 years of leaving school.

Antisocial behavior is believed to be developmentally salient by age 3 or 4 and is relatively stable by age 8. Researchers have suggested that after age 8, antisocial behavior and conduct disorders should be viewed as chronic lifelong disorders, such as diabetes. In other words, the disorder can be managed, but there is no cure. This is not to suggest that it becomes "too late" to intervene, just that the intervention shifts from prevention to remediation.

As previously mentioned, the stability of antisocial behavior over a 10-year period is about equal to the stability of intelligence, with the correlation for IQ approximating 0.70 and the correlation for aggression approximating 0.80. In general, the more severe the antisocial behavior pattern, the more stable the behavior over time and across settings (e.g., home, school, and community). These youngsters are at severe risk for a host of aversive short-term and long-term negative consequences ranging from school failure, school dropout, impaired social relationships, substance abuse, employment problems, higher rates of motor vehicle crashes, higher rates of hospitalization, and higher mortality rates.

Given that children and youth with antisocial behavior patterns become less amenable to intervention efforts over time, it is important that early detection

and intervention techniques be employed to divert these youngsters from going down this destructive path.

### **INTERVENTIONS**

The research community is in agreement that the best way to intervene with antisocial behavior is to identify these youth as early as possible and then provide interventions that encompasses (a) parents and the home setting, (b) teachers and the classroom setting, and (c) peers and the playground setting.

A single intervention program is rarely sufficient to address the multiple challenges of antisocial behavior. Antisocial behavior represents a wide array of behaviors that differ in onset, etiology, risk factors, and clinical course. Dimensions within a behavior can vary in frequency, intensity, repetitiveness, and chronicity. Despite the challenges of addressing antisocial behavior, many evidence-based interventions have proved effective in decreasing antisocial behavior in children.

Family-focused interventions that have proved effective in decreasing antisocial behavior in children are family therapy and parent management training. Both interventions focus on the family unit to increase positive communication skills, structure within the home, problem solving, and social-learning techniques.

Classroom interventions are often child centered and require commitment from the school as well as the classroom teacher. Behavior therapy and problem-solving skills training have met with demonstrated success in decreasing antisocial behavior patterns in children. Behavior therapy focuses on learning new positive behaviors that will replace the antisocial behaviors. Problem-solving skills training focuses on improving cognitive processes and problem-solving skills that underlie social behavior.

Another intervention approach that is useful in developing prosocial behavior and connections with peers is community-wide intervention. This intervention type focuses on activities that promote prosocial behavior that is incompatible with antisocial behavior.

Other intervention efforts, such as individual psychotherapy, group therapy, pharmacotherapy, and residential treatments, have been attempted to prevent the development of antisocial behavior. Individual psychotherapy and group therapy have not produced strong effects. Pharmacotherapy and residential treatments are usually reserved for the more severe antisocial behaviors. Pharmacotherapy is designed to affect the biological systems that research findings have

correlated to aggressive and emotional behaviors. Although residential treatments have yielded behavior changes, these changes typically do not sustain when children are reintegrated into their school and home settings.

As mentioned earlier, the focus of intervention efforts employed vary according to the age of the child. For example, interventions for children in pre-school through grade 3 focus on prevention strategies such as social skills instruction (designed to improve teacher-, peer-, and self-related forms of adjustment), academic instruction, family support, and early screening and identification. Interventions used for children in grades 4 through 6 focus on remediation, such as social skills training, study skills to improve academic performance and competence, and family support. Interventions used for children in grades 7 and 8 focus on amelioration, such as self-control, academic skills, prevocational skills, and family support. Finally, interventions used at the high school level (grades 9 through 12) include survival skills, vocational skills, transition to work, and coping skills.

In general, interventions should focus on achieving school success, gaining acceptance from teachers and peers, staying in school as long as possible, and going on to lead a productive life. These can be best accomplished by teaching replacement adaptive behavior patterns. Factors that increase positive outcomes of interventions include the comprehensiveness, intensity, length, and fidelity of the intervention.

Schools that have demonstrated effectiveness in preventing antisocial behavior problems have many common characteristics. They ensure the principal's support, provide high-quality staff training, supervise prevention activities, use structured materials and programs, integrate programs into normal school operations, embed programs in a school planning activity, and create structures and systems to promote the use of best practices and implement them with high degrees of fidelity.

With sustained commitment to school-wide reform and institutional commitment to empower staff, students, and parents, children with antisocial behavior patterns are likely to improve and become productive members of society.

## ANXIETY DISORDERS

---

Anxiety is a common experience to all, including children and youth. Although many people may consider anxiety to be a negative experience associated with stress or problems, it can serve a positive function by alerting one to imminent threats or danger. Anxiety is also a marker for typical developmental patterns and can serve as an indicator that social and emotional development is progressing as expected. The first major developmental signs of anxiety occur at about 6 to 7 months of age, when the infant becomes distressed about the presence of unfamiliar people. This pattern is known as *stranger anxiety* and indicates that the child is now beginning to differentiate people in the environment, which is a cognitive skill. These reactions usually subside by about 12 months of age. At about 12 to 15 months of age, toddlers may demonstrate signs of *separation anxiety* and become upset when a familiar caretaker, most often the parent, leaves them with someone else. They may cry, cling, and plead for the parent not to leave. This pattern also indicates that the child is progressing cognitively and is beginning to understand that parents can leave and express fear that they might not return. These behaviors usually resolve by about 2 years of age, and although the child may prefer the presence of parents, he or she is able to separate from them and

**Table 1** Major Signs of Anxiety

enjoy being with others. These patterns are normal and should not cause undue concern, unless they are severe, protracted, or occur at ages not expected of the child. For example, it is common for children to have some separation anxiety when starting school, but it usually resolves quickly and does not remain a problem.

## SIGNS OF ANXIETY

Anxiety may be shown in several behaviors, which can be cognitive, behavioral, or physiological in nature. Cognitive signs include difficulties with memory and concentration, whereas behavioral manifestations include rapid speech and sleeping problems. Physiological responses include excessive perspiration and rapid heart rate. Table 1 summarizes the major signs of anxiety.

The central cognitive characteristic of anxiety is *worry*, which is apprehension about an anticipated real or imagined event or threat over which the person feels to have inadequate control. Worry has a predictable developmental pattern that corresponds with levels of cognitive development. Being able to worry requires that the child be able to anticipate a future event or outcome. At preschool and young childhood levels, children have difficulty thinking about more than one future event at a time and anticipating outcomes. At elementary ages, children increase their ability to consider multiple possibilities and outcomes, increasing their proneness to anxiety. Adolescents and adults develop abstraction skills and hypothetical-deductive reasoning ability and can think about their own thinking. Although these skills may be helpful,

they may also provide a basis for being able to anticipate several outcomes over which little control is perceived, which may contribute to the development of anxiety that interferes with functioning. The specific conditions that create anxiety are not well understood, but the ability to anticipate even one negative event may cause anxious reactions. In particular, high levels of anxiety can interfere with problem solving by causing impairments in perceiving all possible solutions, selecting a solution, or applying a selected option.

Excessive worry does not have to have a basis in reality, but if a child *perceives* a situation to be threatening, anxiety can result. I once worked with a young boy whose parents were flying out of state for a short time while he stayed with grandparents. He was extremely fearful that the plane was going to crash and that they would be killed. Although acknowledging that the likelihood of such a catastrophe occurring was very small, he could not resolve the fear that it might happen. To him, the fear, however irrational and unlikely, was extremely worrisome and interfered with his daily behavior.

## TRAIT AND STATE ANXIETY

Anxiety that is chronic and is seen as a typical personality or behavioral characteristic is termed *trait anxiety*. This type of anxiety is most commonly associated with anxiety disorders and is manifested across a range of situations. *State anxiety* is experienced in specific situations, such as when taking tests or public speaking. Although there is not necessarily a high

correspondence between trait and state anxiety, people with high trait anxiety are more prone to state anxiety and to experience performance problems.

## ANXIETY DISORDERS

When anxiety is extremely high in frequency, duration, or intensity, an *anxiety disorder* may occur. Anxiety problems that warrant intervention occur in up to 15% of the population. The estimated prevalence rate of anxiety disorders in children and adolescents is about 2.5% to 5.0%. These disorders often are not detected because children with anxiety disorders often are not disruptive or do not call attention to themselves. As a way to cope with anxiety, children often withdraw from anxiety-producing situations, and they may appear to be uninterested or unmotivated. Some anxious types of behavior often are seen in children with attention deficit hyperactivity disorder, which may make it difficult to differentiate the two conditions. Anxiety disorders also co-occur with depression in about 50% of cases, although anxiety is associated with positive affect, whereas depression is associated with negative affect. When anxiety and depression disorders coexist, the anxiety disorder most likely preceded the depressive disorder. Girls tend to report anxiety symptoms more often than boys, although the difference may be due, in part, to boys' reluctance to report them. Up to about 10 or 11 years of age, there are few meaningful differences between the genders, although boys' anxiety seems to dissipate faster. Consequently, girls and women are more likely to be given diagnoses of an anxiety disorder.

The only anxiety disorder specifically associated with children, *separation anxiety disorder* (SAD) is characterized by developmentally inappropriate difficulties with separation from adults, usually parents. The reasons for SAD can be complicated and cannot be covered here. Otherwise, children may have the same types of anxiety disorders as adults, including generalized anxiety disorder, posttraumatic stress disorder, and obsessive-compulsive disorder.

## CAUSES OF ANXIETY DISORDERS

The causes for anxiety disorders can be based in either biological or environmental factors. Although environmental factors may contribute to the development and maintenance of anxiety symptoms, there is ample evidence to suggest that children with anxiety

disorders may be biologically predisposed to anxiety. These children often are described as fearful, cautious, perfectionistic, apprehensive, "high strung," or having social difficulties. Evidence also suggests that some children may have a pattern termed *behavioral inhibition*, which appears to be a biologically based pattern associated with being fearful, less sociable, and easily distressed and having low attention shifting and high levels of negative affect (distress, fear, inhibition). These children appear more likely to develop anxiety disorders.

Children and adolescents who are exposed to chronic stressful and unpredictable circumstances that are not resolved easily may be at greater risk for developing anxiety disorders. Parenting practices also may contribute to anxiety disorders. For example, some research suggests that parents who are overprotective may encourage and reinforce avoidant and inhibited behavior in their children. New situations remain new to the child, leading to impaired ability to cope and perceptions that the environment is negative.

## INTERVENTIONS FOR ANXIETY DISORDERS

Interventions for anxiety disorders in children and youth often are complex and require multifaceted approaches, including working with the family. It is beyond the scope of this entry to give details about interventions, but there are some methods that have shown evidence of effectiveness in treating anxiety disorders. With proper intervention methods, most anxiety disorders can be successfully treated. It is not usually realistic to expect that all anxiety will be removed; rather, the goal should be to reduce it to a manageable level.

### Cognitive-Behavioral Interventions

These methods emphasize changing distorted or deficient beliefs that contribute to the development and maintenance of anxiety. The most effective methods include multiple sessions of instruction, practice in learning and applying new skills, and homework assignments.

### Behavioral Interventions

These methods include systematic desensitization, muscle relaxation training, self-reinforcement, self-management, and positive reinforcement techniques.

## Counseling Interventions

Although these types of interventions may not be as effective in treating specific anxiety symptoms, they may be helpful in learning needed adaptive and social skills.

## Family Interventions

Because anxiety often is associated with family and parenting issues for children and youth, family-based counseling and parent training may be indicated to alter dysfunctional parent-child-family interactions.

## APGAR SCORE

---

For more than 50 years, the Apgar scoring system has been used universally in the delivery room to assess the overall health and integrity of the newborn immediately after birth. A score of 0 to 2 is assigned in each of five areas at 1 and 5 minutes after birth. If prolonged resuscitation is needed, scoring continues at 5-minute intervals until the infant is stabilized. The five areas are **Activity**—from no movement (0) to tone, movement, and flexion (2); **Pulse**—from absent (0) to more than 100 beats per minute (2); **Grimace**—from no reflex irritability (0) to cough or pulling away (2); **Appearance**—from blue-gray color (0) to normal (2); and **Respiration**—from absent (0) to regular with crying (2). A change in the score from 1 to 5 minutes reflects the effectiveness of the resuscitation, and thus the 5-minute score is considered a better predictor of survival in infancy than the 1-minute score. A 5-minute score of 7 to 10 is normal. A score of 4 to 7 signals a need for resuscitation. A score of 3 or below signals the need for intense, and sometimes prolonged, resuscitation. A low score (less than 3) of long duration (greater than 10 minutes) may correlate with future neurological dysfunction.

The Apgar was intended to be a means of rapidly evaluating the clinical condition of the infant at birth,

not a marker of asphyxia or a predictor of neurological outcome. Although the former remains a valid use of the Apgar, the latter must be qualified. Many factors, including premature birth, prenatal factors, infection, maternal anesthesia, and congenital malformations, may affect the Apgar score. Thus, a low Apgar score alone cannot be interpreted as evidence of asphyxia. Additional criteria must be met. In 2001, the *New England Journal of Medicine* published the findings of a retrospective cohort analysis of 151,891 live-born singleton infants delivered at 26 weeks' gestation or later, which concluded that the 5-minute Apgar score continues to be a valid predictor of neonatal survival in large populations, but is not predictive of long-term neurological outcomes. This conclusion held true for both prematurely born and full-term infants. Also published in 2001 were the findings of a large cohort study in Norway, which found that a 5-minute Apgar score of 3 or less was associated with a significantly increased risk for subsequent death or cerebral palsy. In 2003, the American Academy of Pediatrics/American College of Obstetricians and Gynecologists (AAP/ACOG) joint task force, in reviewing all the recent study data, continued to affirm the findings of their 1996 joint statement. The task force concluded that the 5-minute Apgar score continues to be a valid predictor of survival and that an Apgar score of 0 to 3 after 5 minutes is an appropriate criterion to use as potentially marking intrapartum asphyxia. The risk for poor neurological outcome increases when the Apgar score remains less than 4 at 10, 15, and 20 minutes.

## APGAR, VIRGINIA (1909–1974)

---

At a young age, Virginia Apgar, born in Westfield, New Jersey, decided upon medicine for her future career. Apgar majored in zoology, chemistry, and physiology

and graduated with a bachelor's degree from Mount Holyoke College in Massachusetts in 1929. She then entered the College of Physicians and Surgeons at Columbia University and completed her degree in medicine in 1933. Upon graduation, Apgar was selected for a surgical internship at Columbia University, an extraordinary accomplishment for a woman at that time. Her supervisor, the chairman of surgery, Dr. Alan Whipple, encouraged her to study anesthesiology. In 1937, Apgar became the first female board-certified anesthesiologist. In 1949, she was the first woman to be appointed Full Professor in Anesthesiology at Columbia University.

Later that year, Apgar began her specialty in obstetric anesthesia. Emerging concerns regarding immediate newborn assessment challenged Apgar. In an attempt to address this issue, Apgar developed what is now world renown and known as the *Apgar score*. The Apgar score is a simple five-point observation scale that nurses and physicians can use immediately after delivery to assess infants for potential problems. The Apgar score was published in 1953 and has become the international standard for assessment of newly born infants.

In 1959, Apgar left Columbia to attend the John Hopkins University School of Public Health. There she studied statistics as well as public health. Upon completion of a master's degree, Apgar was appointed Director of the National Foundation–March of Dimes (now the March of Dimes Birth Defects Foundation) to assist in promoting public awareness in birth defects. Between 1967 and 1972, Apgar continued as Director of Basic Research of the National March of Dimes Birth Defects Foundation. In addition to many scholarly publications, Apgar coauthored the book, *Is My Baby All Right?* in 1972 with Joan Beck, which dealt with identification of birth defects.

---

## APNEA

---

*Apnea* is a brief pause in one's breathing pattern. When it occurs for extended periods or frequently

during sleep, it may be a cause for concern. Pauses of 20 seconds five or more times per hour in adults indicate the presence of sleep apnea syndrome, whereas the syndrome is diagnosed when pauses of 10 seconds one or more times per hour occur in children 1 to 12 years of age.

There are three types of apnea: obstructive, central, and mixed. Obstructive sleep apnea (OSA) is the most common type of apnea in both children and adults. Estimates of OSA in children range from 1% to 10%. Most have mild symptoms, and many outgrow the condition. Caused by an obstruction of the airway, childhood OSA is associated with enlarged tonsils and adenoids. Problems related to allergies, neuromuscular disease, and craniofacial abnormalities also may be involved. Although obesity is the most common cause of OSA in adults, it is not as frequently associated with childhood OSA. The most common symptom is snoring, although not all children who snore have OSA. Other symptoms are labored breathing while sleeping, gasping for air, sleeping in unusual positions, bedwetting, and changes in color.

Central apnea occurs when the part of the brain that controls breathing does not start or maintain the breathing process properly. This form is very rare in older children and adults. In very premature infants, it is common because the respiratory center in the brain is immature. Even with premature infants, a few short central apneas are normal. Only when these pauses are frequent or prolonged do they become cause for concern.

Mixed apnea is a combination of central and obstructive apnea. It usually begins with a central episode followed by collapse of the muscles in the throat. This obstruction causes the child to struggle to resume breathing.

Treatment for OSA related to enlarged tonsils and adenoids involves surgical removal. Facial reconstructive surgery is required for the small number of patients with craniofacial abnormalities. Weight loss is indicated for overweight children. For those whose conditions do not indicate the above approaches, a continuous positive airway pressure (CPAP) device, used to keep the airway opened, is recommended. Treatment for central or mixed apnea involves the use of a bilevel positive airway pressure device (Bi-PAP). With the Bi-PAP device, the pressure varies during each breath cycle. If the user does not breathe independently, the machine will initiate a breath.

Although children often outgrow mild forms of sleep apnea, particularly central sleep apnea, OSA has serious consequences for development. Infants and

children with OSA are more likely to have elevated diastolic blood pressure, abnormal cardiac function, and decreased muscle tone than are those with no sleep disorders. They are also more likely to be diagnosed with the general condition of failure to thrive. Infants with sleep disorders have reduced levels of alertness, intensity, and activity as well as deficits in reflexes, motor movements, motor symmetry, visual and auditory functioning, balance, and tactile functioning. This suggests that neurological problems may be associated with sleep disorders. Perhaps because of the sleep deprivation associated with all forms of apnea, school-age children with OSA have poor attention spans, intermittent hyperactivity, sleep “spells,” and overall decreases in academic performance. Children with mild hyperactivity behaviors are more likely to have sleep disorders than those with significant symptoms of attention deficit hyperactivity disorder (ADHD), suggesting that some behaviors that result from apnea and other sleep disorders are misattributed.

Current medical thinking suggests that the damage from lack of oxygen that occurs with OSA may be permanent. In addition, apnea of childhood and infancy may progress at faster rates than for adults. Thus, the early and accurate diagnosis and treatment of this disorder are imperative in order to prevent possible extensive and permanent developmental impairments.

## APPLIED BEHAVIOR ANALYSIS

---

Applied behavior analysis is the scientific study of behaviors of social importance. Established principles of behavior, described in large part by B. F. Skinner through his meticulous empirical investigations with nonhuman animals, are applied to the improvement of behaviors about which people in our society care. Applied behavior analysis attempts to understand behavior through precise and reliable measurement of interactions between individuals’ behavior and their environment, while isolating the conditions that create important behavior change.

Unlike approaches in psychology that rely on behavior to provide information regarding hypothetical entities (e.g., a young boy’s aggression is an indicator of low self-esteem or a faulty information-processing system), in applied behavior analysis, behavior itself is the subject matter of interest. Contrary to popular belief, applied behavior analysis does not restrict the variables that influence behavior to those found in the environment outside the skin. Applied behavior analysis acknowledges the influence of genetics and other biological variables and recognizes that biological research contributes to a broader understanding of behavior. In addition, applied behavior analysts consider private events, that is, those events that can be observed by only one person (e.g., somatosensory stimuli), to be real events that can influence behavior. Nevertheless, most applied behavior analysis researchers have looked where the light is good—the environment outside the skin—for variables responsible for changes in behavior, both public and private (e.g., thinking), primarily because these variables lend themselves to objective measurement and manipulation given the current state of technology.

## HOW IS APPLIED BEHAVIOR ANALYSIS RELEVANT TO CHILD DEVELOPMENT?

Because of its ability to describe, predict, and improve important behavior, applied behavior analysis represents a particularly practical approach to understanding children's development. In psychology, development is typically characterized as orderly changes across time. In contrast, Sidney W. Bijou and Donald M. Baer, who contributed greatly to the behavior-analytic approach to development, defined *development* as progressive changes in interactions between the behavior of individuals and events in their environments. Their use of the term *progressive* emphasizes not that development necessarily advances in a linear fashion, but instead that development depends on earlier conditions. This definition shifts the emphasis from a search for time-related variables (e.g., ages and stages) to the behavior-environment processes that produce behavior change.

Much of what is known about child development is collected through normative studies in which population samples are surveyed to determine the most likely age at which a particular skill can be reliably observed (e.g., children learn to walk when they are about 1 year old). These data are essential in determining typical and atypical development. Applied behavior analysis goes beyond this focus on when a particular behavior occurs during one's lifetime, to analyze why and how particular behaviors emerge. In this way, once atypical development is identified, a behavioral analysis will attempt to identify the conditions that will remediate the developmental trajectories of children. In other words, applied behavior analysis attempts to identify and describe the specific learning history and present environmental variables that combine to give rise to specific important behaviors, such as walking, eating with utensils, talking, problem solving, and caring for others in distress.

Many developmental psychologists imbue specific behaviors with great importance because they mark the point of some other, more important change for the individual, such as the passage to a more advanced stage (see the work of Jean Piaget). An applied behavior analysis of development and more traditional approaches to development agree that development is not linear, but instead is punctuated with qualitative changes in behavior. Traditional developmental psychologists often consider these changes to be caused by the emergence of an internal hypothetical structure

(a walking or problem-solving schema) or that the behavior (e.g., understanding that fluids in tall and wide containers may have the same volume) is a product of a particular stage (e.g., period of concrete operations). The applied behavior analysis approach considers the stages to be descriptive, in that they too need to be explained. Therefore, qualitative changes in the rate and form of development are considered to be a product of necessary physical conditions, the child's history of interactions with the environment, and present circumstances.

In summary, an applied behavior analysis approach to development shifts the emphasis from the importance of behavioral topography (what a behavior looks like) and when particular topographies of behavior emerge as a means to infer changes in some hypothetical constructs, to behavioral function, which entails identifying the specific preconditions for the emergence of a behavior. Before describing some of the contributions made by an applied behavior analysis approach to development, a brief review of the applied behavior analysis conceptual system is necessary.

## DESCRIBING AND UNDERSTANDING BEHAVIOR

Principles of behavior are derived from experimental analyses of the behavior of human and nonhuman animals. This literature suggests the existence of two main types of behavior—respondents and operants. Respondents, also known as *reflexes*, were initially described by the Russian scientist Ivan Pavlov in his now famous experiments in which dogs reliably salivated at the sound of a bell owing to the dog's earlier history in which food was presented with the sound of a bell. Respondents are automatic, involuntary, and typically physiological responses (blinking, changes in heart rate) that are a function of preceding environmental events (e.g., loud noise). Contrary to the popular belief that behavior analysis is a stimulus-response (S-R) psychology, applied behavior analysis does not consider all behavior to be respondent or mechanically elicited from environmental events. In fact, respondents make up a small proportion of the behaviors that are the subject matter in applied behavior analysis.

Operants are the important behaviors of everyday life. They are generally what we do—walking, eating, socializing, working, playing—or say. They are the primary behaviors of interest in applied behavior

analysis. Operants are not defined by what they look like (saying, “Excuse me,” raising a hand in class, making eye contact, or yelling across a noisy room); they are defined by their common consequences (attention). The effects or consequences of an operant on the environment are responsible for determining the future probability of that behavior. In other words, operants, unlike respondents, are thought to be sensitive to their consequences. If a behavior results in a change that is an improvement for the individual, then that behavior will be more likely to occur in the future. This is the process of *reinforcement*. An infant’s raising and moving her arm is reinforced by music and the mobile’s movement, if under similar conditions, these behaviors occur again. By contrast, if a behavior results in a change that is worse for the individual, then that type of behavior will be less likely to occur. This is the process of *punishment*. Operant behavior and its associated consequences also occur in a context, and therefore, events that precede operant behavior come to influence its occurrence through their association with its consequences. For instance, a child may learn that crying will only result in a bottle when her mother, but not when her brother, is present. Behavior occurring in a context makes up what is known as a *contingency*. An analysis of a behavior involves identifying relevant aspects of a contingency—what are the momentary conditions that make the reinforcer valuable (referred to as *establishing operations*) and clearly available (referred to as *discriminative stimuli*), and what are the consequences that either maintain (reinforcers) or suppress (punishers) important behaviors?

### APPLIED BEHAVIOR ANALYTIC CONTRIBUTIONS TO CHILD DEVELOPMENT

Understanding child development entails careful observation and description of important behavior in relevant environments in order to discover the necessary and sufficient learning histories that give rise to important behaviors. These “functional analyses” have been used to understand how children develop motor, language, and social skills, as well as problem-solving and moral behaviors. The behavior-analytic conceptual system and the concept of reinforcement in particular were invoked by Donald M. Baer to explain the qualitative changes in behavior described in many normative developmental studies. He described how, at various points in time, children

learn particularly important behaviors, referred to as *behavioral cusps*, which bring the child in contact with a variety of reinforcers for new behavior. An example of a behavioral cusp is learning to walk, which permits the toddler to see and touch (and taste!) things that were previously inaccessible. This, in turn, leads to improved play, greater social interactions, and so on.

Understanding the conditions under which important behaviors emerge has contributed to the conceptualization of child development, but perhaps more important, it has allowed for applied behavior analysts to solve a wide range of problems for children with learning and developmental disabilities. Behavior analysts have developed highly effective interventions for severe problem behaviors exhibited by children diagnosed with autism or other developmental disabilities, childhood eating disorders, and mental illnesses such as depression. From preschool classrooms to middle school, from language to leisure skills, and from community involvement to quality of life, behavior analysts continue to explore, attempt to understand, and enhance development in a variety of socially important arenas.

## APTITUDE

---

*Aptitude* is a very complex term with different meanings and uses. According to *Merriam-Webster’s*

*Collegiate Dictionary* (2003), aptitude can be defined as (1) an inclination, tendency, or a natural ability; (2) a capacity for learning; and (3) general suitability. The most common definition of aptitude involves an innate ability to perform an activity or task. It is, in essence, the predisposition we all come into the world with to do well in certain areas and maybe not so well in others. This ability supersedes environmental variables and “nurture”; we are born with a certain aptitude for particular domains, such as music, drawing, language, and so forth. Aptitude refers to a generalized ability to learn; the environment may contribute to us being able to manifest this ability but is not responsible for instilling it, if it was not present at birth.

Over the years, there has been much confusion surrounding the terms aptitude, achievement, and intelligence. These constructs are closely related, and often they have mistakenly been used interchangeably, especially in the educational setting. It thus becomes important to understand how these constructs differ. After many transitions throughout the history of psychological assessment, intelligence tests now assess generalized ability, learning that occurs in a wide variety of settings, and acquired experiences (e.g., verbal reasoning skills, spatial perceptual abilities, memory); achievement tests, such as reading and mathematics tests, seek to measure the specific learning that has already taken place in school or at home; and aptitude tests attempt to measure the individual’s capacity to be successful at a particular task (e.g., the Scholastic Aptitude Test attempts to measure how well an individual would perform in a higher education setting).

How do we measure aptitude, given that it is such a general and broad term? Aptitude tests are structured, systematic ways of evaluating how people perform tasks or react in different situations. They are characterized by standardized methods of administration and scoring, with the results quantified and compared with how others have done at the same tests (norms). Furthermore, aptitude tests are administered under timed conditions.

Aptitude assessment is widely used in career counseling because the process seeks to help the individual identify particular professional areas in which they might be successful. For example, the individual might take a variety of tests measuring different areas of ability and skill in order to identify those skills and abilities that not only are of interest but also are relatively well developed. Following the results, the individual then may choose a particular career more

closely affiliated with her or his identified strengths. Scores can be used in a variety of ways. In the employment arena, a prospective employer might have determined a particular score that must be achieved in order for the prospective employee to be considered for employment or for advancement.

Often, under the auspices of aptitude assessment, individuals may be administered Personality Questionnaires that may be used to ascertain reaction to particular situations, such as measuring the attitudes of an individual. Generally, these questionnaires are not timed, nor do they have right or wrong answers. As mentioned earlier, more traditional aptitude tests are typically designed to assess an individual’s ability to learn the skills necessary to succeed in a particular endeavor.

In conclusion, aptitude can be thought of as natural talents, special abilities, or the capacity to learn—traits that are considered highly stable over a long period of time. Currently, aptitude tests are used to determine how successful an individual will be at a particular task or which areas of strength exist within the individual’s skill set that might be helpful in making career or other decisions. Accurate development of a genuine understanding of one’s aptitude is a critical step that may well lead to more lifelong satisfaction.

## APTITUDE TESTS

---

Aptitude tests are standardized instruments assessing specific cognitive, perceptual, or physical skills. These tests are frequently used in industry to inform decisions about hiring, placement, and advancement. In addition, aptitude tests are used in selection procedures for college, professional programs, and career

planning. Aptitude tests are also useful for program evaluation and answering research questions based on scientific inquiry. In most cases, aptitude tests are administered in group format.

Although there may be some overlap in skills assessed, aptitude tests differ from intelligence tests primarily in their purpose and scope. Whereas intelligence tests assess global ability, aptitude tests target a specific domain or set of domains. In fact, aptitude tests were originally derived from subcomponents of intelligence tests. The development of aptitude tests corresponds with the discovery of a statistical technique called *factor analysis*. Using factor analysis, relationships among various items are revealed. These interrelationships are grouped together to create a test assessing specific skills or abilities.

Hugo Munsterberg and Walter Dill Scott were two of the earliest contributors to the creation of modern-day aptitude testing. Before World War I, Munsterberg's research resulted in the prototype for career-based aptitude tests described in his industrial psychology textbook, *Psychology and Industrial Efficiency* (1913). Scott's 1915 landmark article, "The Scientific Selection of Salesmen," called for the use of aptitude tests to identify the most highly qualified personnel. In 1928, Clark Hull published *Aptitude Testing*, in which he advocated for a more objective approach to vocational guidance.

Both World Wars I and II sparked an increased interest in developing tools for applied work in psychology. In particular, the Army's need for an efficient method of selecting individuals for a range of task-specific jobs spurred the development of the Army Alpha and Beta tests to aid in decisions about military placements. The Army Alpha was administered in written form, and the Army Beta used a nonverbal format. The results of these tests were used to determine suitability for specific work (i.e., artillery, flight engineer, navigator, or potential leader). Also during this time, consulting firms began to specialize in publishing tests to aid in industry. In addition to World Wars I and II, other momentous events in the United States stimulated the advancement of aptitude test development. For instance, attention to fairness in employment practices was heightened by the passage of Title VII of the 1964 Civil Rights Act. The passage of Title VII led to practices in aptitude test construction and use that minimized test bias. However, debates about the fairness of using aptitude tests to make employment and admission decisions about minority groups continue.

The Differential Aptitude Test (DAT), a popular multiple-aptitude battery to guide vocational and academic planning, consists of eight independent tests addressing several areas of aptitude, such as verbal reasoning, perceptual speed and accuracy, and language usage. The General Aptitude Test battery (GATB), developed by the U.S. Department of Labor, is another multiple-aptitude battery and includes 12 tests predicting training success in cognitive, perceptual, and psychomotor skills of high school seniors and adults for different levels of job complexity. Although these aptitude batteries are useful in predicting scholastic aptitude, they are less useful in predicting specific technical abilities. Aptitude tests such as the Seashore Tests of Musical Aptitude, the Modern Language Aptitude Test, and the Bennett Mechanical Comprehension Test measure specific sets of skills and are often part of selection or admission procedures. In addition, the Armed Services Vocational Battery (ASVAB) screens potential recruits and assigns personnel to different jobs and training programs. Consisting of 10 subtests, it is the most widely used pencil-and-paper test in existence. Other aptitude batteries, such as the Scholastic Assessment Test and the American College Test, serve as entrance criteria into college, universities, and professional training programs.

## ARTERIOSCLEROSIS

---

*Arteriosclerosis* is the scientific term used to describe what is commonly referred to as "hardening of the arteries." The process most often responsible for this transformation is atherosclerosis, arterial hardening due to the deposition of fat, calcium, cellular debris, and other substances within the arterial

wall. Because of its greater specificity, the term *atherosclerosis* will be used here. The importance of atherosclerosis lies in the fact that it is the process responsible for most forms of cardiovascular disease, the leading cause of death in the United States and many other Western nations. About 60% of all deaths in the United States are completely or partially attributable to underlying cardiovascular disease. Thus, the process of atherosclerosis has important implications for the individual as well as society at large.

Atherosclerosis is a progressive process that has been shown to begin in childhood. The disease is characterized by changes within the arterial wall in the space just beneath the innermost layer of the vessel. Fats migrate into this space, where they are chemically modified; this triggers an accelerating cascade of biochemical events that causes an influx of inflammatory cells, dysfunction of the cells lining the blood vessel, and remodeling of the vessel wall with the deposition of calcium and other substances. The end result is the formation of an atherosclerotic plaque.

As the plaque grows, it impinges on the arterial lumen, thereby reducing blood flow. When the tissue downstream from the lesion becomes sufficiently starved of oxygen and other nutrients, the patient begins to experience symptoms. Initially, this manifests as pain when the oxygen and nutrient demands of the tissue are greatest, that is, during exercise. Decreased blood flow through peripheral arteries causes attacks of lameness and pain in the legs with walking, whereas reduced perfusion of the heart presents as chest pain that radiates to the left arm and shoulder (angina pectoris). By inducing aberrant behavior among the cells that form the inner lining of the artery, atherosclerotic plaques also predispose the vessel to sudden occlusion by promoting the formation of blood clots. Clots formed in an artery supplying the heart result in a heart attack, whereas clot formation in a vessel feeding the brain manifests as a stroke.

Several atherosclerosis risk factors have been identified, including high concentrations of low-density lipoprotein cholesterol ("bad cholesterol"), low concentrations of high-density lipoprotein cholesterol ("good cholesterol"), smoking, high blood pressure, ovarian dysfunction, and diabetes. Some psychosocial factors have also been shown to correlate with the development of atherosclerosis. These include depression, anxiety, personality and character traits (e.g., competitiveness, anger, and hostility), social isolation

and lack of social support, and acute and chronic life stresses. In contrast, submissiveness appears to be protective. It has been proposed that these psychosocial factors affect the development of atherosclerosis through their effects on behaviors (smoking, diet, compliance with therapeutic regimens) as well as by directly modifying the biochemical cascade responsible for the disease. The ultimate development of atherosclerosis is likely the result of several risk factors working in concert through multiple mechanisms.

Treatment of atherosclerosis focuses on risk factor modification. This includes smoking cessation, control of blood sugar for patients with diabetes, blood pressure control, and modification of cholesterol levels. The latter can be accomplished by reducing dietary saturated fat and cholesterol, which decreases bad cholesterol, and by increasing exercise, which increases good cholesterol. Several drugs are also available to modulate cholesterol levels. When cardiovascular disease becomes clinically evident (e.g., heart attack or stroke), treatment focuses on the surgical restoration of blood flow through the atherosclerotic artery using techniques such as angioplasty and arterial bypass grafts. In general, these treatments are aimed at slowing the progression and limiting the consequences of atherosclerosis; much less is known about ways to reverse the process once it has begun.

## ASPERGER SYNDROME

---

*Asperger syndrome* (AS) is the term applied to the mildest and highest functioning end of the autistic (or pervasive developmental disorder [PDD]) spectrum, which ranges from AS to classic autism. People with AS typically display impairments in three areas: social difficulties (i.e., reading social cues, social awkwardness, and poor social skills), subtle communication problems (i.e., pedantic tone of voice and rate of speech, lack of fluidity in speech, difficulty understanding linguistic humor such as sarcasm and irony), and repetitive, rigid, or restricted behaviors (i.e., extreme interest in a topic or activity, insistence on particular behavioral routines). Compared with children with other autistic spectrum disorders, children with AS are characterized as having higher cognitive abilities and relatively normal language functioning.

Although Hans Asperger originally described children with this clinical picture in the 1940s, AS was not officially recognized until 1994 in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*. Within a year of one another, Leo Kanner and Asperger each published papers describing children displaying symptoms in each of the three areas of developmental impairment. Lorna Wing's (1981) paper was the major work to stimulate further review of Asperger's description and its relationship Kanner's. Wing estimated that Kanner's definition of autism applied to only 10% of children with autism, and she called attention to the need for new diagnoses or a broader definition of the disorder. Wing also changed the disorder's name from *autistic psychopathy* to *Asperger's syndrome*.

Research suggests that AS is considerably more common than autism. Whereas autism occurs in about 4 of every 10,000 children, estimates of AS have ranged as high as 20 to 25 per 10,000. Probably about 3 or 4 of every 1,000 children develop the full clinical picture of AS before about 10 years of age. Like autism, AS is much more common in boys than girls. In fact, studies suggest that males are about 5 times more likely to have AS than females are. Because females with AS sometimes exhibit different patterns of symptoms, prevalence figures may underestimate the proportion of females with AS in the general population.

AS is commonly associated with other disorders, including obsessive-compulsive disorder (OCD), attention deficit hyperactive disorder (ADHD), central

auditory processing disorder (CAPD), Tourette's syndrome, hyperlexia (ability to read very quickly, but deficient understanding of verbal language), depression, and anxiety. Although these difficulties commonly appear alongside AS, the syndrome can exist by itself or in combination with other disorders as well.

AS is usually congenital or arises following brain damage sustained during birth or the first few years of life. It is uncommon for AS to appear as a consequence of brain damage suffered later in life. In some cases, there is a clear genetic component (i.e., one parent has AS). Research suggests that the genes involved do not cause AS but instead cause a variety of language and social differences and personality styles, of which the autistic spectrum disorders are the extreme form. The strengths of people with AS can run in families, too. Parents and siblings often have similar talents and interests as those of people with autism spectrum disorders. For example, strong visual-spatial, mechanical, and memory skills are often found in the families of people with autism spectrum disorders. Thus, AS is just one of several possible outcomes of having certain genes.

In addition to a genetic component, a number of other causes for AS and other disorders along the PDD continuum have been suggested, including infection during pregnancy or in the first years of life (e.g., herpes simplex virus); inherited immune system deficiency (e.g., diabetes); and various pregnancy, labor, and delivery complications. Although research supports many of these potential causes, there is absolutely no evidence to support the claim that the measles-mumps-rubella (MMR) vaccine plays a role in AS.

During the first 2 years, there might be nonspecific indications that development may not be quite normal; however, it is not possible at this early stage to determine the future course or the diagnosis. Some of the nonspecific symptoms (meaning that plenty of children who do not go on to develop AS also show these) include sleeping difficulties, poor attention, overactivity or extreme passivity, and poor body adaptability. Before age 2, some children with AS may also display classic autism symptoms such as heightened sensitivity to certain sensory stimuli; stereotypical, self-stimulatory behavior such as rocking; echolalia (excessive repeating of stock phrases previously heard); or difficulty with initiating or maintaining eye contact with others.

The *DSM-IV* requires basically normal early language development for a diagnosis of AS; however,

most children with AS have some delays in the development and understanding of spoken language. For instance, when other people try to communicate with these children, they may stare vacantly or overfixate on people or objects during communication. About one in three children with AS is quite delayed in speech development but begins using complicated phrases only a few months after starting to talk. Also, many children diagnosed with AS are awkward with their motor behavior in that they may be clumsy, have difficulty with balance or with judging distances, have poor fine motor coordination, and have an unusual gait or posture.

Between the ages of 3 and 5, the problems that children with AS have with social interaction and language become more evident. Preschool boys with AS tend to be more interested in toys and objects than their peers. In fact, they tend to withdraw from the group to engage in their own special interests. When they do interact with others, their actions are often awkward or rough (e.g., pushing or taking toys). Unlike boys, girls with AS seem to have more social interests. The girls may fixate on others and may even smell, taste, or bite the people and objects around them. Interestingly, despite the inability of many late preschool-age children with AS to maintain normal social interactions and conversation, many are already good readers by this time.

Although some symptoms are present at earlier ages, AS is rarely diagnosed until the elementary school years. At about age 10, nearly all the characteristic symptoms are present. They tend to naïvely trust others, talk excessively, have difficulty forming friendships, and behave in emotionally inappropriate ways. They are often perceived as “being in their own world” and are limited by extremely narrow interest patterns. Children with AS can have a few interests at once and can change interests over time. The content is not so much the problem as is the way they become absorbed in their interest, leaving little time for anything else.

Another characteristic of AS is an obsession with rituals and routines that can be handicapping in early and middle childhood and very disruptive for the family. The routines are often linked to the child’s special interests, but they can also interfere with daily activities such as eating, dressing, and brushing teeth. Although the *DSM-IV* does not include communication problems in the diagnosis of AS, most researchers believe that both speech and language are affected.

Children with AS may have an excellent vocabulary but have difficulty understanding language in context and difficulty carrying on effective conversations. In addition, articulation problems are also possible. These communication problems may also affect nonverbal skills, resulting in inappropriate body language, poor facial mimicry, and a fixated gaze. Motor control problems continue to affect children with AS throughout adolescence.

Although people with AS face major difficulties, they also have tremendous strengths. They tend to have good general IQ, excellent rote memory, perseverance, and perfectionism. Thus, it is typically important to have appropriate education and treatment to ensure the best possible development for children with AS. Individuals with AS who have serious problems in the area of psychosocial adaptation may need a competent diagnostic workup. Most children with AS are able to function well in “normal,” yet highly structured and predictable classrooms. To ensure the best outcomes, there should be a great deal of collaboration between parents, teachers, and other school officials (e.g., school psychologists) to determine the specific educational needs of each child. With training, other students can help teach children with AS socialization and communication skills. Social skills training can help people with AS and can also help facilitate communication with others. Individual talks with a psychologist or doctor may also have a positive effect, especially in times of depression or social isolation. Group sessions may also benefit older children and adults with AS.

As for medication, research has not indicated one pharmacological treatment that can effectively treat the basic impairments of AS. However, medications can often help treat some of the problems associated with AS. Serotonin reuptake inhibitors (SRIs) such as citalopram, sertraline, fluoxetine, fluvoxamine, and paroxetine can effectively treat mild to moderate depression, social phobia, and extreme rigidity and obsessive-compulsive symptoms for some AS children; others find antidepressants (e.g., imipramine and amitriptyline) and antianxiety medications to be more effective in treating these kinds of symptoms. Mild to severe ADHD symptoms can often be alleviated by central nervous system stimulants.

**ASSIMILATION**

---

In Piaget's theory of cognitive development, the purpose of children's thinking is to help them adapt to the environment in increasingly efficient ways. The techniques children use to adapt to the environment are called *schemes*. Schemes are action patterns that children transfer or generalize by repeating them in similar circumstances or in meeting recurring needs. A scheme can be a relatively simple pattern of actions, such as a baby grasping and shaking a rattle, or it can involve a complex series of actions, such as those used by an older child taking up a bat and swinging to hit a ball. Children, regardless of their age, have sets of schemes that are known to and used by them. For infants, schemes are largely reflexive (grasping an object laid in the palm), but as children mature, reflexive schemes are enlarged and enhanced as additional sensorimotor abilities develop. When children experience a need or a new stimulus in the environment, they take stock of the schemes already developed to determine how the need might be met or the new stimulus

explored. When a match between the need or stimulus and an existing scheme is found, adaptation has occurred. If, however, a match cannot be identified, children proceed to either *assimilation* or *accommodation* to achieve adaptation.

Adaptation is a process of limited change—limited because only some things actually change during adaptation; other things remain the same. When children assimilate, it is their schemes that remain largely the same. During assimilation, children act on the environment or objects in the environment to make them fit into their existing schemes. Piaget believed that play is basically assimilation because during play children are acting on what they already know. Rules for games, roles in dramatic play, and toys and play equipment give children the opportunity to practice previously acquired schemes for social interactions and pretend responsibilities. For example, a child playing firefighter uses what he or she has learned from books, television, and visits to the fire station to act out the role of firefighter. In omitting the firefighter's training, fitness activities, and routine responsibilities around the station from his or her play, the child has unconsciously modified the role of firefighter to fit into existing schemes. The child has assimilated the role of firefighter, limiting it to only those things he or she has previously encountered.

Assimilation is the action of the child on objects in the environment, whereas accommodation is the action of the environment (objects) on the child. When accommodation occurs, children modify their schemes to fit new information or experiences in their environment. In Piaget's theory, assimilation and accommodation actually work together. During interactions with the environment, children's minds interpret information using existing schemes, but they also refine those schemes somewhat to fit particular experiences. Assimilation will dominate accommodation when children are intent on practicing recently formed schemes. Accommodation will dominate, however, during periods of intense learning and development.

## ASSISTED LIVING

---

Assisted living facilities (ALFs) are a relatively new type of housing for older adults, which provide variable levels of care in a dignified and homelike environment. ALFs fulfill the needs of older adults who are not able to live independently in their own homes but do not require the greater care provided in nursing homes. There is considerable variability among ALFs in terms of housing arrangements, services provided, social milieu, and cost.

Currently, assisted living is the fastest growing segment of the older adult housing industry. There are about 1 million ALF residents in the United States, and that number is expected to continue rising as the population ages.

### CHARACTERISTICS OF ASSISTED LIVING FACILITIES

One of the defining characteristics of assisted living is that it provides residents assistance with activities of daily living (ADLs). Residents can expect to receive at least two meals a day, basic housekeeping services, transportation, and 24-hour access to staff. In addition, most ALFs have activity programs and social events, although the attendance at these events is often quite low. Many of the extra services available to assisted living residents are provided for a fee. For example, many ALFs charge residents for pharmaceutical services, bathing, laundry services, and driving them to medical appointments. The menu of services allows residents to customize their care to fit their needs and limitations. Some care requirements may disqualify someone from living in an ALF. For example, some facilities do not accept people who have behavioral problems, dementia, or urinary incontinence or

need help with transfers (e.g., bed to wheelchair). The lack of uniform policies and services stems from the fact that there is no federal regulation of the assisted living industry; rather, individual states are responsible for regulating ALFs.

### CHARACTERISTICS OF ASSISTED LIVING RESIDENTS

About 75% of residents are female, and a similar proportion of residents are unmarried. The average age of ALF residents is about 82 years. Many older adults move to ALFs after rehabilitating in a nursing home or hospital, but about half move there directly from their own homes. Most ALF residents have some health or mobility problem, which requires assistance with ADLs. In addition, it is rare for ALF residents to drive; therefore, the transportation services are important. Increasingly, many ALFs are caring for individuals with varying levels of cognitive impairment. Most residents stay in an ALF for several years.

### COST

The cost of living in an ALF is highly variable and depends on a number of factors, including geographic region, size of living space (e.g., studio or apartment), extra services, availability of nursing staff, and overall quality of the facility. Most ALF residents use private funds to pay \$1900 to \$3500 rent on a monthly basis. Clearly, the cost of most ALFs is prohibitive for lower- and some middle-income older adults. However, many ALFs are now accepting residents who are on public assistance (e.g., Medicaid), and many older adults will “spend down” their savings in order to qualify for government assistance. The cost of high-quality ALFs often makes them available only to more affluent individuals.

### FACILITY CHARACTERISTICS

There is an average of 50 residents per facility, but the number of residents varies from 12 to more than 100. Most assisted living units are private and designed for one person; however, most facilities also offer a limited number of rooms designed for couples. The average ALF is relatively new and has nicely furnished and decorated common areas. ALFs have become an increasingly safe place to live because of handrails, specifically designed bathrooms, and nonslip floors. All ALFs have a common dining area, and most

have other common areas (e.g., game rooms, sitting rooms, libraries, private dining rooms, and patios).

In most “stand alone” ALFs, the residents can vary the number of services they receive, but they cannot move to another area of the building to get more intensive nursing care. There are also multilevel retirement communities that can accommodate different levels of care. These multilevel campuses offer independent living options (e.g., condominium or cottage), assisted living, nursing home care, and sometimes memory wards for individuals with dementia. Some have called this approach “aging in place,” and it has the benefit of not requiring disruptive moves when someone needs additional care.

Most ALFs transport residents to medical appointments. In addition, most have either an on-site nurse or one that will make regular visits to the community. Although the physical needs of residents are generally being met in ALFs, a number of researchers are reporting evidence that suggest residents’ psychological needs are not being fully met.

## PSYCHOLOGICAL ASPECTS OF ASSISTED LIVING

ALFs and the people who operate them generally do an excellent job of providing for residents’ physical needs. However, because the staff perform many ADLs for residents, many residents do not get the cognitive stimulation necessary to maintain good cognitive and memory abilities. Residents do not necessarily have to make and remember appointments, plan meals, plan social events, remember to take medication, clean, go shopping, or do many of the other daily activities that challenge the mind and exercise the brain. Given the recent evidence in favor of the “use it or lose it” theory of memory and aging, it is important that older adults get enough cognitive stimulation. Some ALF residents live an active life; however, many do not get enough stimulation, which can lead to memory problems and possibly an increased likelihood of developing depression. There is considerable variation in the quality and participation rates of activity programs in ALFs. Therefore, it is important to consider the social milieu of ALFs because that may be related to the likelihood of developing depressive symptoms and also the quality and quantity of cognitive stimulation that residents receive.

The transition from independent to assisted living can be difficult for some residents. Many residents

have experienced numerous losses that affect the quality of their social support networks. For example, because most ALF residents no longer drive, they have lost some of their independence and ability to visit friends and family. The typical ALF resident has lost his or her spouse, many close friends, and family members. It is often difficult for ALF residents to meet other residents once they move into a facility, especially if they are living around people with very different levels of cognitive functioning. Poor social support, in addition to medical problems, can lead to depression among ALF residents. A recent survey found that 25% of ALF residents had significant depressive symptoms, which is lower than nursing home rates, but higher than community dwelling rates of depression. ALF residents with depression are 1.5 times more likely to move to a nursing home than are individuals without depression.

Depression among older adults can lead to impaired cognitive functioning, which can lead to a need for more intensive care. Another risk factor among some ALF residents is memory loss and cognitive decline. Dementia is one of the primary reasons ALF residents are forced to move to facilities that provide additional care. However, high-quality ALFs can help people stay mentally, physically, and socially active.

## ASSISTED SUICIDE

---

Physician-assisted suicide (PAS) is the intentional termination of a human's life, at the explicit request of the one who dies, with the aid of a physician. The so-called "Doctor Death," Dr. Jack Kevorkian, brought attention to PAS when he assisted several terminally ill patients end their lives. Kevorkian was imprisoned for his activities.

Related to PAS is *euthanasia*, from the Greek term for "good death." Euthanasia is generally defined as including *active* euthanasia and *passive* euthanasia. Passive euthanasia is the hastening of death by withdrawing or altering a form of support. This includes removing life support, stopping medical procedures or medications, cutting off food and water, and not giving cardiopulmonary resuscitation (CPR) to a person whose heart has stopped. Active euthanasia is the causing of death of a person by way of a direct action, in response to a request from that person. Active euthanasia is usually accomplished by supplying the person wishing to die with the means to end life, often with the help of a medical doctor. The means may include barbiturates, carbon monoxide gas, or coma-inducing levels of the drug morphine.

The U.S. Supreme Court ruled in two companion cases that the states have the right to decide individually on the legality of assisted suicide. The cases were *Vacco v. Quill* and *Washington v. Glucksberg*, both decided in 1997. Although the Court did not hold that there is a constitutional right to assisted suicide, it did hold that states can pass their own laws dealing with the subject. The Court wrote that patients did have a right to palliative (pain-reducing) care, even if that care resulted in the hastening of death of the patient.

In the United States, only Oregon has legalized physician-assisted suicide. Oregon's Death with Dignity Act, passed in 1996, is a comprehensive piece of legislation outlining the steps patients and physicians must follow to end the life of a terminally ill patient.

From 1998 through 2003, 171 terminally ill patients were reported to have died after ingesting lethal doses of medications. Efforts to pass similar legislation in other states have failed. Thirty-eight states have laws that specifically ban assisted suicide by statute. Six states have no laws regarding assisted suicide; other states criminalize assisted suicide through the common law. Of the states that have no laws regarding assisted suicide, most do have laws prohibiting euthanasia.

According to statistics released by Oregon, men and women were equally likely to use PAS in Oregon. Terminally ill younger patients were much more likely to request and receive PAS than older citizens; 18- to 34-year-olds were 5 times more likely to use PAS than were those 85 or older. Oregon Asians were about 3 times as likely to die by PAS than whites in Oregon. Divorced and never married citizens were about 2 times more likely to use PAS than married and widowed citizens. The use of PAS has been strongly associated with a higher level of education; Oregonians with a bachelor's degree or higher were more than 7 times more likely to use PAS than those who did not graduate from high school. People with amyotrophic lateral sclerosis (ALS), HIV/AIDS, and malignant neoplasms were most likely to use PAS.

The American Medical Association and the American Nurses Association both have official stances against assisted suicide. Both organizations state that allowing health care providers to assist in death violates the ethical traditions of physicians and nurses. No major religions in the United States condone the practice.

Internationally, only the Netherlands allows PAS. Although there is no legislation officially condoning PAS, the laws of the country are written to ensure that physicians who assist a terminally ill patient in dying will not be prosecuted.

## ASTHMA

---

Asthma is a chronic, inflammatory disorder of the airways associated with variable airflow obstruction that reverses either spontaneously or with treatment and bronchial hyperresponsiveness to a range of triggers such as tobacco smoke, cold air, exercise, and strong emotion. It is characterized by recurrent episodes of wheezing, breathlessness, chest tightness, and cough that are usually more pronounced at night and in the early morning.

### ASTHMA PREVALENCE

Asthma is an increasingly common and chronic disorder that affects the health and quality of life of a considerable number of children and adults worldwide. This disease is estimated to afflict more than 100 million people globally; in the United States, 16 million people (7.5% of the population) report having been diagnosed with asthma, two thirds of whom are younger than 18 years. In 2000, asthma was responsible for 4,487 deaths, 465,000 hospitalizations, and an estimated 1.8 million emergency department visits.

Asthma prevalence, morbidity, and mortality increased exponentially among U.S. adults between 1980 and 1999, with a substantial 75% increase in prevalence between 1980 and 1994. Asthma prevalence varies by age, gender, and ethnicity. For example, more children than adults have asthma, and among children, more boys than girls have asthma; however, in adolescence, these rates begin to change, although at exactly what point and by what mechanism this change occurs is not known. Compared with males, adult females have higher asthma prevalence rates and higher asthma-related mortality rates. Recent reports suggest that asthma-related mortality rates have been declining since 1996; however, it is also noted that disparities remain between rates for non-Hispanic whites and other ethnic minority groups, particularly African Americans, in regard to asthma-related emergency department visits, hospitalizations,

and deaths. Several probable factors have been recognized as contributing to these disparities, but identifying interventions to ameliorate their effects has proved more difficult. For example, ethnic minorities are more likely to be poor, uninsured, and undereducated—all factors associated with suboptimal health status, increased morbidity, underutilization of health services, and poorer health outcomes.

Studies have also revealed that asthma is far more common in Western countries than in developing countries; it is more prevalent in English-speaking countries; and as developing countries become more westernized or communities become more urbanized, asthma prevalence increases. These features of asthma prevalence have led to new directions in asthma research other than examining the established risk factors (i.e., allergen exposure and atopy). Recent attention has focused on the interaction between environmental and lifestyle factors in the developed world. For example, the trend toward greater obesity in the developed world has led to a closer scrutiny of an association between asthma and obesity.

In addition, some researchers have begun to examine in utero exposure as well as exposure (or lack of exposure) in the early years that may make an infant susceptible to the development of asthma. Certain issues have emerged as significant in predisposing infants to asthma, such as being born premature, low birth weight, or both, and in utero, as well as postnatal, exposure to tobacco smoke. Research also suggests that a small family size is associated with an increased risk for asthma development. The reason is unclear, but it is suggested that a small family size reduces an infant's exposure to older siblings, in turn reducing exposure to infections and thereby increasing the risk for atopic disease at older ages.

Another explanation for the increase in prevalence that has garnered a great deal of interest is the "hygiene hypothesis." The premise is that exposure to naturally occurring infections and microbes essentially immunizes individuals against asthma and other diseases and that reductions in these exposures during the past century, due to the cleaner living of industrialized societies, has led to the increase of allergic diseases such as asthma. Some support for this hypothesis comes from a large U.S. study that found that previous exposure to hepatitis A and herpes simplex virus 1 infections was associated with less asthma, hay fever, and allergen sensitization.

## ASTHMA DEVELOPMENT

A summary report from a national survey estimated that 9.3 million annual office visits result in a new, principal diagnosis of asthma, and evidence suggests that a large portion of new diagnoses can be attributable to children. In fact, research indicates that asthma onset occurs early in childhood, often before 2 years of age. Epidemiological studies have suggested that there are several different asthma phenotypes that follow a common final pathway characterized by recurrent airway obstruction. Transient wheezing, one phenotype of asthma, for example, usually resolves by age 3 and is not associated with a family history of asthma or allergic sensitization. Nonatopic asthma, another phenotype, is precipitated by viral infection. Many school-age asthmatic children have been found to have a history of airway obstruction their first 2 to 3 years of life, and in many cases, this obstruction is associated with viral infection. Studies reveal that this infection increases the risk for wheezing up to age 10, but then the risk decreases with age and is no longer significant at age 13.

The third phenotype is atopic asthma. Asthma that begins early in life is often associated with atopy, the genetic predisposition for sensitization to allergens; and allergic sensitization seems to be an important precursor to persistent asthma. Half of the cases of persistent asthma begin before age 3, and 80% begin before age 6; evidence indicates that early onset of symptoms is associated with increased severity of the disease and increased bronchial hyperresponsiveness. Moreover, patients with early-onset asthma also have considerable deficits in lung function growth. Thus, research suggests that mild asthma during childhood may resolve, but in most cases, asthma is a progressive condition, especially in children with a severe form of the disease. These findings highlight the need for early treatment not only to control the often debilitating effects of the disease but also to prevent the irreversible structural lung change or airway remodeling that can lead to permanent airway obstruction.

## ASTHMA MANAGEMENT AND TREATMENT

The National Asthma Education and Prevention Program (NAEPP) guidelines are considered the gold standard for asthma diagnosis and management. The guidelines recommend a stepped-care model of pharmacotherapy treatment matched to level of asthma

severity that should determine successfully managed disease and good health outcomes. There are four levels of asthma severity (mild-intermittent, mild-persistent, moderate-persistent, and severe-persistent) that are distinguished by a combination of factors such as lung function and day and nighttime symptoms. The multiple goals of effective asthma therapy are to prevent chronic and bothersome symptoms such as day or nighttime coughing or breathlessness or exacerbations after exertion, to maintain normal or near-normal lung function, to maintain normal activity levels, and to prevent recurrent exacerbations and reduce the need for emergency department visits or hospitalizations. In addition, the patient's asthma should be controlled with the least amount of medication necessary, reducing the possibility of adverse effects.

Asthma medications are categorized into two general classes: long-term control medications used to achieve and maintain control of persistent asthma and quick-relief medications used to treat acute symptoms and exacerbations. Current asthma therapy is based on the concept that chronic inflammation is a major feature of asthma. Subsequently, inhaled steroids, the most potent anti-inflammatory asthma medications, have emerged as the cornerstone of the management of persistent asthma, even in young children. There are, however, many medications that can be used at each level of asthma severity, and it is up to the physician to judge the individual patient's needs and to determine at what step to initiate therapy. The list of medications can be found in the NAEPP guidelines.

Asthma management in children is exceptionally challenging because assessment is primarily based on symptoms and pulmonary function cannot be measured reliably in young children and infants. The approach to asthma control is similar, and the same classifications are used; however, pharmacotherapy can also pose a challenge, given that adequacy of medication delivery is often in question. In addition, there is a limited amount of information on the appropriate dosage of medications for children younger than 5 years; however, recent studies have recognized inhaled corticosteroids as the preferred long-term controller for all levels of persistent asthma in all age groups.

## IS THERE A CURE?

A great deal has been learned in recent years about the pathogenesis and progression of asthma that has

led to new directions in the management of childhood asthma. These directions include the need for early recognition and early intervention with environmental controls and long-term control therapy (inhaled corticosteroids) to prevent adverse effects later in life, but a great deal remains to be learned. It is possible that with the right interventions, the disease could be controlled on a long-term basis and that thus a remission or relative “cure” could be sustained; however, no specific cure as yet has been found for this disease.

---

## ATHLETICS

---

Few aspects of Western culture touch as many people or command as much attention as athletics. Historically, athletics helped shape the beliefs, values, and behavior of many societies. The Greeks, for example, created the Olympic games to celebrate cultural, artistic, and individual excellence. Athletic training was part of every Greek boy’s education and was intended to instill “arête,” meaning a sense of skill, dignity, honor, and valor. Today, many people believe strongly that athletics builds character and helps individuals develop the physical, social, and emotional competencies required to succeed in the modern world.

### TRENDS IN PARTICIPATION

Athletics and organized sport are distinguished from physical activity by their systematic structure and competitive nature. Although there is no precise accounting of the number of youth or adults who participate in sports programs, estimates suggest that 15 to 20 million 5- to 18-year-olds participate in community sports programs and an additional 6 million 14- to 18-year-olds are involved in school athletic programs. Youth sport participation increased substantially over the second half of the 20th century, but recent evidence suggests a leveling or decline in overall rate. Patterns in these rates vary by sport, age, gender, racial or ethnic status, and socioeconomic status.

Although the number of youth playing historically popular team sports of basketball, baseball, soccer, football, and volleyball remains high, only soccer and basketball have increased participation since 1990. Participation in organized athletics peaks in childhood and adolescence, whereas younger children and adults are more likely to engage in sport or physical activity on their own. By age 15, however, 75% of youth drop out of sports. Athletics has always involved more males than females, although this gap is closing. The Title IX legislation of 1972 dramatically

increased opportunities for girls to participate in school-based athletics. Since then, the number of female athletes has increased more than 800%. In nonscholastic sports, however, girls start later (10 years old vs. 8 years old) and drop out earlier than boys. Minority youth of all ages are less likely than whites to be involved in athletics. Lack of opportunity may be a primary factor for this disparity. Although athletic programs flourish in wealthier communities, poor urban communities, which are overrepresented by minority individuals, may not have the financial and social capital to provide adequate facilities, supervision, or programming.

### BENEFITS AND DISADVANTAGES TO ATHLETIC PARTICIPATION

The reasons for and the benefits of participating in athletics cluster into three primary areas of human development: (a) *physical development* (e.g., get exercise and stay in shape, learn and improve physical skills, demonstrate physical competence), (b) *affective-motivational development* (e.g., have fun, be active, do something challenging), and (c) *social development* (e.g., play as part of a team, make new friends, get coach's/parent's approval).

The *Surgeon General's Report on Physical Activity and Health* clearly documented the physical health and fitness benefits derived from regular physical activity, including athletic participation. Youth sports help children stay fit and develop the fundamental motor skills needed for advanced skill development across sports and leisure contexts. Basic skill development promotes positive perceptions about one's athletic abilities and facilitates lifetime interest, enjoyment, and participation in physical activity. Youth who play sports tend to maintain more active lifestyles through adulthood, reducing their lifetime risk for obesity and related health problems.

Conversely, sport participation also carries heightened risk for physical injury. Almost half of youth athletes report having at least one injury during an athletic season. Sixty-five percent of injuries are minor, but at least 3 to 5 million youth suffer some form of sport-related injury each year that is serious enough to require emergency room treatment. Risk for injury is elevated by age (older), type of sport (collision and contact), lack of coach education regarding injury, hazardous field and playing conditions, inadequate equipment, and training errors or poor instruction.

Athletics is a key context for experiencing and expressing emotions, both positive and negative. More is known about sport's influence on negative emotions (e.g., anxiety, shame, anger) than positive emotions (e.g., enjoyment, pride from accomplishments). Young athletes' enjoyment is related to intrapersonal factors, such as perceived competence and approach-oriented achievement goals, and to interpersonal factors of lower parental pressure, more parental emotional involvement, and better teaching environment. Sport enjoyment is also related to positive outcomes such as sport commitment and long-term participation.

In contrast, sport participation sometimes elicits negative emotions such as anxiety, shame, and anger. Sport anxiety is related to the intrapersonal factors of low self-esteem, avoidance-oriented achievement goals, and performance expectations, and to the situational factors of higher parental pressure and greater social evaluation. Youth experiencing high levels of sport anxiety are likely to have more problems with injury, gastrointestinal ailments, and sleep or eating disturbances. They are also more likely to drop out of sports. Sports, as competitive and evaluative contexts, are ideal for helping youth recognize and regulate their own emotions and develop emotional intelligence (e.g., empathy, effective interpersonal skills).

Development of social competence, as reflected in one's peer interactions and peer relations, is also central to the athletic context. Athletes report considerable social benefits of participating in sports, such as making friends, enhancing social skills, and gaining confidence in relating to peers. It is not known, however, whether athletics promotes these more than other structured activities. In general, athletic competence is strongly associated with peer acceptance for children and adolescents. Male and female high school athletes who are participating in traditionally gender appropriate sports are more likely to be rated as popular by their peers. Often, athletes develop a "best friend" friendship with someone involved in their sport or on their team. Help and guidance, emotional support, good conflict resolution, loyalty, intimacy, trust, and prosocial behaviors typically characterize these friendships. Close friendships and cohesive teams, however, can also have negative influence on individuals' sociomoral development. Athletes are more likely to commit aggressive acts or cheat during competition if prevailing team or friends' norms and beliefs condone these behaviors.

## SYSTEMS AND CONTEXTUAL VIEW OF ATHLETICS

The benefit from athletics, particularly for youth, is substantially a function of the quality of the interactions youth have with involved adults (e.g., parents, coaches, officials, and spectators) and the structure and philosophy of the community organizations overseeing sports programs.

Parents exert a powerful influence on youth sport experiences. They are usually the ones to initiate and encourage their children's participation in athletics and have a positive effect on experiences by reinforcing skill development, praising effort, modeling appropriate behavior, and focusing on their children's needs and expectations. Conversely, parents can undermine youth sport experiences by exerting pressure, by behaving inappropriately, and by using unkind words and actions.

Coaches also determine the quality of youths' athletic experiences. Despite their powerful socializing influence, little is known about coaches' characteristics. Most volunteer youth sport coaches are involved because their child is participating. They commonly have some athletic experience, but only about 10% are trained in coaching techniques. Experimental research has indicated that coaches can be trained to use specific techniques for encouraging their players, for helping their players to develop skills, and for avoiding punishment and negative interactions. Youth who play for trained coaches experience less anxiety, higher motivation, higher perceived competence, and greater enjoyment and are more likely to return to play the following year. Trained coaches also help build self-esteem, especially in those players who start the season with low self-esteem. Coaches who use positive praise and instruction frequently and liberally, and eliminate punishing tactics, are more likely to foster the positive psychosocial effects of athletics.

The operating structure and philosophy of the athletic organization are also critical influences. Some youth sports leagues have adopted a more "professional" philosophy that has contributed to a "win at all costs" mentality and to increased competitiveness, expectations, and pressure on youth. Additionally, many young athletes are exposed to values that tolerate disrespectful behavior and cheating. These factors contribute to high rates of negative experiences, "burnout," and dropout. Overall, evidence indicates that the benefits of athletics come not from simply

participating, but from participating in a program in which there are positive interactions with caring, supportive adults and in which the teaching of sport skills and healthy development are purposefully planned and structured.

## ATTACHMENT

---

Very few topics in the field of human development have garnered as much attention as the nature and significance of the parent-child relationship. The theoretical approach to parent-child relationships that has generated the most extensive research, social policy changes, and controversy is attachment theory. At the core of attachment theory is the premise that early relationships are critical for a child's development. First articulated in the 1950s by London psychiatrist John Bowlby, the normative components of attachment theory integrate principles from fields as diverse as psychoanalysis, ethology, and cognitive science. Bowlby later incorporated into his theory a systematic conceptualization of individual differences in parent-child relationships, based on the pioneering work of his colleague Mary Ainsworth at Johns Hopkins University. Empirical research on attachment has since exploded and continues to be central to the study of socioemotional development across the life span.

### HISTORICAL ROOTS OF ATTACHMENT THEORY

During his training as a psychiatrist in the 1930s and 1940s, Bowlby's interest in the importance of

early experiences with caregivers was sparked by a growing collection of clinical case studies, including his own observations of juvenile thieves. These reports revealed that some individuals who had experienced lengthy or repeated early separations from their parents were later observed to be superficially and indiscriminately friendly, emotionally flat, and aggressive; failed to form meaningful emotional connections to adults or peers; and often lied and stole. These retrospective findings complemented the results of prospective studies of children's behavior during separations from parents, documented most memorably in a series of films by Bowlby's collaborator James Robertson. These reports revealed that children older than 6 months who were separated from their parents progressed from an active phase of protest, during which they cried and called out hopefully for hours or days, to a passive phase of despair, during which they sobbed weakly and refused food and comfort. Some children then entered a phase of detachment, during which they became generally aggressive as well as superficially and indiscriminately friendly. Upon reunion with parents, even children returning to loving homes exhibited a period of unusual clinginess and hostility that lasted weeks or months; those who had become detached also temporarily failed to recognize the previously preferred parent. These findings on early separations were further complemented by studies of children reared in institutions without consistent caregivers. These children often suffered difficulties in forming selective emotional ties and, in some cases, also suffered other behavioral or psychological disturbances that persisted even after adoption.

Bowlby summarized this collection of findings in a report to the World Health Organization in 1951, concluding that stable early relationships with caregivers are as necessary to a child's mental health "as are vitamins and proteins for physical health." The evidence presented in this report initiated social policy changes that emerged over the subsequent decades. For example, parents began to be allowed to stay in the hospital with their ill children, prospective adoptive parents began to be encouraged to adopt children as early in life as possible, orphanages began to provide more personalized care for their children, an organized foster care system emerged, and parents lessened their casual temporary use of residential nurseries. In the wake of his report and the ensuing policy changes, Bowlby turned his attention to

explaining the phenomena he had documented, carefully examining existing theoretical views.

Psychoanalysis emphasized several issues relevant to the nature and significance of the early parent-child relationship. First, many psychoanalysts emphasized that psychological disturbances emanated not from real experiences but from unresolved fantasies related to parents. However, a group of psychoanalysts who came to be known as *object relations theorists* challenged this view, drawing on the findings discussed earlier. Despite this challenge, these clinicians nevertheless retained allegiance to psychoanalysis by explaining the influences of early experiences using other key aspects of the theory. They asserted that the ego—responsible for the development of emotions, intelligence, language, and the control of bodily functions—developed based on the mother satisfying as well as frustrating the infant's biological drives such as hunger. They asserted that the emotional ties that infants form to their mothers were, in fact, a secondary by-product to the reduction of the hunger drive. In addition, these psychoanalysts did not believe that children had the cognitive capacity to mourn. Thus, as long as an infant had caregivers who could satisfy and frustrate his or her biological drives through consistent personalized attention, these caregivers could be interchangeable.

Other contemporary views downplayed the importance of an emotional bond to a consistent caregiver altogether. The biological-maturational perspective, popular within the eugenics movement and among psychologists concerned with developmental milestones, viewed the child as a genetic entity unaffected by external forces. In fact, prominent representatives of this view discouraged early adoption on the grounds that adoptive parents who delayed choosing a child could better identify a child's defects and physical characteristics. Within the biological-maturational perspective, deleterious effects of separation and institutionalization were thought to be due to biological defects in the child.

Proponents of environmental learning views deemphasized the role of emotional bonds for quite different reasons. Early behaviorists viewed parental affection as dangerous to the development of a child's character because, for example, it reinforced bothersome behaviors such as crying. Consequently, these theorists advised parents not to hug or kiss a child, pick up a crying child, or feed on demand. In the wake of the findings on institutional care, later learning

theorists proposed that “maternal” deprivation was simply stimulus deprivation. Specifically, these researchers suggested that children separated from parents experienced psychological and behavioral problems not because they lacked emotional bonds but because they lacked an important source of perceptual input and reinforcement.

Bowlby concluded that none of these theories adequately explained the research findings on early separations and institutional care. Consequently, he devised a new theory of the parent-child relationship. First proposed in 1958 in an article titled “The Nature of the Child’s Tie to His Mother,” then expanded and refined in his trilogy *Attachment* (1969), *Separation* (1973), and *Loss* (1980), Bowlby’s theory integrated his training in psychoanalysis with evolutionary biology, ethology, control systems theory, and cognitive science. Bowlby proposed that specific emotional ties to parents are primary and based on survival—not secondary by-products of feeding or perceptual stimulation. Bowlby further proposed that caregivers are not interchangeable and that real experiences influence behavioral and psychological functioning throughout the life span. Over the past three decades, many researchers have contributed significant insights and nuance to Bowlby’s theory.

## ETHOLOGICAL ATTACHMENT THEORY

The crux of attachment theory is that all infant ground-dwelling primates possess a biologically based attachment behavioral system that evolved through natural selection to promote survival. Unlike other animals who flee to a burrow or a den for protection, young primates are completely dependent on the care of older members of their species for protection from predation, starvation, freezing, and other dangers. By the time they are 6 to 9 months of age, almost all infants have formed enduring emotional ties, or “attachments,” with one or a few specific significant caregivers who serve these protective functions by virtue of their own caregiving behavioral system.

The attachment system functions to automatically motivate an infant to seek physical proximity to an attachment figure in times of threat—to use the attachment figure as a haven of safety. Threats that activate the attachment system may be internal, such as illness or fatigue, or external, such as darkness or an approaching animal. Many fears are thought to be based on the presence of one or more biologically

based natural clues to danger, such as being alone, strangeness, rapid approach, and sudden changes in stimulation. The activation of the attachment system is terminated either by the elimination of the threat or through proximity to the caregiver—achieved through social signals and behaviors as superficially diverse as crying, smiling, vocalizing, approaching, following, and clinging.

The attachment system works in conjunction with several other biologically based control systems. In times of threat, attachment is activated simultaneously with the fear system, which motivates the individual to flee from the source of alarm. Because the attachment and fear systems both function in the service of immediate survival, their activation typically takes priority over other behavioral systems in times of threat. However, in the absence of threat, activation of the attachment and fear systems is typically replaced by activation of the exploration and affiliation systems. Exploration and affiliation are crucial to long-term survival because they allow the infant to learn about and engage in the physical and social environments. Under these nonthreatening circumstances, the infant uses the attachment figure as a secure base for discovering the world—keeping the attachment figure nearby lest threat reemerge. Under optimal circumstances, an infant achieves balance between attachment/fear and exploration/affiliation—focused inflexibly neither on threat nor away from it.

Because protection offered by adults is indispensable for infant survival, almost all infants become attached to their primary caregiver—even when that caregiver is maltreating. The process of forming an attachment typically follows four general phases. Initially, infants nonpreferentially send out social signals such as crying and smiling that elicit care from different adults. Then, in the second or third month of life, infants begin to discriminate caregivers and to develop differential expectations related to the consistency, contingency, and appropriateness of care that they receive. Even in the earliest weeks of infancy, social stimuli are perceived as unique and significant, and it is toward these stimuli that infants direct their social signals. However, infants in these first two phases have not yet developed a well-formed concept of the parent as existing when out of sight and thus are not yet selectively attached. Consequently, infants who are separated from their primary caregivers during these phases do not mourn their loss and respond well to consistent substitute caregivers. Infants who

do not receive a substitute caregiver but rather are cared for in an impersonal group setting often fail to flourish; if these infants are not reunited with their caregivers or never receive a substitute caregiver, they will lack the opportunity to form attachments and may suffer some of the socioemotional or behavioral problems described previously.

Sometime between 6 and 9 months, infants begin to show the first signs of true attachments to those caregivers who have responded consistently and contingently (whether positively or negatively) to their social signals. Although infants often form more than one attachment, they typically prefer one figure to the others. At this time, infants begin to use their attachment figures as a secure base and a haven of safety. In addition, they begin to demonstrate stranger and separation anxiety and to protest separations for days or weeks after they have occurred. These emotional responses are conceptualized as biologically adaptive because they lead infants to engage in behaviors that increase their chances of survival. Specifically, haven-of-safety behaviors oriented toward an attachment figure provide immediate protection, whereas secure base behaviors, stranger anxiety, and separation anxiety function to keep the haven of safety accessible. Likewise, the phase of protest following separation is active and hopeful, involving a variety of social signals oriented toward alerting and drawing the absent caregiver.

Finally, as the infant becomes a young child, he or she becomes increasingly adept at integrating his or her own goals with those of attachment figures as well as negotiating with those figures—promoting the development of a “goal-corrected partnership.” It is this increasingly reciprocal form of attachment relationship that continues to be influential throughout the life span—with parents, very close peers, and significant romantic partners. Although needs for physical proximity are less acute than they were in infancy, cognitive advances allow children and adults to rely increasingly on psychological proximity to attachment figures and, provided that these caregivers have been sensitively responsive, to carry a sense of “felt” security. Whether in infancy or beyond, attachments are a special kind of bond that is based on protection and survival, are long lasting, and are characterized by high emotional involvement. Thus, all relationships cannot be considered true attachments. In addition, not all aspects of relationships are relevant to the attachment system—attachment refers specifically to

aspects related to fear, distress, protection, and comfort and not to aspects such as play, morality, discipline, achievement, or intellectual growth.

Throughout the life span, individuals are thought to form and maintain complementary mental representations of the self, others, and relationships. The content of these models reflects an individual's expectations about how an attachment figure will respond when one is frightened, hurt, ill, or otherwise upset. These expectations are thought to develop largely based on a real history of interactions within those relationships. Although these relationship-specific “internal working models” do not capture every aspect of reality, they allow the individual to make predictions and plan actions within these relationships. Over time, these models are stable as well as dynamic. They resist change because they easily assimilate information that confirms expectations about the self and others. However, working models necessarily transform and update in response to changes in relationships and life circumstances (e.g., parental divorce or unemployment) as well as in response to cognitive and social developments (e.g., increasing capacity for abstract thought and a broadening social sphere). Over the life span, individuals gain an ever-increasing amount of information about different relationships across a variety of domains. The overarching attitude about attachment that emerges from the more specific working models has been termed *state of mind with respect to attachment*. It is these mental representations of relationships that serve as the basis for individual differences in attachment patterns.

## INDIVIDUAL DIFFERENCES IN ATTACHMENT IN INFANCY AND CHILDHOOD

Attachment theory has perhaps been expanded most significantly by a systematic conceptualization of individual differences in attachment behaviors and representations, first identified in infants by Mary Ainsworth in the 1960s and later expanded and refined by other researchers. Between the ages of 12 and 18 months, these differential responses to stress are indexed behaviorally using the “strange situation,” a controlled laboratory procedure designed by Ainsworth. In this procedure, a parent and infant are twice separated and twice reunited in an unfamiliar toy-filled room. This procedure is meant to be just stressful enough to activate the child's attachment system because of the presence of multiple natural clues

to danger (being alone, in a strange room, with a strange experimenter), but not so stressful that the child cannot employ a strategy to cope with the fear. Based on their behaviors within the strange situation, infants are assigned to one of four classifications; three groups were identified in Ainsworth's original work, whereas a fourth group was later added to the system based on work in Mary Main's laboratory at the University of California, Berkeley.

Infants are classified as "secure" when they balance their attention and behaviors between attachment (when stressed by the separations) and exploration (when physical or psychological proximity to the parent is achieved). Even if not visibly distressed, these infants show signs of missing the parent when separated, then are glad to see the parent upon reunion. Infants who are overtly distressed by the separations are calmed when reunited with the parent and are able to return to play. The secure pattern is associated with sensitive caregiving, such that the parent notices the infant's signals, interprets them correctly, and responds to them promptly and appropriately. In low-risk samples worldwide, about 60% of infants are classified as secure, with the remaining infants classified as one of three forms of insecure.

Infants are classified as "ambivalent-resistant" when they show extreme distress at the parent's departure, then are inconsolable and often angry upon reunion, unable to turn their attention away from the parent and back to exploration. Infants are classified as "avoidant" when they show little concern for the parent's departure then avoid the parent on reunion. Although infants displaying the avoidant pattern often appear to focus their attention on exploring the toys, their stress is belied by elevated heart rate and stress hormones as well as decreased quality of play. Ambivalent-resistant and avoidant patterns are associated with a variety of forms of insensitive caregiving, especially inconsistency (in the case of ambivalent-resistant infants) and rejection of infant bids for attachment (in the case of avoidant infants). Both patterns typically are conceptualized as insecure responses to threat and distress, in that they do not allow for the optimal balance of attachment and exploration. However, because these strategies are thought to develop based on insensitive parental care, they are conceptualized as organized and adaptive alternatives to the flexible secure strategy.

An organized behavioral strategy is not evident in a fourth group of infants. Instead, these infants show

any of a variety of unusual behaviors such as freezing in anomalous postures, rocking, and contradictory behavior patterns such as approaching the parent with head averted. These infants are classified as "disorganized-disoriented," and are thought to display a collapse in an otherwise organized behavioral strategy. Consequently, the disorganized classification is always assigned in conjunction with the best-fitting organized strategy (secure, avoidant, ambivalent-resistant)—the strategy thought to collapse. In contrast to the association of organized patterns of attachment with various degrees of parental sensitivity, disorganized infant behavior is predicted by caregiving that is either maltreating or subtly frightening (e.g., quasi-dissociative). Infants are thought to develop disorganized responses to such caregiving because they are placed in a behavioral paradox. When frightened, an infant seeks to flee from the source of threat and flee toward the attachment figure. When the attachment figure is the source of alarm, the infant cannot employ an organized strategy to cope with the fear.

The strange situation has been associated with a wide range of behavioral correlates in childhood and adolescence. Several longitudinal studies, including seminal work in the laboratories of Alan Sroufe and Byron Egeland at the University of Minnesota, have revealed that children and adolescents classified as secure with mother in infancy, compared with those classified as insecure, demonstrate higher levels of empathy, social competence, ego-resilience, self-reliance, internalization of moral standards, and leadership abilities; they also show lower levels of aggression, anxiety, anger, and dependence. Although children classified as insecure in infancy have shown difficulties in many of these areas overall, avoidance and disorganization have, in particular, been associated most strongly with aggression, whereas ambivalent-resistance has been associated most strongly with anxiety and dependence.

In addition to its behavioral and representational correlates, security has been associated with various manifestations of resilience and is considered a protective factor for development. In contrast, insecure attachment is considered a risk factor that, in concert with other factors, may contribute to the development of various forms of psychopathology. Among those later diagnosed with psychopathology, avoidant attachment in infancy, especially when it occurs in conjunction with disorganization, has been most strongly

associated with externalizing disorders such as conduct disorder, ambivalent-resistance with internalizing disorders such as anxiety, and disorganization with dissociative disorders.

The strange situation has served as a source of validation for other indexes of attachment quality, including the Attachment Q-Sort in infancy, as well as an assortment of assessment procedures for children in preschool and early elementary school. Behavioral assessments in childhood typically involve age-appropriate separation and reunion procedures, whereas representational assessments typically involve asking children to respond to hypothetical scenarios presented on picture cards, to engage in doll play, or to draw pictures of their families. However, the literature using these childhood procedures is small compared with literature grounded in the strange situation or the Adult Attachment Interview—the procedure that opened up the now-burgeoning field of adult attachment.

## INDIVIDUAL DIFFERENCES IN ATTACHMENT IN ADULTHOOD

The assessment most commonly used by developmental and clinical researchers to assess attachment in adolescence and adulthood is the hour-long Berkeley Adult Attachment Interview (AAI), developed in the laboratory of Mary Main. The AAI involves describing and evaluating early attachment relationships, loss of attachment figures, and the possible relation between those experiences and later personality development. Unlike the strange situation, the AAI does not assess attachment quality in relation to a single other, but rather assesses an overarching state of mind that is applied to thinking about attachment-related events in the past and present. Furthermore, the AAI is not scored based on experiences explicitly described, but rather on the interview's internal consistency and the speaker's collaboration with the interviewer.

The AAI identifies three organized and adaptive patterns for thinking about threat and distress. Adults are classified as “secure-autonomous” in the AAI when they are able to reflect on positive and negative (even traumatic) memories in a manner that is not excessive in length yet is still complete, semantically consistent, flexible, thoughtful, and valuing of relationships. Individuals are classified as “dismissing” on the AAI when they provide terse discourse and unsupported statements about parents. These interviews often idealize rejecting parents, show an insistence on

lack of memory for childhood, distort rejection as a positive force, emphasize personal strength and independence, and devalue the need for relationships. Individuals are classified as “preoccupied” on the AAI when they provide long interviews full of irrelevant details, digressions, and current anger. Individuals are assigned to “cannot classify” when they exhibit high levels of more than one of these three linguistic strategies.

Adults are classified as unresolved-disorganized on the AAI when they show lapses in speech or reasoning during discussions of loss or trauma that are analogous to the lapses in behavior demonstrated by disorganized infants during the strange situation. Lapses in reasoning include, for example, speaking as though the dead person was simultaneously alive in the physical sense. Lapses in discourse include, for example, falling silent for many seconds then resuming discussion without acknowledging the silence. As in the case of behaviorally disorganized infants, unresolved status in adults is viewed as a collapse of an otherwise organized representational strategy and is always assigned in conjunction with the best-fitting organized category.

Samples worldwide have found AAI classifications to remain stable for up to 4 years and to be unrelated to intelligence, general memory capacities, general discourse patterns, or self-reports of attachment quality. Instead, the AAI consistently predicts the behavior of one's child in the strange situation—the purpose for which the interview was originally designed. Specifically, a parent's secure-autonomous classification in the AAI predicts infant security; a parent's dismissing classification predicts infant avoidance; a parent's preoccupied classification predicts infant ambivalent-resistance; and a parent's unresolved classification predicts infant disorganization. These predictions are thought to be mediated by parental behavior toward the infant across the previous year. In addition, in some middle-class samples, one's AAI classification can be predicted by one's strange situation classification nearly 20 years prior.

Furthermore, the AAI is associated with a variety of mental health variables. Individuals classified as secure-autonomous experience a lower incidence of mental illness overall. In contrast, among those diagnosed with mental illnesses, the dismissing classification has been most strongly associated with disorders involving aggression such as antisocial personality, whereas the preoccupied classification has been most strongly associated with disorders involving hypervigilance to threat

cues, such as anxiety and borderline personality. Among those diagnosed with mental disorders, the unresolved classification has been uniquely associated with dissociative disorders and also is more associated than other classifications with mental illness overall. “Cannot classify” has been found most commonly within samples involving abuse and criminal behavior. Although individuals diagnosed with mental illness typically have AAI transcripts classified as insecure, it is important to note that among individuals with transcripts classified as insecure, most are not diagnosed with mental illness.

### DEBATES AND CURRENT TRENDS IN THE STUDY OF ATTACHMENT

Attachment theory and its methods for assessing individual differences have generated heated debates. For example, critics have directly questioned the validity of the Ainsworth strange situation as an index of the parent-child relationship. One branch of this debate suggests that the procedure is more stressful for some infants than others, based on their different kinds of experiences with separations. This debate grew out of early findings suggesting that infants in a Japanese sample were more likely to be judged ambivalent-resistant than infants in American samples, infants in a North German sample were more likely to be judged avoidant than infants in American samples, and infants in an American day care sample were more likely to be judged avoidant than infants in American home-reared samples. However, samples drawn from cultures as diverse as the United States, Germany, Japan, Israel, and West Africa have shown that there is more diversity in classifications within cultures than between cultures. Specifically, in middle-class samples worldwide, most infants are typically classified as secure, whereas in poverty and abuse samples worldwide, most infants are typically classified as insecure. The specific organized form of insecurity, not whether or not one is secure, is thought to be influenced by cultural practices related to separations and independence. Furthermore, an ongoing multisite American study has revealed that children in day care are as likely to be secure as their home-reared counterparts when that care is of high quality, and that maternal sensitivity in the home is the strongest predictor of their security.

A second branch of this debate suggests that strange situation classification is driven by temperament, not by a history of interactions with caregivers.

However, although biological temperament is manifest in the amount of distress experienced by an infant during the strange situation, this distress is unrelated to the child’s response to reunion with the parent. In addition, an infant may demonstrate a different attachment pattern with each parent; an infant’s pattern can be predicted before the child is even born based on the mother’s AAI; a foster child’s attachment pattern can be predicted by the AAI of a foster mother who is genetically unrelated; and a recent behavioral genetics study of 800 dyads has shown no connection between temperament and strange situation classification. Although temperament does not appear to have direct effects on strange situation classification itself, studies do indicate that it may influence the relationship indirectly when a difficult temperament in the infant is combined with a mother who has low social support and is thus unable to respond to the infant in a consistently sensitive manner.

In addition to critiques of attachment methods, many researchers and members of the general population have raised concerns about basic premises of attachment theory. Because the theory emphasizes the importance of early experiences with specific caregivers and warns of the dangers of separations, many people have been concerned that attachment theory chains women to their homes, blames parents for negative outcomes in their children, and is fatalistic in its emphasis on early development. However, these concerns are based on a misrepresentation of attachment theory. Because attachment security develops through interactions within relationships, primary caregivers need not be mothers, nor even biological parents. Furthermore, attachment theorists emphasize that one’s representations of attachment are constantly updated and can—and should—change over time to adapt to new circumstances.

It is this aspect of attachment theory that represents one of the most exciting frontiers of current research in the field. For example, long-term longitudinal studies following individuals from infancy through young adulthood have begun to emerge, and results have begun to suggest that attachment patterns reflect both continuity and lawful discontinuity. Specifically, in some studies, individuals who were assessed as secure in both infancy and adulthood typically experienced ongoing supportive relationships with parents, those who were insecure at both points experienced ongoing unsupportive relationships, and those who moved from security to insecurity typically experienced intervening

losses and traumas. A related trend in attachment research is the investigation of individuals who begin life in insecure relationships and have harsh childhoods yet emerge as secure-autonomous adults—a phenomenon termed earned security. Potential contributors to earned secure status currently being investigated include supportive relationships outside the family, metacognitive abilities, and forgiveness.

Other current trends in the study of attachment include preventive and treatment interventions to foster security within dyads at risk for insecurity. In addition, clinicians have been using the AAI within a treatment context, for example, administering the AAI before and after treatment or administering adaptations of the interview that index state of mind with respect to the therapist-client relationship. Also at the frontier of attachment research are studies investigating biological processes, including the roles of stress hormones, brain structures, brain activation, and genes. Other studies are focusing on behavioral and representational correlates of the AAI, including its utility for predicting behavior in romantic relationships, responses to subliminally presented threat stimuli, and the processing of information related to threat and distress. Further research seeks to bridge the developmental literature on attachment with the self-report literature on “romantic attachment style” popular in social psychology. All of these studies will contribute to the growth of a theory that has remained strong for more than 50 years.

## ATTENTION

---

Attention is what helps us to maintain perception, thought, and behavior despite distraction. There are many varieties of attention, each with a different purpose and dependent on different brain mechanisms in order to function. Attention can be separated into three main categories: selection, vigilance, and control. There are many theories regarding the mechanisms of different types of attention.

We are exposed to more sensory stimulation at one time than we can process fully. Without attention, we would be unable to sift through it all to process what we must and disregard what is irrelevant. Different sensory impressions compete with each other for our attention. Selection is the mechanism by which the brain's resources are directed toward the processing of relevant information and away from irrelevant distracting information, and in this way, the competition between different sensory stimuli is resolved. There are two main types of selective attention: exogenous and endogenous attention.

*Exogenous attention* refers to attention that is reflexively drawn by the sensory events themselves. For instance, if you hear an unexpected noise or see a flash of light in the corner of your eye, that draws your attention to investigate what just happened. This form

of attention is not conscious, that is, you do not plan to move your attention to the location of the unexpected flash or noise—it happens automatically. Endogenous attention is initiated by your conscious desire to gain more information about something in your environment. For example, looking for a friend in a crowded airport involves moving your attention between faces until your friend is seen. Another example is listening to a conversation in the midst of a crowded party. In this case, you attend to the voice of a single person while filtering out other voices and irrelevant noises. Divided attention is another example of selective attention, but one that requires you to maintain your focus on more than one thing at a time. For instance, while driving, you must balance your attention between monitoring your own steering and speed, while also watching for other vehicles, traffic signals, and hazards such as pedestrians. Adding other tasks to these puts further demands on your attentional system, such as talking to a passenger or on a cell phone, and the chances of having an accident are increased.

*Vigilance*, or *sustained attention*, is the act of maintaining attention on one thing for a length of time without losing focus. As you read this passage, if you are unable to disregard noises and other distractions, then you may not be able to finish the task. A loss of vigilance can also have more severe consequences. Air-traffic controllers must watch their screens for long hours and quickly detect and respond to signs of danger even when fatigued. Driving a car also involves vigilance. Vigilance involves a number of brain regions, including right frontal and parietal cortex and the dorsal anterior cingulate cortex. Dorsal anterior cingulate is involved in resolving response conflict, such as happens when you are trying to pay attention to something and resist distraction.

*Attentional control*, or *executive function*, is the process by which the higher levels of your brain direct the activity of lower levels. There are many forms of attentional control. Planning involves organizing a sequence of behaviors to achieve a goal. Prospective memory involves remembering to do tasks at a specific time, such as paying bills.

There are many theories of attention. Norman's theory of selective attention states that all stimuli, whether relevant or irrelevant, are simultaneously comprehended to some degree. However, only those events that hold the greatest amount of meaningful information are given close attention, with competition between stimuli based on both "bottom-up," or

sensory-driven, and "top-down," or conscious, processes. Broadbent's filter theory is based on the assumption that human information processing has a finite capacity. This filter permits only a limited amount of sensory information to be processed at any one time. This means that if too much information arrives simultaneously, some of the information is placed on hold or rejected. Posner postulates that attention can be divided into three functions: disengagement, shifting, and engagement of attention. These functions are mediated in turn by three core structures: the posterior parietal lobe, superior colliculus, and pulvinar, respectively.

Babies begin their lives primarily with reflexive exogenous attention and develop other forms of attention as they mature. This parallels the development of brain areas involved in these different forms of attention. Babies have many subcortical networks nearly intact at birth or soon after (such as the colliculi and thalamus), which are involved in exogenous attention, but with immature cortical regions, especially the higher-order regions involved in vigilance and attentional control. These brain regions continue to develop well into adulthood. Thus, our attentional control may improve as we grow into adulthood because our brains are maturing. Conversely, because young children lack these brain networks, it may be impossible for them to use these forms of attention until they develop.

Many psychiatric and neurological disorders involve deficits of attention. People with attention deficit hyperactivity disorder (ADHD) demonstrate many inattentive behaviors. They may not pay attention to details, do not seem to listen, do not follow through on instructions, and do not engage in tasks that require attention, and they may make careless mistakes, have difficulty sustaining attention, have difficulty organizing, often lose things, and be easily distracted and forgetful. If these symptoms cause significant impairments for an extended period of time, then the patient is diagnosed as having ADHD. Inattention may also be combined with hyperactivity and impulsivity, although these are considered separate from symptoms of inattention. Many people grow out of these symptoms or learn to cope eventually, but most will carry them through their school years and into adulthood if not treated. The most popular treatment historically has been methylphenidate (Ritalin), which is a mild stimulant, although a number of other behavioral and pharmacological treatments have been

developed recently with fewer side effects. At present, there is some controversy regarding whether or not these inattentive behaviors occur during normal development and should be allowed to persist, or whether they are evidence of a true disorder that needs to be treated aggressively at a young age. A number of other psychiatric disorders also include deficits of attention. Two primary features of schizophrenia include the inability to filter out unwanted stimuli, and the inability to control thoughts and behavior. In fact, schizophrenia may arise in part as a reaction by the patient being overstimulated, owing to a lack of attentional filtering and control. Autism and Asperger's syndromes may also involve a deficit of attention, in which affected people are unable to reduce excessive stimulation and become uncomfortable with situations that others normally find pleasurable, such as close human contact. Obsessive-compulsive disorder (OCD) is another disorder that may involve deficits in attention. Individuals with OCD can have recurrent intrusive and inappropriate thoughts that they cannot suppress and that cause distress. This can be thought of in part as a disorder of attentional control because it involves the inability to control one's own thoughts. Other brain disorders, such as Alzheimer's disease, Parkinson's disease, and Huntington's disease, all involve some deficits of attention.

A number of attentional disorders can occur with damage to specific brain regions. Left hemifield neglect occurs after right parietal lobe injury. Patients with severe left hemifield neglect are completely unable to attend to stimuli in the left visual field. For instance, when asked to draw a picture of a house, they may only draw the right side of the house, leaving the left side empty. Vigilance and attentional control can also be disrupted by damage to the frontal and parietal lobes. Patients with damage to the frontal cortex often appear normal for the most part, but have severe difficulty organizing their behavior and planning for the future.

Attention is something we are born with and that develops naturally over our lifetime. Impairments of attention associated with conditions resulting from brain damage, developmental disorders, or other means can lead to severe deficits in behavior. Some forms of attentional deficits may be improved with drug treatment, such as in ADHD, whereas other forms of attention may be improved with training, such as meditation. Further research may lead to a better understanding of the brain mechanisms of attention in

healthy individuals and of the causes of attentional disorders, which may ultimately lead to better treatments for attentional disorders.

## ATTENTION DEFICIT HYPERACTIVITY DISORDER (ADHD)

---

Attention deficit hyperactivity disorder (ADHD) is one of the most common, most talked about, and most vexing of the psychiatric disorders. Symptoms of restlessness, distractibility, and poor self-control have been recognized since the mid-1800s when Heinrich Hoffman, a German physician, wrote a poem about “Fidgety Phil.” Over time, the disorder has been seen as a manifestation of brain damage, “brattiness,” and poor parenting. Diagnostic manuals have focused on the high level of physical activity, later on the short attention span, and more recently on the inadequate self-control features of the disorder. Few disorders have been surrounded by the controversy about assessment, treatment, and even its very existence!

### DESCRIPTION

The primary features of ADHD are inattention, hyperactivity, and impulsivity. People with ADHD are described as often failing to attend to details, giving up on a task before completion, and having organizational difficulties. Restless, impatient, and intrusive are other common descriptors. However, individuals can show different levels of these features, and therefore, different subtypes of ADHD are currently recognized (e.g., predominately combined, hyperactive-impulsive, and inattentive types). Because these symptoms are part of the human condition, some question the legitimacy of the disorder. Therefore, for a diagnosis of ADHD, symptoms must be so severe that the person has significant difficulty functioning in a variety of settings. Further, the symptoms must be consistently present for at least 6 months, with an onset in childhood. People with ADHD also experience a number of

other symptoms. For example, it is often very difficult for people with ADHD to keep information “in mind” while trying to solve problems or follow directions. They may have difficulty getting started and, once under way, are likely to lose interest or energy to finish the project. Emotional control is often lacking, and intense, but usually brief, emotional outbursts are common. Those with ADHD may have difficulty keeping things to themselves and are excessively talkative. The ability to think of alternative solutions to problems is diminished. Social problems, underachievement, and conflict with authority are common to ADHD.

### CAUSES

Although there are many theories about the cause of ADHD, current thinking has suggested that ADHD is the result of multiple biological processes. First, ADHD has a very strong tendency to run in families, at about the same rate that height does. Second, the genetics seem to lead to differences in brain anatomy (e.g., a smaller frontal area of the brain), function (e.g., underactivity in certain brain areas), and chemistry (e.g., abnormalities in amounts of neurotransmitters). Third, prenatal complications, maternal substance use, brain damage, and lead consumption increase the risk for developing ADHD. Certain psychosocial factors, such as low socioeconomic status, a chaotic environment, and poor parenting, make it more likely that one will be diagnosed with ADHD.

### FREQUENCY

ADHD is a common disorder and one of the most frequent reasons for bringing a child to a professional for assessment and treatment. Although the number of people diagnosed with ADHD varies according to the methods of the study that identified them, the accepted figures are 3% to 5% in the United States. Worldwide rates of ADHD range from 3% in the Netherlands to 20% in the Ukraine. Thus, the data are overwhelming that ADHD exists across cultures. More boys than girls are diagnosed with ADHD, with the ratios again varying according to method and ranging from 2:1 (in community-based investigations) to 6:1 (from clinic referrals). Although there has been recent debate about differences in the presentation of ADHD between genders, it appears that males and females with ADHD show about the same symptoms,

with roughly the same onset, with similar co-occurrence of other disorders, and with the same potential for impairment.

## DEVELOPMENTAL COURSE

The conventional wisdom about ADHD was that it was a disorder of childhood and would be grown out of. We now know that ADHD is a chronic disorder that persists across the life span. When research takes into account the decrease in hyperactivity and impulsivity symptoms that occur with age, 40% to 80% of ADHD children grow into adulthood with at least some impairment in functioning. The appearance of adult ADHD differs from childhood, and most adults who seek treatment for ADHD complain of inattention, forgetfulness, problems focusing, and organizational difficulties. ADHD places adults at risk for relationship problems, job dissatisfaction, traffic accidents, underachievement, and health problems.

The co-occurrence of other disorders is the rule with ADHD. The disorder has a strong association with other disruptive behaviors, and between 35% and 60% of referred children demonstrate defiance, conduct problems, and aggression. Fewer adults (12%–21%) persist in these antisocial behaviors. Anxiety disorders frequently occur along with ADHD and may be even more common with ADHD adults (25%–50%). Twenty to 30% of people with ADHD may also have a mood disorder. It is not surprising that children with ADHD have difficulties in the academic setting. Disorders of learning are commonly found in children with ADHD (10%–50%). Compared with others, children with ADHD, as a group, score slightly lower on intelligence tests and are more likely to repeat a grade, be suspended, and drop out of high school. There is some controversy about the risk that ADHD poses for future substance abuse. One in every two or three adults with ADHD has a problem with alcohol abuse. Although most studies have attributed the increased frequency of substance abuse to the other disorders (particularly conduct problems) co-occurring with ADHD, a recent study has suggested that ADHD carries its own risk, independent of other conditions.

## ASSESSMENT

The assessment of ADHD is a complex process. Given the controversy about ADHD, it is important that those assessing the disorder use professionally

accepted, rigorously researched diagnostic criteria. Further, information should be gathered from a variety of sources, across numerous settings, using diverse methods. First, a medical examination should be conducted to ensure that the behavioral disturbances are not caused by any of a variety of medical conditions (e.g., thyroid disorder, medication, seizure disorder, sensory deficits, genetic syndromes). Next, interviews with the family and important others will cover family history, development, medical history, school performance, work history, current stressors, a detailed description of the symptoms, and the steps that have been taken to resolve them. Questionnaires, some with a narrow focus on ADHD symptoms and some with a broad view of other behaviors, are used to make normative comparisons and rule out alternative disorders. Formal testing can include computerized measures of attention and self-control and tests of memory, problem solving, decision making, and mental efficiency. At times, there may be questions that can be answered by tests of intelligence, academic achievement, or language proficiency. The clinician then assimilates all the information in order to answer the family's questions, including making a diagnosis, if appropriate.

## TREATMENT

In addition to the more traditional treatment approaches, such as medication, behavior management, and classroom or workplace accommodation, there has been much recent interest in alternative treatments such as natural remedies, biofeedback, and dietary supplements. The most effective treatment for ADHD is also the most controversial. Psychostimulant medications, and newer nonstimulants, enhance the effectiveness of specific neurotransmitters and, theoretically, increase activity in the areas of the brain that regulate behavior and attention. The clinical effects of medication include improved concentration, reduced random activity, enhanced self-control, greater academic productivity, and less frequently, reduced oppositional and aggressive behavior. Medication is effective in about 70% to 80% of children and 60% to 80% of adults. The most common side effects of these medications are reduced appetite, headache, and sleep disturbance. Long-term studies have shown that concerns about growth retardation are exaggerated and that there is no increased risk for later substance abuse as a result of the use of medication.

Nonetheless, some parents are strongly opposed to using medication with their children.

The use of behavior management strategies is also very common. The approaches that are most effective are those that address the problems with behavioral regulation. A frequent approach is to provide extra reminders, guidelines, and feedback in order to have rules and expectations that have a greater impact on behavior. This might involve making a list of chores or assignments, posting it in prominent places, and providing frequent and meaningful consequences for efforts that are directed toward the completion of the assignment. Points or tokens are often used to provide immediate feedback and can later be redeemed for rewards. To retain their effectiveness, consequences may need to be more powerful and varied than those used with other children. Intervention should take place when and where the desired behavior is to occur, thus compensating for the individual's difficulties in reflecting on past behavior and thinking ahead.

School environments are often difficult for children with ADHD because the academic demands emphasize their weaknesses. Teachers and parents will often make informal accommodations that support the child with ADHD. For example, these children may be granted alterations in their curricula, take tests in alternate sites that reduce distractions, use daily report cards, have more time to complete assignments, or use assistive technology, such as computers or recorders. At times, formal procedures will establish goals and teaching methods, with accommodations, by which they will be accomplished.

Alternative treatments have received much interest but little in the way of scientific support. Diets and dietary supplements have not been shown to be effective, and the side effects of many herbal remedies remain unknown. Biofeedback, the use of sensitive equipment to monitor subtle changes in the body's activities, has been suggested as a method to alter brainwaves and reduce ADHD symptoms. The claims of biofeedback advocates have yet to meet scientific standards that would demonstrate its effectiveness, long-term effects, or competitive cost.

## ATTENTION SPAN

---

Attention is a component of higher cortical cognitive functioning and refers to a person's ability to (a) detect and focus on general environmental stimuli, and (b) select important environmental stimuli. Once an important stimulus is selected, its relevant or important characteristics must be identified while irrelevant competing stimuli are ignored. To "pay attention," the individual must be able to employ and integrate a combination of visual, visual-motor, language, auditory, kinesthetic, and perceptual motor skills (these are the functional domains). The successful individual will use his or her attention skills to respond effectively to environmental stimuli and cues. Appropriate application of those skills means that the individual is able to make suitable adaptations to those cues, which allows the individual to engage in responses that optimize positive outcomes and minimize negative outcomes.

The ability to focus and sustain attention is normally developed by age 10 years. Youth who experience deficits in one or more of the functional domains or experience delayed maturation in the integration of those domains will most likely experience problems with attention. By age 13, youth have effective attention skills. However, their ability to maintain alertness and awareness, detect novel stimuli, discriminate between various intensities of the properties of a stimulus, recognize changes in stimuli, and sustain attention improves through the maturation process to

adulthood. Attention skills begin to decline in older adults (after 60 years) as they attempt to manage multiple important stimuli.

## ETIOLOGY

Researchers do not know the exact causes of specific attention deficits. The identified causes are diverse and complex and stem from multiple factors, including the following:

1. Damage to the developing brain can occur as a part of heredity, including genetic factors, neuroanatomy, neurotransmitters, and the association between neurological and familial-hereditary factors.

2. Damage can also occur during pregnancy, during birth, or at any stage of maturation of the developing brain (e.g., errors in fetal brain development; tobacco, alcohol, and other drug use, such as cocaine or crack cocaine; complications during pregnancy or delivery; toxins in the child's environment, such as cadmium; subtle disturbances in brain structures and functions; and difficulties in bringing together information from various brain regions).

3. Postnatal exposure to toxins in the environment, chemotherapy or radiation therapy, or deficits in the maturation of visual or perceptual motor skills may impair attention skills.

4. Multiple psychosocial factors can also impair attention skills, including depression and trauma (e.g., exposure to natural disasters, severe physical or mental neglect or abuse, parental violence or conflict, rape, sexual molestation, the violence of war).

## ROLE OF ATTENTION

Attention plays a significant role in the development and function of the following areas: cognitive (short- and long-term memory, comprehension), visual, auditory, language, kinesthetic, perceptual motor, and integrative-adaptive. Attention allows us to orient to conditioned responses (hearing one's name being called, seeing that name written on a paper), and it allows us to recognize danger and alert our other functional domains to prepare for action. Paying attention to a stimulus can allow kinesthetic changes, such as a change of body posture; changing direction of a gaze; changes in physiological state (e.g., brainwaves, galvanic skin responses, pupillary dilation,

quickened pulse); and changes in emotional responses (e.g., laughter, anger).

Some events in the environment capture our attention by causing changes in the stimuli around us. Some attention-arousing stimuli are composed of novel, complex, or shocking events in the environment (visual, auditory, or physical). A change in the physical properties or characteristics of familiar stimuli can also arouse our attention (i.e., variations in intensity, size, color, and pitch).

For example, Mary is watching the birds in a tree outside of her classroom window. The teacher says Mary's name in her regular voice. Mary does not notice or detect her name being called and continues to gaze at the birds in the tree. Mary's teacher remembers that if you want to get a person's attention, you must sometimes vary the physical properties of a familiar stimulus. Mrs. Jones changes the pitch and the volume of her voice and calls Mary's name again. This time, Mary detects the conditioned stimulus of her name being called and shifts her gaze and orients her body toward her teacher and says, "Yes, Mrs. Jones." Now that Mrs. Jones has Mary's attention, she knows that she will have to vary her teaching technique to maintain Mary's attention and compete with the stimuli outside the window.

Some theorists contend that without attention, there can be no learning. The ability to concentrate or maintain attention is crucial to the ability to learn. The variation of stimuli is crucial to prevent habituation in learning situations or in activities in which detection of errors or dangerous defects is essential. Teachers in preschool, elementary, secondary, and adult learning situations are taught to vary stimuli, change their modes of communication (slides, written materials presented using slides, articles, books, audio stories, field trips, didactic lectures using humor, enthusiasm, and response-eliciting techniques).

## HOW IS ATTENTION ASSESSED?

Attention is often measured by a psychologist using several different types of testing instruments, including a mental status exam. These tests assess a person's ability to detect a specific stimulus in the presence of other similar and dissimilar stimuli. The most common methods of measuring attention involve giving the person being assessed bits of information; next, the person is asked a series of questions about that information. The person's responses to the questions will determine whether or not the person was paying attention. For example, Mr. Smith

is assessing John's ability to pay attention and identify relevant information. He gives John a brief story to read on attention and then asks him some specific question about that story. One of the test questions is: "What is attention? Give a one-sentence response."

John writes the following:

Attention is a component of cognitive functioning and refers to a person's ability to detect and focus on general stimuli and to select important environmental stimuli.

John's response demonstrates that he paid attention to the whole question and answered it correctly. However, John might have written the following:

Attention is a component of cognitive functioning and refers to a person's ability to detect and focus on general stimuli and to select important environmental stimuli. The successful individual will use his or her attention skills to respond effectively to environmental stimuli and cues. Appropriate application of those skills means that individual is able to make appropriate adaptations that optimize positive outcomes and minimize negative outcomes.

This answer demonstrates that Johnny did not pay attention to the whole question. He did not follow the second part of the question: "Give a one-sentence response."

## SUMMARY

Attention is a component of higher cortical cognitive functioning and refers to a person's ability to detect and focus on general stimuli and to select important environmental stimuli. The ability to focus and sustain attention is normally developed by age 10 years. Attention plays a role in the development and function of the following areas: cognitive (short- and long-term memory, comprehension), visual, auditory, language, kinesthetic, perceptual motor, and integrative-adaptive. Youth who do not develop this skill may develop a range of developmental problems or disorders.

## ATTITUDE

---

The research of attitudes is probably one of the most controversial, yet fascinating, areas of psychology. Although contemporary psychologists tend to define attitudes as evaluations of people, objects, and ideas, attitude theories and research have looked at attitudes in many different ways and from several varying perspectives. The study of attitudes was already popular in the 1920s and 1930s when they were being studied and developed by well-known psychologists like Thurstone and Allport. From the mid-1950s until the early 1970s, the research of attitudes in general, and of attitude formation in particular, had been approached from several different perspectives, including behavioral, cognitive, and even psychodynamic. However, by the late 1970s and 1980s, the cognitive revolution that influenced psychology in general had a decisive effect on the study of attitudes. As a result, sociocognitive perspectives dominate

today's approaches to attitude research. One of the most widely accepted models that emerged at that time was the sociocognitive tripartite model of attitude structure, proposed by Katz and Stotland. In this model, attitudes are mainly structured by three components—cognitive, affective, and behavioral—that interact to serve as the backbone of the attitudinal model. The cognitive element encompasses all the *information* the individual has about a particular attitude object. The affective component contains the individual's *feelings and emotions*. The behavioral component consists of the overt *actions* (physical or verbal) of the subject toward the attitude object. Each of these components or dimensions is represented as an evaluative continuum that can go from the extremely negative to the extremely positive, resulting in a three-dimensional representation for any particular attitude.

This and other sociocognitive models became dominant at the time and have been very useful in explaining the structure and processes involved in attitude development. However, approaches from the sociocognitive perspective have been criticized for being unable to adequately explain attitude formation and for their lack of predictive value. They are unsuccessful in explaining the low attitude-behavior consistency dilemma and fail to integrate mediating variables such as individual differences in attitude formation, change, and expression. After the development of sociocognitive models, it was believed that attitudes were formed first by acquiring information about the attitude object, then generating an affective evaluation of it, and finally expressing this evaluation with physical or verbal behavior. Therefore, the study of the cognitive and the affective components was regarded as relevant because of their expected predictive value of the behavioral component. However, it was later discovered that the three elements do not necessarily correlate at the individual level, or are not "consistent." Wicker, for example, concluded that there was only a weak correlation between verbally expressed beliefs and actual behavior. The tripartite model, although not entirely refuted, was vigorously attacked. There was great disappointment, and for a while the study of attitudes fell into abandonment.

It was not long, however, before other researchers realized that the problem was that "mediating factors" intervened in the transfer from the belief (cognition) to the emotion or feeling (affection) to the actual manifestation (behavior) of a particular attitude. For example, Triandis found 40 different social factors

influencing the relationship between cognition, affect, and behavior. Still, not all the lack of consistency could be explained by social factors. Some factors had to be intrinsic to the individual. Therefore, some attempts were made to revise the tripartite model while integrating individual factors in the attitude process. Ajzen and Fishbein proposed in their *theory of reasoned action* that the interaction between beliefs, feelings, and behavior were mediated by intention, whereas Zajonc proposed that the weak relation between attitude and behavior could be explained because, for some individuals, it was possible to have an affective response for an object without the need for a cognitive-evaluative process.

Today, the revised tripartite model is again considered the basis for attitude research not only because it is the most consistent but also because it is the one the empirical evidence most supported. Furthermore, new evidence supports the cognitive-affective-behavioral models when controlled for different situational variables.

For example, Eagly and Chaiken proposed a composite model that includes several new variables, such as habit as both an antecedent and a determinant for behavior and individual factors such as self-identity as moderators of attitudes. They further differentiate between attitudes toward objects and attitudes toward behaviors.

In another example, the *theory of planned behavior*, developed by Ajzen and others, proposes that attitudes and traits do have predictive value when, in interaction, they are viewed through the "principle of aggregation": multiple aggregated patterns instead of individual instances of attitude should be the unit of analysis. Meanwhile, these attitude-behavior dyads have to be controlled primarily for four groups of "moderating variables":

1. Secondary characteristics of the disposition
2. Circumstances surrounding the performance of the behavior
3. Nature of the behavior selected to represent the underlying predisposition
4. Characteristics of the individual

It is clear that the tripartite model remains the most empirically supported and popular model for the explanation of attitudes. Furthermore, even among detractors of the model, there is general consensus in

the idea that attitudes are linked to affect, cognition, and behavior. There is still disagreement, however, on whether these three factors are structural components of attitudes, as Katz and Stotland and Rosenberg and Hovland first proposed; evaluative responses, as Fishbein and Ajzen and Eagly and Chaiken thought; or processes, as Zanna and Rempel, Eiser, and Petty and Wegener believe. Most researchers, however, even those who do not concur with a process-like view of the tripartite model, agree that during attitude formation, there are cognitive processes, from the perception of the attitude object to storage and analysis of information about it, affective-evaluative processes, and of course, motor and verbal processes involved in the expression of the attitude.

---

## ATTRIBUTION THEORY

---

Attribution theory is a prominent and widely researched theory of motivation that was developed by Bernard Weiner and colleagues from the University of California, Los Angeles, in the 1970s and 1980s. The focal point of attribution theory is the general human tendency to ask “why” an outcome occurred, especially outcomes that are negative, unusual, or unexpected. For example, imagine a third grader who gets an F on a spelling test. According to attribution theory, the student would then implicitly or explicitly ask: “Why did I fail this test?” Depending

on his or her performance on previous tests and the performance of classmates, the student might variously perceive that the poor grade was due to poor preparation, to bad luck, to the teacher not liking him, or, most disastrously, to his own low academic ability. Although any number of attributions can be enlisted to explain achievement outcomes, ability and effort appear to be the most dominant. In Western cultures at least, individuals attach the most importance to their perceived competencies and how hard they tried. That is, when students succeed, they often say, “I worked hard” or “I am smart.” And if they fail, they are likely to conclude, “I didn’t work hard” or “I am not very smart.”

### DIMENSIONAL THEORY

Because there are so many possible causes of success and failure in so many different domains, attribution theory has focused on the underlying properties of causes, which are labeled *causal dimensions*. Weiner defines three primary dimensions: locus of causality, stability, and controllability. Locus refers to the location of a cause, either internal or external to the subject; stability describes whether the cause is permanent (stable) or temporary (unstable); and controllability reflects whether the cause can be regulated by the individual. For example, low ability (aptitude) as a cause of failure is typically perceived as internal to the person, stable over time, and uncontrollable. Lack of effort, in contrast, is also internal, but more often perceived as unstable and controllable. That is, effort can fluctuate from situation to situation, and people have control over how hard they try. Among the other prominent attributions for failure, task difficulty is external, stable, and uncontrollable and bad luck is external, unstable, and uncontrollable.

### CONSEQUENCES OF CAUSAL ASCRIPTIONS

Each dimension of causality relates to certain psychological consequences. The locus dimension relates to self-esteem and pride. When subjects make internal attributions after failure experiences, they tend to experience decreased self-esteem, but when they make internal attributions after success experiences, they feel greater pride and self-esteem. Because pride and self-esteem have been shown to foster achievement strivings, internal causal ascriptions are desirable and generally motivating following success experiences.

The dimension of stability influences expectancy of future success. When individuals experience success and attribute the cause of their success to stable factors such as ability, they are likely to expect future success, but when they encounter failure and make similar stable attributions, they perceive that future success is unlikely or impossible. Making unstable causal attributions in the face of failure (e.g., “this happened because of bad luck or poor effort”) has been shown to increase subject persistence.

The dimension of controllability relates to emotions such as anger, guilt, pity, and shame. Individuals tend to experience anger when success is thwarted owing to factors controllable by others, and guilt when failure seems due to internal controllable causes such as lack of effort or neglectfulness. Pity is felt when the failure experiences of others are perceived as caused by uncontrollable factors (e.g., lack of ability or handicap), and shame or embarrassment is felt when failure seems due to internal uncontrollable causes such as low ability. When guilt is experienced, goal-directed activity is increased, but shame tends to lead to task withdrawal.

## APPLICATIONS OF THE THEORY

### Self-Serving Bias

Individuals constantly make attributions in their efforts to understand their environment. Yet even the most competent people are not immune to biases or errors in the way that they perceive their causal world. One such error, labeled the self-serving bias, is the tendency to take credit for success but blame others for failure. For example, when a fan returns from a sporting event and a friend inquires, “How was the game?” the person is likely to respond, “We won,” which linguistically evidences a measure of personal triumph for the winning team’s accomplishment, or “They lost,” which squarely places external blame on the losing team’s defeat. Similarly, parents of children with academic problems tend to provide external explanations for their children’s difficulties (e.g., the teachers are inadequate, the curriculum is subpar), but parents of gifted children tend to claim personal responsibility (e.g., their good genetic contribution, use of effective child-rearing techniques). Self-serving biases are often adaptive and are correlated with good mental health. They can become dysfunctional when they lead to poor interpersonal relations, ineffective

problem solving, or undue hostility toward others. For example, one of the precursors of child and spousal abuse is a low threshold for blaming family members for negative events.

### In Teaching

Many studies have substantiated a strong locus–esteem relationship. Investigators, for instance, have found that teachers tend to take the credit when their students perform well by making ego-enhancing attributions, but assign blame to students when they perform poorly by making ego-defensive attributions. By blaming student failure on external causes, such as poor home environment, teachers “save face” and protect their self-images. Interestingly, effective teachers tend to view student learning difficulties and behavior problems as unstable, or temporary, and thus amenable to intervention. When teachers see student failure as potentially avoidable through personal intervention, expectancy for future student improvement is enhanced and teacher persistence is increased. Some have even suggested that teachers’ attributions should be assessed as part of the teacher selection process.

The dimension of controllability has been shown to be associated with certain teacher emotions and behavior intentions. Teachers are most likely to reward students when success is seen as a result of effort, a controllable cause, whereas teachers tend to exhibit more anger, rejection, and punishment when failure is seen as resulting from lack of effort. Teachers are less committed to helping students when they perceive problem causality to be controllable by the students. Teachers’ emotions and messages have also (sometimes paradoxically) been shown to act as ability cues to students. For example, when a teacher expresses pity to a child who does poorly on a test, the student is more likely to think that the teacher believes the student to possess low ability, but if the teacher expresses anger to the student, the student is more likely to internalize a high-ability message: That if the student had tried harder or studied more, they could have been more successful.

### Attribution Retraining Programs

Attribution theory is guided by the belief that causal thoughts (e.g., “Why did I fail?”) guide feelings and behavior. Therefore, changing maladaptive

causal thoughts to more adaptive causal beliefs should result in improvements in achievement-related feelings and behaviors. That line of reasoning has been the basis of a program of intervention research known as *attribution retraining*. Most of the studies have focused on teaching students to attribute their failures to unstable causes that are within their control (e.g., low effort) rather than stable causes that also are uncontrollable (e.g., low ability). Attribution retraining programs have been implemented with both children and college-age students and have proved quite successful. Retrained students have reported more attributions to poor effort than to low ability when they encountered failure, higher expectations for future success, and more persistence in the face of challenging tasks. Although the research has focused on the change from low ability to lack of effort, any failure attribution that is both unstable and controllable would be adaptive. Furthermore, attribution retraining might also be appropriate for success. Some students have benefited from being trained to attribute their success to internal and stable causes rather than external and unstable causes such as unusual help from others or good luck.

### In Peer Relations

Although attribution theory has primarily been applied to academic achievement outcomes, it also has been very useful in the study of social success and failure. In the domain of peer relations, for example, students also ask “why” they have no friends or are the targets of others’ harassment. As in the achievement domain, moreover, some kinds of attributions for social failure might be particularly maladaptive. It has been documented that when victims of peer harassment attribute their plight to internal, stable, and uncontrollable causes, they feel more depressed, lonely, and anxious than if they attributed their harassment to external or unstable factors, such as being in the wrong place at the wrong time. It is evident that victims of peer harassment cope much better if they do not blame themselves for those negative social experiences.

### Attributional Style

Attribution theory concentrates on the situation under study—a person might endorse one type of

attribution in achievement situations but another type when they confront social dilemmas or health challenges. However, some people appear to have a general propensity to explain good and bad events in a particular way. That propensity has been defined as *attributional style*, which allows people to be classified as either pessimists or optimists. People who explain negative outcomes as internal (“it’s me”), stable (“things will always be that way”), and global (“it affects many areas of my life”) are judged to have a pessimistic attributional style. In contrast, those who typically attribute negative events to external, unstable, and specific events are considered to have an optimistic attributional style. Attributions for good events can also be considered pessimistic (external, unstable, specific) or optimistic (internal, stable, global). Research on attributional style has shown that optimists do better in school, enjoy greater work productivity, and have better long-term health.

### FUTURE DIRECTIONS AND CONCLUSION

Attribution research has documented how individuals’ causal ascriptions affect their emotions, motivation, and behavior in a variety of subtle and powerful ways. Most importantly, the model has provided researchers, educational psychologists, sociologists, consumer analysts, and medical professionals with a framework to describe and understand why individuals are motivated to exert effort (or avoid tasks) in a wide variety of contexts. Studies related to causal attributions and human behavior offer an array of implications for parents, students, teachers, school leaders, and employers.

## AUTHORITARIAN PARENTING STYLE

---

Authoritarian style is one of the three original parenting styles Diana Baumrind recognized. In describing parenting styles, Baumrind identified two dimensions of parenting. The first relates to how demanding parents are. This element speaks to parents' levels of strictness or supervision. The other dimension Baumrind acknowledged relates to how responsive parents are. In other words, highly responsive parents are ones who are accepting of and warm toward their children.

Parents who are strict and demanding yet rarely accepting and responsive are categorized as having an authoritarian parenting style. These parents often lack flexibility and offer less give-and-take or compromising with their children. On the opposite end of the spectrum is permissive parenting style, which incorporates a highly accepting technique but also lacks supervision. Authoritarian and permissive parenting styles generally are less desirable than authoritative parenting style, which utilizes a warm but firm technique in parent-child relationships. Although Baumrind initially described only three parenting styles, some literature describes a fourth commonly recognized style labeled *neglectful*. Neglectful parents are those who provide neither supervision nor acceptance.

Authoritarian parents tend to expect and value obedience. They have clear and rigid rules designed to limit their children's freedom. They do not tolerate defiance, and they may employ strict punishment for rule breaking. Instead of teaching their children to make logical decisions, they teach their children to do what they say. In a sense, they want their children to be blank slates.

Although authoritarian parenting often elicits obedience from young children, research shows that several less desirable outcomes can occur when the children reach adolescence. For example, adolescents of authoritarian parents might be anxious and withdrawn because of the fear of their parents. Girls might become overly dependent on others, whereas boys might react aggressively to others. To express dislike of authoritarian parenting style, these adolescents may also enter a period of rebellion in which they learn to believe misbehavior is not wrong as long as their parents do not find out about it. This strategy hinders

communication between the parents and children and undermines the importance of moral reasoning.

However, although the authoritarian parenting style paves a road to some undesirable outcomes, other correlates of authoritarian parenting style are constructive. Studies show that children of authoritarian parents have lower levels of drug or alcohol abuse than do children of permissive or neglectful parents. In addition, these children usually do fairly well academically in their later school years. This case is especially true for children from Asian American families, which tend to adopt a more authoritarian style and also tend to have high regard for academic excellence. Nonetheless, with the exception of Asian American adolescents from authoritarian homes, academic performance of adolescents in authoritarian homes usually falls a bit short of the scholastic achievement of adolescents in authoritative homes. Authoritarian parenting styles can be, but are not always, the most advantageous for the scholastic realm.

Although authoritarian parenting style has the ability to engender both positive and negative outcomes for children, research indicates that authoritative parenting is the most beneficial style for the welfare of children and for achieving rewarding parent-child relationships. This indication is especially true in societies that value change and independence. Authoritarian parenting styles work best in societies such as agrarian-industrial societies that place value on accepting one mapped-out way of achieving goals.

### SUMMARY

Some studies have argued that parenting style influences children's levels of happiness, assertiveness, independence, and aggression even more than attachment style. Clearly, parenting style has an instrumental role in children's development. Individuals' parenting styles often resemble their personalities and therefore typically remain in the same category over time. However, if parents are aware of the positive effects of practicing a combination of warmth and firmness, they might be more inclined to attempt incorporating some authoritative techniques into their parenting styles and therefore increase the likelihood of healthy development for their children.

## AUTHORITATIVE PARENTING STYLE

---

“Parenting styles” are simply one way to think about and classify the many differences from family to family in how parents go about rearing their children. Diana Baumrind, in the early 1970s, formulated a categorization scheme for parenting that is still used today. One’s parenting style is determined by an analysis of where along a continuum of two parenting dimensions a person falls: warmth and control. Warmth is the degree to which parents are understanding, compassionate, and responsive to their children’s physiological and psychological needs. Control is the degree to which parents are involved in regulating children’s behavior through the provision of goals, expectations, behavioral standards or rules, and discipline-authority. Parenting that incorporates a high level of control with a low level of warmth is labeled *authoritarian parenting*. Parenting characterized by high level of warmth and low level of control is labeled *permissive parenting*. Although each of these two styles has strong points, Baumrind believed that the parenting style that facilitates most optimal child development incorporates high levels of warmth as well as relatively high levels of control. She labeled this style *authoritative parenting*.

Authoritative parents are supportive and affectionate with their children. They listen to their child’s

point of view and encourage their child to be appropriately independent and autonomous in the physical and social world. Authoritative parents are clear about what types of behavior are acceptable and not. They reason with their children and, when providing discipline, attempt to convey an understanding of why behavior is inappropriate. Discipline, for these parents, is less about punishment and more about the child learning from mistakes. As a child matures, authoritative parents allow for greater independence while at the same time requiring children to take on greater responsibilities.

Although this entry discusses parenting in terms of categories or types, parents labeled as authoritative are not necessarily authoritative all of the time—there is certainly variability in parenting depending on the situation, but this situational variability is centered on an “on-average” authoritative style. Different children can also elicit different parenting practices. The parent-child dynamic is highly transactional, such that the parent influences the child and the child influences the parent. One style might work best with a certain child, whereas a different style might work for another.

A wealth of research has shown that authoritative parenting is linked with generally positive outcomes for children, especially within middle-class, white families in the United States. Children raised in an authoritative manner are more likely to be socially competent. These children tend to be well liked and cooperative with their peers, have high self-esteem, and show empathy toward others. These children, on average, show relatively few behavior problems at home and school. Authoritative parenting is also linked to greater academic achievement on the part of the child when compared with the other parenting styles. Authoritative parents tend to have expectations for, and place certain demands on, their children, and together with strong parental support and encouragement for achievement, this parenting style appears to drive children to succeed.

During adolescence, the impact of authoritative parenting remains visible. Authoritative parents tend to be the most effective at conveying their personal, religious, and moral values to their children. Children of authoritative parents also show improved behavioral self-regulation skills compared with children reared with different styles, meaning that they tend to be less impulsive, resist temptation better, and engage in fewer at-risk behaviors, such as drug and alcohol

use and sexual promiscuity. It is important to note that this style of parenting can be difficult to maintain because it entails continuous interest, responsiveness, and involvement in children's lives.

## AUTISM

---

Many are familiar with Dustin Hoffman's portrayal of a man with autism in the movie *Rainman*. We laughed as he repeatedly stated that he only buys his underwear at K-mart and were amazed that he could count the number of toothpicks on the floor with a single glance. Yet, we were mystified that he did not know the cost of a candy bar, how to converse with another person, or how to stop hitting himself when he was upset. Rainman did not pick up on the social nuances of everyday life and often had difficulty effectively communicating his wants and needs. He perseverated on topics that were often not of interest to others and had some unusual and repetitive behaviors. Rainman had autism.

### WHAT IS AUTISM?

Autism, one of several pervasive developmental disorders (others include Asperger's syndrome, pervasive developmental disorder not otherwise specified, Rett's disorder, and childhood disintegrative disorder), is a lifelong neurological disability that affects how the brain functions. It is characterized by delayed and atypical social and communication skills, as well as by the demonstration of repetitive behaviors and restricted interests, which begin before 3 years of age. To receive a diagnosis of autistic disorder, an individual must meet the criteria set forth in the *Diagnostic*

*and Statistical Manual of Mental Disorders* (4th edition, text revision; *DSM-IV-TR*). The criteria focus on qualitative impairments in (1) social interactions (e.g., failure to develop peer relationships, a lack of sharing enjoyment with others, and poor social reciprocity), (2) communication skills (e.g., delay in language, difficulty initiating or sustaining conversations, stereotypical or repetitive use of language, lack of make-believe play), and (3) repetitive and stereotypical patterns of behavior (e.g., preoccupations, inflexibility, repetitive motor movements).

Although each individual with autism is different, some hallmark characteristics and behaviors include poor eye contact, need for sameness, fascination with parts of objects, selective listening, repeating the same thing over and over, disliking to be touched, preoccupations, rocking, sensitivity to certain textures, hand flapping, delays in communication skills, lack of pretend play, and difficulty understanding social relationships. Individuals with autism have varying levels of cognitive and language abilities, ranging from significantly delayed to above-average abilities.

The prevalence rates for autism vary. Some speculate that 1 in 3,000 people has autism; others suggest that 1 in 250 has some form of autism. The numbers of individuals diagnosed with an autism spectrum disorder have increased over the past few decades. There are numerous theories on why the prevalence rate has increased so dramatically. The increase might be due to a better understanding and acceptance of autism in society, better tools for diagnosing, and the introduction of the autism category for serving children with disabilities in the schools. Autism tends to affect more males than females, although females tend to be more impaired by the disorder than males. Autism affects individuals of all cultures and socioeconomic levels.

The etiology of autism is not clearly understood. When it was initially diagnosed by Leo Kanner in 1943, autism was believed to be the result of unloving and detached parents. As opposed to environmental contributors, autism is now believed to have a biological cause. Although the exact biological cause is unknown, autism has been linked to brain abnormalities and genetic differences on a variety of chromosomes. Recent research suggests that there is a 3% to 7% chance of recurrence of autism in siblings, including fraternal twins. There is a 60% chance that if one identical twin has autism, so will the other. Autism has also been associated with disorders such as fragile X and tuberous sclerosis. Recently, there has been

speculation that autism is caused by measles-mumps-rubella (MMR) vaccinations, vitamin deficiencies, and food allergies; however, current scientific research does not support these theories.

## INTERVENTIONS FOR INDIVIDUALS WITH AUTISM

There are currently no medical tests to measure the biological markers of autism. Instead, professionals must rely on observations and reports of behavior. There are various measures available to observe and assess the social, communication, and atypical behaviors of individuals with autism (e.g., Childhood Autism Rating Scale, Autism Diagnostic Observation Schedule—Revised, Checklist for Autism in Toddlers, Autism Diagnostic Interview—Revised). Recently, new instruments have been developed to screen for and detect behaviors and characteristics associated with autism in children as young as 12 months old. Skilled clinicians using available instruments can reliably diagnose children with autism as young as 18 months. Early diagnosis is essential to ensure that appropriate interventions are provided while the brain is still developing.

Although there is not yet a cure for autism, effective treatments to decrease the associated symptoms are available. Some of the more popular interventions include using behavioral techniques, particularly applied behavior analysis (ABA). When using ABA, the antecedents and consequences of behaviors are considered to determine the function of the behavior. For example, does the child engage in the behavior in order to avoid less preferred tasks, to obtain a desired object, to gain attention, or as a means of responding to sensory overload? ABA also focuses on breaking tasks into their component parts. Skills are then systematically taught using direct instruction. Frequent, positive reinforcement is offered. This technique is particularly useful if basic skills, such as eye contact and imitation, are being taught.

Another type of intervention for individuals with autism focuses on teaching developmentally appropriate skills within typical, daily activities. These programs often utilize typically developing peers to act as models for the child with autism. Highly structured classrooms with a small teacher-to-student ratio are essential.

Medical interventions, although not a cure for autism, assist in treating symptoms, such as anxiety,

inattention, and obsessive-compulsive behaviors. Medications might include tranquilizers (e.g., haloperidol [Haldol], risperidone [Risperdol]), or selective serotonin reuptake inhibitors (e.g., fluvoxamine [Luvax], fluoxetine [Prozac]). Some of the more controversial treatments for autism include special diets (e.g., gluten-casein free) or high doses of vitamins (e.g., B<sub>6</sub>). Injections of secretin have also been attempted. These various treatments are considered controversial because there is not a research base supporting their effectiveness, particularly in young children with autism spectrum disorders. Information describing their effectiveness is based on informal data only.

In 2001, the National Research Council formed a committee to review existing literature and research on treatments for children with autism. Based on their findings, the committee put together a list of best practices for the education of children ages birth to 8 with autism. Their findings emphasize the importance of early intervention, 25 to 40 hours per week of intense intervention, one-on-one and small-group instruction to meet individual goals, and the use of planned teaching opportunities that focus on developmentally appropriate activities. Inclusion of families in the intervention processes is emphasized. The National Research Council further suggests that the priorities of intervention should focus on increasing (1) functional communication skills (using words, signing, visual supports), (2) social skills (eye contact, imitation, give-and-take of interactions, using communication skills to interact with others), (3) play skills (playing with a variety of toys, including others in play schemes), (4) cognitive development, and (5) strategies to address challenging behaviors.

## CONCLUSION

Researchers are beginning to have a better understanding of the causes and treatments of autism. However, there is still so much to learn. Just as Rainman methodically looked at the world and recorded his observations, so must we if we are to make a difference in the lives of individuals with autism.

## AVERAGE LIFE EXPECTANCY

Life expectancy is the average number of years remaining to an individual of a specified age if the mortality conditions implied by a particular period (cross-sectional) or cohort (longitudinal) life table applied; the former projects the years remaining to all people of a given age, and the latter projects years remaining to all people born in a given year. Life expectancy is widely used as an indicator of mortality conditions because it is based on the mortality experience at all ages and is independent of age structure.

The conventional demographic notation used for life expectancy is  $e_x$ , which denotes the remaining expectation of life at age  $x$ . For example,  $e_0$ ,  $e_{50}$ , and  $e_{85}$  refer to the average number of years remaining to people 0 (newborn), 50, and 85 years of age, respectively. Life expectancy at birth ( $e_0$ ) is the most widely used value, so that where life expectancy is referred to without qualification, the value at birth is normally assumed. High levels of infant mortality may mean that those who survive this high-risk year may have higher life expectancies than the newborns themselves. The inverse of life expectancy at birth ( $1/e_0$ ) gives the per capita death rate in a population. For example, the 80-year life expectancy at birth of contemporary U.S. females implies a per capita annual death rate of 0.0125 ( $1/80$ ).

The increase in life expectancy can be illustrated by data for women in the United States as given in Table 1, which shows the range of life expectancies at

**Table 1** Life Expectancy (Years) Trends in U.S. Females

	1900	1950	2000
At birth ( $e_0$ )	49.0	71.1	79.7
At 50 years ( $e_{50}$ )	21.5	26.5	31.9
At 85 years ( $e_{85}$ )	4.0	5.0	6.9

SOURCE: U.S. Center for Health Statistics.

**Table 2** Life Expectancy (Years) at Birth in Selected Countries\*

	Both Sexes	Men	Women
Kenya	45	46	44
India	64	63	65
Japan	82	78	85
Germany	78	75	81
United States	77	74	80

SOURCE: United Nations, 2004.

\*Estimated by United Nations, 2000–2005. Japanese women currently experience the highest life expectancy of either sex for any country in the world.

birth as well as at middle and old age over a single century in the United States.

Women enjoy life expectancies 2 to 10 years longer than men in most countries, the difference of which is referred to as the life expectancy gender gap. The life expectancy at birth in less developed countries (e.g., Kenya, India) generally is lower than in developed countries (e.g., Japan, Germany, the United States), as shown in Table 2. Japanese women currently experience the highest life expectancy of either sex for any country in the world.

Life expectancy at age 65 is important in the context of social security (Table 3) because it gives the average number of years the average individual will be expected to collect (unreduced) retirement benefits. For example, men attaining 65 in 2000 can expect to live 16.2 years, compared with 12.7 years in 1940. Thus, the increase in time that men can anticipate receiving social security in 2000 relative to 1940 is 3.5 years.

Whereas *life expectancy* at birth is a life-table measure that refers to the average number of years remaining to a newborn or the average age of death in the cohort, *median survival* refers to the ages at which half of all

**Table 3** Life Expectancy (Years) at Age 65 in the United States

<i>Year</i>	<i>Men</i>	<i>Women</i>
1940	12.7	14.7
1960	13.2	17.4
1980	14.6	19.1
2000	16.2	19.3

SOURCE: U.S. National Center for Health Statistics.

deaths have occurred, and the *mode of survival* refers to the age corresponding to the highest frequency of deaths. For example, the *mean*, *median*, and *modal* ages of death for newborn U.S. females in 2000 were 80, 83, and 88 years, respectively. In every population on record, the mode of the length of life is several years higher than the mean, which is pulled down by premature (early) deaths. An additional concept that is important to understand for context is *life span*,

defined in both empirical and theoretical contexts, the former as the “record age” of a species (122.5 years in humans) and the latter as the “hypothetical upper age limit of a species under a specified set of conditions.”

## Brain Development

*The brain is a wonderful organ. It starts working the moment you get up in the morning and does not stop until you get into the office.*

—Robert Frost

---

## BABBLING

---

Babbling is the stage of language development during which children produce speech sounds arranged in nonsensical combinations, such as “bababa,” “deedeede,” or “badegubu.” All normally developing children babble. Parents and family members may view babbling as an endearing but trivial behavior produced by infants; however, babbling represents a stage of language development during which the child is laying the foundation for future adult-like language production.

### THE SOUNDS OF BABBLING

The first vocalizations produced by infants include crying, laughing, and cooing. When infants are between 2 and 3 months old, they begin to coo. Cooing infants produce sounds that most closely resemble the vowels a, e, and o. Cooing may be an extended single vowel as in “oooo” or “aaaa” or a complex series of vowels, “aaaeoooo.” Babbling typically begins by the 6th month. Table 1 provides a summary of the types of utterances produced by the child in the first year.

Between the 6th and 7th months, infants gain greater control of jaw movements, enabling them to produce the vowels i and u and the consonants g and k.

Over time, infants begin producing the consonants m, n, p, b, and d. During this time, infants engage in vocal play. They may produce nonspeech sounds such as squealing, yelling, and growling. They may also produce *raspberries*, which are created when the tongue is extended through rounded lips and air is forced through the mouth.

Between 6 and 9 months, infants begin to combine a single consonant and vowel together in a long repetitive sequence, such as “bababababa” or “deedeedeede.” Such sequences are characteristic of *canonical babbling*. Over time, infants’ babbling becomes more complex. Productions typically involve different syllables produced in the same utterance, as in “badegubu” or “deekidobu.” Such sequences are characteristic of *variegated babbling*. Between the ages of 12 and 14 months, infants’ babbling is likely to contain intonational contours or prosody. Infants may produce streams of speech sounds that have the melody of adult speech. It may sound as though the infant is making a statement or asking a question, even though they are not saying anything meaningful.

### DEVELOPMENT OF BABBLING

There are physical changes that occur in the young infant that make babbling possible. At birth, infants’

**Table 1** Types of Utterances Produced by a Child in the First Year

Age	Type of Utterances
Newborn	Crying
1–3 months	Cooing (“ooo,” “aaa”) Laughing Distinct crying to indicate hunger, anger, or discomfort Vocalizes in response to speech
4–6 months	Single syllables emerge (“ba,” “ga”)
6–8 months	Babbles with duplicated syllables (“babababa,” “dadadada”) Attempts to imitate sounds
8–12 months	Babbles with multiple syllable types (“bagadabu,” “dabuga”) Babbling is produced with sentence-like intonation

vocal structure closely resembles that of nonhuman primates, with a shorter vocal tract and a much higher larynx than adults. Before babbling can occur, the vocal tract must mature, and the infant’s larynx must descend from high in the nasal passage to a lower position in the throat. During the 3 months of life before the larynx descends, infants can eat and breathe simultaneously. Before the larynx descends, infants are incapable of producing complex speech sounds, such as syllables composed of consonant-vowel combinations. Infants are capable of producing cries, clicks, groans, and sighs. After the larynx descends, infants can produce cooing sounds, such as “ooo” and “aaa.” By the age of 4 months, the vocal tract more closely resembles that of adults, and babbling generally emerges. In the months following the descent of the larynx, infants’ vocalizations become more and more complex.

Research has shown that 95% of infants’ babbled vocalizations involve the 12 speech sounds that are most common across the world’s languages: m, d, j, p, h, b, w, t, n, k, g, and y. The vocalizations babbled by all infants are strikingly similar across the world, regardless of the infants’ native language. It is common for infants to produce speech sounds that are not among the speech sounds of their native language. For example, infants reared in English-speaking environments may produce

non-English speech sounds, such as the click sounds that occur in certain African languages. Likewise, infants reared in Japanese-speaking environments may produce speech sounds not occurring in Japanese, such as [r]. As infants mature, more of the speech sounds produced are those speech sounds heard in the environment in the language or languages of the home, and fewer of them are speech sounds from other languages. This phenomenon has been referred to as *babbling drift*.

### WHEN BABBLING IS DELAYED OR DOES NOT OCCUR

An absence or substantial delay of babbling may occur in infants born with certain medical conditions or infants with developmental disorders. For example, infants who have had a tracheotomy typically do not babble and show persistent abnormalities in their vocal patterns if their normal breathing is not restored by the second year of life.

Some infants may be unable to produce speech due to a disorder affecting the motor control system. This disorder is called *apraxia*. Infants with severe apraxia may not coo or babble and may fail to produce a first word. They may attempt to communicate by pointing and grunting. Less severe forms of apraxia may be characterized by a delay in the production of the first word. When words are produced, speech sounds that are difficult to articulate may be consistently replaced with speech sounds that are easier to articulate.

Babbling may also be delayed or completely absent in infants affected by autism. Autism is a disorder characterized by abnormal social development. Autism is typically accompanied by delays in language development and may be accompanied by mental retardation. Those with the severest forms of autism may not speak at all. Those with mild forms of autism may produce some speech, but the amount of speech that is produced is far less than that of the typical infant.

Babbling may be delayed in infants born with Down syndrome, a chromosomal abnormality that causes mental retardation. Approximately 1 in 800 infants is born with Down syndrome each year. Down syndrome children typically experience delays in language development. Down syndrome infants start the canonical babbling stage 2 months later than other infants do. However, when babbling does occur, it is similar to the babbling produced by normally developing infants. Due to abnormalities in the development

of the vocal tracts, palates, and tongues of Down syndrome children, speech production is likely to be challenging for the Down syndrome child.

Babbling occurs without a delay in infants born with hearing impairments. Each year, approximately 1 in 1,000 children is born with a severe hearing loss. The early vocalizations made by profoundly deaf infants cannot be easily distinguished from those made by hearing infants. Deaf infants will cry, coo, and begin to babble. However, deaf infants are unlikely to produce repeated consonant–vowel syllables characteristic of the canonical babbling stage. The amount of babbling and the quality of the babbling produced by deaf infants may be less than that produced by hearing infants. Deaf infants who are exposed to sign language from birth develop sign language skills in the same stages as hearing infants develop speech and listening skills. Signed languages such as American Sign Language (ASL) are unique languages, each having its own rules of grammatical structure. Deaf infants who are exposed to a signed language will produce *manual babbling*—sequences of gestures that can be viewed as language practice. Manual babbling typically emerges around 10 months. In contrast, hearing infants who are exposed to a signed language during the first year of life produce very little manual babbling.

## SUMMARY

Babbling is a routine stage of language development, observed in all normally developing infants. Starting at the 6th month, infants practice the speech sounds that will later be used to form syllables, words, and sentences. Over time, the sequences that are babbled become more complex. By the end of the first year, infants have produced their first words. For infants with certain developmental disorders, babbling may be delayed or absent.

## BABINSKI REFLEX

The Babinski reflex is also known as Babinski's sign or hallucal dorsiflexion reflex, and was first described by Dr. Joseph Francois Felix Babinski (1857–1932), a French neurologist. The reflex is a neuromuscular one elicited by drawing a blunt point (such as a thumbnail or the end of the handle of a reflex hammer) along the outer sole of the foot from the heel to the metatarsal pads and then toward the great toe (hallux). This should be done with light pressure; a painful stimulus is incorrect. The normal (negative) response is downward extension of the great toe and often other toes, often with extension of the ankle. Abnormal (positive) responses include upward flexion of the great toe, fanning of the toes, upward flexion of the ankle, and flexion of the knee and hip. Some or all of these may be present. This is a superficial reflex, mediated by nerves from the fourth lumbar through the first or second sacral segments and involves activation of the tibial nerve. In the absence of tibial nerve palsy, a positive response indicates dysfunction of pyramidal tract motor neurons in the cortex and subcortex, brain stem, and spinal cord.

Babinski's sign is one of a group of primitive reflexes, also known as infantile reflexes. These are present at birth but are normally suppressed by higher neural functions as growth and development proceed. The abnormal upgoing response of the toes or an absence of response may be seen in newborns and infants, but the normal response should emerge permanently by the age of 2 years. Other primitive reflexes include the snout reflex, sucking reflex, and grasp reflex, which, when seen in older children and adults, are indicative of significant cortical neurological dysfunction.

Abnormal Babinski responses may be present in meningitis, head or spinal cord injury, brain tumor, spinal tuberculosis (Potts' disease), hepatic encephalopathy, stroke, amyotrophic lateral sclerosis, multiple sclerosis, some forms of poliomyelitis, and other, less common diseases.

## BABY BOOMERS

Baby Boomers have had a tremendous impact on 20th century history and culture. Baby Boomers are defined as anyone born between 1946 and 1964. In the United States, nearly 30% of the population constitutes Boomers. The increased birthrate in the post–World War II era also impacted Canada, where the generation is known as “boomies.” In Britain, Baby Boomers are simply referred to as “the bulge.” Baby Boomers have left an indelible mark on the modern history of the United States.

Throughout the course of human history, the optimism or pessimism of a civilization can be measured by the birthrate. An increase in birthrate usually represents a more optimistic culture, whereas a decrease may indicate pessimism. For example, a declining birthrate contributed to the fall of the Roman Empire in 476 AD. In the modern era, a similar trend surfaced in France as the birthrate declined in the second half of the 20th century and pessimism reigned, while in the United States the rate of birth skyrocketed, signifying the rise of extreme optimism and the Baby Boomer generation. In 1940, there were about 2.5 million births in America, and by 1946 the number grew to 3.3 million births. The rate continued to rise in the United States from 1955 to 1964 as the birthrate continued to expand, and the rate never fell below 4.0 million each year.

There was good reason for optimism in the United States. Not only did the nation emerge from the Great Depression and World War II virtually unscathed, but the United States would also dominate global politics in an unprecedented fashion. In 1946, the United States constituted 6% of the world’s population, yet it controlled 63% of the world’s industry and 75% of the world’s capital. As the American economy continued to grow in the second half of the 20th century, the Boomers were uniquely positioned to contribute to the expansionism.

The outlook of the Baby Boomers was distinctly different from either of their two predecessors, the Greatest Generation (1900–1929) and the Eisenhower Generation (1930–1945). The postwar world represented tremendous hope and opportunity, and the Boomers sought to take full advantage. The generation experienced the hope and aspirations of the New Frontier of the Kennedy Administration, the Civil Rights and Voting Rights acts, while they also encountered disillusionment in Vietnam and Watergate. The

assassinations of John Kennedy, Martin Luther King, Jr., and Bobby Kennedy left a permanent mark on the usually optimistic generation. The culture, music, and attitudes of the nation were directly influenced by the Boomers. More than anything else, the group contributed sweeping changes to modern America.

The Baby Boomers were also better educated than earlier generations. This was due in large measure to the G.I. Bill. American servicemen used Franklin Roosevelt’s G.I. Bill to obtain college degrees, and this benefit was also extended to Boomers. The Boomer generation was about twice as likely as their parents to be high school or college graduates and nearly 25% of the postwar group earned bachelors’ or advanced degrees. The value of higher education continued as the children and grandchildren of Boomers headed to colleges and universities throughout the United States in unprecedented numbers.

Perhaps most striking of all was the impact that Baby Boomers had and continue to have on the national economy. The Boomers have the highest labor force participation of any generation in American history. Nearly 90% of the postwar generation works—over half of the entire workforce in the nation. Nearly 80% of female Boomers worked, which opened the door for tremendous opportunities. The economic prosperity of the 1990s was due in large measure to Boomers reaching their peak in both earning and spending. Baby Boomers are also less apt to marry, more apt to divorce, and have fewer children than earlier generations.

Baby Boomers have had an enormous influence on modern America. The sudden population growth impacted the nation politically, culturally, and economically. Baby Boomers have left a significant mark on the history of the United States.

—Timothy Crain

## BABY TALK

Babies learn to speak by listening to their caretakers. People help them by modulating the sounds of speech in fundamentally the same way. A topic of much speculation among researchers who study language acquisition is the observation that caretakers consistently address their infants in this unique tone and manner of voice, a form that has come to be known as “baby talk,” “infant-directed speech,” or motherese. Motherese is a linguistic register based on exaggeration of pronunciation and simplification of syntax. It is found in virtually every culture and has certain common characteristics: The sentences are very short, there is a lot of repetition and redundancy, there is a sing-song quality to it, and it contains many diminutive words. It is also embedded in the context of the immediate surroundings, with constant reference to things and goings-on nearby. Certainly there is a social component to this form of speech. Infants respond more positively and listen longer to infant-directed than to adult-directed speech. Furthermore, while researchers disagree over whether exposure to this type of speech is necessary for successful first language acquisition, there is general agreement that motherese contributes to the ease with which infants are able to break into their particular language of exposure.

For the language-learning infant, identifying the components that make up spoken language is a difficult task. Instances of words vary phonetically and acoustically, depending on the discursive, syntactic, and phonological contexts in which they occur. This is in addition to variations introduced by changes in, for example, talker identity and speaker affect. At the earliest stages, word recognition must be guided by features of the individual instances of words themselves. Although it remains unclear precisely which aspects of the auditory signal initiate recognition, acoustic prominence—an important characteristic of infant-directed speech—is one factor that has been considered particularly influential in jump-starting this process. Data supporting this view indicate that infants generally prefer to listen to acoustically salient speech, where “salient” can mean either effectively or emphatically so. Conveniently, the natural form of input to the language-learning child is modified in just such a way.

Infants face another difficulty when it comes to speech segmentation. In fluent speech, words are not

separated by pauses, and the cues that may serve to signal word boundaries vary from language to language. Nevertheless, and despite these challenges, normally developing infants begin to succeed at recognizing words in fluent speech about midway through their first year. This has been attributed, in large part, to caretakers’ tendency to repeat content words when addressing their infants. Repetition of the full form of a word is perfectly reasonable—even expected—in speech directed to infants, and this repetition is quite distinct from the reduction to pronominal form that occurs across mentions of content words in adult-directed speech. Although repetition is often cited as one of many characteristics of speech directed to infants, it is generally viewed as subordinate to the prosodic quality of such speech. While repetition appears to be an important feature in guiding speech segmentation, it is not the aspect of motherese that is most often referred to as influential in language learning. However, given the problems the language-learner faces, it may well be just as important as other aspects of this unique register.

Generally speaking, infant-directed speech involves clear and careful pronunciation, exaggerated intonation, relatively few abstract words, reference to tangible objects that a child can see and touch, and a focus on the actions the child is doing or witnessing. Not only mothers speak motherese. Anybody who communicates with young children will adopt this modified form of speech. And while it is arguably not fundamental to a child’s ability to acquire language, its apparent universality points to its importance in aiding that process.

## BALTIMORE LONGITUDINAL STUDY OF AGING

---

The Baltimore Longitudinal Study of Aging (BLSA) is a major clinical research program in human aging conducted in Baltimore by the National Institute on Aging, National Institutes of Health (NIA, NIH). The events that started the BLSA have become almost a legend in the research field of aging. In 1958, Dr. William W. Peter, an officer of the U.S. Public Health Service, decided to bequeath his body to science. An inquiry to NIH yielded the suggestion that he consult Dr. Nathan Shock, who at that time was leading a group of NIH scientists interested in understanding “the biological factors that produce what we perceive as aging” and “the mechanisms that produce impaired performance with age.” Dr. Shock had become convinced of the need to study community-dwelling people over time, that is, “longitudinally.” Thus, when Dr. Peter placed a phone call to Dr. Shock to find out how he could arrange to donate his cadaver for scientific study, Dr. Shock replied, “Let’s have it when you are still alive!” The two scientists met and the BLSA came into existence. Over the subsequent near half-century, the scientific knowledge generated from the BLSA has become so vast that the study is universally considered the most comprehensive study on aging in human subjects ever attempted.

The BLSA study population consists of a series of healthy volunteers of different ages followed indefinitely with serial evaluations over time. A consortium of scientists collects and analyzes data from this study population with the aim of characterizing normal and pathological aging. Thus, the BLSA can be envisioned as a series of nested longitudinal and cross-sectional studies oriented toward (1) describing the anatomical, physiological, and functional changes that occur over the aging process, independent of diseases; (2) identifying the biological, behavioral, and environmental factors that account for these changes; (3) studying factors that predict healthy aging; and (4) developing hypotheses concerning possible targets for interventions that may positively affect several aspects of the aging process and prevent age-related pathology.

In just under 50 years of operation, and with approximately 3,000 participants enrolled and more than 800 manuscripts published in peer-reviewed journals, the BLSA has generated most of the current knowledge of the aging process in humans. Perhaps

the BLSA’s most important contribution involves disentangling the effect of disease and illness from the aging process and the development of the notion that aging is distinct from disease. Accordingly, most of the initial BLSA analyses were dedicated to describing changes in physiology and behaviors that are caused by aging *per se*, independent of disease. The BLSA portfolio includes original discoveries in the physiology and pathophysiology of the cardiovascular system, diabetes, diet and energy metabolism, age-associated modification of and risk factors for changes in cognition and personality, early predictors of prostate cancer, specific patterns of decline in sensory function, age-associated changes in body composition, decline in kidney function, secular trends in physical activity, and dietary intake. These domains represent a small sample of the wealth of information that the BLSA has provided.

In 2002, the BLSA underwent a major change in its design and objectives. Over the previous decade, the fields of genetics and molecular biology have made tremendous steps forward in the understanding of cell biology. Some of the traditional questions concerning the aging process had to be revisited and, to some extent, even reformulated. For example, the plausibility of a clear distinction between aging and disease had come under question. Thus, building on previous experience, the BLSA in 2002 entered into a new stage where its focus was on mechanisms that, over the aging process, lead to the condition of “frailty” conceptualized as increased susceptibility to disease and reduced ability to sustain stress. Additionally, frailty is believed to involve multiple physiological systems, including those important for mobility and cognitive function. It is hypothesized that over time, frail older persons show parallel, accelerated declines in anatomical integrity and function in multiple physiological systems, while individuals that develop specific diseases show, at least initially, clinical features that suggest selective and localized organ or physiological system damage. In accordance with this view, frailty is considered to contribute to fluctuation and instability of health status, high risk of multiple negative health-related outcomes and exhaustion of functional reserve. It is also hypothesized that (1) the destabilizing impact of acute medical events or traumas in older individuals is higher in frail than in non-frail individuals; (2) early stages of frailty may be detected only by tests that challenge functional reserve and compensatory ability; and (3) frailty

stems from dysfunction of some core mechanism that maintains integrity and function at a cellular level.

The paradigm used in the BLSA to study age-related frailty covers three basic levels of measurement: (1) mobility and physical function and cognitive capacity; (2) anatomical integrity and functionality of the physiological systems important for mobility, including the central nervous system, the peripheral nervous system, the muscular-skeletal system, the energy production and delivery system, and the sensory system; (3) physiological signaling systems important at the whole organism level for maintaining biological homeostasis, including energy production and delivery. These features include dietary intake, physical exercise, and immunology, with particular focus on inflammatory markers, autonomic nervous system, and oxidative stress/antioxidants. All of these measures are included in the BLSA core, in order to study their concurrent and longitudinal relationships and understand how changes in these parameters affect aging, age-related diseases and the development of frailty, loss of physiological reserve, and functional decline.

## BANDURA, ALBERT (1925–)

---

Albert Bandura is a past president of the American Psychological Association (1973) and has been a professor at Stanford since 1953. Bandura was born in Alberta, Canada. He received his BA from the University of British Columbia in 1949 and his PhD in clinical psychology from the University of Iowa in 1952. Following his graduation, Bandura began teaching at Stanford and continues there as a faculty member to this day.

Bandura was trained as a psychologist in the behavioral tradition, believing that only the observable is worth studying. However, as his career developed, he became interested in cognitions, including mental images and language. Resulting from his interests

in both behavioral and cognitive study, many of his theories contain concepts from both paradigms.

One of Bandura's most prominent theories, social learning, stems from his famous Bobo Doll Studies. In these studies, he showed children a video of a woman beating up an inflatable doll (a Bobo Doll). Following the video, they were allowed into a room that contained toys and a Bobo Doll. Bandura observed that the children would often model the woman's behavior in the video and abuse the doll instead of playing with the other toys. Many variations of this study were conducted, all resulting in the same conclusion—that children model violent behavior.

According to Bandura's social learning theory, there are four steps to modeling: (1) attention—the more attentive the observer, the greater the learning; (2) retention—being able to remember what is observed; (3) reproduction—recreating what has been observed; and (4) motivation—reason to model behavior. This notion of past reinforcement became important to Bandura; he believed that reasons for motivation include promised reinforcement, vicarious reinforcement, past punishment, promised punishment, and vicarious punishment. Bandura believed that punishment does not stimulate or negate behavior as well as reinforcement; therefore, reinforcement is more important in development.

From social learning came Bandura's belief that violence in children is not inherent, but learned. Children model behavior from others in their lives (most prominently family members) and from the media. Since he believed that aggression is learned, Bandura claimed that potentially criminal behavior can be avoided if aggression is diagnosed early and other learning behaviors are used to rectify the aggressive behaviors.

Another major contribution of Bandura's is the theory of self-efficacy. Self-efficacy is an individual's belief in their ability to accomplish certain goals. This belief stems from various sources and is domain specific, meaning that a person has efficacy beliefs regarding a specific task in a given situation and does not necessarily generalize those efficacy beliefs to other situations. Self-efficacy develops in people throughout their lives, and their past situations influence their current and future efficacy beliefs.

## BAR/BAT MITZVAH

---

Bar Mitzvah means “son of commandment,” a rather elliptical term connoting that a young Jewish male has reached the age of majority, and thus become obligated to perform ritual commandments. A child reaching Bar Mitzvah age may be counted toward the 10 adults required for a prayer quorum. A similar term—Bat Mitzvah—is used for Jewish females at the same juncture in life, even though they are not subject to the same ritual obligations as males. Many misunderstand the precise meaning of the term, taking it to connote, first and foremost, the ceremony that often celebrates a young person’s coming of age. In essence, however, the terms apply to the *person* who becomes a Bar or Bat Mitzvah, a transition that takes place simply by virtue of turning 13; that the ceremony celebrating that juncture has come to be better known by the same term does not negate its true sense. It should be noted that, insofar as becoming Bar or Bat Mitzvah marks reaching puberty, many congregations have girls hold their ceremony at age 12, owing to the fact that girls usually reach puberty about a year earlier than boys. Also worth mentioning is the fact that, whereas the idea of holding a ceremony and celebration for boys is quite ancient, for girls it is under a century old, having originated in the United States. (The first female to hold a Bat Mitzvah ceremony, incidentally, was Judith Kaplan, daughter of Reconstructionist Movement founder Rabbi Mordecai Kaplan.)

Before turning to the ceremony and celebration, let us say a word about the religious significance of becoming majority age in Judaism. As explained in the entry under “Judaism,” the Jewish religion, in practice, is a system of commandments that can be bifurcated between ethical and ritual. Whereas ethical commandments are always binding, ritual commandments are binding on different people at different times. The commandment of thrice-daily statutory prayer, for example, holds only for Jewish adult males; Jewish law exempts females, so as to prevent religious duty from conflicting with domestic duties, especially child rearing.

Minors are also exempt from such commandments, owing to the fact that their minds and sensibilities are not yet able to grasp the significance of such religious activity. Puberty thus demarks the onset of attaining these assets. Once maturity is reached, the ritual commandments become binding for Jewish males. Traditional Jewish theology addresses failure to perform such commandments as sinful; thus, reaching Bar Mitzvah age elevates the spiritual onus, if you will, for neglecting ritual behavior.

Much more widely known are the trappings associated with reaching Bar and Bat Mitzvah age, especially as it is celebrated outside the deeply orthodox Jewish world. At their worst, some families have thrown lavish parties—renting yachts, spending thousands on famous entertainers, and the like—which have tainted the beauty and significance of the rite. For the most part, however, families have adhered to appropriate good taste and proportion, holding festive celebrations that aptly mark their child’s coming of age.

In North America, most Bar and Bat Mitzvah ceremonies are held on Sabbath in the synagogue and call for the youngster to lead substantial portions of a worship service—much if not mostly in Hebrew—and usually speaking to the congregation about what the rite means to him or her. The Bar or Bat Mitzvah worship service usually is preceded by year-long preparation under the guidance of a special tutor, often the rabbi or cantor of the family congregation. The child usually learns to chant Hebrew parts of the Pentateuch designated for his or her Sabbath service, as well as a longer portion of Hebrew from Prophets called the “haftarah.” Many young people also learn how to chant parts of the liturgy and lead the congregation in prayer.

It is, of course, customary for family and friends to give gifts to the Bar or Bat Mitzvah youth, especially in monetary form. Children often realize substantial sums that usually become savings toward college or car. In the best of outcomes, Bar and Bat Mitzvah training equips the youngster with prayer and speaking skills suitable for leading the congregation in prayer, scriptural cantillation, and study and instills in him or her the desire to regularly put his or her skills to use.

## BARKER, ROGER (1903–1990)

---

Roger G. Barker was a professor of psychology at the University of Kansas and a recipient of the Distinguished Scientific Contribution Award (1963) from the American Psychological Association (APA), the Kurt Lewin Award (1963) from the Society for the Psychological Study of Social Issues, and the G. Stanley Hall Award (1969), APA, Division 7 (1969). Barker was born in Macksburg, Iowa. After receiving a PhD from Stanford University, Barker spent 2 years as a postdoctoral fellow with Kurt Lewin at the University of Iowa and then devoted the initial decades of his career to studying child development and physical disability/rehabilitation. His career took a distinctive turn in the 1940s when he came to the disquieting realization that, after more than a half century of empirical research, psychologists knew little more than laypersons about the behavioral patterns of individuals as they go about their daily lives. In response to this shortcoming, Barker followed the path of naturalist researchers in the biological sciences by establishing a field research station that was intended to provide “easy access to phenomena of the science, unaltered by the selection and preparation that occur in laboratories.” This groundbreaking effort was accompanied by the development of empirical methods for observing and recording the activities of individuals in everyday settings.

Through these methods, Barker learned that the order he observed in individuals’ actions could not be adequately accounted for solely by considering the environment at the level of the individual. Instead, it was necessary to operate at the extraindividual (ecobehavioral) level of *behavior settings*, which are naturally occurring, dynamic, ecological structures generated from collective actions of individuals in a physical milieu. Behavior settings arise from such collective actions, while reciprocally constraining individuals’ actions within their boundaries.

One property of behavior settings explored in detail by Barker and Gump in their landmark book *Big School, Small School* (1964) is level of staffing (or manning). Typically, behavior settings have an optimal number of individuals needed for adequate functioning; as a result, departures from that optimum have predictable effects. Individuals in an understaffed setting must be especially active, responsible, and flexible to maintain the functions of the setting, whereas individuals in an overstaffed setting tend to

feel somewhat marginalized and less involved because their separate contributions may not be vital for its operation. Notably, these findings from studies of high schools were replicated in other kinds of settings.

A second program of research employed behavior setting surveys of a community to provide an account of the activity possibilities in that place, and in doing so, detail its ecological resources considered from a psychological viewpoint. Using this methodology, different communities can be compared, as Barker and Phil Schoggen did in *Qualities of Community Life* (1973), and the same community can be examined at different points in its history to assess qualities of stability and change.

The legacy of Barker’s research program, overall, is the demonstration that psychology must maintain an *ecobehavioral focus* if it is to account for psychological phenomena in everyday settings.

—Harry Heft

## BATTERED CHILD SYNDROME

---

Battered child syndrome (BCS) has been defined as “the collection of injuries sustained by a child as a result of repeated mistreatment or beating.” If the injuries sustained by the child suggest that physical trauma was inflicted intentionally or if the injuries appear on examination to be more severe than one might expect to have reasonably been produced by accident, BCS may be indicated. These injuries typically have been inflicted by an adult caregiver. BCS also has been referred to as shaken baby syndrome, child abuse, and nonaccidental trauma, but none of these terms accurately captures the *repeated* nature of the physical trauma to which BCS specifically refers.

Although the hallmark symptoms of BCS are physical trauma such as internal injuries, lacerations,

burns, bruises, and broken or fractured bones, emotional and psychological problems also tend to characterize children for whom BCS is an accurate clinical descriptor. Emotional and psychological problems, in turn, can manifest as serious behavioral problems and disorders later in the child's life, including alcohol abuse, narcotic abuse, and the physical and psychological abuse of others.

The incidence and prevalence of BCS are unclear but may characterize a majority of the nearly 14% of children in the United States who are physically abused each year. More specifically, in comparison to all other causes of child deaths, traumatic injury is the leading cause of child death. Nearly 2,000 of those children who are abused die as a result of this abuse, and for these children, BCS is particularly likely to be an accurate clinical label.

There are many theoretical frameworks that propose explanations for BCS. However, only one theoretical framework—evolutionary psychology—hypothesized and led to the knowledge that a particular parent-child relationship, namely, the stepparent-stepchild relationship, poses the greatest risk that a child will be abused and perhaps eventually display BCS. Research hypotheses derived from socioecological theoretical models purport that BCS can be explained in terms of the integration of individual factors and social contexts, referred to as sociosituational models. But residence with a stepparent was not identified among those individual factors or social contexts. Research hypotheses derived from family systems theory propose that family relationships function as a set of systems and subsystems. According to family systems theory, the formation of a stepfamily creates a disruption of the expected system and hence leads to negative outcomes, including child abuse and BCS. Because stepparental behavioral and legal responsibilities to stepchildren are fewer than the behavioral and legal responsibilities of genetic parents to their children, stepparents are at increased risk for abusing their stepchildren. This logic does not provide a complete explanation for why the risk of BCS is higher in stepfamilies, however.

Although previous research has found that stepparents report feeling unprepared for the new parental duties, stepchildren have been documented to feel adamant about a stepparent not “filling the shoes” of their genetic parent. Daly and Wilson argue that it is not that stepparents do not know what their role is as

a stepparent, but instead that they do not want to do what is expected of them—invest in children unrelated to them, without receiving the benefits associated with investing in children of their own. Regardless of one's theoretical perspective, it is agreed that BCS is an important social problem that demands the attention of thoughtful scholars and the research efforts of behavioral and social scientists.

## BATTERED WOMAN SYNDROME

---

Battered woman syndrome (BWS) is a psychiatric and legal term that refers to the constellation of psychological effects experienced by abused women and is intended to explain, for example, why women stay with their abusive partners and why abused women sometimes kill their abusive partners. The term emerged in the late 1970s and has been a source of legal and academic controversy ever since. BWS is considered as a subcategory of posttraumatic stress disorder (PTSD) but is not listed by name in the *Diagnostic and Statistical Manual of Mental Disorders*. BWS is associated with the presentation of symptoms such as learned helplessness, reexperiencing

trauma, generalized anxiety, lowered self-esteem, social withdrawal, and intrusive recollections. Women in abusive relationships experience learned helplessness as a result of cycles of abuse and are thus repeatedly exposed to more violence. One feature of BWS holds that women stay with their abusers because of learned helplessness; this is one of the most controversial features of BWS, with many researchers arguing that the data are not supportive.

According to BWS, intimate partner violence proceeds through cycles composed of three phases: the tension-building phase, the active battering phase, and the loving, respite phase. During the tension phase, the victim is subjected to verbal abuse and minor physical abuse. The active battering phase results from the release of tension from the batterer and results in violence for a period of 2 to 24 hours. During this phase, the victim is unable to control the batterer with techniques that worked during the tension-building phase. This inability to control the batterer is theorized to result in learned helplessness. During the loving, respite phase, the abuse subsides and the batterer expresses remorse and promises that it will never happen again. The batterer exhibits loving and affectionate behavior shown earlier in their relationship. These affectionate behaviors result in falsely assuring the victim that the abuse was isolated and will not occur again.

There are several theories put forth to explain BWS. The three most common theories are Walker's battered women's syndrome theory, Gondolf and Fisher's survivor disorder theory, and PTSD theory. Survivor disorder theory differs from battered woman's syndrome theory in the emphasis of learned helplessness. Survivor disorder theory emphasizes a lack of support resources available to abused women as the primary reason they do not leave the abusive relationship. PTSD theory views BWS as a subcategory of PTSD and is currently a predominant theory of the development of BWS.

The validity of BWS as a psychiatric disorder has been debated intensely. Many have argued that the value of BWS lies primarily in its educational role in informing individuals about the impact of abuse on women through high-profile judicial proceedings. Others have argued that BWS is the product of legal defense teams negotiating a defense for the abused woman's actual or attempted murder of her abusive partner. The premises of BWS appear to have validity in the scientific community, but the rigorous standards

for admitting the syndrome into DSM-IV-TR requires further empirical work.

Identifying the psychological and demographic characteristics of women in abusive relationships will be of substantial benefit to clinicians. By identifying such characteristics, clinicians will be in a better position to understand the abuse and, more importantly, understand women's reactions to the abuse and the effectiveness of various treatment programs. Recognition of BWS as a distinct disorder may result from an examination of these issues.

## BAUMRIND, DIANA (1927– )

---

Diana Blumberg Baumrind is considered to be among the foremost experts on parenting in the United States. She has also had a distinguished career as an academic researcher and commentator on the role of ethics and understanding of research findings. She has been awarded multiple national grants over a 40-year career devoted to family socialization and parenting research. Baumrind is the author of 58 articles in journals or as book chapters, as well as three books and monographs. She has also served as an editor and consultant to numerous professional journals and has been an esteemed member of multiple national psychology organizations.

Baumrind earned undergraduate degrees in both philosophy and psychology from Hunter College. She then completed graduate work at the University of California, Berkeley, earning her PhD in the specialty areas of clinical/social/developmental psychology. She served a postdoctoral clinical residency (1955–1958) at Cowell Hospital/Kaiser Permanente where she began to investigate families and socialization. In 1960, Baumrind began her association with the UC Berkeley Institute of Human Development, where she has remained her entire career.

Baumrind would come to develop a description and formulation of parenting styles and their impact on how children develop. As a single parent of three daughters, she chose research in part because the work hours allowed her more time with her family.

It was Baumrind who, in a series of reports, first identified styles of parenting she termed authoritative, authoritarian, and permissive. Observing children directly, as well as the parenting they received in their homes, she was then able to comprise a list of important parenting behaviors and compare those to how competently the children behaved.

Baumrind's model of parenting styles examined parenting behavior on two broad dimensions: accepting, nurturing, and responsive behavior; and parental expectations, controls, and demands. Parenting styles were a subset of whether behavior was high or low on the dimensions. Her work has served as a useful system for characterizing parenting behavior as it impacts child development outcomes.

Among Baumrind's contributions are critiques of research ethics in psychology and a defense of spanking as an appropriate discipline method within a parental repertoire of rewards and punishment strategies. Her honors include the G. Stanley Hall Award from the American Psychological Association (1988) and selection as an NIMH Research Scientist Award recipient (1984–1988).

## BAYLEY, NANCY (1899–1994)

---

Nancy Bayley was born and reared in The Dalles, Oregon, and died in Carmel, California. In the history of developmental psychology, few other individuals loom so large.

After grade school and high school in her home town, Bayley attended the University of Washington in Seattle. She planned to become an English teacher but changed to psychology after taking an introductory class taught by Edwin Guthrie, a leader in the psychology of learning. She earned her BS and MS degrees from the University of Washington in 1922 and 1924, respectively. Bayley studied the construction of performance tests for preschool children, a project prefiguring her later work on the development of intelligence. For her PhD, awarded in 1926 from the University of Iowa, she conducted one of the first studies of children's fears using the galvanic skin response.

From 1926 to 1928, Bayley taught at the University of Wyoming and then joined the Institute of Child Welfare (now Institute of Child Development) at the University of California at Berkeley as a research associate. There, she began what became known as the Berkeley Growth Study, a landmark longitudinal investigation on a large sample of healthy infants born in 1928 and 1929. Over the next half-century, Bayley and her colleagues followed these individuals as they grew from infancy to middle age. The work yielded important discoveries about physical, motor, and mental development; variability and individual differences; the relation of mental performance to environmental factors including socioeconomic factors such as parental education; and the predictability of later mental and physical status from child scores. It remains a treasure trove for scholars today. It also helped advance the study of adult development and the effects of historical forces on child development, including World War II and the Korean War. Over this period, Bayley also developed the Bayley Scales of Motor and Mental Development, still acknowledged as providing the best standardized measures of infant development and used throughout the world.

In 1954, Bayley moved to Bethesda, Maryland, to become chief of the section in child development at the National Institute of Mental Health. Her many accomplishments there included participation in the National Collaborative Perinatal Project for the study of cerebral palsy and other disorders. In 1964, she

returned to Berkeley, where she continued her studies of individuals from her growth study.

Bayley's many honors and awards include the G. Stanley Hall Award (1971) for outstanding contributions to developmental psychology, the Presidency of Division 7 (developmental psychology) of the American Psychological Association (1953–1954), and the Gold Medal from the American Psychological Foundation (1982). Throughout her long and distinguished career, Bayley sought to apply "scientific knowledge in the interests of human welfare and happiness" (1956, p. 121). She succeeded, and we are all the richer for it.

## BAYLEY SCALES OF INFANT DEVELOPMENT

---

The Bayley Scales of Infant Development (BSID-II), published by Psychological Corporation, are a set of scales that takes 45 minutes to administer and assess mental, physical, emotional, and social development. Because the scales provide an overall picture of the child's developmental status, they are often used to evaluate whether children are developing normally or may need further testing to determine if they need intervention or treatment of some kind.

The Mental Scale assesses sensory and perceptual ability, memory, problem solving, learning, and early verbal skills. Sample items include measuring infants' responses to a bell or to tracking a toy with their eyes. The Motor Scale evaluates physical activities that require the use of both gross and fine motor skills, including large muscle activities (e.g., sitting and walking)

and small muscle activities (e.g., picking up small objects). The developmental level for the status of emotional and social development is assessed through the use of a Behavior Rating Scale (formerly called The Infant Behavior Record or IBR) using a five-point scale. The Behavior Rating Scale assesses variables such as attention and arousal, orientation and engagement, and emotional regulation. The Behavior Rating Scale scores are based on the caregiver's input as well as the examiner's judgments. The test is completed by the examiner after the administration of the Mental and Motor Scales and produces a percentile score for comparison to a nonclinical population. Both the Mental and Motor Scales produce a standardized score.

The test was updated in 1993. Some of the changes include an increase in the age range from 1 month to 42 months, the revision of stimuli, and the addition of almost 50% in new items to reduce racial and gender bias and make the stimuli more attractive to children. New normative data are now available for children with various clinical diagnoses such as Down syndrome and prematurity. The BSID is widely used in research settings, has excellent psychometric characteristics, and has the largest standardization sample of any test.

## BEREAVEMENT

---

The process of human development inevitably ends in death. Bereavement, grief, and mourning are terms used to describe distinct aspects of people's reactions following the death of a loved one or other significant loss. *Bereavement* is the state that results from having experienced the death of a loved one; so to be bereaved is to have suffered a loss. And when someone is bereaved, they grieve. *Grief* is the personal

reaction to both death- and nondeath-related losses, which includes feelings, physical sensations, and thoughts. *Mourning* is the internal struggle to reorient to life and the outward behavioral expression of grief that is shaped, in large part, by social and cultural norms, rituals, traditions, and practices.

The terms bereavement, grief, and mourning are distinct concepts, but both the general public and professionals frequently use the terms interchangeably, although often with different intentions and different definitions. To maintain consistency with general and professional use, in this entry the terms grief and mourning will be used interchangeably to describe how people respond to and cope with the state of bereavement.

### GENERAL CHARACTERISTICS OF GRIEF AND MOURNING

It is important to understand some basic characteristics of grief and mourning. First, they are natural processes that facilitate healing; in that respect, they are helpful, albeit painful, experiences. Second, they are not linear, orderly, predictable, or generalizable processes. Third, although there are some similarities across people, each individual experiences grief and bereavement differently. Additionally, each person mourns all deaths differently since each death and relationship is unique. Accordingly, the phrase so commonly uttered to the bereaved, “I know just how you feel,” can never be true. Additionally, the processes of grief and mourning do not result in the bereaved person “getting over” the loved one who has died. Rather, grief and mourning are more likely to result in a gradual adjustment to the loss that is often never fully resolved or “gotten over.” Finally, grief is pervasive, affecting potentially every aspect of the bereaved person’s life.

### ELEMENTS OF GRIEF AND MOURNING

The bereaved experience grief in all areas of life: physical, psychological, social, and spiritual. Common *physical/somatic* grief-related reactions include sleep difficulties, appetite changes, nervousness, restlessness, heart palpitations, chest or throat tightness, shortness of breath, nausea, muscle weakness, exhaustion, trembling, dry mouth, sighing/yawning, and crying.

*Psychological* reactions to grief include emotional, cognitive/intellectual, and sensory components.

Common emotional reactions include sadness, fear, anxiety, anger, guilt, depression, hopelessness, helplessness, frustration, shame, irritability, tension, and a sense of being overwhelmed. Common cognitive responses include yearning (longing for the deceased), disbelief, preoccupation with thoughts of the deceased, lack of concentration, and impaired memory. Altered or heightened sensory responses are also reported by the bereaved. For example, some may experience dreams, apparitions, or hallucinations related to the deceased.

*Social* grief-related reactions may include isolation, alienation, or withdrawal. Conversely, some bereaved people cannot tolerate being alone and experience anxiety or even panic when not in the presence of others.

*Spiritual* grief-related reactions may include spiritual emptiness, loss of meaning in life, or disillusionment or anger with God or a higher power. However, bereaved individuals may also find more spiritual comfort than at any other time in their lives and seek to nurture an initial or stronger relationship with God in an effort to find meaning and comfort.

### THEORIES/MODELS OF GRIEF AND MOURNING

In order to better understand how bereaved people grieve and mourn and how others might best support them, researchers and clinicians have developed different models or theories that attempt to account for how people react to and recover from the death of a loved one. Early conceptualizations of grief and mourning presented by researchers such as Elizabeth Kübler-Ross and Collin Murray Parkes focused on predictable stages or phases of reactions that bereaved individuals went through. These approaches have been criticized for assuming that all bereaved persons grieve in similar, prescribed ways. Most current conceptualizations of grief and mourning incorporate individual differences into the models and are task- rather than stage-oriented.

#### William Worden's Task-Based Model of Mourning

William Worden has proposed one popular model of mourning that includes four tasks that the bereaved undertake following a loss. *Task 1: Accepting the reality of the loss* means accepting the reality of the death

intellectually as well as emotionally. *Task 2: Working through to the pain of grief* is surrendering to and experiencing the physical, emotional, social, and spiritual pain that results from the death of a loved one. This task can be complicated by societal expectations to quickly “get over it” and “move on.” *Task 3: Adjusting to an environment in which the deceased is missing* means adjusting to the end of one’s physical, emotional, spiritual, and social life that existed in relationship with the deceased. *Task 4: Emotionally relocating the deceased and moving on with life* involves realizing that although the deceased will always be in one’s thoughts and memories, life continues and it is important to go on to live and love fully.

### Therese Rando's Task-Based Model of Mourning

Therese Rando offers an alternate task-based model of mourning, which includes the six R’s (Rando, 1991). To *recognize* the loss is to acknowledge and understand the implications of the death. To *react* to the separation of the loss involves experiencing the pain by feeling, identifying, accepting, and expressing one’s reactions. To *recollect* means to realistically remember and reexperience feelings associated with the deceased. To *relinquish* attachments to the deceased and to one’s assumptive world involves the process of letting go. To *readjust* is to move adaptively into the new world by developing a new relationship with the deceased and forming a new identity. Finally, the bereaved must *reinvest* in their new world.

Both Rando and Worden present task-based models of mourning that support the long-standing conceptualization of grief as “work.” However, researchers Margaret and Wolfgang Stroebe and Henk Schut have highlighted shortcomings with the traditional “grief work” conceptualization including lack of definitional clarity and operationalization, absence of strong empirical evidence to support the model, and lack of generalization across cultures. Accordingly, Stroebe, Stroebe and Schut have argued that grief “work” is not always essential or necessary for adjustment during bereavement. Regardless of which model of grief and mourning one considers, all share the challenge of adequately capturing the complete essence of the experience across all bereaved persons because there are so many factors that combine to individualize bereavement.

### FACTORS THAT INFLUENCE GRIEF, MOURNING, AND BEREAVEMENT

Bereavement is shaped by numerous factors, such as the *bereaved’s psychological stability, intellectual level, maturity, and loss history*. The *deceased person’s role in the family* also influences one’s experience of bereavement. For example, if the deceased person was the center of the family or had daily, close contact with the bereaved, the impact of the death will often be greater than that of a more distant, less central loved one. The *nature of the relationship with the deceased* also influences bereavement. For example, ambivalent relationships characterized by both love and pain are generally difficult to mourn. The *circumstances of the death* also influence grief and mourning. Sudden and unexpected deaths are often difficult to adjust to because of the lack of preparation for the death and because they often result from traumatic circumstances (e.g., accident, homicide, and suicide). Additionally, the *perceived timeliness of the death* influences grief and mourning. Generally, the death of a child is considered to be untimely, whereas the death of someone who has lived a longer life is viewed as more timely. Finally, one’s *ethnic, cultural, and religious background* also shapes the bereavement experience.

### CULTURE AND BEREAVEMENT

The specific role that culture, religion, and ethnic background play in bereavement varies. Additionally, most researchers have focused on cross-cultural mourning practices rather than on intrapersonal, emotional experiences of grief. In general, those researchers who have studied grief across cultures (e.g., Chinese, Taiwanese, British, African, Mexican, Puerto Rican, Anglo-American, Native American, and African American) have not found significant differences in the grief experience.

Conversely, mourning rituals and practices have been found to vary widely across cultures. For example, funeral rituals, the length of the period of mourning, and other acceptable and expected customs and practices (e.g., what color clothes to wear and for how long, what social events are permissible to attend, how publicly or privately one mourns, whether to speak the name of the deceased during the mourning period) reflect unique and distinct cultural and ethnic values.

Often the mourning rituals and practices of a cultural or ethnic group are intimately connected to its religious

beliefs. For example, among African Americans, funeral rituals are tied to one's religion. Traditional or more conservative Catholic and Episcopalian services involve formal rituals performed by priests in robes. Conversely, less formal Baptist services often include singing of hymns, readings by family and friends, and a eulogy delivered by the family pastor.

## SUMMARY

Experiencing loss and death is a normal part of life, and all people grieve and mourn during the period of bereavement that follows the death of a loved one. Exactly how a bereaved person mourns and experiences grief, however, is shaped by many unique biopsychosocial and cultural factors.

—Brenda Moretta Guerrero

## BEREAVEMENT OVERLOAD

---

The term “bereavement overload” was coined by psychologist and gerontologist Robert Kastenbaum over 30 years ago to refer to circumstances in which a grieving individual confronts multiple losses simultaneously or in rapid succession, such that one loss cannot be accommodated before another occurs. Although bereavement overload can be triggered by a great range of circumstances (e.g., deaths of multiple friends or family members in a vehicular accident, war, fire, natural disaster, or even from unrelated causes over a short span of time), much of what is known about its impact has resulted from the study of the AIDS pandemic and the mounting losses of later life. Viewed in a developmental frame, however, overwhelming grief can arise at any point in the life cycle, posing challenges that are distinctive to each phase of life and type of loss.

Much of the focus on bereavement overload in the lives of children has been stimulated by a concern for the plight of AIDS orphans, particularly in developing countries, where entire communities can be decimated by mounting losses in the context of inadequate or nonexistent healthcare. In such cases, complications in grief *per se* (e.g., chronic depression, trauma, and separation distress resulting from ruptured attachments to parents and other caregivers) can be compounded by pervasive insecurity about one's very survival in a social system that is overwhelmed by the pandemic and related stresses engendered by poverty and unemployment. Even in developed countries, AIDS orphans confront unique problems of stigmatization and secrecy regarding the nature of their loss and do so without the benefit of the more developed psychological and social resources on which most adults can draw.

In the working years of adulthood, members of the gay community and healthcare workers are particularly likely to experience bereavement overload, which may be exacerbated by the inherent stress associated with these roles. Gay men grieving multiple losses to AIDS must also contend with stigmatization, societal invalidation, and the absence of traditionally available support systems. Men contending with a high number of such losses—averaging dozens of friends and partners over the 20 years of the pandemic—often report death anxiety, defensive avoidance, and intrusive experiences, which can be managed through seeking social support or counseling and reconstructing a meaningful self-identity in the wake of loss.

Healthcare workers experiencing multiple losses are put in the position of balancing their own grief for dying patients with their desire and need to be competent care providers. Striking this balance can be a tremendous strain, whose traumatic impact grows with accumulating experience in “high death” specializations. In general, it appears that processing emotion, seeking the support of peers, and active confrontation rather than avoidance of loss are therapeutic for this population.

Finally, later life can usher in a predictable sequence of losses, as one's parents, older relatives, and eventually siblings, spouse, and peers age and die in increasingly quick succession. Feelings of helplessness, guilt about outliving other family members, and diminished self-esteem are common responses to this seemingly relentless progression, especially for older adults who are themselves in failing health or who suffer from social isolation. Suicide can be a particular risk at this stage of life and requires close

monitoring by health care professionals who might mistakenly interpret the silent depression of stoic elders as a normal response to changing life circumstances. Although antidepressant medication can make a useful contribution to treating mood disorders associated with bereavement overload in the final decades of life, mobilization of social, familial, and spiritual supports are especially important at this time.

In summary, the germinal literature on bereavement overload highlights a cluster of responses—depression, helplessness, death anxiety, isolation, survivor guilt, and traumatic stress—that are common to circumstances of multiple loss, as well as distinctive issues that arise in connection with different stages of the life cycle. Conversely, coping strategies that concentrate on helping others, joining groups, strengthening ties to family and community, grieving shared losses, and seeking to make meaning of catastrophic bereavement can help promote its integration into a changed life, but one that nonetheless is characterized by newfound purpose and reconnection.

—Robert A. Neimeyer and Jason Holland

## BERKELEY/OAKLAND LONGITUDINAL STUDIES

---

The three longitudinal studies that constitute the Intergenerational Studies (IGS) of the Institute of Human Development (IHD) were initiated in the late 1920s, and the study members represent two birth cohorts: people born in Berkeley in 1928–1929 and people entering an Oakland middle school in 1932 (born in 1920–1921). Data were collected from and about them and their families through adolescence

and, subsequently, from them and their spouses, parents, and children.

### GUIDANCE STUDY

The 248 original subjects in the Guidance Study (GS) were drawn from a socioeconomic survey of every third birth in Berkeley, California, during the 18 months between January 1, 1928, and June 30, 1929. The focus of the study was behavior problems of preschool children.

### BERKELEY GROWTH STUDY

The Berkeley Growth Study (BGS) was initiated with a sample of 61 healthy, full-term infants born in one of two Berkeley hospitals between September 15, 1928, and May 15, 1929, to white, English-speaking parents. The study was designed to trace normal intellectual, motor, and physical development in the first year of life.

### OAKLAND GROWTH STUDY

Recruited for the Oakland Growth Study (OGS) (initially called the Adolescent Growth Study) were 212 youngsters from five elementary schools in Oakland, California, who intended to attend the junior high school selected as the center of observation for the research. The subjects ranged in age from 10 to 12 at the time of initial data collection in 1932. The focus of the OGS was normal adolescent development, especially physical, physiological, and social.

### DATA COLLECTION—PRE-ADULT

#### Guidance Study

During the first 18 months of the subjects' lives, data were collected by staff of the Berkeley survey. Pre- and perinatal data were obtained from physicians, hospitals, and mothers. From the infant's 3rd through 18th month, a public health nurse visited the home every 3 months to collect data on height, weight, health, diet, and behavior. Parents provided information about their health histories and the health histories of their parents as well as detailed demographic and socioeconomic data on the family at the time of the child's birth.

Data collection by GS staff and the institute began when the study members were 21 months old. The subjects were assessed regularly for physical and

intellectual development, and their mothers provided information about the subjects' habits, interpersonal behaviors, interests, and personality. Interviews with the children on the same topics began when they were 6 years old. In addition, school performance and other behavioral data were collected from teachers, and social and personality data were collected with sociometric measures, projective tests, and interest and vocational inventories.

### **Berkeley Growth Study**

During the subjects' first 4 days of life, physical, physiological, and neurological assessments were done. The subjects were assessed frequently through age 3 and less frequently in later childhood and adolescence. At all visits, subjects were rated on personality traits and behaviors, and narrative notes were made about their behaviors, attitudes, and reports of events in their lives. In addition, projective tests and leisure-time, interest, personality, and vocational inventories were included on an irregular schedule.

### **Oakland Growth Study**

The data primarily are (a) responses to self-report questionnaires devoted to personality, attitudes, interests, and activities; and (b) ratings of subjects' characteristics by study staff based on observation of the subjects in various situations.

In the early 1960s, the first steps were taken toward collaborative planning for the three studies. Despite considerable differences in stated objectives and data collection, the staff of each of the studies had secured rich data on adolescent development and reasonably comparable data on early adulthood, including data on occupational involvement, marriage and children, relations with parents, social attitudes, and intellectual and emotional status.

### **DATA COLLECTION—ADULT**

Subjects in the three longitudinal studies participated in data collection as adults prior to the first of the integrated data-collection efforts. In the most comprehensive of these recalls, the GS subjects were 30 years old, the BGS subjects were 36–37, and the OGS subjects were 37–38. Between 1969 and 1972, GS and OGS subjects were seen in the first consolidated data collection. The second consolidated data collection took place

between 1981 and 1983 and consisted of interviews, cognitive assessment sessions, collection of physical information, and self-administered questionnaires.

The three longitudinal studies that constitute the Intergenerational Studies of the IHD at the University of California at Berkeley provide a wealth of demographic data, personality data, data about parents and families of origin, data concerning attitudes and behavior, physical and medical data, and cognitive assessment data about participants. For more information, contact the longitudinal studies' archivist at IHD or the director of the institute. The address is 1203 Toldman Hall-1690, University of California, Berkeley, CA 94720-1690.

## **BILINGUALISM**

---

Bilingualism refers to the regular use of two languages by speakers who have a high level of proficiency in each language. In contrast, multilingualism refers to the regular use of three or more languages on a regular basis. Between one third and one half of the world's population is bilingual or multilingual. In the United States, bilingualism and multilingualism are much less common than in other countries. According to the 2000 United States census, one in five respondents indicated that they spoke a language other than English at home. Public schools report that approximately one child in eight speaks a language other than English at home. In the coming decades, the number of bilingual speakers in the United States is expected to rise due to continued immigration.

### **CHILDHOOD BILINGUALISM**

Children who are raised in an environment where more than one language is used on a regular basis can

easily acquire two or more languages concurrently. This type of bilingualism is referred to as *simultaneous bilingualism* and contrasts with *sequential bilingualism*, which occurs when a second language is learned after a first language has already been acquired. Circumstances giving rise to simultaneous bilingualism include when each parent is a native speaker of a different language or when the infant is raised in a home where a single language is used, but there is regular contact with a speaker of another language, such as a relative or household worker. There is no evidence that learning more than one language during childhood places an unmanageable burden on the child or results in long-term delays in the use of either language.

Becoming bilingual is much more easily accomplished during early childhood than later in life. Eric Lenneberg argued that the ideal time for learning any language was from birth to puberty. His view was called the *critical period hypothesis* and is described in his 1967 book *Biological Foundations of Language*. Following this view, learning a second language after puberty may require more effort and be less successful than learning a second language during early childhood. In the United States, most students receive second language instruction after puberty in high school or college. In general, this type of second language instruction rarely results in native-like proficiency in a second language. In countries where the rates of bilingualism are higher than in the United States, school children routinely receive second language instruction in elementary school. This comparison suggests that one factor in producing large numbers of highly skilled bilinguals may be providing second language instruction to children before the critical period has ended. However, it must be noted that the motivation to learn a second language is also an important factor in determining whether one who receives second language instruction will become bilingual. It may be the case that high school and college students in the United States are generally less motivated to learn second languages than students in other countries.

There is compelling evidence that learning more than one language during childhood produces benefits in general cognitive development. Having experience with more than one language may enable the child to achieve a mental flexibility at an earlier age than monolingual children. This mental flexibility may enable the bilingual children to develop an early

awareness of how language works. Research reported by Sandra Ben-Zeev in 1977 showed that bilingual children outperformed monolingual children on verbal as well as nonverbal tasks. Ben-Zeev suggested that the bilingual children were more skilled than monolingual children at discovering and applying the rules required in each type of task. Research reported by Ellen Bialystok in 1991 showed that bilingual children outperformed monolingual children on verbal and nonverbal tasks requiring children to direct attention to a task in the presence of distracting information. However, it must be noted that children who succeed at becoming bilingual at an early age may differ in a variety of ways from same-age children who are not bilingual. It may be the case that the actual cause of bilingual children's superior performance on cognitive tasks also accounts for their ability to become bilingual at an early age. It is not known how many young children receive exposure to more than one language, yet fail to become bilingual.

## BILINGUAL EDUCATION

In the United States, there has been resistance to bilingual education since the end of World War I, when the use of languages other than English was viewed as un-American. In 1968, the Bilingual Education Act was established to provide federal money to local programs addressing the needs of children for whom English was a second language. In 1974, state and local governments were required to meet the needs of school children with limited proficiency in English. The United States Supreme Court ruled in the case of *Lau v. Nichol* that when schools fail to provide bilingual instruction to school children who have limited proficiency in English, they are violating the children's civil rights. The ruling was a landmark for advocates of bilingual education; however, the ruling did not mandate how bilingual education should be delivered to students. Consequently, local communities implemented a variety of strategies to avoid violating the law.

One of the most commonly used bilingual education programs is Transitional Bilingual Education (TBE). In TBE, school children study English but receive instruction in all other academic subjects in their native language. In such programs, children eventually transition into classrooms in which English is the only language of instruction. The length of time children are allowed to transition to English may vary

across school districts. Many school systems use transition periods of only 3 years. A second type of program is called two-way or dual programs. In these programs, children receive instruction from bilingual teachers who encourage students to improve their skills in their native language as well as English. These programs may use the students' native languages not only to teach them the standard curriculum but also to teach them about their ethnic heritage, culture, and history. In 1992, the National Academy of Sciences published a report reviewing studies that evaluated bilingual education strategies. The results suggested that students who receive bilingual education scholastically outperformed students who did not receive bilingual education.

## SOCIAL IMPLICATIONS

In the 1970s, immigration to the United States reached record levels. Four million legal immigrants and approximately 8 million undocumented or illegal immigrants came to reside in the United States. Since then, many federal, state, and local agencies have addressed the need for multilingual services, for education as well as voting, tax collection, delivery of social services, disaster assistance, and information about consumer rights. Many states now offer driver's license tests in languages other than English. For example, Massachusetts offers driver's license tests in 24 languages. In Miami, Florida, there are areas of the city where street signs are printed in both English and Spanish. In New York City, classroom instruction is provided in 115 different languages. Projections of future immigration suggest that the numbers of immigrants in the United States will continue to rise in the coming decades. It is reasonable to assume that there will be increased burdens placed on schools and government agencies to provide services in languages other than English.

Data from the 2000 United States Census confirm that English remains the most widely spoken language in the United States with 215.4 million speakers. The second most widely spoken language in the United States was Spanish with 28.1 million, followed by Chinese with 2 million speakers. The language with the largest proportional increase in the number of speakers was Russian. The number of Russian speakers nearly tripled in the 1990s, from 242,000 to 706,000. The second largest proportional increase was among speakers of French Creole whose number of

speakers more than doubled, from 188,000 to 453,000. Despite the growing linguistic diversity of the United States, the vast majority of U.S. residents use English on a regular basis. Overall, 92% of respondents in the 2000 U.S. Census reported having no difficulty speaking English.

There has been opposition to bilingual education in public schools by the English-only movement. The movement is composed of a number of political groups who have supported making English the official language of the United States. There are 28 states in which English has been distinguished as an official language. In Hawaii, English and Hawaiian are recognized as official languages. In New Mexico, English and Spanish are recognized as official languages. However, the United States government has not yet identified any language as the official national language.

## SUMMARY

While current rates of bilingualism in the United States are well below of those in other parts of the world, the number of speakers for whom English is a second language is expected to rise in the United States. The increase in bilingualism will continue to create challenges for local schools and government agencies and fuel the political debate regarding the extent to which education and government services should be provided in languages other than English.

—Shelia M. Kennison

## BINET, ALFRED (1857–1911)

---

Alfred Binet was a French pioneer of modern psychological testing who developed the prototype of many intelligence tests in use today, including the Stanford-Binet Intelligence Scale. Binet was born in 1857, the only child of a physician father and artist mother. His independent wealth allowed him to pursue his interests and work without remuneration throughout his life. Binet earned a law degree and attended medical school, but he abandoned both fields and turned his attention to experimental psychology. This led him to volunteer to work for Charcot, the famous neurologist who directed the Salpêtrière Hospital in Paris. Through his study of hypnosis during this period, Binet came to appreciate the value of the case study method and the role of suggestibility. In 1891, he went to work with Beaunis at the Sorbonne's Physiological Psychology Laboratory; in 1894, Binet became director of that lab, where he remained for the rest of his life. Binet's interest in psychology caused him to start the first French journal in the field, *L'Année Psychologique*, in 1895.

As an experimental child psychologist, Binet led a research program he called "individual psychology." Binet believed that intelligence could never be isolated from the actual experiences of individuals or their environments. His use of case studies helped him to appreciate the fact that intelligence is complex and needs to be measured with multidimensional scales. He doubted the value of the sensorimotor tests for assessing mental abilities that predominated at the time. Binet believed testing should tap higher order mental abilities instead of elementary processes. His 1903 book, *L'Étude expérimentale de l'intelligence*, is a notable work that recounts Binet's observations of many mental tests he tried on his two daughters.

In 1904, following the enactment of universal education laws in France, Binet was appointed to a commission formed by the government to investigate mental subnormality—as mental retardation was then known—in children. Realizing the need for a reliable diagnostic system to identify this condition, Binet and his collaborator Theodore Simon set out to develop a series of test tasks that would differentiate levels of retardation. Binet quickly came to see that the age at which children were able to accomplish certain tasks was a crucial factor in discriminating levels of mental acuity, with normal

children able to pass the same tests at younger ages than those who were deficient. The Binet-Simon Intelligence Scales, published in 1905, used items of increasing difficulty that assessed a wide variety of mental functions and were tied together by the use of practical judgment. Revised scales incorporating standardization and a formula for calculating "intellectual level" were issued in 1908 and 1911. Nevertheless, Binet was hesitant to quantify intelligence because he believed that one could improve the intelligence levels of retarded children and that intelligence is a not fixed quantity. At the time of his death in 1911, Binet was working on a further revision of his scale.

## BINGE DRINKING

---

The term "binge drinking" has traditionally been used in reference to extreme levels of alcohol consumption over a prolonged period of time, a drinking pattern common among alcohol-dependent individuals. More recently, the term has been used to denote a pattern of "heavy episodic drinking" common in adolescents and young adults. Although this type of drinking behavior is likely to result in intoxication, it represents a level of consumption considerably lower than the original definition and generally over a limited time interval. Most commonly, binge drinking is defined as five or more drinks on a single drinking occasion for men and four or more for women. Binge drinking in its current definition has become a major public health issue over the past two decades due to the established relation between this type of drinking and the experience of significant consequences to the individual and society.

Attention to the topic was heightened with the initial publication of binge drinking rates from a national sample of college students in 1994. This study indicated that more than 40% of college students were binge drinkers and nearly 20% were frequent binge drinkers (at least three times in the past month). Despite increased prevention efforts on college campuses, rates of binge drinking have remained relatively stable over the past decade. In 1996, results of the "Monitoring the Future" surveys conducted by the National Institute on Drug Abuse reported binge drinking rates in secondary school students, finding a disturbingly high rate among high school seniors (30%) that has not changed appreciably in the past 8 years. Although rates significantly decrease after college, approximately 25% of individuals in their 30s engage in binge drinking and 14% of the U.S. adult population met this standard in a recent nationally representative sample.

The current definition of binge drinking has been criticized on several grounds. First, the 5/4 criterion does not account for a number of important variables including time over which drinking occurs, body weight, and stomach contents. The result is that nearly half of the individuals who met the binge drinking criterion in one study were not drinking to intoxication as defined by a .08 blood alcohol concentration (the legal limit in most states). Another concern is that this definition leads the public to believe that dangerous drinking is normative based on the high percentage of young people meeting this criterion. The concern is that individuals who might not otherwise drink at this level will do so in order to meet societal norms. Despite the limitations of the 5/4 standard, it has demonstrated utility from a public health perspective.

Binge drinking is associated with an increased likelihood of other behavioral risks including driving after drinking, unprotected sexual behavior, and physical and sexual aggression. For example, binge drinkers in the general population are 14 times more likely to drive while impaired by alcohol than nonbinge drinkers. As a result of increased risk behavior, binge drinkers also report an increased incidence of a variety of negative consequences including alcohol-related motor vehicle accidents, HIV and other sexually transmitted diseases, alcohol-related injuries, and legal difficulties. Wechsler and colleagues (2002) found that infrequent binge drinkers were 3 to 4 times more likely to experience a range of negative consequences relative to nonbinge drinkers and frequent

binge drinkers were roughly 10 times more likely to experience these same consequences.

## SUMMARY

The term "binge drinking" has come to refer to a pattern of heavy episodic drinking common among adolescents and young adults. Although this standard may have limited clinical utility in terms of identifying individuals with alcohol use disorders, it has considerable relevance from a public health perspective. Individuals who meet or exceed this level of consumption are at increased risk for a variety of negative consequences, with frequent binge drinkers at particularly high risk.

## BINGE EATING

---

Binge eating is defined as the uncontrolled eating of a large amount of food within a discrete period of time (e.g., within any 2-hour time period). Within the current *Diagnostic and Statistical Manual of Mental Disorders*, binge eating has two distinguishing characteristics: (1) the consumption of an amount of food that clearly is larger than most people would eat in a

similar period of time and under similar circumstances and (2) a lack of control over what or how much is consumed or how long the eating episode lasts. In 1959, Albert Stunkard originally described binge eating as a pattern of eating seen among a subset of obese patients. Currently, binge eating is a cardinal symptom of two eating disorders, bulimia nervosa and binge eating disorder, and it also may be present in a third eating disorder, anorexia nervosa.

Historically, there has been some controversy regarding the definition of a binge episode, particularly with respect to the amount of food and, correspondingly, the number of calories consumed during a binge. This controversy emerged from a literature indicating that individuals who binge often consume an extremely large number of calories during a binge. However, there also was evidence that there was a large range in the caloric content of the food consumed during a binge, with the caloric content of a binge episode comparable to that consumed during a large meal or snack. Findings such as these suggest subjectivity in individuals' views of what constitutes a binge episode. Consequently, Fairburn (1995) and Fairburn and Wilson (1998) introduced the distinction between objective binges and subjective binges. During an objective binge, the individual engages in the uncontrolled eating of an excessively large amount of food. In contrast, during a subjective binge episode, the individual consumes a relatively normal or even small amount of food, but he/she views the amount of food as excessive and experiences a sense of loss of control.

Binge eating is associated with a variety of emotional consequences. Binge episodes frequently are triggered by negative affect, suggesting that bingeing may serve as a way to manage or avoid negative affect, to self-soothe, to distract oneself from a stressful situation, or to numb or escape painful or distressing emotions, if only temporarily. Binge episodes typically are followed by negative emotions, including guilt and shame. In addition, binge episodes frequently are followed by a fear of weight gain. This fear may lead to purging via self-induced vomiting or the use of laxatives or diuretics and/or severe restriction as a means to counteract the binge and prevent weight gain. When this occurs, binge eating, purging, and restriction may become part of a self-perpetuating cycle.

Binge eating also is associated with impaired interoceptive awareness, a difficulty recognizing and accurately responding to internal states, including sensations of hunger and fullness. Individuals who

binge may have difficulty discerning sensations of hunger and fullness. Impaired interoceptive awareness is more likely to emerge if the individual vacillates between periods of strict dietary restraint (during which hunger cues may be ignored) and periods of binge eating (during which satiety signals may be overridden or ignored).

Binge eating is associated with short-term and long-term physical consequences. The short-term physical consequences of binge eating primarily consist of feeling uncomfortably full, which may be associated with abdominal pain or discomfort, stomach distension, and bloating. Less common but more severe long-term consequences of binge eating include gastric dilation or gastric rupture. Binge eating in conjunction with other eating disorder symptomatology, including restriction and/or purging, is associated with health risks such as electrolyte disturbances, cardiovascular abnormalities, decreased bone density, and erosion of dental enamel.

## BIOLOGICAL CLOCK

---

Life on earth has evolved with the ability to cope with cyclical changes in the environment. The length of these environmental cycles is determined by our planet's rotational period (day-night cycle) as well as the period of its revolution around the sun (e.g., seasonal cycles). The survival of an organism depends on its ability to initiate physiological (e.g., body temperature, hormonal secretions) and behavioral events (e.g., activity, migration, hibernation) at the appropriate point in the environmental temporal cycle. In order to do so, an organism needs an effective time-keeping mechanism. Biological timekeeping ensures

that this occurs by anticipating important events in the environment and keeping track of the passage of time. The biological clock, the body's internal chronometer, is responsible for regulating and maintaining an internal temporal structure that is stable and synchronized with the appropriate environmental time cycle. Biological rhythms are the output of the biological clock, and their cycle can range from a few milliseconds to days or even months.

The most commonly observed biological rhythms are circadian rhythms. The word circadian comes from two Latin words, "circa," which means "about," and "dies," which means "a day." Circadian rhythms are the output of the circadian oscillator or clock. We can measure the endogenous period of the circadian oscillator by observing its output rhythms under constant environmental conditions. The period of the circadian oscillator when measured under these conditions is called the free running period (FRP). It is generally a little longer or a little shorter than 24 hours and will remain the same under constant conditions. The free running period will also remain unchanged when measured at different ambient temperatures.

One of the functions of the circadian oscillator is to anticipate events in the environment and estimate the passage of time so that key physiological and behavioral events occur at the appropriate point in the environmental time cycle. To achieve this, the circadian oscillator needs to be synchronized with the environmental time cycle. Since the endogenous period of the circadian oscillator is a little shorter or a little longer than 24 hours, it has to be either delayed or advanced to match the 24-hour period of a natural environmental cycle. There are many different environmental factors such as temperature, humidity, light, social variables, and food availability that oscillate with a period of 24 hours and serve as effective synchronizers. The environmental stimulus that synchronizes the circadian oscillator is called the *entraining agent* or *zeitgeber*. Research has demonstrated that the 24-hour light-dark cycle is the most powerful entraining stimulus. Exposure to light can cause the circadian rhythm to shift appropriately (i.e., advance or delay) to match the period of the entraining environmental stimulus.

In the 21st century it has become very important for us to develop an understanding of the circadian system and its functions. The need for constant availability of essential services in modern society requires many in the workforce to reverse their normal diurnal sleep/wake schedule as in the case of rotating- or night-shift

work. Such schedules result in an individual's physiological and behavioral rhythms being initiated at inappropriate points in the environmental time cycle. This can exact a substantial cost in terms of health and degraded performance. Understanding the circadian system, in particular its entraining mechanism, can provide us with useful solutions to these problems.

—Nayantara Santhi

---

## BIRTH DEFECTS

---

Birth defects are also termed congenital anomalies or inborn errors. While not always diagnosed at birth, they are believed to have been present at birth and have their origin in some perturbation of the normal developmental process. The causes of birth defects include genetic abnormalities inherited from either or both parents; genetic abnormalities that spontaneously arose in the individual itself; insufficiencies in the mother, such as placental abnormalities or nutritional deficiencies; maternal disease (such as diabetes); exposure to drugs or environmental factors (summarized under the term *teratogen*, and including such diverse factors as hyperthermia, alcohol, or viruses); or physical trauma during the developmental period.

Developmental defects, as the name implies, occur as a result of changes in development processes that cannot be repaired or compensated for. It is generally believed that earlier perturbations affect the developing embryo more profoundly than later episodes, with the first trimester of pregnancy being the most critical period.

In the first 7 to 10 days after fertilization, the human embryo undergoes several cell divisions, with implantation into the uterine wall marking the successful establishment of pregnancy. Contributing some of its own tissue, the embryo ensures access to nutrients through the formation of the placenta, which is a combination of maternal and embryonic tissue.

Insufficiencies in placental function profoundly affect growth and survival of the developing embryo. In rapid succession, the territories for the primordia of major tissue systems are laid down in a process that defines the overall body pattern of a vertebrate embryo. During a 4- to 10-week phase of development, which spans the events scientifically referred to as gastrulation and neuralization, embryos are most sensitive to perturbations that cause birth defects.

Highly coordinated processes of growth, movements, and interactions of cells are critical to proper formation of the primordial of major tissues and body parts and to subsequent development of each organ. Perturbations may affect groups of cells, changing their behavior, or the interactions between cells, resulting in miscommunication, or their growth, causing asynchrony. A single change can thus fundamentally influence one or more subsequent developmental pathways.

In many cases, the primary cause of the developmental defect cannot be unequivocally determined, but for genetic abnormalities, an increasing number of tests are becoming available that detect trisomies, translocations, deletions, rearrangements, and mutations. If the mutation was inherited, there is a higher risk of recurrence in future offspring.

Birth defects are classified as major and minor, generally reflecting clinical severity. Some birth defects are lethal, such as absence of the brain, malformations in brain structures (lissencephaly), severe skeletal dysplasia (thanatophoric dysplasia), or severe heart malformations or lung dysfunction as often seen with premature births. Major malformations include neural tube defects, heart defects, or agenesis of body parts that collectively affect from 1/1,000 up to several percent of births in special populations.

Minor malformations, such as vertebral anomalies, may go undetected at birth and include digit

abnormalities, cleft lip or altered facial features, or internal organ defects.

A group of birth defects that may or may not be associated with physical deformities is referred to as inborn errors of metabolism. In these cases, the ability to take up and properly utilize nutritional compounds is diminished or the removal of intermediates or end products is compromised. Cognitive impairment and neural retardation, even though not always detectable at birth, also have strong developmental components, as they often reflect subtle structural abnormalities of the brain.

Blindness and deafness may also be considered birth defects insofar as they result from abnormal development of eyes and ears or inborn tendency to degenerate. Since much of the development of sensory and cognitive systems in humans occurs after birth, the term "developmental defect" rather than "birth defect" would be more appropriate.

Historically, a distinction has been made in classification of birth defects as syndromic or isolated, depending on whether a combination of anomalies was present or not. With more refined combinations of clinical and genetic diagnosis, this distinction has become less meaningful in recent years.

The incidence of certain birth defects appears to be related to maternal nutrition. It has long been recognized that the risk for neural tube defects can be reduced by supplementation of maternal diet with folic acid (folate). In many countries, it is recommended that women supplement their food intake with folate-containing multivitamins; in the United States, grain products such as flour, bread, and cereal are fortified with folic acid. However, for folate to be effective, adequate levels have to be maintained during the early pregnancy, prompting the recommendation that all women of childbearing age consume either supplemental folate at 400 mg/day through a multivitamin that contains this amount or folate-only supplements. This will ensure adequate folate supply even if the pregnancy was unplanned or not recognized early on. Yet, even though folate can lower the risk, it cannot prevent all neural tube defects. Furthermore, it has recently been recognized that folate is also beneficial in reducing the incidence of cleft lip and palate and possibly skeletal defects.

Given that birth defects are the leading cause of child mortality in developed countries, the importance of proper nutrition cannot be overstated. Exposure of the developing embryo to potential teratogens is difficult to assess, unless outcomes point to well-defined

syndromes, such as fetal alcohol syndrome. Time of exposure, intensity, and duration may affect embryonic development. In recent years, it has become increasingly recognized that fetal exposure may not only cause acute insults but also predispose to disease later in adult life. For example, maternal use and exposure to tobacco during pregnancy are associated with increased risk for respiratory disease in progeny. Similarly, maternal diabetes during pregnancy appears to predispose to susceptibility for metabolic syndrome in the offspring. A rising concern is the increasing prevalence of babies born small for gestational age or prematurely. While not a birth defect in the classical definition, developmental immaturity at birth is associated with substantially increased childhood morbidity, mortality, and disease susceptibility later in life.

Most progress in understanding the causes of birth defects has been made for anomalies caused by mutations in single genes. In these cases, the availability of diagnostic tests has enabled screening of at-risk pregnancies, although in utero prevention of already manifest birth defects is currently not possible. However, in case of continuing pregnancy and birth, early diagnosis is often critical to choosing treatment options or timely enrollment in appropriate support programs. However, it should be emphasized that even in cases of a well-known genetic origin for a given disorder, the specific manifestation may cover a range of severity from profoundly to mildly affected or even asymptomatic individuals. This phenomenon of variable expressivity and incomplete penetrance makes estimates of recurrence risks difficult. The confounding factors in this variability are of great research interest and have important implications for individual treatment and long-term care.

## BIRTH ORDER

---

Alfred Adler, founder of the theory known as Individual Psychology, first introduced the concept of birth order. Adler identified characteristics of different ordinal positions, but he also emphasized the importance of psychological birth order. Adler believed that a family member's perception of his or her position within the family of origin may or may not match the actual ordinal position. For example, in a family with three siblings in which the oldest becomes chronically ill, the second born may hold typical first-born traits.

Each child's personality develops in relation to specifics of the sibling group. Or, in the case of the only child, the absence of siblings clearly impacts development. Adler saw variables such as family atmosphere, gender, and spacing among siblings as significant in the development of an individual's perceptions about birth order position. Individual Psychologists still identify psychological birth order position as well as actual position as fundamental in the development of a child's personality. The White-Campbell Psychological Birth Order Inventory was developed specifically to help clinicians and researchers identify psychological birth order position in relation to actual ordinal position.

Since the time Alfred Adler first introduced the concept of birth order, many clinicians and researchers (some of whom are not specifically related to Individual Psychology) also have influenced the development of this concept. Researchers have examined relationships between birth order and variables such as personality traits, achievement and intelligence, and interpersonal relationships. Additionally, the birth order concept has received media attention and become a popular subject in areas such as parenting education, personal growth, and intimate relationships. For example, Kevin Leman has written several popular books on the birth order concept including the relationship between birth order and selection of a mate.

While many professionals find the birth order concept interesting to use clinically and in research, specific research findings are seemingly inconclusive. Some wonder, then, Is birth order a myth or is it science? Statistically significant findings may only be difficult to interpret because of the phenomenological nature of the concept. Using psychological birth order or information about an individual's family atmosphere in relation to that person's actual ordinal position may lead to the most accurate interpretation of the meaning of birth order. For example, family dynamics to be explored that have been identified as influencing perceptions about a child's place in the family include (1) parenting styles, (2) death of a sibling, (3) miscarriage, (4) large age gaps between siblings (e.g., more than 3 years), (5) siblings with disabilities, (6) gender, and (7) divorce and step-siblings.

## CLINICAL PERSPECTIVE

Helping professionals often use birth order in terms of conceptualizing, understanding, and forming insight regarding clients' lifestyles or views of themselves in the world. Researcher Alan Stewart cautions the use of birth order characteristics in clinical judgment, indicating that information regarding birth order taken out of context can lead to inappropriate conclusions. From a clinical perspective, it is helpful to learn how clients perceived their position in the family of origin and how that relates to current concerns presented in therapy. Individual Psychologists believe that the family of origin is a child's first opportunity to see him or herself in a social context. Within the family, children develop personality characteristics as well as specific social skills.

Some general characteristics have been observed as typical birth order traits. Any personality trait can have both positive and negative aspects. For instance, a high achiever is often successful in certain areas of life but may suffer from excessive anxiety. Similarly, any birth order position may create a place for strengths of character as well as weaknesses. Again, the birth order position is phenomenological, and many variables exist. However, clinicians and researchers have identified general patterns of the following birth order positions.

## ONLY CHILDREN

Only children tend to be outgoing, mature, and verbally skilled. They are often surrounded by adults and therefore typically seek approval. They also may tend

to expect attention, or even prefer to be the center of attention. However, being an only child can sometimes feel lonely, as there are often fewer opportunities to practice peer social skills. It makes sense that when there is only one child, that child receives all the adult attention and resources of that family. In fact, early writings about birth order position describe the only child as at risk for being overindulged or pampered. As Alan Stewart noted (2004), current research contradicts these more negative stereotypes.

## FIRSTBORN CHILDREN

Firstborn children are often the example of responsible behavior for the other siblings. As the oldest in the family they typically take on the characteristics of perfection and high achievement. Firstborns tend to be characterized as organized, serious, and even bossy. As these children develop socially, they may have only a few close friends. Firstborns are thought to be more competitive and often thrive in leadership positions.

## SECONDBORN CHILDREN

The secondborn child enters the family in competition with the older sibling. Often, the secondborn will develop skills or interests opposite of the older sibling in an attempt to find his or her sense of belonging within the family. Secondborn children tend to be very social, competitive, and hard working, frequently in an attempt to compete or even overthrow the older sibling. They are often less serious and less focused on academic achievement, especially when the firstborn has already taken that position.

## MIDDLE CHILDREN

Middle children often feel squeezed between an older and a younger sibling, and are therefore usually concerned with fairness. Because of their middle position, these individuals are sensitive to injustices. Middle children may have more difficulty developing a sense of belonging and significance within the family. Because of these individuals' unique position within the family, middle children tend to be either skilled negotiators or instigators.

## YOUNGEST CHILDREN

The youngest child in the family is typically referred to as the "baby" and never experiences feelings

of being dethroned. These individuals are usually charming and socially outgoing. Youngest have the advantage of observing and learning from the successes and failures of older siblings. Being the youngest child in a family presents an opportunity to continually be pampered by older siblings and parents, thereby developing a lack of independence or self-reliance, or to use their position to excel.

Again, while these general birth order characteristics have been observed, it is important to emphasize that family atmosphere dynamics greatly influence individual perceptions about position in the family. Still, recognizing birth order positions and typical patterns provides a greater understanding of human development. The concept of psychological birth order, which expands the ordinal position concept, enhances this understanding.

## BIRTH WEIGHT

Birth weight is the actual weight of the baby determined immediately after delivery. The average birth

**Figure 1** Birth weight distribution of 150,000 deliveries in a tertiary medical center in Israel between 1988 and 2002.

weight in the United States varies between 3,000 and 3,600 g, depending on factors such as race, size of the parents, and gender (boys are heavier). Birth weight distribution of 150,000 deliveries between the years 1988 and 2002 in southern Israel is shown in Figure 1, with a mean of 3,200 g. Estimated fetal weight can be calculated in utero by ultrasound, based on fetal weight percentile, according to previously established gestational age. Fetal weight increases especially during the second half of pregnancy.

Estimated fetal weight less than the 10th percentile is considered small for gestational age, which may be due to intrauterine growth restriction. Low birth weight, defined as less than 2,500 g, has contributed appreciably to neonatal morbidity including neurological and intellectual deficits. However, such morbidity exists specifically in extremely low birth weight newborns (<1,000 g). It is estimated that 3 to 10% of infants are growth restricted. An important determinant of fetal weight is inheritance, and indeed a small woman is likely to have a small baby. Socioeconomic status of the mother is an important determinant of birth weight. Socioeconomic deprivation is associated with lower fetal growth rate, basically due to smoking, alcohol, or other substance abuse and poor nutrition. Other possible causes for growth restriction are problems in the placenta (which carries food and blood to

the baby), birth defects and genetic disorders, maternal infections, hypertensive disorders, and even several toxins and medications.

Management of growth restriction includes an attempt to determine the underlying etiology, including a careful ultrasound search for malformations. Fetal karyotype should be considered if structural anomalies are present. Also, testing for infectious diseases such as rubella, varicella, CMV, syphilis, HIV, and toxoplasmosis should be performed. Obvious environmental toxins or drugs should be removed from the maternal environment. Women are encouraged to cease smoking, eat a variety of healthy foods, and achieve optimal weight gain during pregnancy, as determined by their prepregnancy weight for height. Fetal surveillance includes serial ultrasound scans and fetal heart rate monitoring. Unfortunately, interventions to improve blood flow to the uterus (including bed rest and low-dose aspirin) failed to improve fetal outcome in randomized studies.

The fetus with enhanced growth is defined by birth weight greater than the 90th percentile for gestational age. Macrosomia is a term used to describe a very large baby and is defined as birth weight of more than 4,000 g. Macrosomia can be ascribed to an exaggerated, linear fetal growth or to abnormal maternal glucose homeostasis (diabetes mellitus). This high birth weight may cause birth trauma due to a serious condition known as *shoulder dystocia*—difficulty delivering the infant's shoulder. Although complicating only 0.13 to 2.1% of all deliveries, shoulder dystocia is associated with adverse maternal and fetal outcomes. Maternal morbidity includes lacerations of the birth canal and postpartum bleeding. Fetal complications include fracture of the clavicle or humerus and neurological complications such as asphyxiation or Erb's palsy. Several clinicians investigated factors associated with shoulder dystocia in an attempt to predict its occurrence. Major risk factors documented by most studies include fetal macrosomia, maternal diabetes, obesity, and operative delivery. Diabetic patients are almost five times more likely to have a shoulder dystocia, mainly due to higher rates of fetal macrosomia, larger shoulder and extremity circumferences, and increased body fat.

Unfortunately, prediction and therefore prevention of shoulder dystocia is virtually impossible. There is no reliable way to detect macrosomia in utero since ultrasound has a wide deviation of up to 22% in fetal macrosomia. Thus, an accurate estimate of excessive fetal size is not possible, and the diagnosis

is generally made after delivery. Reduction in the time interval from delivery of the head to the delivery of the body of the baby is important for survival. Several maneuvers exist to deliver the anterior shoulder and relieve shoulder dystocia, which are familiar to the attending obstetrician. Most cases are handled successfully.

## BIRTHING CENTERS

---

Birth centers are places where women and their families can experience the joys of childbirth. They provide intensive care to the childbearing family through extensive education and offering choices throughout pregnancy, labor, birth, and the postpartum period. The philosophy is family centered, and all birth centers provide a home-like environment that offers a nurturing and protected milieu for the mother. The woman is in control at a birth center, much like being in her own home.

The modern birth center was developed in 1975 as a pilot project by the Maternity Center Association (MCA) in New York City. The MCA has a long history of meeting its goal to improve the health of mothers and its infants. Established in 1925, the MCA has initiated such innovations as developing prenatal care, establishing the first school for nurse-midwives in the United States, and promoting childbirth education.

The birth center was an innovation for women who were dissatisfied with typical hospital births that consisted of many routine interventions like shave preps, enemas, and isolation of the mother from her family. It offered safe birth care, including the ability to transfer mothers to an acute-care hospital when that type of care was necessary. For the majority of women then and now, birth is an uncomplicated physiological event that can safely take place in a birth center with a qualified attendant usually a midwife. Midwives are skilled in attending normal birth, while the hospital and physicians are reserved for the complicated cases.

Birth centers provide safe, sensitive, and personalized care. This means that time is spent with the woman and her family during the pregnancy, questions are answered, and women become partners in their care. They weigh themselves and write in their own chart. They decide who will be with them in labor.

During labor, pain relief measures used in birth centers include position changes, massage, hydrotherapy, visualization, hypnosis, and the continuous presence of the birth attendant. Continuous presence of the birth attendant has been shown to decrease the length of labor and the number of operative births. The natural process of labor is enhanced by having mothers walking, drinking, and eating lightly. The attendant midwife carefully monitors the condition of the mother and baby using intermittent auscultation of the fetal heart rate and feeling the contractions with a hand rather than relying on machines to do this very sensitive surveillance. Women birth in the position that is most comfortable for them and in the place they choose, such as the tub.

Family members are very involved with the woman in labor. They encourage her, hold her, and offer cool compresses and drinks. Siblings are often present to see the birth of the newest family member.

Extensive research has demonstrated the safety of birth centers. In 1989, the results of a prospective study of more than 11,000 women who went to birth centers for care was published in the *New England Journal of Medicine*. In addition to validating the safety of the birth center model of care, the study documented the tremendous consumer satisfaction. There are now 90 birth centers throughout the country with more in the development stages.

The National Association of Childbearing Centers (NACC) is the national organization for birth centers and has midwives, physicians, nurses, administrators,

and consumers as members. NACC has developed national standards for birth centers, and the Commission for the Accreditation of Birth Centers accredits centers that meet these standards.

Birth is a joyous event, and birth centers celebrate it by providing women and their families with time-intensive, personalized care that results in a healthy baby and a new nurtured and happy family.

—Suzan Ulrich

## BISEXUALITY

---

The term bisexual can be used to refer either to people's sexual behavior or to their sexual identity. This distinction is made because behavior and self-selected labels do not always correspond. The prefix "bi" literally means two and is therefore used to refer to the dualistic nature of attraction to or sexual behavior with members of both sexes. In strictly behavioral terms, bisexuality indicates that an individual has had sexual experiences with members of both sexes. Based on research from the Kinsey Study on human sexuality, it is believed that as much as 28% of women and 46% of men have been behaviorally bisexual at some point in their lives. In terms of using bisexuality to refer to an individual's sexual identity, it applies to individuals who have chosen to identify, either outwardly or inwardly, as bisexual. In this case, bisexuality

1	2	3	4	5	6	7
Other Sex Only	Other Sex Mostly	Other Sex Somewhat More	Both Sexes Equally	Same Sex Somewhat More	Same Sex Mostly	Same Sex Only

**Figure 1** A Continuum of Bisexuality

is believed to indicate the potential to feel attracted to members of both sexes, regardless of whether the feelings are acted upon or not. Due to the controversial nature of assuming and maintaining an openly bisexual identity, it is difficult to estimate what percentage of the population is bisexually identified.

### BISEXUALITY ON A CONTINUUM

While it may be tempting to conceptualize the world as comprised of three groups, heterosexual, homosexual, and bisexual, research indicates that it is more helpful to conceive of sexual attraction and orientation as existing on a continuum, such as Figure 1, which has been adapted from Kinsey:

The area between the end points of 1 and 7 represents those who are attracted to both sexes to varying degrees. While many people assume that bisexuality must represent the exact midpoint between the two poles of exclusive heterosexuality and exclusive homosexuality, studies indicate that rarely do bisexually identified individuals perceive themselves as being equally attracted to both sexes. Rather, most self-identified bisexuals indicate that they have a clear preference for one sex over the other, often in a 40/60 split, represented by 3 or 5 on the above scale, or 30/70 split, represented by 2 or 6 on the above scale.

### BISEXUAL IDENTITY DEVELOPMENT

Although a number of people may engage in sexual activity with members of both their own sex and the other sex across the life span, relatively few will choose to identify as bisexual. Also, there are some who choose to self-identify as bisexual, despite never having had sexual experiences with members of their own sex and/or members of the other sex. This raises the question of how a person comes to claim a bisexual identity if sexual behavior does not always determine identity.

While there are numerous models describing gay and lesbian identity development, there are

relatively few models that define bisexual identity development.

This is believed to be reflective of the general lack of attention that has been paid to bisexuality by theorists and researchers alike, who tend to combine bisexuality with gay and lesbian identities. Bisexual identity development models are different from gay and lesbian identity development models because they tend to be nonlinear, more complex, and remain open-ended due to the fluid nature of bisexuality. The following four-stage model in Figure 2, which is based on interviews with bisexually identified individuals, was proposed by Weinberg, Williams, and Pryor in 1994.

### COMPETING THEORETICAL MODELS

#### Conflict Model of Bisexuality

Some theorists within the fields of psychology and sex research believe that sexual orientation is dichotomous, meaning that people are either exclusively heterosexual or exclusively homosexual. This idea stems from the notion that men and women are opposites and therefore it is not possible for one person to experience attraction to both sexes. In the conflict model of bisexuality, it is believed that bisexual people are confused and conflicted over their sexual orientation, likely to be in a transition phase from heterosexuality to homosexuality, and employing the bisexual label as a defense against adopting a homosexual identity. The conflict model fits well with many of society's stereotypes about sexual orientation including the idea that any amount of same-sex attraction is indicative of an underlying exclusive same-sex orientation. Also, the conflict model reflects the suspicion and skepticism present both within mainstream heterosexual society and some gay and lesbian groups about the validity and permanence of a bisexual identity. Research indicates that while popular wisdom may hold that this model fits the majority of bisexually identified people, in reality it represents a small minority of bisexuals.

Stage 1	<i>Initial Confusion</i>	Characterized by feelings of confusion, doubt, and struggle. Sources of confusion include (1) experiencing attraction to members of both sexes, (2) recognizing that available labels of heterosexual and homosexual do not fit, (3) facing the same-sex component of one's sexuality in a homophobic world.
Stage 2	<i>Finding and Applying the Label</i>	Characterized by trying on the bisexual label and recognizing that it fits one's experience of one's sexuality.  Various reasons for entering this stage include: (1) discovering that the category of bisexuality exists and fits one's experience, (2) having sexual experiences with both men and women that confirm one's feelings of attraction to both sexes, (3) deciding that there is no need to choose between a heterosexual or homosexual identity, (4) receiving encouragement and support from others for identifying as bisexual.
Stage 3	<i>Settling Into the Identity</i>	Characterized by increasing self-acceptance and decreasing concern about others' negative opinions of the bisexual label. The increase in self-acceptance is influenced by (1) receiving support from others for continuing to identify as bisexual, (2) knowledge of others who identify as bisexual, either through direct contact or reading.
Stage 4	<i>Continued Uncertainty</i>	Characterized by the ambiguity that is inherent in maintaining a bisexual identity. Many bisexuals continue to experience periods of doubt and uncertainty about their chosen identity. Sources of this continued uncertainty include (1) the lack of validation and support by the larger society, (2) the absence of bisexual role models and a bisexual community, (3) being in a monogamous relationship or otherwise not having a sexual relationship with both sexes.

**Figure 2** Four-Stage Model of Bisexuality

### Flexibility Model of Bisexuality

In contrast to those who support the conflict model of bisexuality, some theorists do not view sexual orientation as dichotomous, but rather as existing on a continuum (see Figure 1). From this viewpoint, it is possible to conceive of bisexuality as existing as a real and enduring identity, rather than as a pathological avoidance of one's homosexual identity. The flexibility model views bisexually identified individuals as capable of moving fluidly between same-sex and other-sex relationships. Although this model does acknowledge that a bisexual identity can result in ambivalence in some instances, it does not insist that the identity is inherently problematic as does the conflict model. The flexibility model is in keeping with the growing body of social science research that indicates

that bisexuality is indeed a valid and enduring identity for some individuals.

### BIPHOBIA

Simply stated, biphobia is the fear of bisexual people and the bisexual identity. Negative attitudes about bisexuality exist both within the heterosexual and gay/lesbian communities. While bisexual individuals are certainly impacted by homophobia, the fear of homosexuality, they also experience a form of oppression and discrimination that is unique to bisexuality. In addition, biphobia can come from an external source or from within. Internalized biphobia refers to the acceptance and internalization of negative messages about bisexuality by bisexual individuals. Fear

of bisexuals and bisexuality stems from and is maintained by a variety of myths about bisexuality. Myths about bisexuality include the notion that bisexuality does not exist or is merely a transition stage between heterosexuality and homosexuality, the idea that bisexuals cannot be monogamous or need to have partners of both sexes, and the belief that bisexuals are more promiscuous or are likely to leave one partner for a partner of the other sex. All of these myths translate into a general sense of distrust of bisexuals. It is important to remember that bisexuals are a diverse group of people, many of whom do not fit within these stereotypes.

## SUMMARY

The notion of bisexuality may be difficult to comprehend because it does not fit within the traditional dualistic conceptualization of the world as being comprised of numerous either/or choices such as black or white, male or female and heterosexual or homosexual. Rather, bisexuality challenges traditional thinking about sex, gender, and the fixedness of sexual orientation. Bisexuality represents a real, valid, crystallized identity that is separate and different from heterosexuality and homosexuality. Nevertheless, bisexual people face discrimination and hate crimes just as gay and lesbian individuals do. Although increasingly more research is being conducted on bisexuality as a unique identity, a deficit still remains in understanding this unique population.

## BMI (BODY MASS INDEX)

Body mass index (BMI) is a measure of human physical fitness that is designed to provide a standard metric for evaluating individuals' weight, relative to their height. Specifically, BMI is calculated as weight divided by height (squared), as shown below. As such, BMI can be thought of as the ratio of weight to height, per unit of height.

$$\text{BMI} = \frac{\text{kg}}{\text{m}^2} \text{ or, } \text{BMI} = \frac{\text{lbs}}{\text{in}^2} \times 703$$

Based on BMI, an individual's weight status can be classified as underweight, normal, overweight, or obese. Some professionals use an additional weight category of "extreme obesity" (or "morbidly obese") when classifying weight status.

## WEIGHT CLASSIFICATIONS AMONG ADULTS

Within adult populations, healthy body mass index values range from 18.5 to 24.9. Adults with a BMI of less than 18.5 are considered "underweight." BMI values of between 25.0 and 29.0 classify individuals as "overweight," and BMI values of equal to or greater than 30.0 classify individuals as "obese." These weight classifications are based upon research findings associating higher BMI scores with increased incidence of health complications such as heart disease, diabetes, and asthma.

## WEIGHT CLASSIFICATIONS AMONG CHILDREN

Although the same formula for calculating BMI is used with children and adults, the process for identifying

normal versus unhealthy growth patterns differs between populations. Because body mass index changes substantially with age, rather than using specific cutoff values, weight classifications for children between ages 2 and 20 are determined by plotting body mass values along growth charts for age and sex. Children whose BMI values fall between the 15th and 85th percentiles on BMI-for-age-and-sex growth charts are considered to be of healthy weight. Children whose BMIs fall above the 85th or 95th percentiles for their age and sex are classified as “overweight” or “obese,” respectively. Similarly, individuals with BMI values below the 15th percentile are considered to be “underweight.”

### ALTERNATIVE METHODS FOR CLASSIFYING WEIGHT

Alternative methods exist for determining weight status including waist circumference, skin fold measurement, underwater weighing (hydrostatic weighing), and bioelectrical impedance. Waist circumference is a general method for determining unhealthy weight status and simply involves measuring a person’s waist circumference. For women, a waist circumference greater than 35 inches is considered unhealthy and 40 inches is unhealthy for men. Skin fold measurement involves using a caliper device to measure the thickness of a fold of skin and its underlying layer of fatty tissue. Specific locations that are to be representative of overall body fat include back of arm, front of thigh, and lower abdomen. Hydrostatic weighing is a method where an individual’s “dry” weight is obtained while wearing minimal clothing. Next, the subject is lowered into a water filled tank where they are weighed underwater. These two weights are then compared to determine the person’s body fat percentage. Bioelectrical impedance uses medical technology to determine body composition including percentage of fat, muscle, and water.

### WHY USE BMI?

Compared to procedures such as skin fold measurement, waist circumference measurement, underwater weighing, and bioelectrical impedance, body mass index proves to be a relatively uncomplicated, inexpensive, accurate, and reliable tool for classifying weight status. Whereas techniques such as underwater weighing and bioelectrical impedance require both extensive training and sophisticated equipment, BMI calculations require only a scale, height rod, and basic mathematical

skills. Furthermore, unlike skin fold and waist circumference measurement, body mass index can be consistently calculated over time and by different people.

However, body mass index calculations are associated with a number of limitations as well. Although highly correlated with other assessment techniques for weight status, BMI calculations do not directly measure body fat percentage. BMI may overestimate body fat in individuals with higher than expected muscle mass (i.e., athletes) and may underestimate body fat percentage in individuals with little muscle mass (i.e., older adults). Similarly, BMI does not take into account the distribution of body fat within an individual, which is highly correlated with certain types of health risks. Thus, two individuals with identical BMI scores may have dramatically different body compositions.

As with any categorical system, specific values and percentiles separating healthy from unhealthy weights are, to some degree, arbitrary. That is, the prospective health status of individuals with respective BMIs of 28 (designated as “overweight”) and 30 (designated “obese”) is probably more similar than the different labels would suggest. Although BMI shares this fundamental problem with other measurement systems that utilize categorical systems, weight status as measured by BMI has repeatedly been shown to be a robust predictor of health problems in the research literature. Currently, BMI is one of the most widely used, accurate, and cost-effective methods for classifying weight status.

## BOWLBY, JOHN (1907–1990)

---

Edward John Mostyn Bowlby is, together with Mary Ainsworth, the founder of attachment theory. In this theory, Bowlby tried to explain the way in which infants establish ties with their mothers or caregivers, and he explored the emotional consequences of disrupted ties.

Bowlby grew up in a typical upper-middle-class family in London. His father, a leading surgeon, was often absent. He was cared for by a nanny and nursemaids. In 1918, he was sent to boarding school. He was further educated at Dartmouth Royal Naval College and Trinity College, Cambridge, where he studied medicine and psychology. He then worked at a progressive school for maladjusted children. This school's view that the present problems of children stemmed from adverse experiences in their families in the past struck a chord with Bowlby. To further explore this field of interest, he completed his medical studies and started at psychiatry and psychoanalysis.

From his first publication (1938) onward, the link between mother-child separation and the later personality development of the child was his major theme. In 1946, he joined the staff of the Children's Department of the Tavistock Clinic, where he remained until his retirement in 1972. Within this department, he was able to establish a research unit to examine the effects on young children of separation from the mother. One of the co-workers in this clinic was Mary Ainsworth, who later translated the basic tenets of attachment theory into empirical findings. She also developed a research instrument (the Strange Situation) for studying attachment of children to their mothers under laboratory conditions.

A breakthrough in Bowlby's career was his 1951 report on the mental health of homeless children at the invitation of the World Health Organization. This report, which was translated into 14 languages, highlighted the importance of continuing loving care by the mother figure for a young child's healthy development. He found the theoretical framework for the effects discussed in the WHO monograph in the supplementation of his analytical knowledge with ethological insights. Bowlby laid down his theory in his well-known trilogy *Attachment* (1969), *Separation* (1973), and *Loss* (1980). Bowlby's work has had (and still has) a great impact. Child care practices were improved on the basis of his ideas. Much fruitful

research has been prompted by his theory. Many clinicians are finding his insights and approach useful.

## BRAIN DEATH

---

Advances in medicine, surgery, and public health have gradually increased the average life expectancy of the population. At the same time, patients with chronic diseases experience increased survival periods in relatively good health, leading to advanced single or only few organ failures, making them adequate candidates for organ replacement via transplantation. The accumulated knowledge and technological progress made up to the late 1950s in critical care medicine allowed physicians to artificially maintain body oxygenation and blood perfusion regardless of brain function. Simultaneously, the highly successful developments in the field of organ transplantation promoted an ever-increasing demand and need for such organs.

The first solid organs (e.g., liver, kidney) for transplantation were obtained from donors in whom cardiac and pulmonary function had ceased, otherwise referred to as cadaveric organ donors. It was soon learned that the continued cardiopulmonary function of the brain-dead donor provided healthier, blood-perfused organs. This promoted deep changes, and with it controversies in the medical, ethical, and philosophical perspectives about death. Through scientific landmark achievements, medicine empowered the dead to help the living through the wonder of organ donation.

The first set of brain death criteria were the Harvard Brain Death Committee Criteria from 1968. These,

with few changes induced by newer medical development, remain the backbone for the diagnosis of brain death. In 1981, the United States Uniform Determination of Death Act established that death can occur by one of two clinical events: cessation of cardiopulmonary function or cessation of function of the entire brain. Brain death is an artificial, technologically driven, clinical condition of oxygenation of a cadaver.

For the diagnosis of brain death, clinical evidence of severe, extensive, and irreversible brain injury (metabolic or anatomic) needs to be present. Confounding factors or diagnoses that can mimic brain death need to be carefully ruled out, such as severe hypothermia or chemically induced skeletal muscle paralysis.

In the appropriate context, three clinical elements are present: coma (cessation of function of either the upper brain stem or both cerebral hemispheres), loss of reflexes from the brain stem, and inability to spontaneously breathe (lower brain stem) even when a maximal respiratory challenge is provided (the apnea test).

The so-called “confirmatory” tests are only used when most of the elements for the diagnosis of brain death are present, but it is not possible to reliably satisfy all of the criteria on clinical grounds. For example, in patients with severe facial injuries or in those with advanced pulmonary disease and chronic carbon dioxide retention. These tests are classified in two subgroups: blood flow studies, such as transcranial Doppler (ultrasound), or electrical tests, such as electroencephalography. These “confirmatory” tests cannot take the place of the clinical criteria.

The diagnosis of brain death is serious and irreversible. It confirms that the person is dead. When the diagnosis is reached, the person becomes a cadaver. If the option of organ donation is not viable, all artificial means of sustaining body oxygenation and blood circulation should be discontinued.

Brain death is a difficult diagnosis for families to understand and for physicians to communicate.

## BRAIN DEVELOPMENT

---

Humans share many similarities with other animals, including the ability to experience sensations, exhibit motor behavior, and even socialize. However, we are clearly different in many important regards. For example, unlike any other animal, humans possess the unique ability to produce and understand language, experience complex emotions, and perform higher cognitive functions. Not surprisingly, each of these abilities is under the control of the brain. What this means, therefore, is that although the human brain is anatomically comparable to the animal brain in regard to “lower” structures required for the production of basic functions, the human brain also contains “higher” structures that produce the behaviors found exclusively in humans. As such, humans possess the most highly evolved brain. This is illustrated by the fact that on average the adult brain consists of 100 billion neurons, each of which makes between 1,000 and 10,000 connections with other cells. What is perhaps even more amazing is that despite its obvious complexity, the entire human brain originates from a single cell, as does the rest of the human body. The following discussion will describe the process of human brain development, beginning at the time of conception and ending when all neurons have arrived at their appropriate target within the brain.

### EARLY CENTRAL NERVOUS SYSTEM DEVELOPMENT

The human central nervous system begins to develop within 2 weeks after conception. Around this time, the single-celled embryo enters its blastulation phase, during which it undergoes a series of divisions leading to the formation of a hollow, multicelled ball called a blastula. The blastula then enters gastrulation, a process marked by the cells’ reorganization into three distinct layers: endoderm, mesoderm, and ectoderm. In contrast to the blastulation phase during which the embryo simply multiplies in size, the gastrulation phase is characterized not only by continued

embryonic growth, but also by the first attempt at becoming a multistructured, multifunctional organism. This is evidenced by the fact that each of the three layers formed during gastrulation is exclusively involved in the formation of specific constituents of the human body. For example, the mesoderm gives rise to muscle, bones, connective tissue, and the cardiovascular system; the endoderm forms the gut and internal organs; and the ectoderm forms the skin and central nervous system (CNS).

Neurulation is defined by the creation of an indentation along the length of the ectoderm. It is considered the earliest stage of brain development and is complete by approximately 3 weeks following conception. During neurulation, cells on either side of the ectoderm's "neural groove" thicken to form two folds that eventually fuse to create the neural tube. The tissue of the neural tube can be divided into two regions: the ventricular zone and the marginal zone. The ventricular zone is the innermost region of the neural tube. Its region is defined by its location (which is adjacent to the neural tube's ventricle), as well as by the presence of neural and glial precursor cells (neuroblasts and glioblasts). All neuroblasts and glioblasts originate and proliferate in the ventricular zone. The marginal zone is the outermost region of the neural tube. It contains a certain type of cell of unknown origin that expresses reelin. Reelin is a substance critically required for normal cortical development and organization. Interestingly, although precursor cells neither reside nor divide within the marginal zone, they do transiently appear in this region throughout the development of the neural tube. Given the function of reelin in brain development, it is therefore likely that the transient expression of neural precursors in the marginal zone is to undergo some process necessary for normal brain development.

### FROM NEURAL TUBE TO BRAIN: HOW DO PRECURSORS FULFILL THEIR DESTINY?

It is amazing that at only 3 weeks after conception the human embryo has developed to such a degree that it now contains all of the hardware necessary to create the entire human brain. What is perhaps even more remarkable, however, is that each neuron throughout the entire adult brain originates from the undifferentiated precursor cells that reside in the ventricular zone of the embryo's neural tube. What this means is that the highly specialized neurons that mediate our sensory

experiences, regulate our motor behavior, influence our cognitive abilities, and affect our emotional reactions can all be traced to the confines of the relatively primitive neural tube of the 3-week-old embryo. Moreover, given that each of the above functions (as well as the thousands of others not mentioned) is generally associated with distinct brain regions, the question arises: How is it that these cells find their way to their ultimate destination?

During the development of the neural tube, special cells called radial glia are also formed. The sole purpose of radial glia is to guide neuroblasts to where they are destined to belong. This is evidenced by the fact that radial glia are transiently expressed. During brain development, they are found in abundance. Once neuronal migration is complete, they essentially disappear. Like all neurons and glia, radial glia are also birthed and proliferate in the ventricular zone of the neural tube. However, radial glia are unique in that their fibers extend all the way to the pial surface of the neural tube, thus forming a scaffold-like structure. This scaffold provides a means by which neuroblasts can migrate from the ventricular zone to their final destination.

Neuroblasts do not simply attach to radial glia and blindly migrate out, however. Instead, they partake in an active process mediated by both genetic as well as environmental factors. Although each neuroblast is genetically predisposed to become a specific type of neuron, it ultimately reaches its destination by processing chemical information in the extracellular environment during its journey. The acquisition of chemical information is made possible by the unique morphology of migrating neuroblasts whose axon and dendrites have extensions called growth cones. Growth cones contain chemically sensitive receptors and tiny, finger-like structures called filopodia that are used to pull the cell along the radial glia. During migration, the neuroblast is either chemically repelled or attracted to specific locations. Following these signals, it uses its filopodia to move along the radial glia toward the target to which it is attracted. Brain development is often referred to as occurring in an "inside-out" fashion in that the oldest neurons are located more deeply within the brain while the newest ones are found at the surface. This is because the first neuroblasts to migrate from the ventricular zone journey only a short distance before reaching their final target. As more new neuroblasts are birthed, they travel over all previous progenies to reach their targets, until the final set of neuroblasts arrives at the outermost layer of the brain.

## THE INFLUENCE OF NEURAL COMMUNICATION ON BRAIN DEVELOPMENT

Once the neuroblast reaches its final destination, it is considered a neuron and defines itself as such by differentiating into the specific type of neuron it is determined to be. That is, it becomes a sensory neuron if it is destined to be involved in a sensory process or a motor neuron if it is destined to perform motor behavior. Arrival at its target also causes the neuron to seek out contact with other cells. This contact is achieved through the creation of synapses (synaptogenesis). A synapse is the tiny gap between neurons (neurons do not touch) and is the fundamental process by which information is communicated from cell to cell. Early in development, neurons send projections to a very general region and synapse with many more cells than is necessary. As the brain continues to develop, some synapses (the appropriate ones) are used more than others. This frequent communication between two neurons leads to the strengthening of that particular synapse and makes the connection more likely to be maintained. In contrast, those synapses that are rarely used become “pruned” away. The result of this process is a very precise connection from one neuron to another. Behaviorally, this process can be illustrated through the examination of infant motor development. For example, early in infancy when babies reach for objects, they often overshoot their target. However, with repeated attempts over time, their reach becomes more skilled and precise. The process by which synapses are maintained can also be illustrated morphologically. For example, although the adult human brain is greater in both size and weight than the developing brain, the developing brain actually contains many more neurons and synapses. This occurs because as the brain develops some regions lose as many as 80% of the cells that inhabit the region through the process of apoptosis (programmed cell death). Incidentally, apoptosis is regulated by a number of factors, one of which is the failure of the neuron to make appropriate synaptic connections. Presumably, if a neuron does not receive sufficient connectivity from other neurons it is not critically required for normal brain function. As such, it commits a sort of cell suicide in order to ensure that it does not get in the way of other activity.

## SUMMARY

Human brain development is truly an awesome process. From its origins of the ectoderm of the gastrula, to its evolution into a multibillion-celled organ, the brain develops in a tightly regulated process under heavy genetic as well as environmental control. Despite our vast understanding of the human brain, the fact that we are continually learning more about it and its processes is alone testament to its complexity. Clearly, scientists for years to come will continue to be amazed by the human brain.

## BRAIN LATERALIZATION

---

The two hemispheres of the human brain are anatomically and functionally asymmetric.

## ANATOMICAL ASYMMETRY

Anatomical differences between the two hemispheres are observed in gross sulcal and gyral patterns

and size. The left Sylvian fissure is often more branched, longer, and horizontal than the corresponding structure in the right hemisphere (RH). The planum temporale (PT), associated with language processing, is larger in the left hemisphere (LH) in two thirds of the population. In addition, the posterior portion of the superior temporal gyrus (area Tpt) is generally larger in the LH, and its size is correlated with that of the PT. Primary auditory cortex (Heschl's gyrus) commonly contains a double gyrus in the RH, but not in the LH. There are also known neurochemical asymmetries, with greater abundance of dopamine receptors in the LH and that of the noradrenergic receptors in the RH. Such chemical asymmetries may play a role in lateralized functions.

### Lateralized Functions

In the majority of right-handers, the LH is specialized for syntactic and semantic aspects of language, whereas the RH seems to be specialized for spatial and affective processing including associative learning to emotional stimuli. Lesions in Broca's area in the left frontal cortex disrupt language production and syntax. Lesions in Wernicke's area in the left temporal cortex disrupt semantic processing. The role of the RH in language processing lies in prosody and pragmatics. The RH is also specialized for spatial attention, vigilance, and arousal. Visuospatially, the LH is more sensitive to high spatial frequencies (e.g., fine-grained features) whereas the RH is sensitive to low spatial frequencies (global, holistic form) with an advantage in face recognition and discrimination.

### ROLES OF DEVELOPMENT AND GENDER

Anatomical differences between the LH and RH are evident in the fetal Sylvian fissure and PT after the gestational midpoint, and rates of hemispheric growth alternate. Following the initial predominant growth of the RH in the first 6 months after birth, a period of predominant LH growth continues for the next 4 to 5 years, which includes the critical period for language acquisition. Handedness, a reliable behavioral signature of hemispheric dominance, is not completely established until about 7 to 12 years of age, but hand or side preference is usually consistent from infancy. Laterality in part is modulated by gender primarily through the effects of testosterone during gestation.

Both sexes are exposed to testosterone, but the exposure is greater in males. Testosterone may delay the development of the Sylvian fissure and Wernicke's area, thereby favoring earlier development of the RH in males. Some studies have reported increased right-handedness and spatial abilities and reduced verbal abilities in males than in females, and these functional sexual dimorphisms may be subsumed by differential gestational exposure to sex hormones. RH cortical thickness is also greater in males than in females.

### OTHER SPECIES

Brain lateralization may not be specific to humans but is more extreme in our species. Larger LH areas, especially the regions homologous to the human PT and the left inferior frontal gyrus operculum (Broca's region), were observed in the majority of chimpanzees studied. Additionally, captive chimpanzees show LH dominance in approximately two thirds of behaviors studied. LH dominance is also pronounced in the orangutan. Some species of birds and fish also show evidence of asymmetry, often biased toward the LH.

## BRAIN PLASTICITY

---

Brain plasticity refers to the observation that both the structure and function of the brain are molded by experience much in the way that plastic is shaped by a manufacturer to suit various demands. Brain plasticity occurs during development of the nervous system, when we learn, and in response to injury. This plasticity is manifested not only by neurons, the principle information-processing cells of the brain, but also by supportive elements including glial cells and the cells that comprise the vascular networks of the brain.

## DEVELOPMENTAL VERSUS ADULTHOOD PLASTICITY

Greenough and his colleagues (1987) have proposed that plasticity in the developing and adult nervous system is similar in form but different in expression. During development, they note that there is a massive overproduction of neurons and synapses (connections between neurons) that are later pruned by experience. They propose that this type of plasticity may be characterized as “experience-expectant.” That is, the nervous system has been programmed by our genes to display an exuberant growth of connections at particular points in time (e.g., eye-opening) in anticipation of experiences that are common to the species. For example, all humans can expect to be born into a world that is visually rich. Our genes, therefore, direct visual centers of the brain to be created in which there are neurons capable of processing visual information (shape, color, movement). However, our genes do not know which type of visual information we will encounter, so the system is programmed to account for all possibilities. Once we open our eyes and start to examine our visual world, the brain prunes away those extra connections and neurons that are not necessary in our particular environment. If we were born into an environment that lacked horizontal lines, our nervous system would retain those neurons and synapses that process vertical lines, color, and movement but would remove those that are responsible for encoding horizontal lines. In contrast, “experience-dependent” plasticity occurs in adulthood in response to novel situations. Plasticity in this case is manifested by smaller bursts of new synaptic growth within localized regions of the brain that is then pruned by the continuing experience. For example, an adult that learns to play the piano would add new synapses in motor regions of the brain that control finger movement. As the adult becomes more practiced, some of these new synapses would be pruned away, leaving only those that provide for coordinated movement.

## EXPERIENCE-INDUCED PLASTICITY OF NEURONS

Studies of brain plasticity indicate that characteristic changes include alterations of neuronal number, cell body (soma) size, dendritic extent and morphology, composition of the cellular membrane, and connectivity with other neurons (synapses). For example, several reports indicate that animals engaging in prolonged

exercise exhibit increased neuronal proliferation (neurogenesis) and survival in the hippocampus. Other studies have consistently reported that the rearing of animals in an enriched environment produces substantial increases in brain volume (around 25%). This increase is distributed across areas of the brain (motor cortex, visual cortex, cerebellum) but is largest in visual cortex. Subsequent studies have indicated that this volume increase is accompanied by increases in the size of dendritic trees, increased numbers of synapses per neuron, and changes in the shape of presynaptic and postsynaptic elements.

## A MODEL OF BRAIN PLASTICITY

Many neuroscientists have hypothesized how experience might promote brain plasticity and modify neuronal output. One of the most influential scientists was Donald O. Hebb, who proposed that the ability of two neurons to communicate with each other should be strengthened if those two neurons are repeatedly active at the same time. A physiological demonstration of this phenomenon was discovered in the early 1970s by Bliss and Lomo and was termed “long-term potentiation.”

Long-term potentiation (LTP) is a long-lasting increase in the excitability of a cell following a high frequency burst of stimulation. Many neuroscientists believe that LTP is a good model for the electrophysiological and structural changes that occur during development and in response to learning. It has most often been studied in the hippocampus, a brain structure strongly believed to play a role in learning and memory. In the hippocampus, LTP occurs when stimulation of afferent pathways causes release of the neurotransmitter glutamate. Glutamate binds to receptors (protein docking sites) on the postsynaptic neuron. Binding of the neurotransmitter opens ion channels that then permit sodium to enter the cell. Movement of the sodium ions into the cell induces a change in the membrane voltage of the neuron. This voltage change in the membrane, if sufficiently large, promotes the expulsion of an ionic blockade by magnesium of a second type of neurotransmitter receptor known as the NMDA receptor. Following the removal of the magnesium blockade, the neurotransmitter glutamate can freely bind to the NMDA receptor and open ion channels for calcium. Increased intracellular calcium triggers a cascade of events including the activation of enzymes that modify existing cellular proteins and that also trigger the synthesis of new proteins. Collectively, these events promote increases in neurotransmitter

release from the presynaptic neuron as well as postsynaptic changes in the composition of the membrane and dendrites (e.g., exposure and/or creation of more glutamate receptors, the formation of more synapses, or larger synapses). The net effect of these events is a relatively permanent change in the excitability of the neuron. For example, hippocampal LTP induction is associated with a 100% to 200% increase in the size of extracellularly recorded field potentials in as little as 10 to 15 minutes after the application of the tetanus. This increase in field potential amplitude is long lasting.

### VASCULAR PLASTICITY OF THE BRAIN

The primary focus of morphological studies of brain plasticity has centered on changes in the quality or quantity of synaptic connections. Recent investigations, however, have observed that the growth of new blood vessels from existing capillaries, or angiogenesis, occurs in response to behavioral manipulations that involve extensive physical exercise. In these studies, rats were trained on a running wheel for 30 days and the cerebellar cortex and motor cortex were dissected and the density of capillaries was determined. These investigations found that capillary density increased approximately 25% in the exercised rats compared to inactive controls. This demonstration of angiogenesis in the adult mammalian brain is especially significant given that early reports suggested that cortical angiogenesis in the rat is complete by 21 days of age. More recent reports of cerebral cortical angiogenesis in adult rats placed in complex environments, undergoing exercise, or exposed to hypobaric hypoxia indicate that the capacity for cortical angiogenesis, while diminishing with age, continues at least into the second year of life in the rat.

### PLASTICITY FOLLOWING INJURY

Plastic changes following damage to the brain are robust. Most CNS neurons attempt to regenerate but typically fail. This failure results in part from the actions of glial cells which show a marked plastic response to brain injury. For example, astrocytes, oligodendrocytes, and microglia rapidly proliferate at the site of injury. Astrocytes and oligodendrocytes both release proteoglycans that inhibit axon regeneration. Activated microglia provide a permissive environment. They release neurotrophins. However, their actions cannot overcome the inhibitory effects provided by the other cells.

Many neuroscientists draw a parallel between mechanisms of recovery of function following injury and the plasticity associated with learning and memory. For example, a now classic study by Raisman and Field examined the synaptic contacts onto septal neurons. Septal neurons receive afferent information from the fimbria and medial forebrain bundle. These inputs make approximately equal numbers of synaptic contacts onto septal neurons. In their experiment, Raisman and Field lesioned one or the other of the inputs and counted synapses over a period of time. They found that, within 1 or 2 days of the lesion, synaptic contacts onto the septal neurons decreased by about 50% (commensurate with axon degeneration of the cut pathway). But, over the course of several weeks, the synaptic numbers once again approached normal levels. They determined that the new synaptic contacts were coming from the pathway that was not lesioned. In other words, neurons from the intact path were sprouting axonal branches and making additional synaptic contact with the septal neurons. This process is known as *collateral sprouting*. This was a landmark study in that it was the first to demonstrate that nondamaged areas of the brain try to compensate for damage.

More recently, this idea of compensation has been examined in the somatosensory cerebral cortex. Michael Merzenich and his group have carefully mapped the topography of the hand onto the somatosensory cortex. In one study, they either lesioned a sensory nerve of one of the fingers or removed the finger and recorded the neural activity from the cortex. They expected to see diminished activity in the region of the cortex that had just lost its input from the finger. Instead, they found that the cortex displayed neural responses to stimulation of parts of the hand adjacent to the damaged nerve or removed finger. This observation is consistent with the idea that adjacent portions of the body make synapses in their own area of the cortex as well as adjacent portions, but that the synapses that are formed in adjacent areas are repressed. When the finger information is removed, a short-term plastic change occurs that removes the repression associated with synapses from the adjacent parts of the cortex. In other words, the motor maps for adjacent portions of the body have expanded or taken over the functions of the denervated cortex. Further, Merzenich's group reports that over the course of a month or two, axons in adjacent regions of the cortex sprout collaterals that will more fully innervate the denervated region. The consequence of this is that adjacent body parts become more sensitive to stimulation.

Subsequent studies have indicated that the plasticity associated with collateral sprouting follows Hebbian rules; that is, synaptic formation and strengthening are dependent on correlated activity in pre- and postsynaptic neurons. Further, this mechanism appears to be dependent on activation of the NMDA receptor and calcium influx.

## BRAZELTON, T. BERRY (1918– )

---

T. Berry Brazelton's role as researcher, clinician, and advocate for parents has been one of the formative influences in pediatrics in the United States for over 50 years. He was born in Waco, Texas, on May 10, 1918, and graduated from Princeton in 1940. In 1943 he graduated

from the Columbia University College of Physicians and Surgeons in New York City, where he accepted a medical internship. In 1945 he moved to Boston to serve his medical residency at Massachusetts General Hospital before undertaking pediatric training at Children's Hospital. His interest in child development led to training in child psychiatry at Massachusetts General Hospital and the James Jackson Putnam Children's Center. He was a Fellow with Professor Jerome Bruner at the Center for Cognitive Studies at Harvard University. There, the process of integrating his dual interests—primary care pediatrics and child psychiatry—culminated in 1972, when he established the Child Development Unit, a pediatric training and research center at Children's Hospital in Boston.

Dr. Brazelton was one of the pioneers in newborn behavioral research. In 1973, he and his colleagues developed the *Neonatal Behavioral Assessment Scale* (NBAS), widely acknowledged as the most innovative and comprehensive assessment of newborn behavior (Brazelton, 1973; 1985; Brazelton & Nugent, 1995). The NBAS has been used in hundreds of research studies to assess the effects of a wide range of pre- and perinatal influences on newborn behavior. It has been used in cross-cultural studies and as a method of intervention to help parents understand and relate to their infants.

While Dr. Brazelton continued his daily pediatric practice, he taught pediatric residents, conducted research, and frequently appeared before Congressional committees in support of parental and medical leave. Like Benjamin Spock, to whom he has been compared, Dr. Brazelton's many books for parents and his television show *What Every Baby Knows* have influenced the beliefs and practices of parents everywhere. His classic book *Infants and Mothers* focused on the nature of individual differences in behavior and was characterized by a deep respect for parents' own decision-making abilities. He has published many other books for parents, more recently the *Touchpoints* and *Brazelton Way* books.

Dr. Brazelton is Clinical Professor Emeritus of Pediatrics at Harvard Medical School and is Professor of Psychiatry and Human Development at Brown University. In 1995, Harvard University Medical School established the T. Berry Brazelton Chair in Pediatrics. Dr. Brazelton is still actively involved with The Brazelton Touchpoints Program, a preventive outreach program that trains professionals to better serve families of infants and toddlers.

## BREAST CANCER

---

Despite considerable advances in diagnosis and treatment in the past few decades, breast cancer remains a significant public health concern. Over 210,000 new cases are diagnosed in the United States annually, making it the most common type of cancer in women. It is predominantly a disease of women, with estimates that one in seven women will develop some form of breast cancer during their lifetime. Although not unknown in men, it is far less common. Approximately 1,300 men in the United States develop breast cancer each year.

A basic introduction to the medical aspects of breast cancer will be provided first. Breast cancer will be described in terms of its biological pathology and symptoms. Genetic, behavioral, and environmental risk factors for breast cancer will be discussed, along with methods of diagnosis and treatment. Equally important are the psychological stresses associated with breast cancer: the initial discovery of a lump in the breast, waiting for biopsy results, undergoing treatment, and facing the possibility of recurrence. The psychological impact of diagnosis, along with factors that promote successful adjustment, are reviewed. The topic concludes with a discussion of promising future directions for the care of both medical and psychological health.

### MEDICAL ASPECTS OF BREAST CANCER

#### What Is Cancer?

Normally, cells in the body divide in a controlled manner to allow normal growth, replace dead cells, or heal an injury. Genes control the cellular mechanisms responsible for keeping cell division in check, but

when a cell's genes mutate or become damaged, cells can begin to divide uncontrollably. In the breast tissue, unchecked cell growth can form masses (tumors). *Benign* tumors do not spread and are not life-threatening. In contrast, *malignant* cancerous tumors can grow and spread. Tumors are referred to as *in situ* (in place) when they remain confined to localized masses, or *invasive* when cells that are capable of breaking away from the tumor invade surrounding tissue or spread throughout the body by traveling in the bloodstream or the lymphatic system. The spread of cancer cells to other parts of the body (e.g., the liver or brain) is referred to as *metastasis*. However, when breast cancer cells are found in other body areas, it is still considered breast cancer. Breast cancer becomes life-threatening when metastases disrupt vital functioning in other areas of the body (e.g., the brain).

#### Types of Breast Cancer

Breast cancer types can be distinguished based on the location of the original tumor. Ductal carcinoma, the most common form of breast cancer, describes cancer occurring in the milk ducts. Cancer occurring in the glands of the breast where milk is produced is referred to as lobular carcinoma. Ductile and lobular carcinoma can be either *in situ* or *invasive*. The most common symptom is the formation of a painless lump in the breast or underarm area. Less common symptoms include change in the size or shape of the breast, distortions in the breast near the surface of the skin (e.g., puckering), and inversion, tenderness, or abnormal discharge of the nipple.

Inflammatory breast cancer is a less common, invasive form of the disease in which dispersed groups of cancer cells obstruct the lymphatic system in the breast, leading to symptoms such as swelling or a red, rash-like appearance on the breast. Tubular carcinoma is a form of invasive ductile carcinoma involving the proliferation of microscopic structures called tubules. Symptoms of tubular carcinoma resemble those of ductal and lobular cancer, but are associated with more favorable prognoses. Paget's disease of the nipple occurs when a carcinoma elsewhere in the breast spreads and affects the nipple and areola. This form of cancer often results in crusting or flaking; itching, burning, and redness; or bleeding and discharge from the nipple.

#### Causes of Breast Cancer

The specific causes of breast cancer are not yet known, but there are a number of genetic, environmental, and

behavioral risk factors known to be associated with increased risk. Being female is the strongest risk factor. Age is also a prominent risk factor. Women in their sixties are 80 times more likely to develop breast cancer than when in their twenties. Another risk factor is the possession of a mutated form of a gene referred to as BRCA. These mutations occur in less than 1% of the population, but are associated with up to an 85% likelihood of breast cancer occurrence by age 70. However, BRCA mutations account for less than 10% of breast cancer diagnoses. A woman's risk for breast cancer is increased two- to fivefold if she has a family history of breast cancer, particularly in first-degree relatives who developed cancer before menopause. Prior *in situ* or invasive carcinomas also increase the risk of developing future breast cancers, as do precancerous masses that can develop into malignancies. To a lesser extent, a greater number of reproductive cycles a woman passes through and hormone replacement therapy are also risk factors, as they increase lifetime exposure to reproductive hormones that can damage genes, alter cell growth, and promote the growth of certain cancers. Other potential risk factors are less clear. There is some evidence that obesity, alcohol use, and use of oral contraceptives may slightly increase one's risk for breast cancer, but the research is not strong to support these as risk factors.

### What Doesn't Cause Breast Cancer

Breast cancer is not caused by a virus, bacteria, contact with someone with cancer, injury to the breast, or surgery. Through the years, a number of myths have perpetuated about potential causes of breast cancer. Some are based on initial research that appeared promising but does not hold up in better-controlled studies. A cancer-prone or "type C" personality has been proposed, characterized by compliance, a hopeless attitude, and difficulty expressing emotion. The mechanism by which personality might influence the development of cancer is unclear, and little support has been found for this claim. Similarly, high life stress as a causal factor has not been supported by recent research. Other myths have no clear basis in scientific research. There is no evidence, for example, that the use of underarm deodorants or wearing bras can cause breast cancer. In recent years, the explosion of unregulated information on the Internet has propagated unscientific or fraudulent claims of causal factors. Although the Internet can be a useful source of

information, readers are strongly recommended to focus on credible, well-known sites (e.g., the American Cancer Society at <http://www.cancer.org>).

### Diagnosis

Most breast cancers are detected either through breast examinations or breast-imaging techniques. Breast examinations involve manually checking the breast tissue for lumps. Available imaging techniques include CAT scan, MRI, ultrasound, and mammography. The most common of these is mammography, an X-ray of the breast, which can identify about 90% of breast cancers, even in women with no symptoms. In combination, mammograms and breast examinations can increase the likelihood of early detection of breast cancer, which can improve the chances of successful treatment. The final stage of diagnosis, the biopsy, involves examining the tissue mass (obtained either surgically or through a needle) under a microscope to determine whether it is benign or malignant. Approximately 80% or more of biopsies reveal that the mass in question is benign. If malignant, the biopsy can also determine whether or not the growth of the tumor is promoted by the reproductive hormones estrogen and progesterone.

### Prognosis

The severity of a breast cancer is described by classification into stages, based on the size of the tumor, the involvement of the lymphatic system, and whether or not metastasis has occurred. Stage 0 breast cancer refers to an *in situ* tumor and is often called precancerous. Stage I breast cancer describes a tumor of less than 2 cm that has not invaded the lymphatic system or metastasized. A designation of stage II requires that a tumor be either between 2 and 5 cm or that cancer cells have spread to the lymphatic system of the same breast but have not metastasized. Stage III is designated when a tumor exceeds 5 cm and involves the lymphatic system of the same breast. Stage IV breast cancer indicates that metastasis has occurred. More advanced stages of cancer are associated with a poorer prognosis and require more aggressive treatment. Statistics show that the percentage of women who survive breast cancer for at least 5 years following diagnosis decreases by stage (stage 0, 100%; stage I, 98%, stage II, 76–88%; stage III, 49–56%; stage IV, 16%).

## Treatment

Treatment of breast cancer has improved greatly during the past three decades. Several methods of treating cancer exist, and they are often used in conjunction with one another rather than individually. Most breast cancer patients undergo surgery to remove the tumor, often along with a sample of the lymph nodes. Smaller tumors (e.g., stage I or II) can usually be removed with a technique called *lumpectomy*, which conserves the cosmetic appearance of the breast. Larger or dispersed tumors sometimes necessitate a *mastectomy* (removal of the entire breast). Side effects of surgery include infection risk, pain, cosmetic disfigurement, and fatigue.

Additional treatments that supplement surgery, called *adjuvant* treatments, are often used to destroy residual cancer cells or metastases. Common adjuvant treatments include chemotherapy, radiation therapy, hormone therapy, and immunotherapy. These treatments can reduce the size of a tumor and are sometimes given before surgery is performed, in which case they are referred to as *neoadjuvant* treatments. Chemotherapy is the administration of drugs that destroy rapidly dividing cells, such as cancer cells. The drugs can be administered in pill form, as an injection, or intravenously. Duration and frequency of treatment depend on the type and stage of cancer. A major side effect of chemotherapy is that it destroys rapidly dividing cells in other areas of the body, including hair follicles and the mouth, often resulting in hair loss and mouth sores. Nausea, fatigue, pain, fertility problems, and cognitive difficulties are other potential side effects.

Radiation therapy involves exposing cancer cells to radiation in order to curb their growth. This is done by directing an external beam of particles towards the tumor or by implanting a pellet of radioactive material near the tumor. External radiation treatments are usually administered for up to 30 minutes daily for several weeks, depending on the particular case. Because radiation directly targets the tumor, adjacent normal tissue is not damaged. However, radiation therapy often produces dry or itchy skin, sunburn-like pain near the target site, darkening of the skin, and fatigue. Chemotherapy and radiation are both effective in reducing intermediate term (e.g., 5- or 10-year) recurrence and death rates by up to 15% relative to surgery alone, but the effectiveness varies by cancer type and stage. Yet, even with treatment, breast cancer recurs in approximately 4 to 7% of patients within 5 years of treatment.

Certain types of breast cancers grow faster in the presence of estrogen and progesterone. These cancers are often treated with hormone therapies, drugs that block the production and activity of estrogen and progesterone. This treatment can be effective in shrinking or slowing the growth of a hormone-responsive tumor but can have menopause-like side effects, including hot flashes and fluid retention. Hormone therapy may also produce nausea, visual disturbances, or vaginal bleeding or discharge. Five years of hormone therapy has been shown to decrease recurrence rates by 12% and increase survival rates by 4%, 10 years posttreatment. Another less common treatment is immunotherapy. Manufactured immune system components (antibodies) are injected into the blood stream, with the goal of boosting the body's natural ability to identify and destroy abnormal cancer cells. Studies show that some immunotherapy drugs increase 1-year survival rates by 11%, above and beyond chemotherapy.

Several complementary or alternative treatments for breast cancer exist. Some believe that a nondairy, high-fiber diet rich in fruit and vegetables may help fight breast cancer. Naturopathic and herbal medicine may also be useful, and a variety of herbs and nutritional supplements may improve one's prognosis. For example, antioxidants may increase the effectiveness of chemotherapy treatments. Mind/body techniques, such as hypnosis and meditation, attempt to exert mental control over treatment side effects and the natural physiological processes that fight cancer. Acupuncture and Reiki are Eastern alternative treatments that treat cancer by redirecting the flow of energy in the body. Many women find psychological benefits from complementary/alternative treatments. However, rigorous research on the benefits of such treatments for physical or psychological health is lacking.

## PSYCHOLOGICAL ASPECTS OF BREAST CANCER

### Stress Associated With Breast Cancer

Breast cancer can bring with it a large amount of stress, including financial strain, disabling side effects of treatment, the impact of cancer on loved ones, and the frightening possibility of death. For some women, the initial weeks following diagnosis are a time of tremendous uncertainty and psychological distress. Upon receiving the diagnosis, many experience disbelief,

shock, fear, or anger. Some may even blame themselves for their cancer, thinking that they somehow put themselves at risk by living an unhealthy lifestyle. Receiving a diagnosis of breast cancer may be especially distressing for men, as they may feel shameful having a disease in a part of the body associated with femininity. Approximately 30% to 40% of patients develop symptoms of anxiety and depression shortly following diagnosis. Recent studies have found that about 3% of breast cancer patients develop posttraumatic stress disorder (PTSD), an anxiety disorder characterized by recurrent intrusive thoughts and emotional distress following a severe trauma. Those that do not develop clinical levels of anxiety or depression often manifest some symptoms of these disorders, such as negative mood, persistent uncontrollable worry, hopelessness, or sleep disturbances.

Treatment demands can be a considerable source of stress. Those with limited financial resources or without medical insurance face the strain of financing medical care or loss of income. Other stressors involve the side effects of treatment itself. The perceived or actual disfigurement resulting from mastectomy can disturb a patient's self-esteem and body-image. For example, a woman may feel that because she has lost a breast, she is less feminine or less sexually desirable to a partner or spouse. For this and other reasons, treatment for breast cancer can interfere with a patient's ability to experience intimacy and sexuality. The side effects of some adjuvant treatments, as well as the time demands of attending frequent treatment sessions, can interfere with a patient's ability to work professionally and domestically.

For most patients, the psychological distress associated with breast cancer decreases in the months following diagnosis. However, the course of distress differs among individuals, and some experience considerable distress long after treatment. Some aspects of breast cancer, such as the fear of recurrence, can continue to induce psychological distress.

### End-of-Life Issues

Patients with a terminal prognosis face an array of challenges. These include saying goodbye to loved ones, settling their affairs, overcoming their fears of pain or loss of control, and the uncertainty of death. Many people dying from cancer also worry that their death will create emotional, financial, and social hardships for their loved ones. Patients often struggle with

decisions about further medical care. Once curative efforts fail, a delicate balance must be found between prolonging life with further treatment and maintaining quality of life through palliative care focused on pain management. Patients can receive palliative care in a hospital, at home, or in assisted-living facilities. Life-prolonging adjuvant treatment, pain management, emotional and informational support, and other services are typically offered.

### Benefit Finding

Despite the negative psychological consequences of breast cancer, it is clear that some patients can identify positive aspects of their experience with the disease. Patients may find that struggling with breast cancer forces them to call upon personal resources of which they were previously unaware, or that they are more resilient than they had expected. Cancer may have brought them closer to loved ones or strengthened their religious or spiritual convictions. Breast cancer may even reorder one's priorities about life. The identification of such benefits allows patients to grow from their experience with breast cancer.

### Predictors of Psychological Adjustment

Surprisingly, the severity of the cancer or the types of surgical or adjuvant treatments are not good predictors of distress levels. In contrast, age and educational level are among the most consistent predictors of levels of distress. Older and more educated women generally experience less distress and better overall adjustment than younger women. These groups of women tend to have an improved ability to cope with the stress associated with the diagnosis and treatment, which may account for better well-being.

The ways a patient thinks about her cancer experience also predicts psychological adjustment. Optimism, or a general predisposition toward hopefulness and expectation of positive outcomes, is related to positive adjustment. It is important to distinguish realistic from unrealistic optimism (i.e., Pollyanna-ism), which may lead one to disregard important health information or lower one's motivation to engage in health-promoting behaviors. Women with a realistic, optimistic attitude tend to experience quicker recovery from health problems in general and less distress related to having breast cancer. Other benefits include better satisfaction with

one's sex life posttreatment and lesser occurrence of negative intrusive thoughts and fears.

A related personal characteristic associated with better adjustment has been termed "fighting spirit," described as a belief in the ability to fight, conquer, and recover from breast cancer. Some researchers believe that fighting spirit may lead to better physical recovery, although evidence is mixed regarding its association with prognosis and survival. In contrast, blaming oneself for the development of breast cancer can impede adjustment, particularly in the months following diagnosis. The strength of one's coping skills also predicts adjustment. Women who actively cope with the illness (e.g., by making appointments, seeking information, and dealing with their emotions) tend to show better adjustment than those who use more avoidant coping strategies (e.g., not answering the phone, missing appointments). Benefits can also come from the ability to find meaning in the experience of cancer. Over time, patients who are able to find meaning in their illness often experience less anxiety, less depression, and higher self-esteem than those who are unable to find meaning in their experience.

Social relationships can provide considerable benefit to a breast cancer patient. Social support can be provided by a spouse, neighbors, co-workers, friends, church members, or other acquaintances. Studies show that the availability of emotional support (i.e., having someone to confide in, vent to, or rely on to boost one's self-esteem) can significantly enhance the well-being of breast cancer patients. Practical support is also important, such as the availability of someone to give the patient a ride to the hospital, pick the children up from school, or provide financial assistance. For many patients, an important source of social support comes from their religious or spiritual community. In general, religious or spiritual beliefs can contribute to enhanced quality of life, lower anxiety, better self-esteem, and the ability to find positive meaning in the cancer experience.

### **Breast Cancer and the Family**

The diagnosis and treatment of breast cancer can also significantly challenge an individual's social network. The immediate demands of diagnostic procedures and surgery, combined with the chronic demands of adjuvant treatments, can significantly impact a patient's ability to maintain social roles within a household or maintain outside employment. Breast cancer

often leads to significant distress in spouses, family members, and friends, who must face the potential loss of a loved one and unexpectedly assume the role of caregiver. The level of distress in spouses of breast cancer patients is generally quite similar to the level of distress in the patient. However, following completion of treatment, spouses and other family members may feel ready to have life return to "normal" and may be frustrated by the patient's continuing support needs.

Breast cancer, like most serious illnesses, requires a rearranging of roles within the family, as family members may need to take over many of the tasks previously the responsibility of the patient. The family may have a difficult time adjusting to the unexpected changes that arise as a consequence of the treatment of breast cancer and may even harbor resentment toward the patient for becoming ill. For families of patients in the terminal stages of breast cancer, psychological distress may be especially high. These families face a number of burdens, including managing the care of a terminally ill loved one, financial hardship, anticipatory grief, withdrawal of support from friends unable to cope with the dying process, and worries about the comfort levels of the patient. Families of terminally ill patients often experience significant fatigue, tension, anxiety, and depression.

Communication is an important factor related to the well-being of both the patient and the family. Studies have shown that while most patients would like to discuss the cancer and their fears, family members often mistakenly believe the patient would prefer they *not* discuss the topic or worry that talking about it will only increase their loved one's distress. Patients often report that after all treatment is completed, they still struggle with the impact of the diagnosis, yet feel that their family is no longer willing to discuss their continuing fears. The open and sensitive expression of desires and feelings can provide significant relief to both the patient and the family.

For a child whose parent is diagnosed with breast cancer, special concerns arise. In general, children of parents with breast cancer are at risk of distress, particularly if the child perceives high stress levels in the family or has poorly developed coping skills. Unfortunately, parents are often unaware of the extent of distress experienced by their children. Young children may not be capable of understanding what is happening, and care is needed in explaining the changes in the family. Although in some situations parents may decide to avoid telling their children about

the cancer, this strategy can lead to more distress in children who sense that something is wrong and may imagine extreme and erroneous explanations. Children who receive increased and supportive interaction with the non-ill parent may cope quite well, especially if the family as a whole copes well with the illness.

## Psychological Care and Intervention

In the last several decades, the medical and psychological communities have experienced a growing awareness of the psychological needs of breast cancer patients, and a number of interventions have been developed. A wide variety of resources is available for patients and their loved ones, including self-help books, individual and family therapy, peer-led support groups, internet and telephone support, and group therapy led by trained professionals. Research has consistently shown that psychological interventions can have beneficial effects on emotional adjustment, functional adjustment, and treatment and disease-related symptoms (e.g., nausea, pain).

Many breast cancer patients find comfort through interacting with others who have experienced a similar illness. Peer-led support groups are one of the most widely available forms of support for breast cancer patients. Typically, these groups meet in local communities and are led by the patients and survivors themselves with a free-flow, conversational format.

Professionally led interventions vary widely in treatment setting (e.g., hospital, therapist office, community centers), treatment provider (e.g., psychologist, nurse, social worker), targeted outcomes (e.g., control of nausea and vomiting, pain, emotional distress, quality of life, end-of-life issues), and treatment length (e.g., 1–40 sessions). Supportive group therapy focuses on guiding patients in the process of exploring and expressing their emotions and encouraging social support among group members. Other group interventions focus on improving skills for coping with the cancer and include training in relaxation and guided imagery techniques, educational information, and training in more adaptive coping skills (e.g., problem solving, communicating with health care providers, rational positive thinking about cancer).

Perhaps the most provocative research on the benefits of psychological intervention for breast cancer patients has suggested that psychological distress can affect biological disease processes and outcomes. Although some early research claimed that psychological interventions

can improve disease outcomes and increase survival times in women with breast cancer, more recent studies have failed to support these claims. While the psychological benefits are clear and may be reason enough to seek intervention, seeking psychological services in an attempt to improve prognosis or prolong survival is not advised.

Partners and family members of breast cancer patients also need support, but spouse, family, or child-focused supportive interventions are rare. Interested readers may wish to contact local cancer organizations, such as the American Cancer Society, for more information about the availability of these types of support groups. There is also growing recognition of the psychological needs of underserved populations, such as men, women of color, and lesbians. In larger cities, support groups specifically targeted for these populations can occasionally be found, but they are less likely to be available in more rural areas. Services generally follow a peer-led or supportive format. Although there is very little research on the effectiveness of interventions for underserved groups, preliminary studies suggest that psychological interventions can have benefits for mood and psychological well-being in these populations, similar to findings from studies with Caucasian women.

## FUTURE DIRECTIONS

Medical advances in the treatment of breast cancer in the last 30 years have been astounding, thanks in part to the millions of dollars that have been devoted to intensive research efforts. Some examples of noteworthy accomplishments include the development of advanced diagnostic techniques using ultrasound and MRIs, the demonstration of the effectiveness of less invasive surgical procedures (e.g., lumpectomy, sentinel node biopsy), the discovery of better chemotherapies to treat systemic disease, antiemetics to manage debilitating side effects of chemotherapy, the use of hormonal therapies to block estrogen receptors, and the identification of genetic markers of susceptibility to breast cancer and genetic tests to predict risk in asymptomatic women. The potential for genetic approaches to cancer treatment in the future has generated quite a bit of excitement. Many women choose to participate in clinical trials of new, as yet unproven treatments. For some, clinical trials are attractive because they may offer a promising new treatment when a good standard treatment is not available.

However, for a number of reasons, women may choose to stay with the standard treatment regimen. For example, clinical trials usually require strict criteria for participation, insurance coverage for clinical trials can be sparse, and participants are generally not able to directly choose the treatment they receive.

Substantial progress has also been made in the understanding and treatment of psychological and behavioral factors associated with breast cancer. These advances have resulted in considerably greater access to psychological services for cancer patients. Often these services are immediately available at the hospital or diagnostic center; however, many treatment centers remain unable to provide psychological services to patients and families. Although most women negotiate the demands of breast cancer well, others struggle in their attempts to cope with the disease. The challenge for the future is to better understand who is in greatest need of psychological health care and to ensure that services are readily available for those in need. Similarly, the future is likely to bring greater opportunities for psychological services directed at those from minority populations. Research is also underway to determine the types and timing (i.e., immediately postdiagnosis or following the demanding treatment regimens) of psychological interventions that are most effective. The availability and sophistication of Internet-based resources, including both peer and professionally developed supportive Web sites, are expected to substantially impact future provision of care for breast cancer. In combination, the increasing recognition of the need to attend to both psychological and medical care promises continuing improvements in the quality of life for those diagnosed with breast cancer.

## BREATHING REFLEX

The optimal natural breathing reflex is the effortless inhale with the best nervous system balance and least effort that supplies oxygen supply and carbon dioxide balance when needed and helps maintain nervous system balance. It is essentially parasympathetic.

### THE REFLEX DURING REST OR INACTIVITY

Optimally it is a “non-pulled-in” inhale that occurs when the body “decides” it needs more oxygen and/or nervous system balance. It can be triggered/induced or completely passive depending on the needs of body oxygen, depths of rest, or release of tensions needed for recovery of energy and nervous system balance.

This reflex causes movement and therefore becomes the key to sensing and feeling one’s physical breathing in a state of relaxation or minimal activity as well as high stress. The expansion (tension) and release of that tension, along with the heart, are the force or pump behind many body sensations of circulation such as buzzing, streaming, and breeze-like sensations. We breathe less and feel less alive. It is a key part of the body’s relaxation and biofeedback system that dictates as well as informs us whether we are relaxed or not. The larger, deeper, and easier it is to develop, the greater the potential for deeper and easier relaxation, and energy and recovery from activity will be achieved. It is a natural interrelationship of respiratory chemistry and breathing mechanics: a deep peace and a key self-healing potential within the autonomic nervous system.

When functioning properly, the breath reflex occurs spontaneously or can be stimulated or “triggered” for profound full body relaxation and recovery from activity. Blood oxygen restoration with proper CO<sub>2</sub> interrelationships is important, but nervous system balance may be often much more important as this balance allows for strengthened parasympathetic rest, digestion, and healing, and facilitates less need for oxygen and increased dilation of arteries and capillaries for increased blood transport during activity and rest.

A compromised resting breathing reflex can stem from several factors, including any movement more than a few seconds in duration; nonoptimal posture in standing, sitting, or lying; stress, pain, body tensions, or negative emotions manifesting as cellular memories/functional inhibitions within the body; surgery that physically hinders it; poor muscular sequencing

and coordination; nerve dysfunction; nutritional deficiencies, and any form of sleep disturbance.

A compromised resting reflex means that kinesthetic breathing awareness is reduced and we become “less in touch” or “out of touch” with our physical energetic feedback mechanisms, including many physical sensations and “feeling our feelings.” Optimal development would be to remove all restrictions to deep, easy, effortless, balanced breathing as well as to remove any aspects of its energetic pathway as it manifests throughout the entire body—to maximize, ease, and flow learning and creativity.

### ENERGY-RESTORING REFLEX

During various levels of activity, the reflex attempts to bring the body back into balance. If we move too quickly, not allowing the reflex to “bloom” fully with each breath, we risk installing permanent shallow or unbalanced dysfunctional breathing (UDB). The key is to develop optimal breathing mechanics and chemistry along with lifestyle choices that allow the reflex enough time, depth, and ease to work as effortlessly as possible. Distressing stress is a lot about stifling the reflex and not giving ourselves time enough to breathe.

Other factors that can influence the reflex’s ability to balance and restore:

1. Lung tissue or upper respiratory air duct compromise
2. Internal lung pressure that aids or lessens increased saturation of blood, cells, and possibly mitochondria
3. Adequate hemoglobin/iron for oxygen transport, without which the organism is dragged down by its own need for primary energy—it works harder and further increases the oxygen cost of breathing

### NERVOUS SYSTEM BALANCING REFLEX

A well-developed natural resting breathing reflex is the doorway to our inner world. Candace Pert states that “your body is your subconscious mind.” It is a key governing aspect of ease in developing balance between conscious neocortical rational choice, in the moment responsibility, spontaneous behavior, and rational survival response. The optimal reflex is parasympathetic, which is about neocortical activity/connection—about choosing life-affirming options. You must always come back to the healing place of the deepest, easiest reflex. A small sample is the *huge* breath-catching breath or deep sigh of relief that

accompanies a strong feeling of tension release. A deeper breath occurs when tension is released, and if less or no reflex occurs, then less or no tension is released. There is a direct relationship between ease, depth, and balance of the reflex and whether we stay in or go out of peace. Developing a natural optimal breathing reflex is the key—the Rosetta Stone—to the breath that creates the connection of consciousness, subconscious, and optimal rational action.

## BREECH BIRTH

---

Approximately 3% to 4% of all pregnancies reach term (38-plus weeks of gestation) with a fetus in the breech presentation, in which the baby’s rear end is introduced before the head. Breech presentation is common when remote from term. However, as term approaches, the uterine cavity most often accommodates the fetus in a longitudinal lie, with head presentation. Predisposing factors for breech presentation are preterm (early) deliveries, excessive amount of amniotic fluid, fibroids, malformations of the fetus or uterus, high parity leading to uterine relaxation, multiple fetuses, abnormal implantation of the placenta on the cervix, and previous breech presentation.

In a complete breech position, the breech comes first with bent knees; in a frank breech, the lower extremities are flexed at the hips and extended at the knees, with feet near the head; the term *footling-breech* applies when the feet enter the birth canal ahead of any other part of the body. Diagnosis of breech presentation can be made by abdominal palpation, when the hard, round head is felt in the upper uterus, and the feeling of small parts or the breech by vaginal examination and confirmed by ultrasound. Breech presentation places a fetus at increased risk for adverse outcome, including morbidity and mortality

from difficult delivery, low birth weight due to preterm delivery (before 36 weeks gestation), prolapse of the umbilical cord, and fetal anomalies.

Discussion and planning for the mode of delivery should ideally take place well before admission to labor and delivery as essential differences exist between labor in head and breech presentations. Undoubtedly, cesarean delivery is preferred when the presentation is footling, the fetus is compromised or large, or has a congenital abnormality that could cause a mechanical problem at vaginal delivery, or when a clinician experienced in vaginal breech delivery is not available. Nevertheless, there is a general consensus that the outcome for the singleton baby is improved by planned cesarean section compared with planned vaginal delivery in any of the breech conditions. In head presentation, the body follows rapidly after the delivery of the fetal head, whereas an infant who arrives breech-first risks having its head stuck in the birth canal because the body does not stretch the birth canal wide enough for the head to pass through. Indeed, spontaneous expulsion of the fetus at breech presentation is seldom accomplished, and assistance of the obstetrician is required. Also, delivery of the breech draws the umbilical cord into the pelvis, which leads to cord compression. This can cause fetal distress, leading to morbidity.

Recently, in a randomized study comparing modes of delivery for breech presentation, neonatal mortality and serious neonatal morbidity were significantly lower for the planned cesarean section group than for the planned vaginal birth group. There were no differences between groups in terms of maternal mortality or serious maternal morbidity.

Most women wish to avoid cesarean section because it is not a risk-free procedure. External cephalic version is the only effective and basically safe intervention to convert a breech fetus to vertex presentation with the potential to help women avoid operations. It is performed exclusively through the abdominal wall by gentle pushing on the abdomen while viewing fetal movement with real-time ultrasound. The buttocks are elevated from the birth canal and grasped laterally, while the fetal head is directed toward the pelvis. Uterine relaxation, induced by certain drugs, is sometimes recommended before the procedure. Fetal heart rate monitoring is performed before and after the external version for assessment of fetal well-being. The risk for urgent cesarean delivery for fetal distress following external version is less than 1%. Studies of external cephalic version at term report a success rate of above 60%. Determinants of unsuccessful version include

uterine contractions, diminished amount of amniotic fluid, maternal obesity, and prior descent of the breech into the birth canal.

## BRONFENBRENNER, URIE (1917– )

---

Urie Bronfenbrenner is the Jacob Gould Sherman Professor of Human Development and Family Studies and Psychology at Cornell University and was one of the founders of Head Start. Bronfenbrenner was born in Moscow and came to the United States when he was 6 years old. He received his bachelor's degree from Cornell University in 1938, a master's degree in developmental psychology from Harvard in 1940, and a PhD from the University of Michigan in 1942. Bronfenbrenner served as a military psychologist during World War II and an assistant professor at the University of Michigan from 1946 to 1948. He moved to his present location at Cornell in 1948.

As a child, Bronfenbrenner's father, who was a neuropathologist, often pointed out the interdependence between living organisms and their surroundings. These concrete examples expanded into theories about the ecology of human development, developing substance during cross-cultural field research, which Bronfenbrenner has conducted in Europe, the U.S.S.R., Israel, China, and elsewhere. Bronfenbrenner realized that the developmental process varies by place and time and that public policy affects the development of human beings by determining the conditions of their lives.

Bronfenbrenner is most famous for creating a major theory of human development called *the Ecology of Human Development*. He conceived the human environment as consisting of a set of nested structures consisting of the microsystem, the mesosystem, the exosystem, and the macrosystem.

Bronfenbrenner defined development as a lasting change in the way a person perceives and deals with the environment, and a child is viewed as a growing, dynamic entity that progressively moves into and restructures the milieu in which it resides. The environment also exerts its influence, requiring a process of reciprocity between person and environment.

Later, Bronfenbrenner and Ceci (1994) extended this theory to behavioral genetics. They recommended that explicit measures of the environment in systems terms should be incorporated, as well as proposing the existence of empirically assessable mechanisms, proximal processes through which genetic potentials for effective psychological functioning are actualized. They hypothesized that when proximal processes are weak, genetically based potentials for effective psychological functioning remain relatively unrealized, and as proximal processes increase in magnitude, potentials become actualized to a progressively greater extent.

Bronfenbrenner's contributions have resulted in honors and awards on an international scale. He has been awarded six honorary degrees, invited to contribute to two Presidential Task Forces, and has been honored by the American Psychological Association for "Lifetime Contribution to Developmental Psychology in the Service of Science and Society."

## BROWN, ROGER (1925–1997)

---

Roger William Brown was the John Lindsley Professor in Memory of William James at Harvard University and recipient of numerous awards, including the Distinguished Scientific Achievement Award

of the American Psychological Association and election to the American Academy of Arts and Sciences and the National Academy of Sciences.

Such widespread recognition was prompted by both the substantive range of Brown's scholarship and research and the distinctively felicitous style of his writing. That range encompassed social psychology (including a "Citation Classic" textbook), linguistics, and cognition (notably, his groundbreaking *Words and Things*), but most importantly in this context, the acquisition of language. Here, in a sense rarely as accurate in the history of science, Roger Brown was the founder of the field of language development.

Two facts support such a characterization. One is the lineage of central figures in the study of language development who were all Brown students (from Dan Slobin and others in the 1960s to Steven Pinker and others in the 1970s and 1980s). These researchers have testified to how, collectively and individually, Brown's intellectual and interpersonal gifts gracefully shaped their ways of working.

The other barometer of Brown's influence comes in the shape of conceptual issues and empirical generalizations that emerged from the research he and his students conducted in the 1960s and 1970s. Best exemplified by *A First Language* (another "Citation Classic"), such ideas and findings—and the associated fine-grained analysis of extensive language samples from a few children—formed much of the core framework for the subsequent study of language acquisition. That framework and influence are no less heuristically significant today.

Brown's style of research and writing was a style as elegantly oriented toward story-telling as it was out of step with psychology's "scientistic tendencies"; in his third-person words, "when he graduated from. . . high school in 1943, Brown's ambition was to become a novelist of social protest, like Upton Sinclair." That he later decided "he was not talented enough to be a creative writer" is for continuing generations of students of language development, and many others, to celebrate.

## BRUNER, JEROME (1915–)

---

Perhaps the most eminent living psychologist, Bruner has made an incomparable contribution to our understanding of cognitive development in a career spanning 60 years. His erudite writings, which draw on anthropology, philosophy, and literary theory among other fields, have inspired several generations of developmentalists.

Born in New York City, Bruner was educated at Duke (BA, 1937) and Harvard (MA, 1939; PhD, 1941). After completing doctoral research on propaganda, he served in the United States Intelligence Corps before joining Harvard's faculty in 1945, where he and George Miller established the Centre for Cognitive Studies in 1960. A leading voice in the cognitive revolution, Bruner's early studies established that perception and thinking are organized by mental categories and representations. In the mid-1960s, he forged an influential distinction between enactive, iconic, and symbolic systems of representation.

Bruner's cognitivism has a strikingly pragmatic orientation. He portrays human beings as actively deploying knowledge for practical ends—to organize experience, solve problems, and make sense of reality. In this, he argues, cultural resources that enhance perception and reasoning and enable the externalization and transmission of knowledge massively amplify our cognitive capacities. Bruner's concern with activity and culture drew him to the ideas of Russian psychologists Vygotsky and Luria, whose work he helped introduce to the West. At the same time, his profoundly developmental approach led him to issues of education and its reform. He worked on the President's Science Advisory Committee under Kennedy and Johnson and on the Head Start program.

From 1972 to 1980, Bruner held the Watts Chair in Oxford, where, influenced by Austin's speech act theory, he studied how children learn to do things with words. Challenging the Chomskian orthodoxy, he argued that the maturation of an innate "language acquisition device" (LAD) was insufficient for language

development unless complemented by the culture's "language acquisition support system" (LASS). He beautifully illustrated this claim by attentive studies of mother-child interactions. This research established the field of developmental pragmatics.

In the 1980s, Bruner focused increasingly on the role of narrative in the construction of self and reality. In 1990, he produced a compelling critique of the legacy of the cognitive revolution. Contemporary psychology, he argued, has become so enraptured by information-processing and computer models of mind, it has lost sight of how meaning is made by human beings as they construct their understandings of themselves and their world. Bruner called for the development of a "cultural psychology" to remedy this failing.

Bruner's most recent work is on narrative and legal reasoning. He presently holds a professorship at New York University Law School.

## BUDDHISM

---

Buddhism is a religious tradition founded by Siddhartha Gautama, who lived in Northern India in the 6th century BC. Gautama was called the Buddha after he attained enlightenment; the name Buddha means "The Awakened" or "Enlightened One." Through study, contemplation, and great effort, the Buddha achieved an understanding of the true nature of reality. He then showed his followers that they, too, could reach the same level of knowledge through their own study and practice. Buddhists believe that everyone has a fundamental Buddha-nature and that every human being has the potential to become a Buddha.

Because Buddhism can be regarded as a philosophy, a religion, and a way of life, it does not fit into one category. Everyone has Buddha-nature. Everyone has

the potential to achieve what the Buddha himself accomplished and escape the endless cycle of sufferings, cravings, and transitory pleasures. Moreover, human beings are responsible for their own actions, which can have repercussions after death due to the law of karma. For these reasons, Buddhism is often regarded as a “do it yourself” religion, with a focus on compassion and wisdom.

Practitioners are instructed by a living master called a lama or a guru. They strive to become a Buddha themselves in order to attain enlightenment—a state of wisdom. There is a belief in a future Buddha. The word *belief* is easily subject to misinterpretation with regard to Buddhism, however; Buddhists do not simply accept by faith what the Buddha taught and leave it at that. Instead, they learn by study, contemplation, and practice to experience the teachings and apply them to their daily lives.

In the latter part of the 20th century, Buddhism has spread to many parts of the world and is growing in popularity in the West. It is estimated that there are 200,000 converts in Europe and America.

## LIFE OF THE BUDDHA

The life story of the Buddha is not as well known in the West as that of Jesus Christ; yet, the story of the Buddha’s journey from great wealth to renunciation to great poverty to ultimate realization is integral to understanding Buddhism and integrating it into one’s daily life.

Siddhartha Gautama was born around 563 BC in a place called Lumbini. His father, Shuddhodana, was the king or leader of a group of people known as the Shakyas. Stories of the Buddha’s life describe him as a prince who was destined to become ruler of his people and who enjoyed a luxurious upbringing. But after 16 years of a confined and protected life within his palace walls, Siddhartha journeyed into the world. There, for the first time, he became aware of old age, sickness, and death; and he began to realize that these sufferings were part of life. He also met a holy man who showed him that the renunciation of cravings for wealth, material goods, and high status was the way out of these universal sufferings.

Siddhartha decided to retreat to the forest, abandoning the palace life and his family. There he lived as an ascetic for 6 long years, but he eventually realized that simply starving himself was counterproductive. So he decided to abandon all extremes and practice a

moderate, middle way instead. Finally, while in deep meditation under the Bodhi tree at a place called Bodhi Gaya (now located in the Indian state of Bihar), he achieved the ultimate realization of the true nature of life and all creatures within it; he thus became the Buddha, the Enlightened One. After spending 7 weeks meditating on what he had realized, he decided to communicate what he had achieved to anyone who would listen. He was then about 35 years old, and he spent the next nearly 50 years teaching what he had learned. The series of teachings, which is called the Tipitaka, is broken into three types:

1. *Sutras*, or conventional teachings and stories
2. The *Vinaya*, or instructions on morality for monks
3. The *Abhidharma*, teachings on moral psychology and philosophy (these are generally attributed to the Buddha, though some scholars believe they grew out of commentaries written by followers of the Buddha)

The accumulated teachings of the Buddha and the spiritual development they bring to the practitioner are frequently referred to as the Dharma. The historical Buddha who originally achieved these realizations is known as Buddha Shakyamuni; he is thus distinguished from others who have attained a state of enlightenment and become Buddhas themselves, as well as from Buddhas who are expected to come in the future.

The Buddha died when he was about 80 years old at a place called Kusinara, leaving behind dedicated and accomplished followers called the Sangha. They and generations of sanghas have carried on his teachings and transmitted them to generations of practitioners throughout the world. Today, Buddhism is one of the world’s great religions, followed by millions in countries including China, Tibet, Sri Lanka, Myanmar, Nepal, Korea, Japan, Thailand, Vietnam, Cambodia, and Laos. The invasion of Tibet by the Chinese in 1959 and subsequent dispersal of Buddhist teachers has brought Buddhism to the United States and to Europe, as well as to other countries.

## BASIC TENETS

Buddhism does not originate in heaven and is not handed down to earth by divine beings, but instead it is derived from the enlightened teachings of a man who lived on earth and achieved great wisdom. Buddhists follow the Buddha’s example in not relying

on divine guidance, faith, or traditional beliefs. Rather, they use experience, reasoning, and meditation to achieve the goals of nirvana and freedom from suffering for all other beings. Tolerance for other religions and cultures and aversion to violence and bloodshed have always been central to Buddhism as well.

Many of the tenets described in the sections that follow have been handed down over 2,500 years by oral tradition. Many Buddhist sects emphasize the importance of obtaining teachings from a qualified master who has received teachings from masters before him. The Theravadan sect emphasizes the importance of studying and interpreting the Buddha's original oral teachings. The Mahayana and Vajrayana schools emphasize a more liberal path in which students must learn from a master but can achieve their own realizations and understanding.

### The Four Noble Truths

Rather than immediately seeking to tackle fundamental questions such as “What is the meaning of life” and “What happens after death?”, Buddhism seeks to explore the state of human existence. The root teaching is that of The Four Noble Truths. The Four Noble Truths are phrased in many different ways, but each describes the nature of existence: Life is transitory and beings are subject to suffering, but a cessation to suffering is found by renouncing worldly concerns and pursuing wisdom. They can be summarized as:

1. The truth of suffering (in Pali, *dukkha*; in Sanskrit, *duhkha*)
2. The truth of the cause of suffering
3. The truth that there is an end to suffering
4. The truth of the path leading to the cessation of suffering

The term *dukkha* has many connotations besides the experience of mental or physical pain. Accordingly, the Buddhist concept of suffering comes in many forms. In addition to pervasive physical suffering, humans confront mental suffering and the suffering of change—birth, death, disease, the satisfaction of desire, the deprivation of not having what is desired. Even in moments of happiness and satisfaction, there is suffering because of the inevitable loss of that state when conditions change and time passes.

Buddhism's emphasis on the suffering that is an integral part of human life leads some to conclude that it is

a negative or “unhappy” religion. But only through clearly perceiving the nature of existence can one obtain true happiness as well as gain the impetus to change one's own life and achieve healthier states of mind.

### Refuge

In order to become a Buddhist, monks and lay people alike go through a refuge ceremony. In this ceremony, they acknowledge their fear of suffering and death and place reliance on the three jewels of Buddhism: the Buddha; his teachings, called the *dharmā*; and the spiritual community, the *sangha*. The refuge prayer is quite simple: “I go for refuge to the Buddha; I go for refuge to the *dharmā*; I go for refuge to the *sangha*.”

Those who become Buddhist monks must observe a strict set of vows. Lay people can also take vows when they decide to commit themselves to the aims of a *Bodhisattva* (a being who seeks to attain a state of enlightenment out of great compassion for all suffering beings) or when they enter the Vajrayana branch of the Mahayana path (see “Vajrayana,” below).

### Karma

The process of life and the events associated with a life may seem to arise from chance, but they result from cause and effect. The system of cause and effect is known as *karma*. Karma holds that individuals can exert some measure of control over their lives by the decisions they make and the conditions in which they place themselves. One who takes risks by driving very fast in crowded traffic on a repeated basis creates the karma for having a car accident, for instance; one who drives slowly and infrequently does not have the same karma. At its essence, the law of karma can be distilled in the phrase *all actions meet with consequences*.

Karma causes sentient beings to exist in different forms from one life to the next; a being can be a human born to royalty in one life, an elephant in another, a cat in another, or a human born to a poor family in another. Karma can cause people to make themselves unhappy or to achieve great happiness; the difference lies in one's motivation. Actions that are motivated by self-interest, greed, or jealousy will cause suffering. Actions that arise from love for others or a desire to help others will bring about happiness.

The Buddhist practitioner seeks to maximize the amount of positive karma he or she generates and minimize negative karma as much as possible. This is

done by avoiding states of mind such as pride, attachment, selfishness, and anger and by cultivating love and compassion. Karma, like everything, is impermanent; actions do leave imprints on the consciousness, but these imprints can be removed or purified by meditation, prayer, and antidote actions. At the time of death, the karma accumulated through one's life plays a role in one's future lives; the belief that karma affects one's existence applies not only to the current lifetime but to lives that have passed and to lives that are to come.

## Dependent Origination

One of the most profound concepts of Buddhist philosophy holds that whatever exists depends on causes and conditions. Nothing exists independently of the way it is perceived, the causes that created it, and the conditions that surround it. Concepts such as "I," "you," "mine," and "yours" are all based on the misperception that there is a solid and definable self that arises independently from causes and conditions. When the causes and conditions are removed, the object no longer exists.

The Buddha taught that the doctrine of dependent origination manifests itself in a series of 12 links that make up a human life. These 12 links of dependent origination are

1. An initial state of ignorance, which leads to
2. Volitional actions, which lead to
3. Consciousness, which leads to
4. Names and forms, which lead to
5. The six bases—the five senses and the mind—which lead to
6. Contact through sense impressions, which leads to
7. Feelings, which lead to
8. Desires or cravings, which lead to
9. Attachment, which leads to
10. Becoming—the process of karma and rebirth, which leads to
11. Rebirth, which leads to
12. Old age and death

These 12 steps are traditionally depicted around the outer edge of a Buddhist image called the Wheel of Life, which shows human existence as a great wheel

being held in the fangs of Yama, the Lord of Death. Inside the 12 steps are the six realms of existence: human, animal, hell, ghost, demi-god, and god. At the center are the three root delusions (also called the three poisons): attachment, in the form of a cock; anger, in the form of a snake; and ignorance, in the form of a pig. The continual cycling through these 12 stages and from one life to another is called *samsara*.

## Samsara

Samsara is a Pali and Sanskrit word that means a perpetual state of wandering and motion. Buddhists use the word to describe cycles of existence that are without end—moving from one life to another and continually suffering without progressing toward liberation from that suffering. One of the Buddha's fundamental teachings is that beings who are trapped by ignorance cycle through all realms of existence—the fires and ices of the many Buddhist hell realms, the perpetual desire of the ghost realm, the animal realm, the human realm, and the god realms where beings are too lazy to seek spiritual growth. The term *ignorance* is seen as the opposite of wisdom; it refers to a state of mind that sees the ego as of preeminent importance and self-interest as desirable. Ignorance keeps beings in a perpetual state of desire, dissatisfaction, and suffering—trapped in *samsara*, in other words.

One of Buddhism's three principles is the liberation from *samsara* through the attainment of wisdom. Wisdom is the realization that the cycle of desire and self-interest brings about suffering, that the "I" is not solid but dependent on causes and conditions, and that all beings seek the same happiness and are interconnected in a state of mutual dependence. Buddhists strive to evade the confusion of the ignorant mind that is bound in *samsara* and achieve a precious rebirth as a human being. Only a human being has the ability to learn and grow and achieve freedom from suffering and *samsara*.

## Nirvana

*Nirvana* is freedom from *samsara*. It is said to be a state of bliss arising from the perception of wisdom—the realization of true reality. Nirvana is attained when the practitioner realizes the ultimate truth that all beings depend on conditions and that existence is marked by impermanence, dissatisfaction or suffering, and the nonexistence of an independent self. The practitioner who attains a state of nirvana is known as an *arhat*.

Of course, the term *nirvana* is itself a label or concept that is created by minds that are fundamentally deluded. The Sanskrit term suggests a state of coolness and peacefulness. This state of mind is not touched by suffering or vicissitudes of desire, aversion, attraction, and ignorance. It is said to be indescribable and unknowable by a mind that clings to concepts.

Nirvana is not a state of nothingness. It is called *emptiness*, but it is not completely empty; it is marked by love and compassion and empty of clinging and the habit of establishing identity, boundary, and separation. It is difficult to put a label on a state of mind that sees labels as relative and dependent. Nirvana is not a place or emotion, but a state of mind marked by clarity of perception and freedom from delusions such as anger, ignorance, and attachment. It is an experience that transcends awareness and simple labels.

## Rebirth

Just as existence involves the combination of mind and matter, death involves the separation of mind and matter. Rebirth is the recreation of mind and matter in a new form after death. The exact form of rebirth is determined by one's accumulated karma at the time of death. A sufficient quantity of positive karma will result in a positive rebirth in the human realm of existence rather than the animal realm or one of the many hell realms.

## Heaven and Hell

Buddhist visions of heaven and hell differ greatly from those of other religions. The Buddha taught that nothing is permanent, including the pleasures of heaven or the sufferings of hell. Accordingly, heaven and hell are not fixed, eternal places where one spends an endless amount of time. Those who are condemned to hell can eventually free themselves and be reborn, depending on the karma that propelled them to hell in the first place. Similarly, places called the Pure Lands, which are pleasure groves that are roughly analogous to heaven, are the destinations of practitioners who have achieved great progress and accumulated positive merit and karma.

Where one's consciousness goes after it is freed from the body at the moment of death is determined by karma and by one's state of mind at the moment of death. Much of Buddhist teaching (particularly the Mahayana and Vajrayana schools) can be seen as preparation for the moment of death. One's state of mind at that moment, which depends on a lifetime of

karma and many years of spiritual practice, can potentially lead one to a state of enlightenment. It can also propel one into a hell realm or a Pure Land. Buddhists believe in many different hell realms. Some are marked by fire, some by ice, and some by endless unquenched thirst and hunger. One can also be reborn as an animal or as a Samsaric God—one who lives in luxury and pleasure that overwhelms any desire for spiritual growth or achievement of nirvana. Samsaric Gods, like others in samsara, eventually leave their present realm and are reborn into another realm marked by a different kind of suffering. The cycle is only broken when one achieves nirvana or liberation from suffering.

## THE TWO VEHICLES

Buddhism is divided into two main schools: Theravada and Mahayana. The Mahayana is further divided into the Mahayana and Vajrayana. These three paths all have the goal of leading practitioners to a state of enlightenment. The dharma is the same for each path, and there is no basic contradiction between the teachings followed by the different schools; the difference is in which principles are emphasized and the methods by which they are put into practice.

### Theravada

Theravadan Buddhists believe that enlightenment can be attained through their individual effort. They rely on the original teachings of the Buddha rather than on subsequent texts developed by later followers. The goal is to seek liberation, or a state of nirvana, from the cares and vicissitudes of this life. The Theravadan Buddhists seek to attain a perfect state of well-being and happiness so that the world will be a better place. Buddhists in Sri Lanka, Myanmar, and Thailand belong to this school.

### Mahayana

Mahayana Buddhists study the original teachings of the Buddha, but these are seen only as foundations for the Buddhist system that others can explore and elaborate on more fully. Buddhist scholar Mu Soeng (2000), in his book *The Diamond Sutra*, describes it as "Visionary Buddhism." Practitioners seek salvation not only for themselves but for all other beings. In fact, they delay their own attainment of Buddhahood until they help others achieve liberation. They believe that, by following the teachings expressed in the

sutras, they can become Buddhas after lifetimes' worth of effort. They call on the help of enlightened beings known as Bodhisattvas to help them achieve this goal; after death, they may seek to attain rebirth as Bodhisattvas in order to help others. Buddhists in Tibet, China, Japan, and Korea belong to this school.

## Vajrayana

Vajrayana Buddhism is part of the Mahayana path. Vajrayana Buddhists follow complex and secret practices obtained through initiations. The goal is to attain Buddhahood as quickly as possible—ideally, within a single lifetime. The quicker one becomes a Buddha, the quicker one is able to help others achieve the same goal.

## MAIN PRACTICES

Although Buddhism developed from the Buddha's intellectual practices, it is not purely a rational process. The attainment of wisdom is also achieved through meditation and practices such as mantras (sayings associated with specific deities or practices) and mudras (hand gestures, often performed with implements such as bells that generate sound). Together, the practices involve the practitioner's body, speech, and mind.

## Bodhisattva Activities

All Buddhist schools agree on the central principle of "Do no harm." When asked by a student "What do I do?", the Buddha reportedly responded with the simple answer: "Do no harm, act for the good, purify the mind. This is the teaching of all the Buddhas." Accordingly, Buddhists seek to avoid 10 nonvirtuous actions (3 having to do with the body, 4 with speech, and 3 with the mind).

The three of the body are

1. Killing or physically harming others (for many, this leads to a vegetarian lifestyle that does not include beings that have been killed)
2. Stealing
3. Sexual misconduct

The four of speech are

1. Lying
2. Using harsh or angry language

3. Gossip
4. Frivolous talk

The three of the mind are

1. Covetousness or greed
2. Anger
3. Wrong view (a misperception about suffering or a belief that there is no karmic result from an action)

Some Mahayana sects take the "Do no harm" principle many steps further and seek to perform "Do good" actions. Their goal is to express love and care for other beings that resembles the love of a mother and child. They accumulate merit—good actions that, repeated over time, bring happiness and good fortune. They also practice six skillful activities, also known as the six perfections:

1. Generosity: the giving of time, energy, resources, or love to those around us
2. Morality: the keeping of one's vows and commitments
3. Patience: the ability to bear abuse and misfortune
4. Enthusiasm: the enjoyment of positive efforts, particularly spiritual development
5. Concentration: the skill needed to study, meditate, achieve realizations, and progress toward enlightenment
6. Wisdom: the realization of the nature of existence

The Bodhisattva seeks to practice these virtuous efforts not only for his or her benefit but for the benefit of all beings. A Bodhisattva, after death, seeks to postpone his or her enlightenment and return to earth in human form in order to help all others achieve enlightenment—a state of mind known as *bodhicitta*. Such is a great love and compassion that motivates this awakened being.

## Studying the Dharma

Buddhism is an inward religion. Followers are those who look inside themselves and study their mind and their behavior, seeking to change habitually negative patterns and cultivate positive ones. They do this by studying the Buddha's teachings, meditating on them, and making them part of their daily lives and activities.

The teachings of the Buddha are called the Lion's Roar for its power and majesty. The Buddha is said to be the doctor, the dharma is the medicine, and the sangha is the nurse. By learning the teachings, the Buddhist practitioner seeks to integrate them into his or her daily activities as a parent, a worker, a friend, a neighbor, or a citizen. Some of the most important principles taught by the Dharma and studied by Buddhists include

- Freedom from attachment. Human beings continually desire objects, experiences, and other human beings, as well as states of mind. Buddhists seek to achieve nonattachment. They may want experiences or objects, but their motivation is not self-interest; rather, it is generated by love and concern for others.
- An understanding of consciousness. The consciousness that enables beings to perceive objects and events and attach labels and interpretations to them is flawed by deluded mental factors called *aggregates* or *skandhas*. Understanding these mental factors enables the mind to begin to have experiences and thoughts that are not clouded by ignorance.
- Overcoming anger and aversion. Anger is one of the three root delusions (anger, attachment, and ignorance), an emotion that can harm others and harm the individual who experiences it by destroying positive actions that may have preceded the angry one.
- The selfless nature of phenomena. Buddhism emphasizes selflessness—freedom from grasping and continually focusing on the self, and realizing the transitory, impermanent nature of events and suffering.

## The Noble Eightfold Path

The fourth of The Four Noble Truths taught by the Buddha is that there is a path that leads one away from suffering and toward wisdom. This path toward liberation has been laid out in a series of steps that Buddhists can follow and that leads toward a state of nirvana: The Noble Eightfold Path. The eight steps are

1. Right understanding
2. Right thought
3. Right speech
4. Right action
5. Right livelihood
6. Right effort
7. Right mindfulness
8. Right concentration

These steps are considered part of the Three Higher Trainings, which are also three of the six perfections (see “Bodhisattva Activities”): morality, concentration, and wisdom. Because these three higher trainings need to be developed together, the eight steps above do not necessarily have to be followed in exact sequence. All of these practices depend on correct motivation: the goal of achieving happiness, transcending suffering, thinking of other beings rather than ourselves, and wanting all other beings to be happy as well.

## Meditation

Meditation is central to all Buddhist schools and practices. Through meditation, the practitioner is able to quiet the “noise” produced by emotions and events. A quiet, calm mind brings benefits in and of itself, but it is also able to learn spiritual principles and remember them more clearly. Buddhist meditation takes two forms:

- *Shamata*, or “calm abiding” meditation
- *Vipassana*, or insight meditation

Meditation begins by examining and correcting one's motivation. One motivation might be to progress and achieve realizations—first, to better help one's immediate circle of friends and family, and then ultimately to help all beings.

The correct posture is also important to achieve insight. It involves sitting cross legged, with one leg placed atop the other. A chair or pillow may be used for greater comfort and to straighten the spine; discomfort can interfere with one's thoughts and be counterproductive. The eyelids are lowered but not closed. The tongue is placed behind the upper teeth, and the mouth is slightly closed. The hands are placed atop one another in the lap.

In *shamata* meditation, concentration is placed on an object or thought. It may be one's own breath—the movement of the breath across the space between the lips and the nose and through the nostrils. It may also involve counting or visualization of colors. When the attention wanders, as it inevitably will, the practitioner gently brings it back to the object of meditation. This will be repeated many times, until gradually one is able to concentrate for greater periods on the desired object.

In *vipassana* meditation, the practitioner initially opens the mind's attention to an awareness of all that is happening in the surrounding environment. Then, the mediator concentrates on a particular teaching of the Buddha or a point of information that has been

conveyed by a teacher or *guru*. The goal is to understand the point fully, to reason through the concept, and to be able to remember it and use it in one's daily life. Ultimately, the practitioner's mind is able to understand that, as the Buddha taught, "everything that arises passes away and is not self."

## Sangha

Like many aspects of Buddhism, the sangha has both a historical context and a real-world application. In a historical sense, the original sangha is the followers of the Buddha himself, who established an oral tradition based on his teachings. In a real-world sense, one's sangha is the group of spiritual practitioners who help one another along the path to enlightenment. Although Buddhism places great emphasis on self-reliance, only the Buddha Shakyamuni himself was able to achieve enlightenment alone. For those in the world today, a group of spiritual friends is essential for creating a space in which to meditate and learn, and for providing the means of supporting a teacher or *guru* who can explain the dharma and guide students along the spiritual path.

## BULIMIA NERVOSA

---

Bulimia nervosa is an eating disorder characterized by recurrent episodes of binge eating (see Binge

Eating, this volume) accompanied by inappropriate compensatory strategies that are used to prevent weight gain. These inappropriate compensatory strategies include self-induced vomiting, fasting, excessive exercise, and the misuse of laxatives, diuretics, enemas, or other medications. Self-induced vomiting is the method used most frequently by individuals seeking treatment for bulimia nervosa. However, it is not unusual for individuals with bulimia nervosa to use multiple strategies to compensate for binge eating. To receive a diagnosis of bulimia nervosa, the binge eating and inappropriate compensatory weight control strategies must occur frequently, averaging at least twice a week for the previous 3 months. There are two subtypes of bulimia nervosa: the *purging type*, characterized by the regular use of self-induced vomiting or regular misuse of laxatives, diuretics, or enemas to prevent weight gain; and the *nonpurging type*, characterized by the regular use of fasting or excessive exercise, but not purging.

In bulimia nervosa, binge eating and the use of inappropriate compensatory behaviors are accompanied by an additional symptom: an overemphasis on weight and shape in one's self-evaluation. The body dissatisfaction experienced by individuals with bulimia nervosa often leads to chronic restriction in the amounts and types of food consumed. When food intake is severely restricted, binge eating is more likely to occur.

Following the binge, an individual with bulimia nervosa may purge to relieve the physical discomfort associated with the binge and reduce the fear of weight gain. Between binge-purge episodes, individuals with bulimia nervosa typically restrict their caloric consumption, limiting their food choices to low-calorie, "diet" foods and avoiding foods perceived as "fattening."

According to the current *Diagnostic and Statistical Manual of Mental Disorders*, bulimia nervosa is fairly prevalent, affecting between 1% and 3% of women. Men are much less likely to develop bulimia nervosa, comprising only 5% to 10% of all cases. Bulimia nervosa typically begins in adolescence or early adulthood. During adolescence, girls experience significant changes in their body shape and weight. Young women's internalization of the extremely thin contemporary beauty ideal promoted in Western society is one factor that may contribute to the much higher prevalence of bulimia nervosa among women.

Bulimia nervosa is associated with depressive symptoms and mood disorders. However, it is not clear whether the depressive symptoms precede or follow the development of bulimia nervosa. There

also are medical complications associated with various forms of purging. Self-induced vomiting and laxative or diuretic abuse may be associated with hypokalemia, a serious electrolyte disturbance. Self-induced vomiting also may be associated with swelling of the parotid glands, esophageal problems, and erosion of dental enamel, while laxative abuse may result in the loss of normal peristaltic function.

There are several different treatments for bulimia nervosa. The most widely investigated form of psychotherapy for bulimia nervosa is cognitive behavior therapy. This treatment focuses on educating individuals about the disorder, normalizing their eating patterns, addressing dieting and the overemphasis on weight and shape in self-evaluation, and preventing relapse. Research has found that cognitive behavior therapy for bulimia nervosa produces substantial reductions in bingeing and purging, gains that are usually maintained over follow-up periods of 6 to 12 months. Many regard cognitive-behavioral therapy as the treatment of choice. Although less widely investigated, interpersonal psychotherapy, a short-term psychological treatment that focuses on identifying and resolving interpersonal problems, also has been used in the treatment of bulimia nervosa. The rationale for this treatment is that interpersonal stressors may precipitate binge episodes. Finally, since bulimia nervosa frequently is associated with depression, antidepressant medications may be used with therapy in the treatment of this disorder.

or intimidation by one child or a group of children to victimize another child. Most definitions of bullying also emphasize a power differential between the two parties involved, such that targets of the aggression (i.e., victims) lack the physical, psychological, or social resources to defend themselves successfully. Bullies may engage in two types of aggression—*overt* and *relational* aggression. Overt aggression constitutes more direct physical and verbal acts, including starting fights, pushing, name calling, and taunting. Relational aggression targets children's social networks in seeking to ostracize victims from the peer group by starting rumors about them or excluding them from group activities. Although there have been incidents in which these types of social interactions have escalated to more serious outcomes (e.g., homicide, suicide), bullying is not traditionally thought to include these more extreme forms of violence.

### PREVALENCE OF BULLYING

Because schools provide a natural structure within which children's peer relationships develop, studies examining the prevalence of bullying have typically been conducted in American and European schools and have identified bullying as a common experience affecting many children and adolescents. In a recent national study of 15,686 sixth through tenth graders in the United States, 29.9% of the total sample revealed that they were involved in bully-victim behaviors at least several times within the current school term. Of these students, 13% were involved as bullies, 10.6% were targets of bullies, and 6.3% reported involvement as both bullies and victims. Additionally, boys were more likely than girls to bully or be victimized, as were students in the sixth through eighth grades. A similar nationwide survey conducted among 130,000 primary and junior high school students in Norway found that 15% of the children indicated involvement in bully-victim problems "now and then" or more frequently. Of this sample, 7% bullied other children, 9% were victims, and 1.6% were both bullies and victims. These national studies of bullying prevalence signify the increasingly accepted trend that bullying seems to increase during the elementary school years and peak during junior high or middle school, with relatively fewer reports of such behaviors during the high school years.

### GENDER CONSIDERATIONS

The common perception and frequent finding that boys seem to be more involved in bullying, as either a

---

## BULLYING

---

Bullying, also referred to as peer harassment or victimization, is defined within the context of peer relationships in childhood and adolescence and involves the frequent, persistent, and intentional use of physical harm

bully or a victim, have led to increased attention in recent years to the notion of gender differences in bullying behaviors. In turn, several studies have suggested some differences in the types of aggression exerted by boys and girls. Overall, boys are more likely to be identified as bullies, engage in overt aggression, and fall prey to overt victimization, while some studies suggest that girls might be more likely to engage in and suffer from relational forms of aggression. Further, aggressive boys tend to victimize both boys and girls, while girls are more likely to target other girls.

### **CHARACTERISTICS AND ADJUSTMENT OF BULLIES**

Bullies and their victims have typically been distinguished from one another to contrast the social, psychological, and academic adjustment correlates associated with these roles in the elementary school peer group. There is some disagreement among developmental researchers as to the function or purpose of the aggression displayed by bullies, as evidenced by the concepts of proactive and reactive aggression. Proactive aggressors are thought to utilize aggression as an instrumental social strategy that is organized and goal-directed (e.g., bullying other children to gain dominant peer status or possession of some material good). Thus, bullies generally view the use of aggression as an acceptable and effective tactic. Reactive aggressors, on the other hand, tend to attribute hostility in any provocation from their peers and, consequently, choose to use aggression in response to perceived threat.

Regardless of the motivation for using aggressive behavior, bullies likely choose aggression as a means of interpersonal negotiation because of exposure to such behavior at home or school, such as coercive or punitive parental discipline. Impulsivity, emotional reactivity, attention deficits, disruptiveness, and other externalizing behaviors commonly characterize bullying children, and these types of traits likely foster the increasing peer rejection that bullies have been found to experience as elementary school progresses. Additionally, these children tend to struggle in their academic pursuits, whether from a coexistent lack of preparation for school or as a result of the distraction from academics that bullying provides in the classroom. Early negative experiences in the school environment seem to put bullies at increased risk for school absenteeism and dropout in middle school and high school. In addition to children's exposure to aggressive

interpersonal strategies in their environments, adults' and peers' tolerance of or lack of attention to bullying problems can further reinforce such childhood peer interactions. Bullying during the school years subsequently places children at high risk for antisocial, aggressive behaviors later in adolescence and adulthood (e.g., delinquency and criminal offenses).

### **CHARACTERISTICS AND ADJUSTMENT OF VICTIMS**

Similar to bullies, the targets of aggression (i.e., victims) have also been subdivided based upon their responses to bullying. Developmental theorists have distinguished between passive victims and provocative victims. Passive victims are defined as anxious and insecure children who tend to avoid conflict and refrain from defending themselves when bullied. They are often physically weaker than their peers, withdrawn, lacking in assertiveness, and respond with passive submission to the requests of others. Provocative victims, on the other hand, frequently try to defend themselves and may provoke bullies to victimize them by losing their tempers and irritating and teasing other children, including the bully. They are frequently characterized as impulsive, overly reactive, and lacking an ability to regulate their emotions. Because provocative victims are often unsuccessful in their use of aggression and attempts to defend themselves, they often become distressed and frustrated in their peer interactions.

When peer harassment becomes a chronic experience, both passive and provocative victims face increasing rejection from their peers. Because the targets of bullying often lack the support of other peers and spend much of their time alone, the emotional impact of their peer group status and experiences is likely internalized. Furthermore, many studies have documented the concurrent link between victimization and internalizing difficulties, specifically anxiety, depression, loneliness, and low self-esteem. Overall, depression and loneliness have a stronger relationship with victim status than anxiety and low self-esteem. A large number of studies have examined the relationship between victimization and psychological maladjustment at the same point in time, but dramatically less is known about how this link persists over time. Little is also known about whether these psychological difficulties precede or follow peer harassment experiences, though some preliminary evidence suggests that anxious/withdrawn children appear to be

easy targets for bullying. Moreover, being bullied serves to further exacerbate this anxiety and additionally leads to low self-esteem and depression. In addition to psychological difficulties, victims of bullying, like the bullies themselves, demonstrate problems in school. Their experiences of victimization at school seem to lead to avoidance behavior evidenced by school absenteeism, likely induced by fear and not feeling safe in the school environment. Victims also tend to perform poorly on academic tasks.

## ASSESSMENT AND SCHOOL INTERVENTIONS

To identify children who are either bullies or victims of bullies, psychologists utilize a variety of assessment methods, including self-report questionnaires, peer nominations, and teacher nominations. Though more practical when studying smaller groups of children (e.g., children's play groups), direct observations and child interviews are also helpful as a means of understanding the dynamics of bullying. Numerous studies have addressed the strengths and weaknesses of relying on information provided by each of these methods of assessment, conclusively suggesting that a comprehensive evaluation using a variety of informants is the most valuable. Because poor psychological outcome among victims of bullying seems to be so closely linked to these children's internalization of their experiences, self-report questionnaires tapping internalizing difficulties (e.g., depression) can be helpful to identify the extent to which victims are suffering.

Prevention and intervention programs addressing bully-victim problems have most often been implemented in schools. Some of the techniques incorporated in Scandinavian schools, for example, include discussing bullying problems with all students and parents in a school, increasing monitoring during recess and lunch, developing class rules that address bullying, and having individual conferences with those children and their parents who are identified as bullies or victims. Additionally, programs in the United States have taken a schoolwide approach to educating all students about bully-victim dynamics and raising awareness about the positive and negative impact of student bystanders (i.e., those students who either support bullies or stand up for

victims). Further, physical education programs have been used for encouraging the development of self-esteem and assertiveness as a defense against bullies, and mentorship programs provide a context for discussing effective conflict resolution. Evaluations of these programs have suggested decreases in victimization and improved overall school climate, though the magnitude and duration of these results vary among outcome studies. The effectiveness of antibullying/antivictimization interventions remains to be fully determined.

## CANCER

---

*Cancer* is a term used to describe more than 100 different diseases that can affect almost any part of the body. In healthy people, cells replicate and create exact copies of themselves to replace dead or damaged cells. Cancer occurs when the deoxyribonucleic acid (DNA) makes an error when copying itself, resulting in a cell that cannot perform its proper function. This bad cell replicates quickly and can form a tumor or can be found in the bloodstream (e.g., leukemia). Thus, cancer develops from our own bodies, but represents a mistake in a normal body process.

### SYMPTOMS

Each type of cancer presents with a distinct set of symptoms, although in many instances the symptoms do not appear until the cancer is advanced. These symptoms tend to be specific to the location of the cancer. However, there are some general symptoms that occur in many forms of cancer. For example, unexplained weight loss, fever, fatigue, pain, and skin

changes (e.g., pigmentation) are often associated with cancer. Other common symptoms include changes in bowel or bladder functioning, unusual bleeding or discharge, a lump in the breast or other part of the body, chronic indigestion, or a persistent cough or hoarseness. Since early detection is important for successful treatment, it is essential to consult with a physician if you are experiencing any number of these symptoms.

### STATISTICS

According to 2003 statistics, cancer causes 23% of deaths among adults, second only to heart disease. In deaths resulting from illness, it is the leading cause of death among children. More than 1.3 million people are expected to be diagnosed with cancer in the year 2004. Far more adults than children experience cancer, as nearly one half of men and one third of women will be diagnosed with cancer sometime in their lives. The most common forms of cancer in adults occur in the prostate, breast, lung, and colon/rectum. Cancer is still rare among children, occurring in about 1.5 of every 10,000 children. Leukemia accounts for approximately 30% of childhood cancer cases.

## TREATMENT

To obtain higher rates of recovery, aggressive treatment including a combination of surgery, chemotherapy, and radiation therapy is frequently needed. Depending on the type of cancer and degree to which the cancer has spread, different treatments are used.

### Surgery

If the cancer is detected early, surgery can be used to remove the cancerous cells and may be the only treatment necessary. Surgery is also used to diagnose cancer by removing a small portion of the tumor (a biopsy) to determine whether the tumor is cancerous. A tumor that is cancerous is termed “malignant,” while a noncancerous tumor is designated as “benign.” Surgery can also provide information to determine how far the cancer has spread, through a process called staging. Almost all cancer patients undergo surgery at some time during their cancer treatment. Although complications can occur during and after surgery, the advantages of removing the cancerous cells usually far outweigh the side effects. Some patients may experience excessive bleeding during the procedure, damage to surrounding organs, or reactions to anesthesia during surgery. Following surgery, most people experience varying degrees of pain. Other side effects can include infections, bleeding, pneumonia, and blood clots. In cases of brain tumors, cognitive or behavioral changes may occur as a result of the cancer or of the surgery.

### Radiation Therapy

High doses of radiation can kill cancer cells or keep them from multiplying. Radiation therapy is a component in the treatment of approximately half of cancer patients. There are two different types of radiation therapy: external radiation (most common) and internal radiation (also called brachytherapy). The side effects differ by type of treatment, site of the radiation, and a number of patient variables. However, the most common acute side effects include fatigue and skin irritation or changes at the radiation site. Very young children who receive cranial irradiation therapy for leukemia or brain tumors may be at greater risk for cognitive or behavioral changes.

### Chemotherapy

For patients with leukemia and those with cancer that has affected multiple parts of the body, chemotherapy

may be necessary. Chemotherapy medications are designed to kill rapidly reproducing cells, such as cancer cells. Multiple chemotherapy medications are given together to create the best treatment for the cancer. Chemotherapy is administered in cycles, rotating between therapy and recovery periods. The length of treatment and number of chemotherapy cycles depends on the type, severity, and location of the cancer. The average length of treatment is 6 months. Side effects result primarily from the fact that the chemotherapy medications kill rapidly reproducing healthy cells such as those in the bone marrow, digestive tract, reproductive system, and hair follicles as well. The damage to the reproducing cells in these areas can result in low white blood cell counts (increased risk for infection), low red blood cell counts (anemia), low platelet counts (difficulty with blood clotting correctly), appetite loss, taste changes, nausea, vomiting, constipation, diarrhea, fatigue, hair loss, and pain. Most side effects start to decrease after chemotherapy has ended and the cells that were damaged have been replaced.

### Supportive Treatment

In some cases, when more aggressive treatments have proven to be ineffective in curing cancer, patients can choose to have only those procedures that will reduce pain and make them more comfortable (called supportive or palliative care). In instances where the cancer has spread to many parts of the body and has not responded to treatment or when it continues to recur, death may be imminent. Palliative care and hospice teams can provide support for the patient and families during the end of life.

## SURVIVAL RATES

Recent advances in the treatment of cancer have resulted in increased survival rates, especially among children. The current 5-year survival rate for pediatric cancer is 78%, ranging from 45% for acute myeloid leukemia to 94% among Hodgkin’s lymphoma patients. Among adults, the average 5-year survival rate is 62%, with rates ranging from 15% for lung cancer to 97% for prostate cancer. The current 5-year survival rate for women with breast cancer is 87%. These rates are average survival rates and do not take into account age, physical health, or degree of cancer spread. Younger, healthy adults whose cancer is detected early on have the higher rates of survival.

## PREVENTION

Although it is unlikely that most forms of childhood cancer can be prevented, experts estimate that 50% to 75% of adult cancer cases result from unhealthy behaviors. For example, 30% of cancer cases have been linked to tobacco use. The American Cancer Society recommends eating five fruits and vegetables daily, remaining at a healthy weight, exercising, and avoiding tobacco and heavy alcohol consumption in an effort to prevent some forms of cancer. Decreased exposure to environmental toxins is recommended for both children and adults.

There are a number of screening methods available to allow early detection or prevention of certain types of cancers. These screening procedures include mammograms, clinical breast examinations, Papanicolaou (Pap) tests for cervical cancer, prostate examinations, and fecal occult blood tests (to screen for colorectal cancer). The guidelines regarding the timing and frequency of these screening procedures can be found on the American Cancer Society's Web page or by consulting with a physician.

## COPING WITH CANCER

The entire family is affected when a member is diagnosed with cancer. Common reactions to a cancer diagnosis can include shock, denial, anger, anxiety or fear, guilt, and sadness. Patients and family members, including children, frequently experience some or all of these symptoms. It is also common for children's behavior to regress (start acting younger than their age). Children and adults may feel overwhelmed by the stress of the cancer diagnosis and uncertainty over the future, or worry over upcoming treatment.

Many people cope with the uncertainty of cancer by learning as much as possible about the disease. This information can help in making treatment decisions and with relieving fears. Although parents naturally want to shield children from bad news, it is important to provide children with age-appropriate information about cancer. Research has shown that it is not helpful to try to hide cancer diagnoses from children because they can usually sense that something is wrong regardless of how careful adults are to keep information away from them. Furthermore, the attempted secrecy may produce more of an emotional burden by sending a message that the children cannot talk with their families about the illness.

During cancer treatment, social support is essential. Extended family members, religious organizations, and community agencies can provide resources to minimize the overwhelming strain on the family. Multidisciplinary teams to treat cancer also include personnel who can assist with the stress and emotions associated with a cancer diagnosis. A social worker, child life specialist, or psychologist can work with the patient and family to teach healthy coping strategies. It is essential that the patient, as well as the caregiver, take care of both physical and emotional needs during cancer treatment and recovery.

## SURVIVING CANCER

Completing the stressful process of cancer treatment successfully is a huge accomplishment. However, adjusting to life after cancer can be stressful as well. Overall, cancer survivors are not different from healthy individuals in terms of psychological adjustment, but they have undergone a life-changing experience that may have impacted them for life. This impact can be positive, as in the case of many breast cancer survivors who reported that their relationships with other people improved following successful cancer treatment. For other people, the cancer experience has left them with physical or mental changes that may negatively impact their life. For example, some people have to adjust to life without a limb that was lost to amputation. Others, such as children who received high doses of radiation therapy at early ages, may face lifelong cognitive difficulties with sustaining attention, learning, and memory.

There is always some uncertainty about cancer recurring. Among children, secondary malignancies can result from the treatment of the first cancer. Each checkup and anniversary can be cause for great anxiety and subsequent celebration if the person remains cancer free. Cancer recurrences tend to elicit strong feelings of sadness, anger, and despair as families face repeating the entire treatment process again.

## CARDIOVASCULAR DISEASE

---

Cardiovascular disease is a general umbrella term that refers to a group of disorders involving the heart and blood circulation systems, such as hypertension, stroke, congestive heart failure, cardiomyopathy, valvular heart disease, and coronary heart disease. Coronary heart disease refers to the narrowing or blockage of one or more coronary arteries by a gradual buildup of cholesterol within the artery wall (atherosclerosis), which reduces blood flow to the heart muscle. Coronary heart diseases include myocardial infarction and angina pectoris. Over 64 million Americans have some form of cardiovascular disease; coronary heart disease and stroke are the first and third leading causes of death in the United States, accounting for more than 40% of all deaths. Cardiovascular diseases also lead to high levels of premature and permanent disability.

### SYMPTOMS

Cardiovascular disease encompasses a broad range of specific disorders, and symptom presentations vary widely across these disorders. Among the most common cardiovascular diseases, some can be asymptomatic (e.g., hypertension) while others can cause acute pain and disability (e.g., angina pectoris, myocardial infarction). Symptoms of cardiovascular disease can include chest pain or radiating pain on the left side of the body and nausea (coronary heart disease), weakness or paralysis on one side of the body

(stroke), and painful breathing, fluid retention, and fatigue (congestive heart failure).

### RISK FACTORS

Risk factors for cardiovascular disease include demographic factors, biological factors, and psychosocial factors.

#### Demographic Factors

Although cardiovascular disease occurs across the life span, the prevalence of most cardiovascular diseases increases with age. The prevalence of cardiovascular disease is slightly higher in women than in men, but the death rate for cardiovascular disease is substantially higher for women than for men. Women tend to experience some cardiovascular diseases, such as myocardial infarction, on average approximately 6 years later than do men. Rates for most cardiovascular diseases are higher for those of ethnic and racial minorities and those of lower socioeconomic status.

#### Biological Factors

Biological factors that predispose individuals to cardiovascular disease include family history of cardiovascular disease, diabetes, high blood pressure, high blood cholesterol, and overweight/obesity.

#### Psychosocial Factors

A variety of psychosocial factors place individuals at higher risk for developing cardiovascular disease. One of the biggest risk factors is depression or depressive symptoms, which is prospectively related to the occurrence of cardiovascular disorders such as myocardial infarction. One particular aspect of depression, hopelessness, has been linked to sudden cardiac death as well as to the development of coronary heart disease. Other negative emotions, such as anxiety (both disorders such as panic disorder and more general anxiety symptoms such as worry) and vital exhaustion (a syndrome of fatigue, irritability, and demoralized feelings) also present significant risk for developing cardiovascular disorders.

Earlier investigations of type A personality (a behavior pattern characterized by competition, hostility, time urgency, and excessive focus on work) seemed to indicate that type A was a strong risk factor for developing cardiovascular disease. More recent research, however,

indicates that rather than the entire constellation being predictive of cardiovascular disease, only certain of the type A traits serve as risk factors, particularly hostility. Hostility refers to a general negative orientation toward relationships with others and high levels of anger, cynicism, and mistrust. Hostility appears to be associated with the development and progression of cardiovascular disease, especially coronary heart disease. Recent research has identified anger as the most potent risk factor within hostility.

In addition to these psychosocial factors, lifestyle factors are strong predictors of cardiovascular disease. Tobacco use, physical inactivity, consumption of a high-fat, animal-based diet, excessive alcohol consumption, and poor stress management and coping skills are all risk factors for development and progression of cardiovascular disease.

Many of the identified psychosocial factors appear to contribute to cardiovascular disease through their influence on health behaviors. Negative emotions such as depression are related to higher levels of cigarette smoking, overeating, and increased alcohol use as well as lower levels of exercise and adherence with treatment. High levels of hostility are related to poorer interpersonal relationships and social isolation. In addition to these influences, many psychosocial factors exert their influence directly on physiological mechanisms, such as the neuroendocrine system, the hypothalamic–pituitary–adrenal axis, cardiovascular reactivity, endothelial function, inflammatory markers, platelets, coagulation factors, fibrinogen, lipids, and glucose metabolism.

## PREVENTION AND TREATMENT

Prevention of cardiovascular disease can be greatly facilitated by the promotion of healthier lifestyles that involve higher levels of exercise and physical activity, maintenance of appropriate weight, consumption of a low-fat diet, and abstinence from tobacco products. Furthermore, regular medical checkups can lead to earlier interventions to treat underlying disease processes (e.g., diabetes, hypertension) and, when appropriate, prescription of medications such as beta-blockers and aspirin. Community interventions that promote healthier lifestyles such as more physical activity or reduced cigarette smoking may be particularly effective in reducing heart disease and stroke throughout entire communities.

Treatment of cardiovascular disease varies, depending on the particular disorder. For example, there are four basic ways to treat coronary heart disease: prescription of lifestyle changes, medication, minimally

invasive interventional procedures, and surgery, all of which are designed to minimize symptoms and prevent myocardial infarction. Lifestyle changes involve increasing exercise, losing weight, eating a low-fat plant-based diet, and, if appropriate, making other changes (e.g., stopping smoking, keeping blood sugar under control). Medications that may be used to reduce coronary artery disease include cholesterol-lowering drugs, aspirin, beta-blockers, nitroglycerin, angiotensin-converting enzyme inhibitors, and other drugs that lower blood pressure. Minimally invasive interventional procedures include stent implantation and percutaneous transluminal coronary angioplasty (PTCA). A common surgery for coronary artery disease is coronary artery bypass surgery (CABG).

## CAREER DEVELOPMENT

---

Career development is, for most people, a lifelong process of getting ready to choose, choosing, and, usually, continuing to make choices from among available occupations in our society. Each individual

undertaking this process is influenced by educational, economic, sociological, cultural, geographical, physical, psychological (e.g., interests, skills), and chance factors. Work may be defined as a productive, gainful activity in a job or profession. Work determines a person's worth and place in society, and it strongly influences one's sense of well-being as well as psychological identity.

Despite the centrality of work in the majority of people's lives and the apparent complexity of the career development process, a survey by the National Career Development Association indicated that only about a third of American adults were in their current jobs as a result of conscious planning. Thus, the majority of people chose a particular job because of chance circumstances. In addition, about 28% of those surveyed reported they would be changing their job within 3 years. Assisting a person through the career development process is the primary task of a vocational psychologist or a career counselor.

Vocational psychologists and career counselors use a variety of techniques and interventions to facilitate a person's career development. These techniques and interventions include individual and group counseling, workshops, mentoring, apprenticeships, internships, job shadowing, assessment (e.g., interests, skills, psychological needs), and use of career resources. One major source of career information is the Occupational Information Network (O\*NET). O\*NET is available on the Internet and is a comprehensive database system for collecting, organizing, and describing data on job characteristics and worker attributes. Generally, there are three major outcomes of career development interventions: (a) making a career choice; (b) development of decision-making abilities; and/or (c) better adjustment to the work situations, such as job success and work satisfaction. Career development theory serves to guide the vocational psychologist or career counselor in the selection of assessment instruments and techniques.

## THEORIES OF CAREER DEVELOPMENT

Theories that explain career behavior provide the conceptual framework for career interventions. The following theories are generally considered to be the most influential theories of career choice and development in terms of research and practice. These theories are presented in chronological sequence beginning in the early 19th century.

### Trait-and-Factor Theory

Frank Parsons, teacher, lawyer, engineer, and social reformer, spearheaded the vocational guidance movement. He was concerned with the exploitation of workers by industrial monopolists. This concern led him to propose a method to help individuals make wise vocational choices by first studying the person (e.g., aptitudes, interests, resources, limitations), then understanding the primary characteristics of occupations, and, finally, by matching the individual with the appropriate occupation. This process, called the trait-and-factor theory, became the origin of career counseling and is still in use today. The assumption is that traits are stable and can be reliably and validly measured (the word *factor* is just a form of statistical evidence that a trait exists). Therefore, assessment instruments on such traits as interests, values, decision-making style, and preferences for work activities were developed that are quite useful in counseling. This theory also led to the study of various job requirements. However, this theory is static in that it does not account for changes in values, achievement, skills, and personality characteristics over a person's lifetime in addition to the impact of major life events (e.g., childbirth, divorce). Thus, this theory is generally considered to be limited.

### Ginzberg's Theory

In contrast with the static view of the trait-and-factor theory, Ginzberg, Ginsburg, Axelrad, and Herma viewed career development as a lifelong process beginning in early childhood. Ginzberg and his colleagues see three stages in the career choice process, each with substages. The first is the fantasy stage (childhood before age 11), in which play activities gradually become more work oriented and reflect the child's initial preferences for certain types of activities. The tentative stage (from ages 11 through 17) is divided into four substages named interest, capacity, values, and transition. During the tentative stage, the person becomes more aware of his or her interests and abilities, types of work requirements, and vocational preferences. During the last stage (ages 17 to young adult), the person narrows his or her career choices by taking into consideration occupational interests and perceived abilities and then selects a job or begins advanced training. In the 1980s, Ginzberg noted that older adults may reassess their career goals and make a career change.

## Super's Theory

Donald Super also recognized the changes that people go through as they mature. Career patterns are influenced by many personal characteristics, economic factors, psychological factors, and physical abilities, as well as chance factors. Super theorized that people seek satisfaction through work roles in which they can develop their self-concept. In fact, Super asserted, "the process of vocational development is essentially that of developing and implementing a self concept." Career maturity, a primary concept of Super's theory, is manifested in the successful achievement of age and stage development tasks across the life span. This developmental theory has five major stages. During the Growth stage (birth to age 14 or 15), the child forms his or her self-concept, which is associated with the development of abilities, attitudes, interests, and needs. The child also forms a general understanding of the world of work. In the Exploratory stage (ages 15 to 24), the individual makes a tentative career choice with related skill development. The Establishment stage (ages 25 to 44) is characterized by work experience. From ages 45 to 64, the Maintenance stage, the person experiences a continual adjustment process to improve the working situation. The final stage is named Decline (65+), during which there is reduced work output and eventual retirement. Super's theory has been refined and expanded over the years. For example, although Super originally presented the stages and tasks in a sequential manner, he later added that we cycle and recycle through the stage throughout our life span.

Super identified six factors in vocational maturity: (1) awareness of the need to plan ahead, (2) decision-making skills, (3) knowledge and use of information resources, (4) general career information, (5) general world-of-work information, and (6) detailed information about preferred occupations. Super also examined the various roles that we play during our lifetimes and how the relative importance of those roles changes over time. Super's theory has increasingly been viewed as the most comprehensive of the developmental approaches.

## Roe's Theory of Early Childhood Influences on Career Choice

Anne Roe's theory focuses on early family relationships and their influence on career choice.

Occupations are classified into two major categories: person-oriented and non-person-oriented. However, empirical research has failed to support Roe's theory. The major contribution seems to be the emphasis on childhood experiences on career development and her job classification system.

## Theory of Work Adjustment

In the theory of work adjustment (TWA), Dawis and Lofquist focus on the major construct of correspondence. Correspondence is the fit between what a particular occupation requires and an individual's attributes. Work adjustment is the dynamic process by which persons attain and preserve correspondence with their work environment. Thus, high correspondence is hypothesized to result in longer tenure on the job (the chief outcome of correspondence and work adjustment), better performance on work-related tasks, and greater job satisfaction. Given these major assumptions and concepts, 20 major propositions have been developed to predict work adjustment. However, few of these propositions have been examined empirically. Those studies that have been done used designs that do not use causal influence, even though TWA posits work adjustment as a continuous, dynamic process.

## Holland's Theory

John Holland's typological theory was developed to organize the data about people in different jobs and the data in different work environments. According to Holland, people function best and find satisfaction in work that is compatible with their personalities. Thus, he developed six personal styles and six matching work environments: realistic, investigative, artistic, social, entertaining, and conventional (often referred to by the acronym RIASEC). People tend to choose a career that is reflective of their personality. Holland suggests that the closer the match of personality to job, the greater the satisfaction, congruence, and persistence. All six types are a part of each of us. However, one to three types are usually evidenced more strongly. A brief overview of the RIASEC types, six work-related activities, and sample occupations is presented in Table 1.

Holland and his colleagues have developed a number of instruments designed to identify individual personality traits and match those traits to occupational groups. These instruments include the Self-Directed Search, My Vocational Situation, and the

**Table 1** RIASEC Activities and Sample Occupations

<i>Type</i>	<i>Activities</i>	<i>Occupations</i>
Realistic	Working with things	Carpenter Mechanical engineer
Investigative	Working with information	Chemist Psychologist
Artistic	Creating things	Writer Painter
Social	Helping people	Social worker Counselor
Enterprising	Leading others	Sales representative Entrepreneur
Conventional	Organizing data	Secretary Auditor

Vocational Preference Inventory. Holland's theory has generated a vast amount of research and has had more influence on career research and practice than any other career development theory.

### Krumboltz's Social Learning Theory of Career Decision Making

John Krumboltz's theory of career development has roots in classical behaviorism, social learning theory, cognitive behavioral theory, such as that proposed by Beck and Ellis, and self-efficacy theory proposed by Bandura. Many factors that have an impact on career decision making are incorporated into this theory. First, genetic factors may expand or limit an individual's options. These genetic factors may include sex, race, and developmental disabilities, as well as those innate capabilities or talents that a person may choose to develop. Second, environmental conditions and events beyond a person's control such as the economy, cultural norms, or even geography may have an impact on career decisions. Individual learning is the third factor. For example, good work habits (punctuality, organization, etc.) and problem-solving skills may be acquired or there might be a failure to acquire these skills. The person may also have some life experiences that are rewarded and lead to a specific career interest. For example, having a parent who is a lawyer may lead to an

interest in law as a career. Finally, Krumboltz's theory focuses on self-observation generalizations or comparing one's performance, abilities, and skills to some standard to draw conclusions about one's own competence and worth. These conclusions are used in making responses to future situations. If the conclusions are unrealistic, this may negatively affect the image of the self as a worker. For example, a belief that one is not good in mathematics is likely to result in avoidance of any math-related activities and career possibilities. Overall, Krumboltz views career development as unique for every individual, and most of the influences on career development (e.g., self-concept, interests) can be changed at any point in life.

### Career Self-Efficacy

Bandura's social cognitive theory focuses on the central role of self-efficacy (SE) beliefs in influencing and guiding important aspects of psychosocial functioning, including career-related behavior. SE expectations are defined by Bandura as "people's judgments of their capabilities to organize and execute courses of action required to attain designated types of performances." These SE expectations are hypothesized to help determine whether a particular action will be initiated, as well as effort expenditure, persistence, and emotional reactions when confronted by obstacles. SE is a dynamic aspect of the self-system that is specific to a particular behavioral domain. Thus, a person can have high SE in regards to achievement in athletics, but not in the area of an academic subject such as mathematics.

Hackett and Betz were among the first researchers to recognize the importance of the SE construct to career development. They developed an extension of Bandura's theory and posited that SE influences the career decisions, achievements, and work adjustment behaviors of both men and women, although the influence may be greater for women. There is growing support from the empirical literature to support the extension of SE theory to career-relevant behavior. For example, in a meta-analytic review of the academic SE literature, Multon, Brown, and Lent found effect sizes of 0.38 and 0.34 for the relation of SE to measures of academic performance and persistence, respectively. Some conclusions can be gleaned from this empirical literature: (a) SE beliefs influence career entry indexes (e.g., range of career options, persistence in education, career indecision), (b) SE relates to important work adjustment outcomes such

as job performance and coping with job loss, and (c) gender differences in SE often explain the male-female differences in occupational choices.

### Other Noteworthy Theories

Other theories of career development (listed chronologically) include the work of Tiedeman and his colleagues on the career decision-making process, the psychoanalytic approach of Bordin, Nachmann, and Segal, and a theory of circumscription and compromise in career aspirations. Tiedeman's holistic theory served to highlight the importance of self-awareness in career decision making. However, it has little empirical support. Bordin and his colleagues hypothesized that psychoanalytically developed need dimensions are established by the age of 6, and these need dimensions influence career choice. Thus, the major contribution of this theory has been to note the importance of early child-parent relationships and development processes to career development issues. Gottfredson contends that occupational preferences emerge from the complexities that accompany mental and physical growth. She postulates that during self-concept development, an individual will narrow career aspirations according to sex-type and prestige. Compromise is also used in decision making in that a person may settle for a less compatible but more accessible career choice.

### Convergence of Career Development Theories

Osipow argued that major career development theories are converging as empirical evidence about vocational behavior accumulates and theories are continually revised. His analysis of four of the major theories (those of Super, Holland, Lofquist, and Davis and Krumboltz) extracted common themes. These themes include the influence of both biological factors and parental upbringing, personality factors, and life-stage influences.

Several researchers (such as Hackett, Lent, and Greenhaus) argued for the need to work toward unifying career development theories. Major variables crucial to a comprehensive theory of career development need to be identified and defined. A unifying theory would bring together conceptually related constructs such as SE and self-concept as well account for the relationships among diverse constructs (e.g., interests, needs, abilities). To be truly comprehensive, variables

that have received little attention in current theories need to be included. These may include what opportunities are available within a particular geographic area, the influence of life roles (e.g., racial identity, sex role, parent role), and economic influences. It must be noted, however, that such a comprehensive theory would pose barriers in both research and practice because of the number of major constructs and the complexity of the interrelationships among constructs.

### CAREER DEVELOPMENT NEEDS OF SPECIAL GROUPS

There are some groups of people for whom certain conditions or circumstances may require some variation in the usual career development process. Of course, the career development process will be somewhat individualized due to the unique characteristics and circumstances of each person, but there are commonalities generally shared within groups of people. Groups that may experience some different circumstances with regard to the career development process include women; racial and ethnic minority groups; delayed entrants into the workforce (e.g., displaced homemakers, returning military personnel, prior offenders); midlife career changers (whether voluntary or involuntary), older workers; and gay, lesbian, bisexual, and transgendered individuals. The exploration of group differences can advance the understanding of career development, although it must be noted that research has shown that differences between persons within a particular group typically exceed the degree of difference between groups. Therefore, it is important for the vocational psychologist or career counselor not to extend these findings rigidly when working with individual clients. In this section, some of the salient issues for three of these groups (i.e., women, racial and ethnic minority groups, and persons with disabilities) will be addressed here.

### Women's Career Development

Compared with men, women may experience some barriers to their career development that have not been adequately addressed in the major career theories. For example, Farmer originally proposed a set of seven internal and external factors that inhibit women's career progress: academic self-confidence, myths about women and work, fear of success, home-career conflict, vicarious achievement motivation (i.e., feeling it is more

important to focus on the career progress of a spouse or children instead of one's own career progress), lower risk-taking behavior, and sex-role orientation. As Farmer refined her model, she included background variables (sex, race, age, socioeconomic status [SES], ability) that are hypothesized to influence personal variables (academic self-esteem, values, attributions, and independence) and environmental factors (parental and teacher support)—all of which, in turn, influence the motivational variables of level of career aspirations, mastery strivings, and commitment to career. Betz and Fitzgerald comprehensively reviewed the research on the career psychology of women and summarized the literature by proposing four sets of factors that positively influence women's career choices: (a) individual variables (high self-esteem, high ability, liberated sex-role values, strong academic self-concept, androgyny); (b) background variables (working mother, supportive father, highly educated parents, female role models, work experience as an adolescent, androgynous upbringing); (c) educational variables (women's schools, advanced work in mathematics, higher education); and (d) adult lifestyle variables (late marriage or single, no or few children). Betz and Fitzgerald proposed a causal ordering of these variables, and Fassinger tested the model using sophisticated empirical methods. Fassinger's findings indicated that higher ability levels, in complex interaction with liberal sex-role attitudes, positively influence career orientation and career choice.

### **Career Development of Racial/Ethnic Minorities**

Research on race/ethnicity and career development has fluctuated widely over the years, but in recent years there is a renewed interest in cultural, racial, and ethnic variables in career development. While there are no comprehensive models of minority career development, there are literature reviews on specific minority groups (e.g., African Americans, Hispanic Americans, Asian Americans) to guide both research and practice. Different cultures may have different conceptions of the family, gender roles, and work-family relationships. For example, *career* may have a collective and not an individual meaning. Although it is important to understand the meaning of work, career, and other related concepts to an individual's racial or ethnic group, it is also important to assess the salience of membership in the cultural group to better understand the person's career behavior.

### **Career Development for Persons With Disabilities**

A person with disabilities is someone generally considered different physically and/or psychologically from most people because of birth, developmental difficulties, accident, or illness. It should be noted that these disabilities may or may not prove to be a vocational hindrance. The Americans with Disabilities Act of 1990 had a major impact on work for persons with disabilities. This act makes a distinction between essential and nonessential job functions, and an employer may only consider the essential functions when hiring or promoting people. Thus, the current disability policy of the United States focuses on the inclusion, independence, and empowerment of persons with disabilities.

### **CAREER COUNSELING**

Career counseling helps people to select careers, find the right job (e.g., by practicing interviewing skills, providing guidance on job applications), manage multiple roles and stressors to enhance adjustment to the workplace, and make decisions regarding retirement. Career counseling first began more than 100 years ago. The National Career Development Association has defined career counseling as "consisting of those activities performed or coordinated by individuals who have credentials to work with other individuals or groups of individuals about occupations, life/career decision making, career planning, career pathing, or other career development related questions or conflicts." In recent years, the relationship between personal and career counseling has been recognized to emphasize the importance of the person's vocational role with overall psychological well-being. For example, Multon, Heppner, Gysbers, Zook, and Ellis-Kalton empirically explored psychological distress as a variable in career counseling. Their results showed that in their sample, 60% of the career clients were psychologically distressed (e.g., anxiety, depression) and that career counseling significantly decreased their level of distress. Thus, career counseling can also have a positive impact on psychological health and interpersonal relationships. This awareness of the need for career counselors to develop competencies to work with increasingly complex issues has resulted in the National Career Development Association developing a list of competencies for career counselors. This list outlines an array of skills including both individual and group counseling skills in addition to legal and ethical issues in the field.

As noted earlier, Frank Parsons was the first person to focus on the importance of vocational guidance, and he is sometimes referred to as the father of career development. His three-step procedure (a trait-and-factor method) for working with immigrants seeking employment in the late 1800s and early 1900s was outlined in his book *Choosing a Vocation*, which was published posthumously in 1909. Parsons wrote, "In the wise choice of vocation there are three broad factors: (1) a clear understanding of yourself, your aptitudes, interests, ambitions, resources, limitation, and their causes; (2) a knowledge of the requirements, conditions of success, advantages and disadvantages, compensation, opportunities, and prospects in different lines of work; and (3) true reasoning on the relations of these two groups of fact" (p. 5). Parsons's method had a lasting impact on how career counseling was conducted for a long period of time in the United States and continues to be influential in today's practice of career counseling. While all the theories of career development described earlier have had an impact on how career counseling is conceptualized and conducted, none have had as much of an influence on career research and practice as the work of John Holland.

The term *career counseling* has been used to describe a great variety of interventions, including individual career counseling, group interventions, classes, one-time workshops, or the use of computerized career information and guidance systems. Spokane and Oliver conducted a meta-analytic study to examine the effectiveness of a number of career interventions across a large number of studies. They reported an overall effective size for career interventions of 0.85, with group interventions having a greater effective size (1.11) than individual interventions (0.87). In 1988, the same authors conducted a second meta-analytic investigation of more recently published empirical studies and found career exploration classes to have the greatest effect size, followed by group test interpretation, workshops, and individual counseling. While it appears career counseling is effective overall, the aspects of career counseling that contribute to this effectiveness are less clear. Although some research has been conducted in this area, conclusions have not been reached.

## CURRENT TRENDS IN CAREER DEVELOPMENT

The world of work has been changing very rapidly in the past few decades. There is ever-changing

technology, shifting requirements for worker knowledge and skills, and a global labor surplus. All these changes are likely to affect the career development of individuals across the life span. Current trends in the area of career development include the following:

1. There is a greater awareness of the need to attend to career development issues across the life span. With this awareness comes an increase in the career development programs available. These programs are in a wider variety of settings and are available from a wider range of personnel. These settings include business and industry, hospitals, prisons, and even shopping centers. Traditionally, counseling psychologists, college counselors, employment (or career) counselors, school counselors, and rehabilitation counselors have provided career development services, but now other groups have become more interested in the area. These include industrial psychologists, social workers, and mental health counselors. This burgeoning interest in career development has generated an increased interest in credentialing career counselors.

2. There continues to be a greater focus on career transitions (e.g., school-to-work transitions, midlife career transition, involuntary job loss).

3. Substantial changes will continue to occur in the economic, occupational, industrial, and social environments, and these changes will influence individual career development. For example, the use and sophistication of technology have increased dramatically. New jobs are created and the need for other jobs are reduced or even eliminated, thus requiring more workers to change jobs or even move to another occupational group.

4. Along with more sophisticated technology and work procedures, there is a greater need for a better educated workforce. There are fewer opportunities for an unskilled workforce because the jobs they do are done for less money in underdeveloped countries.

5. There will be more participation in retraining programs to develop new skills and update and enhance current skills due to changing job opportunities.

6. It is likely that flexibility in work schedules (e.g., job-sharing, part-time, 4-day work weeks with 10-hour days) will increase, giving more options to workers with particular needs, such as mothers with young children. More workers will also spend at least part of their time working from home.

7. There will be even greater attention to the career development of a more diverse population. The workforce today includes more women (including mothers of young children), members of racial and ethnic groups, openly homosexual and bisexual individuals, and persons of various types of disabilities (e.g., cognitive deficits, physical limitations, mental illness).

8. Of increasing concern will be the impact of employment and unemployment on mental health. The interaction between interests, personality characteristics, and variables in the work setting (e.g., environment, type of supervisor) may result in certain mental health problems (e.g., depression, anxiety, increased interpersonal sensitivity). Similarly, the loss of employment may produce certain adjustment problems for both the worker and his or her family.

9. As the “baby boom” generation approaches the traditional retirement age, more research has been generated concerning decisions regarding when to retire and how to plan for retirement. Financial status is a critical factor in the decision to retire, but other factors such as health problems and psychological issues also play a role.

10. There will be a greater emphasis on work adjustment factors, particularly as they relate to productivity and quality.

—Karen D. Multon

## CASE STUDY

---

A case study is a research technique used to study an individual or group providing intense description and analysis. This particular method was the cornerstone of Freud’s work in his psychodynamic theory; his classic case study of “Little Hans,” a child terrified of horses, was used to demonstrate how psychological difficulties of an individual can be interpreted to explain basic psychological and developmental processes. Case studies, however, are not limited to pathology; Piaget used the intense observation characteristic of the case study with his own children to develop his stage theory of cognitive development. Additionally, case studies are not limited to the individual. Study of a group, even if large, offers insights into the impact of various cultural and historical events. For example, studying the coping of the rescue workers, survivors, and witnesses on the scene of the Murrah Building bombing in Oklahoma City provided mental health professionals a starting point when they arrived on the scene of the World Trade Center attacks.

The best understood advantage of the case study is the opportunity to study rare phenomena. For example, genius in children is often studied using case studies. Case study can offer valuable insights into the parameters of giftedness in children and, for example, its impact on social behavior.

A second advantage is that case studies of people in extreme circumstances offer an opportunity for developmental researchers to address questions that would be unethical to study otherwise. For example, a central question in language development is whether a critical period exists: do children have to be exposed to language by puberty to develop language? “Genie” was approximately 13 when she was found by social services, having had virtually no human contact or exposure to language since she was 2.

Genie’s case demonstrates the third and perhaps most powerful advantage of the case study. The case study offers the possibility of challenging a theory if it violates a critical, general proposition of the theory. Because

Genie was capable of developing some language, her case offered a refutation of the absolute view of the critical period theory that language would not be acquired at all without exposure during this critical period.

The disadvantages of the case study method are threefold. First, there is typically a considerable lack of control in the case study, usually because nature provides the arrangements rather than a researcher. For example, Genie suffered such extreme emotional deprivation that her failure to develop normal language cannot be solely attributed to the critical period theory.

Second, the ability to generalize from a case study is limited. If the researcher is investigating developmental phenomena that are considered to vary from one individual to another, such as personality, it is impossible to claim that a case study of one individual is representative of others.

Third, the data collection process itself in case studies is open to bias and distortion, albeit unintentional. Much case study data come from archival data and observation. It is difficult to avoid systematically recording those events and behaviors that are consistent with the hypothesis being investigated. However, it is important to note that this disadvantage is by no means limited to the case study.

In conclusion, it is important to understand both the benefits and problems of the case study methodology. The case study method is typically considered an exploratory method useful for generating new hypotheses but hampered by issues of generalizability and control. Case studies are perhaps best thought of as complementary to the other research methodologies as opposed to an inferior alternative.

—Melinda C. R. Burgess

## CATEGORIZATION

---

In cognitive psychology, categorization focuses on how knowledge is organized. Objects in the same category are likely to share certain attributes, and category

membership allows inferences to be drawn. The term *category* refers to a set of things (objects, ideas, events) that are grouped together. The term *concept* often refers to the mental representation of such knowledge.

Categorization has obvious functions for learning, organizing, and storing information. From an evolutionary standpoint, it benefits an individual to be able to amass as large an amount of information with the least amount of effort or time. By grouping known items together, one can better identify novel items as well as predict some of their likely attributes.

Neuroscientific studies support an underlying categorization organization for semantic knowledge in the human brain; subjects with neurological damage can lose the ability to retrieve categorically selective information. For example, a person may be able to name tools or utensils, but not animals or fruits. These specific deficits point to a key organizational role for categorization in cognitive processing.

Categorization is a process that occurs cross-culturally as well. But while some objects tend to be universally grouped together, such as shapes and colors, others may be grouped differently as a function of cultural background. Consider a classification task for the items *shovel*, *hoe*, *dirt*, and *hammer*. Someone from an industrialized background with formal education might use a taxonomic grouping and thus omit *dirt* because it is not a tool. Someone from an agrarian background without formal education might use a thematic grouping and thus omit *hammer* because the other items are used together.

### LEVELS OF CATEGORIZATION

Many items can be categorized hierarchically, and the following scheme is often used in describing this organization:

*Superordinate*—The superordinate level is a broad, inclusive level in the hierarchical scale of categories (e.g., animal, vehicle). Often the superordinate level will consist of several basic-level categories.

*Basic*—The basic-level category (e.g., cat, boat) is often used when one labels an object. Items within a basic-level category share many features in common and are distinct from items in other basic-level categories. Researcher Eleanor Rosch argued for the primacy of basic-level categorization in early development.

*Subordinate*—Subordinate-level categories offer a more specific breakdown within a basic level category (e.g., tabby [for cat], canoe [for boat]).

## THEORIES OF CATEGORIZATION

Researchers continue to debate various theoretical approaches for describing categorization processes. Most theories can be classified as either similarity based or explanation based.

### Similarity-Based Categorization

The classical defining-attribute theory identifies members of a category based on certain traits that all items have in common. The set of common attributes is both essential and sufficient for an item to be included in the category. All squares have four equal sides and four 90-degree corners. A shape that does not meet all the standards is not a square. This all-or-none explanation implies that no item within a given category is more representative of that category than another item. This theory has been disputed on the basis that most categories are not clearly marked but rather have fuzzy boundaries. Philosopher Ludwig Wittgenstein used the example of games, pointing out that among all possible games (those with boards, balls, cards, sticks, etc.) no set of features is necessary or sufficient for a particular game's inclusion or exclusion.

The prototype theory states that because there are no absolute boundaries, some items of a category are indeed more representative than others. The theory explains that a set of characteristic attributes, not defining attributes, is what identifies objects as belonging to a category. A prototype is created by averaging features together to create a typical or central example. Rosch cited one example as the category *birds*, stating that *robin* is far more "typical" than *penguin* and thus closer to the prototype, because it contains more of the characteristic attributes. The research finding that people are quicker to judge a robin as a bird than a penguin as a bird has been used to support this theory.

The exemplar theory states that we categorize items based on examples, rather than on a prototype that becomes abstracted over time. In other words, people are capable of drawing on multiple instances when locating or placing an object into a particular category. The mental representation of the category is presumed to contain information from various specific exemplars.

This theory is consistent with the finding that understanding variability and typicality of instances within a category plays a role in predicting category membership.

### Explanation-Based Categorization

Instead of emphasizing similar features, explanation-based approaches define categories based on

theory-driven inferences. For example, categories may be based on nonobvious features, such as the presumed internal characteristics that differentiate animate from inanimate objects. Also, ad hoc categories that ignore perceptual similarity can be created, such as the category *things at a yard sale*. These categories cannot be explained using a similarity-based view, but instead require fundamental theoretical knowledge.

## THE DEVELOPMENT OF CATEGORIZATION

Questions about the development of categorization help us characterize how infants and children understand their worlds and provide information about the building blocks of adults' cognitive skills.

Current research explores some critical questions about how categorization and conceptual processing develop. For example, do infants first recognize basic-level categories, followed by elaboration of the hierarchical organization of superordinate categories? Does development proceed from perceptually based categories to conceptually defined categories?

Psychologist Eleanor Gibson argued that laboratory studies of categorization often focus on static presentation of visual stimuli (e.g., pictures), whereas infants in the real world use dynamic information from various modalities. She emphasized the benefit of a symbiotic connection between perception and action. Acting on an object provides more information about it, and its perceptual characteristics allow for plausible actions. She proposed that perception is not separate from meaning, and thus the distinction between perceptual and conceptual categorization may be unnecessary.

### Categorization in Infants

Studying categorization in infants requires methods that do not rely on verbal explanation. In one popular method, infants are shown a series of objects from the same category (e.g., cats) and the time that they look at each item is measured. The subsequent test measures how long the infant looks at a novel member of that same category (cat) compared to how long they look at a novel member of a different category (e.g., rabbit). The inference is that a preference for the novel category demonstrates the infant's categorization of the initially presented category.

Using this method, researchers have demonstrated that infants as young as 3 months can discriminate

categories such as shapes, colors, and animal types. Between 6 months and 1 year, infants attend to categories such as vehicles, tools, facial expressions, and gender.

Researchers propose that early conceptual understanding occurs for distinctions such as animate versus inanimate objects, and that infants begin to categorize based not only on perceptual appearance, but also on function. During the second year, infants can group toys with different attributes into different piles, actively demonstrating their categorization skills. As linguistic skills develop, children's abilities can be tested with verbal tasks.

### Categorization in Childhood

Later in childhood, hierarchical classification skills emerge. Rosch found that preschool-aged children are more adept at sorting objects at the basic level than at the superordinate level. Children's language learning and adults' labeling of objects to children follow this same trend. Other researchers suggest an early appreciation of more global characteristics of object categories.

The development of explanation-based categorization has also been studied. For example, researcher Frank Keil tested children with stories about an animal (e.g., raccoon) that was physically transformed to look like a skunk. Preschoolers tended to be fooled by appearance, but second-graders were able to classify the animal using internal characteristics.

### Categorization and Language Development

Another area of debate is the developmental connection between categorization and language. This debate reflects the classic distinction between theorists Lev Vygotsky and Jean Piaget on the connection between language and thought. That is, do children's linguistic processes (e.g., labeling) simply reflect their level of cognitive understanding of categories, or does the acquisition of language influence and facilitate developing processes of categorization?

Researchers have proposed that linguistic development is important in categorization and conceptual development because the use of a common label (e.g., *vehicle*) across multiple things (e.g., boats, planes, cars) highlights common features of the category and allows for inferences about internal and functional

properties. Many studies reveal young children's ability to link language and concepts. For example, children's sensitivity to linguistic distinctions has been revealed through the use of nonsense phrases such as "this is *a* nax" versus "this is *some* nax"; they correctly map the first label to the count noun (e.g., a whole object) and the second label to the substance of a mass noun (e.g., sand).

### SUMMARY

Categorization is a fundamental aspect of cognition, and there is growing interest in the organization and mental representation of categories. Perceptual categorization is evident early in infancy. Preschool-aged children categorize adeptly, use concepts for inductive reasoning, and notice linguistic cues for categorization. During middle childhood, theory-based reasoning continues to unfold and hierarchical classification is evident. The mental representation of categorical knowledge in children and adults continues to be debated, and each of the various theoretical approaches has advantages and disadvantages.

## CATHOLICISM

---

Catholicism is a Christian religious tradition that has as its central belief that Jesus Christ is both God and man; that he is the Son of God and freely chose to become man to be the Savior of humankind.

Catholicism dates back to the time of Christ, and early Church records show the use of the term Catholicism in 2 AD. Consistent with Protestant Christian denominations, those who profess this faith, Catholics, are monotheistic (believe in one God) but also believe in the Holy Trinity (there is only one God, but He is made up of three persons: God the Father, God the Son, and God the Holy Spirit). Unique to Catholicism is that its leaders (the Magisterium) can trace their roots back to the original followers (apostles) of Christ. This is what Catholics mean by the term apostolic tradition. There are both Western (Latin or Roman) and Eastern (Byzantine) rites of the Catholic Church, and both are led by the head of the Magisterium, the Pope.

The term *Catholicism* literally means “universal” and expresses a particular worldview that includes the belief that Jesus Christ died for all of humankind. Catholics share various beliefs and ways of worship, as well as a distinct outlook on life. Catholicism recognizes that for each human being there is a unity of the body and soul. The physical world of the body is viewed as part of God’s creation and is considered inherently good until misused by individual choices. Thus, inherent in Catholicism is the belief that people are intrinsically good, but that sin (any act against God) can wound or kill a person’s soul. Sin is only cured by God’s divine grace (supernatural gift from God to aid humankind on their journey to God) that is best received through the sacraments such as baptism, communion, and marriage. Sacraments are visible, outward signs of God’s inward grace, instituted by Christ, to aid humankind on their journey toward sanctification. The sacraments allow individuals to “see” the invisible grace of God.

## BASIC TENETS

The Catholic faith is based on God’s revelation that comes from two sources: the Bible and sacred tradition, the written and the unwritten word of God. Catholics believe that the Bible is the inspired and revealed word of God. Sacred tradition is the “deposit of faith” (the teachings of the Church) that has been passed down through the ages by the Church leaders. Because stories were first told orally, sacred tradition serves as the basis for the Bible before it was put into text. The Apostles’ Creed, an oral statement of faith often repeated aloud during church ceremonies, is an example of this sacred tradition and summarizes what Catholics believe as divinely revealed truth. Another basic tenet of the

Catholic faith is that baptism, a ceremony involving water for the forgiveness of sins and the rite of becoming a Christian, is necessary for salvation, as well as that God’s Ten Commandments, as presented in the Bible, provide a moral compass by which to live.

## The Four Hallmarks of the Church

The four hallmarks of the Catholic Church include the belief that it is “one, holy, catholic, and apostolic.” These beliefs are contained in the Nicene Creed (the profession of Christian faith approved at the Council of Constantinople in 381 AD) and are recited each Sunday at Mass. The Creed is a synopsis of all the core beliefs of Christian dogma common to the Catholic Church and formulated by sacred tradition (part of the unwritten word of God).

The first hallmark is unity. This unity is expressed at multiple levels across liturgy, doctrine, and authority. The same seven sacraments that mark the major stages of development are celebrated by Catholics around the world and are drawn from the same deposit of faith (sacred oral tradition + sacred scriptures). Both the Western (Latin) Church and the Eastern (Byzantine) Church are led by the one supreme pontiff, the Pope. The hallmark of unending holiness stems from the Church being united by Christ and sanctified by Him. The Catholic Church is considered the bride of Christ as well as the embodiment of the mystical body of Christ. Consequently, the Church as a whole cannot sin, but individual members are capable of sin. The holiness of the Church is articulated in daily prayer and through the celebration of the Mass. The third hallmark of the Church is catholic, meaning universal or according to the totality. That is, Christ is present in the Church and because of this, the Church bears and administers the totality of the means of salvation. The Church is also sent on a mission to the whole of humanity. By *apostolic*, it is meant that the Church can trace origins back to the original 12 apostles that Christ chose to lead His Church.

Catholics have at the source of their beliefs both the written and the unwritten word of God. The revealed truth is expressed in the Bible as inspired, infallible, and inerrant. Likewise, the unwritten word of God is expressed through sacred tradition. The Apostles’ Creed is an example of sacred tradition and summarizes what Catholics believe as divinely revealed truth.

There are 12 articles of faith in Catholicism that when put together constitute the Apostles’ Creed. This

Creed contains all of the basic tenets of Christianity. Article 1: "I believe in God the Father, almighty, creator of heaven and earth." Here it is affirmed that God exists and created everything from nothing in the universe. Article 2: "And in Jesus Christ, his only Son, our Lord." This statement highlights the divinity of Jesus as savior or anointed one. Article 3: "Who was conceived of the Holy Spirit." Here the human nature of Christ is articulated as he had an earthly mother, Mary, but no earthly father. His divine nature is reinforced by this statement where He is considered both God and man. Article 4: "He suffered under Pontius Pilate, was crucified, died, and was buried." Christ's human nature is stressed again in this statement, and his death is placed in earthly context giving it a specific time and place in history. Ultimately, this places Christ's death on all humanity. Article 5: "He descended into hell, the third day He rose again from the dead." Prior to the Messiah coming to open the gates of Heaven, souls were gathered in the world of the dead. Catholics believe Christ literally died and rose again 3 days later by his own accord to open the gates of heaven. Article 6: "He ascended into heaven and sits at the right hand of God the Father almighty." This clause asserts that Jesus remains intimately connected to His human body and went body and soul into heaven, providing hope for humankind to follow in His path. Article 7: "From thence he shall come again to judge the living and the dead." The Second Coming of Christ as judge at the end of time is expressed here. Catholics believe in a personal judgment that will occur at the end of their life as an accounting for how they lived their life. Those who are unpure will be purified in an intermediate place, known as purgatory, in preparation for heaven. Then at the end of time, God will disclose everyone's private judgment for eternity. Article 8: "I believe in the Holy Spirit." Here the concept of the Blessed Trinity is highlighted as God existing in three divine persons: God the Father, God the Son, and God the Holy Spirit. Thus, Catholics affirm their belief that He is truly one God in three divine persons. Article 9: "(I believe in) the holy Catholic Church, the communion of saints." Here the Church is highlighted as a necessary component of the continuation of Christ's mission to teach, sanctify, and govern. The teaching authority of the Church, the Magisterium, continues this mission through sanctification through the celebration of the sacraments. Through the use of hierarchy, the Church continues the mission of governing the faithful. The communion of saints serves as a reminder that the Church is composed of

those baptized on earth, but also those in purgatory, as well as those in heaven. Article 10: "(I believe in) the forgiveness of sins." This belief is essential for all of Christianity in that Christ came for sinners to realize His mercy and forgiveness. Article 11: "(I believe in) the resurrection of the body." An intimate and inseparable connection between the soul and body exists in Catholic thought. At death, the body is temporarily separated from the soul, but will be united on the last day as both body and soul go into heaven or hell. Article 12: "(I believe in) life everlasting." This final article of faith explains the belief in a reunification between the soul and body for all eternity.

The Holy Eucharist, the belief in Christ's real presence under the appearances of bread and wine, serves as the source and summit of all Catholic beliefs. Catholics believe that the Eucharist is the literal body and blood of Christ and therefore believe that Christ is present in both forms during each Mass. Because *Eucharist* means "thanksgiving," Catholics express their thanks to God for providing the body and blood of Jesus to nourish their souls. The Eucharist is also present during Mass when the bread and wine are consecrated as Holy Communion and outside of Mass under the title of the Blessed Sacrament.

## MAJOR PRACTICES

The Mass is the most important, central, and sacred act of worship in the Catholic faith. The key to this understanding is the belief by Catholics that the bread and wine are transformed into the body and blood of Christ, the Holy Eucharist. This transformation can only occur by means of the Mass, so therefore, Catholics offer the same degree of reverence and adoration that is due God the Almighty. Because of the significance of the Mass, it serves as the primary worship ceremony for the Catholic Church and is celebrated all over the world, in exactly the same way, every day of the week. To understand the Mass is to understand Catholicism because it exemplifies the beliefs, actions, and techniques associated with the faith. For example, more than just mere physical attendance of the congregation is required at a Catholic Mass. By singing, praying, speaking, sitting, and kneeling, Catholics fully, actively, and consciously participate in the celebration. Through these series of interactions, an intimate communication is established between the priest and the people. Another key aspect to understand about the Mass is that it is

not just a reenactment of the Last Supper. In the Mass, the past, present, and future are all united at the same time. The past is remembered by reciting the words of Jesus, “This is my body, this is my blood.” Graces, spiritual nourishment, and instruction for the people participating are offered in the present, whereas the future foreshadows the sacred banquet in heaven.

Because the Mass is so critical to Catholic worship, it is referred to as the sacred rite, or the formal, official worship service of Catholicism. The Mass is composed of two parts, the Liturgy of the Word of God and the Liturgy of the Eucharist. Every prayer and sacrament begins and concludes with the priest and individuals using their hands to make the sign of the cross, and the Mass follows suit. During the Liturgy of the Word, the priest gives a short greeting and the Penitential Rite commences. During this time, the congregation publicly acknowledges that they are sinners and have sinned in some capacity since the previous week. Next the Gloria is prayed to give praise to God and an opening prayer is said. Scripture readings follow with a reading from the Old Testament, a psalm, a selection from the New Testament Epistles or Acts of the Apostles, and concluded with a gospel reading. The priest or deacon will deliver a homily incorporating the messages from scripture followed by prayers of the general intercession. The second half of the Mass is composed of the Liturgy of the Eucharist. The essential characteristic here is one of offering. The gifts of bread and wine are collected and prepared on the altar followed by a cleansing ritual of the washing of the priest’s hands. Prayers of offering are said on behalf of the people by the priest and homage is paid to God. The Eucharistic Prayer begins next where the priest uses the same words that Christ used at the Last Supper, commanding his followers to eat his flesh and drink his blood as the new and everlasting covenant. Catholics refer to this as the Consecration—the point where a miracle occurs and the bread and wine are transformed into the literal body and blood of Jesus the Christ. Next the Our Father prayer is recited as well as a sign of peace exchanged among the faithful. The Lamb of God is said next prior to preparation for the distribution of Holy Communion. The Mass is closed by a final blessing with the command to go out into the world and spread the gospel of Christ.

The Church believes that the Mass is the highest and supreme form of prayer, so it contains all elements of Catholic prayer to include adoration (praising God), contrition (asking for God’s forgiveness),

petition (asking God for a favor), and thanksgiving (showing gratitude to God).

Catholics do have an obligation to attend and participate fully in Mass on Sundays (or during the vigil Mass on Saturday evening) as well as on Holy Days of Obligation in order to fulfill the Third Commandment to keep holy the Sabbath day. At the Mass, Catholics believe that the three levels of the Church converge and are united with one another, meaning the saints in heaven (church triumphant), the believers on earth (church militant), and the suffering souls in purgatory.

## Sacramentals

Because God is the author of all created things, both spiritual and physical, Catholics attempt to directly connect to the spiritual world through worship utilizing all of the senses. In this manner, Catholics have developed many objects, tools, and techniques to draw the believer into a closer union with God. These are known as sacramentals. Holy water is a common example of a sacramental. All sacramentals give the recipient a special grace necessary to fulfill the mission of a particular sacrament. Holy water is used as a symbolic reminder of the sacrament of baptism.

Other sacramentals include actions, such as the sign of the cross. This is a common expression that is authentically Catholic because it draws one into a deeper union with the eternal. Catholics make the sign of the cross by using their right hand to touch it to their forehead, middle of the chest, their left shoulder, and then their right shoulder while saying, “In the name of the Father, and of the Son, and of the Holy Spirit, amen.” The sign of the cross communicates, symbolically, two basic tenets of the faith: the Holy Trinity (Father, Son, and Holy Spirit) and humankind’s salvation through the cross of Christ.

Genuflection is the act of touching one’s right knee to the floor while bending with the left knee while making the sign of the cross. Catholics genuflect in front of the Holy Eucharist or the place where it resides because they believe it is truly the body, blood, soul, and divinity of Jesus and they want to show respect and acknowledgement of this true presence.

The crucifix is another authentically Catholic symbol. It consists of the wooden cross with a corpus of Jesus’s crucified body mounted on it. The crucifix serves as a constant reminder of the ultimate price paid for humankind’s sins (death on a cross) and inspires Catholics to turn away and repent of their sins

and be grateful for the salvation obtained by Jesus's passion, death, and resurrection.

The five senses of sight, touch, smell, sound, and taste are all used in Catholic worship to draw one into a more intimate relationship with the eternal. Because the internal action of divine grace entering the human soul cannot be actually experienced by the senses, Catholics believe in using external symbols perceived by the senses while the soul receives the divine grace. A genuine Catholic use of the visual surfaces in stained glass, great masterpieces in art, and church architecture are a few examples of how the visual senses are used to connect to the divine grace. Similarly, depending on the liturgical time of the year of the Church, priests and deacons wear different colored liturgical vestments, garments for worship at the Mass. These vestments also have symbols on them such as the cross, the first and last letters of the Greek alphabet (the alpha and omega) representing Jesus, who is the beginning and the end, or the letter M for Mary, the Mother of Jesus.

The sensation of touch is another of the senses that is used in Catholic worship to draw the faithful into a deeper communion with the spiritual. During baptism, one can feel the water being poured over oneself; during anointing of the sick, one can feel the oil of the sick being applied to their forehead and palms; and during confirmation, one can feel the bishop laying his hands on the head. Other areas where touch is highlighted during Catholic prayer is when praying the rosary. The beads are used to meditate on the mysteries of Jesus and Mary. Similarly, on Ash Wednesday, Catholics feel the burnt ashes being traced on their forehead in the sign of the cross. Holy water fonts are placed at the entrance of every Church for Catholics to make the sign of the cross upon entering to remind themselves of their baptism and that they are entering a holy place.

The sense of smell is articulated by burning incense to remind the faithful of the delightful aroma of the sweetness of God's divine mercy. Similarly, the chrism oil has a distinctive scent of balsam emanating from it and is used to consecrate bishops, anoint the hands of the priest, confirm Catholics, baptize Catholics, bless bells, and consecrate altars and churches.

Listening to the word of God through scripture readings at each Mass calls the auditory senses into use. The prayers of the priest and congregation are also considered important, so the congregation is asked to pay attention and respond at the appropriate time. Catholics use plenty of music generated by both the human voice and instruments as reminders of God.

The sense of taste is employed primarily during the celebration of the Mass when Catholics consume the body and blood of Jesus under the appearance of unleavened bread and grape wine. The central mystery and dogma of the Catholic faith is that the substances of bread and wine are really changed into the substances of the body and blood, soul and divinity of Christ by the priest when he says the words of consecration at Mass. Although the appearance of bread and wine remain, Catholics believe the substance has inherently been transformed to enable them to literally eat his body and drink his blood.

The seven sacraments of the Catholic Church stem from a developmental perspective. There are three sacraments of initiation (baptism, Holy Eucharist, and confirmation) and four sacraments of community and mercy (marriage, holy orders, penance, and anointing of the sick). Baptism is usually conferred just after birth, Holy Eucharist at the age of reason (about age 7), and confirmation at the start of adolescence (around age 14). The Sacraments form the basis by which God communicates to His people.

Baptism is the sacrament of initiation into the family of God by which one is adopted. During baptism, original sin (the sin of the original parents of the human race) is washed away and the person is made new in Christ. Likewise, sanctifying grace is also conferred during baptism. Sanctifying grace includes the forgiveness of sins, birth into the new life by which man becomes an adoptive son of the Father, a member of Christ, and a temple of the Holy Spirit. Baptism also imprints on the soul an indelible spiritual mark that marks the baptized for Christian worship. For this reason, baptism cannot be repeated nor does the Church believe there is need to repeat it. Typically, water is poured over the child's head and while saying, "I baptize you in the name of the Father, the Son, and the Holy Spirit."

Following a developmental perspective, the next sacrament to be received by the faithful is the sacrament of penance. Three actions by the penitent and the absolution by the priest comprise this sacrament. The penitent's actions include sincere repentance, honest disclosure of the sins to the priest, and the valid intention to make and do works of reparation. The priest then offers a penance or performance of certain actions of satisfaction to the penitent to repair the harm caused by sin and to reestablish suitable Christian practices. Because individual sin affects all of mankind, the Catholic Church extends the need to

confess one's sins to all of mankind. The priest represents society during the sacrament as well as Christ and maintains the power to forgive all transgressions confessed. This power to forgive sins can be traced to Jesus conferring this upon his apostles in John 20:22–23 when he stated, "Receive the Holy Spirit. Whose sins you forgive are forgiven them, and whose sins you retain are retained."

Only after the sacrament of penance is experienced for the first time are the faithful able to receive the sacrament of Holy Eucharist. During this sacrament of initiation, children receive the body and blood of Christ. This sacrament is the most central and critical to Catholicism because of the belief that the consecrated bread and wine are truly and substantially the body, blood, soul, and divinity of Christ. This act of consecration is known as transubstantiation. Holy Eucharist is the only sacrament that can be received repeatedly by the faithful because it is celebrated at each Mass during the Eucharistic Prayer. Because Catholics believe that Holy Eucharist is truly the body, blood, soul, and divinity of Christ, they have strict laws permitting only those who are in communion with the Church to receive the Eucharist. Thus, by taking Holy Communion, one is expressing union with all Catholics around the world in faith, life, and worship of the community. For Christians not fully united with the Catholic faith to receive Holy Eucharist would imply a oneness which does not exist in beliefs on doctrines, laws, and obedience to leadership.

The final sacrament of initiation is known as confirmation. Throughout the believers' entire faith life, the Catholic is growing and being nurtured spiritually. At confirmation, the adolescent makes a conscience decision to enter deeper into a mature relationship with God, and the Holy Spirit is invoked to descend upon the person as at Pentecost, when the Holy Spirit descended on the Apostles and Mary in the upper room in Jerusalem, infusing them with confidence and courage to go and spread the Gospel. Confirmation builds on what was initiated at baptism and nurtured through Holy Eucharist. Catholics view confirmation as the spiritual equivalent to the natural growth process. Sometimes confirmation is referred to as the process of making soldiers of Christ and signifies a spiritual maturing into a young adult, ready to go out and defend the faith. The 12 fruits of the Holy Spirit are invoked at confirmation and include charity, joy, peace, patience, benignity, long-suffering, mildness, faith, modesty, continency, and chastity. The Holy Spirit also delivers supernatural graces to the soul. These graces are referred to as the

seven gifts and are wisdom, understanding, counsel, fortitude, knowledge, piety, and fear of the Lord.

As the young adult progresses into adulthood, the sacraments of community become more relevant and serve as the basis for social development. They include matrimony and holy orders, and both are considered to be vocations in the Catholic faith.

The sacrament of matrimony is considered a sacred covenant between the husband and wife and Christ. It also signifies the union of Christ and the Church. Because it is a sacrament, it imparts grace on the couple to love each other in the same way that Christ loved his Church, strengthens their indissoluble unity, and sanctifies them in preparation for eternal life. The three components necessary for a valid marriage include a permanent unity unto death, faithfulness in the marriage, and an openness to the possibility of children. The sacrament of matrimony is different from the legal state of marriage, which is regulated by civil authorities. In this regard, Church annulments are also different than the legal proceeding of a divorce, and annulments have no bearing on the legitimacy of the children. Annulments declare the marriage as null and void, meaning it never took place in the first place, because it was entered into invalidly, by factors affecting them either unknowingly or unintentionally, by the parties.

The sacrament of holy orders, another vocation in the Church, is the process by which deacons, priests, and bishops are formed. These sacred ministers serve the spiritual needs of the greater Church, and thus this sacrament creates the hierarchical structure associated with the Catholic faith. St. Ignatius of Antioch claimed that without the three degrees of the ordained ministry, one cannot speak of the Church. This hierarchy also confers a certain sense of dignity and respect indicative of the sacraments these ministers confer. Holy Orders are conferred by the laying on of hands followed by a solemn prayer of consecration asking God to grant the ordained the graces of the Holy Spirit required for his ministry. A permanent sacramental mark is imprinted on the soul of the priest during this sacrament. Only baptized men can receive this permanent mark in the sacrament of Holy Orders because of the natural property of the sacrament. Because God endowed things with definite natures to fulfill certain purposes, it does matter to God what things are used as means to ends. Henceforth to Catholics, matter matters. Therefore, because of the unchanging nature and element of the sacrament being conferred, neither popes, councils, nor bishops can change it. This is similar to the use of water in baptism

and bread and wine for Holy Eucharist. The three reasons noted by the Catholic Church for why women are unable to be ordained into Holy Orders include (1) the valid matter or material necessary for any of the seven sacraments cannot be changed by the Church, (2) there is a sacred tradition of 2,000 years that has never had an instance of female priests, and (3) Christ only called men to be apostles, even to the point of excluding his mother. Each degree of holy orders can only be received once, but each lower degree is necessary before moving on to the next level, meaning that the order of ordination is first as a deacon, then as a priest, and finally as a bishop. Only bishops have the ability to administer all seven of the sacraments, while priests can celebrate five (baptism, penance, Holy Eucharist [Mass], matrimony, and anointing of the sick), and deacons can celebrate two (baptism and matrimony, assuming that the matrimony does not include a Mass).

Finally the sacrament of the anointing of the sick is delivered as the final and last sacrament that a person can receive and often has been referred to as extreme unction or last anointing. In centuries past, this sacrament arrived at the close of the life span in a typically developing Catholic, void of a premature death. Anointing of the sick is the other sacrament of mercy along with penance. The primary purpose of anointing of the sick is to offer prayers for potential recovery from illness, but also to strengthen the soul of the sick person. An additional benefit of the sacrament is that it absolves all sins the person is sorry for but may not have had a chance to confess in the sacrament of penance. Oil of the sick is used as a sincere sign of spiritual assistance during this sacrament and administers to the senses of touch, sense, and sight. Like Holy Eucharist, Catholics can receive this sacrament more than once. Redemptive suffering, or the uniting of one's suffering to that of Christ's, is believed to provide a person with meaning and purpose and is highly emphasized through the sacrament of the anointing of the sick.

To continue to remain in good communion with the Church, Catholics must be free of mortal (grave sin cutting one off from the grace of God) sin, attend Mass on all Sundays and holy days of obligation, receive the Holy Eucharist during the Easter season, confess sins at least once a year, fast and abstain from meat on appointed days, observe the marriage laws of the Church, and contribute to the support of the Church.

—Richard W. Puddy and Michael C. Roberts

## CENTERS FOR DISEASE CONTROL

---

The Centers for Disease Control and Prevention (CDC) is an agency of the Department of Health and Human Services responsible for developing and implementing disease prevention and control, environmental health, and health promotion and education aimed at enhancing the health of people in the United States. The CDC started in 1946, and since then, it has become the chief federal agency for protecting the health and safety of people, offering reliable information to improve decisions about health, and promoting health by forming sound partnerships. The CDC's mission is "to promote health and quality of life by preventing and controlling disease, injury, and disability." Part of this mission includes protecting people from some of the most prevalent, deadly, and baffling threats to personal health. CDC employees often travel to investigate and try to control infectious diseases that threaten individuals, communities, and nations.

The agency has formed national and international partnerships in order to develop prevention strategies, encourage healthy behaviors, identify and explore health problems, conduct research, foster safe environments, and impart leadership and training. The CDC also assists state and local departments with tasks such as ameliorating environmental hazards, identifying illnesses, educating the public on sexually transmitted diseases, stressing the importance of immunizations for children, and other community undertakings. In addition, the agency values relations with private corporations and media outlets that team up to promote public safety and health.

One goal of the CDC is to continually provide significant, accessible, up-to-date information that is necessary public knowledge. As listed on the official CDC Web site, the agency has set goals to conquer future challenges as well. Some of the current and future challenges for the CDC include putting science into action, preventing violence and unintentional injury, meeting the health and safety needs of a changing workforce, employing new technologies to provide credible health information, protecting individuals against up-and-coming infectious diseases, eliminating racial and ethnic disparities, fostering safe and healthy environments, and cooperating with partners to advance global health.

The CDC includes 12 centers, institutes, and offices that specialize in certain aspects of health. The Office of the Director (CDC/OD) manages and oversees the activities of the CDC. The National Center for Infectious Diseases (NCID) prevents illness, disability, and death that result from national and global infectious diseases. The CDC also has a national center that specifically targets preventing and controlling human immunodeficiency virus, sexually transmitted diseases, and tuberculosis—the National Center for HIV, STD, and TB Prevention (NCHSTP). The National Center on Birth Defects and Developmental Disabilities (NCBDDD) leads the country in preventing birth defects and developmental disabilities and also focuses on enhancing the wellness of people with disabilities. The National Immunization Program (NIP) prevents disease, disability, and death caused by vaccine-preventable diseases. The National Center for Chronic Disease Prevention and Health Promotion (NCCDPHP) prevents untimely death and disability from chronic diseases and encourages healthful personal behaviors. The National Center for Environmental Health (NCEH) promotes prevention of disease

and death that occur as consequences of interactions between people and environments. The Epidemiology Program Office (EPO) works on advancing the public health system through coordination, support, and training. The Public Health Practice Program Office (PHHPO) fortifies community practice of public health. The National Center for Health Statistics (NCHS) offers statistical information that helps determine what actions to take and policies to put in place to improve the health of Americans. The National Center for Injury Prevention and Control (NCIP) prevents death and disability from both unintentional and violent injuries. The National Institute for Occupational Safety and Health (NIOSH) fosters safety and health for people in the workplace.

The CDC's official Web site provides general information about the agency, national and state data and statistics, and CDC publications.

## CHARTER SCHOOLS

---

Charter schools represent a relatively new school reform strategy in the United States for children in kindergarten through 12th grade (K–12). Starting with the passage of the first charter school law by the legislature of Minnesota in 1991, the number of states with charter school legislation has grown to 41 states and the District of Columbia. At the beginning of the 2004 school year, there were approximately 3,000 charter schools with an estimated enrollment of more than 650,000 K–12 children.

What are charter schools and why were they created? A charter school is a publicly funded school operating under a charter or contract granted by a state or a local education agency such as a school board, public university, or state board of education. Charters may be entirely new or conversions of existing public schools. The charter determines the operating provisions for the school, including funding, performance objectives, mission, and student population. Because charters operate as public schools and are users of public funds, they must be nonsectarian. They may recruit students from a particular geographic area or

for a specific academic theme, although they must take all applicants. If demand exceeds available space, students are admitted by lottery. As schools, charters tend to have smaller enrollments than traditional public schools and are found in a variety of grade-level configurations from kindergarten through high school.

When considering charter schools, it is important to identify the state in which the charter operates because charter school laws differ significantly from state to state. Some states, such as Arizona and California, have more than 500 charter schools. In these instances, the state laws are very favorable and encouraging to charters, while other states have more restrictive laws. Rhode Island, Tennessee, and Virginia, for example, each have fewer than 10 schools. As of January 2005, 10 states were without charter school legislation.

Contracts to operate charter schools are granted for anywhere from 3 to 10 years depending on the state law. As public schools, charters must address state curricular frameworks and meet state testing requirements. They also are responsible for the mandates imposed by the federal legislation, P.L. 107–110, known as the No Child Left Behind Act enacted by Congress in 2000. Charters receive support from many political groups and national organizations. Both former President Clinton and President George W. Bush have actively supported the concept and have approved federal expenditures to provide technical assistance to these schools.

In general, charter school laws embody several important school reform theories. The first is that parents should be given greater opportunity and voice to choose among a variety of options for the education of their children. Parents, it is believed, will know what is best for their children. Second, by granting charter schools greater autonomy and freedom from existing bureaucratic requirements, charters will be liberated to become more creative and innovative in their ability to deliver effective educational services. A third view is that charters will introduce a desired market-like environment into public education, causing traditional and charter schools to compete for students. Through this competition, it is argued, poorly performing schools will lose customers and be driven out of business. These theories embody what is often called a basic bargain, in which charters accept increased autonomy in exchange for greater accountability from the chartering agency. Should a charter fail to meet the conditions of its charter, it will be closed.

Charter schools are viewed contentiously in some quarters. Several organizations and individuals worry

that charters are draining public dollars from public schools. When a child leaves a traditional public school to attend a charter school, money that would have gone to the traditional school to support the child is transferred to the charter school. In another area, opponents and supporters argue about the academic success of these schools. Several recent studies report conflicting answers on this question. In the end, far more research and investigation of charter schools will be necessary to determine whether these schools represent a viable reform strategy for the improvement of K–12 education.

## CHILD ABUSE

---

Child abuse is a global problem. The World Health Organization (WHO) estimates that 40 million children between birth and 14 years of age are abused or neglected annually around the world. Thus, child abuse is found across all societies and cultures, almost always surrounded by secrecy and denial. The exact number of children who are abused is not known due to underrecognition and underreporting. Children are often too young to understand or to communicate what is happening. Moreover, because abuse is often perpetrated by parents or caregivers, even when children understand that they are being abused, they often feel loyalty, dependency, and emotional ties to the perpetrator, which keep them from reporting the abuse. In the United States alone, an estimated 879,000 children suffered from abuse and neglect in 2000. In 2001, about 2,475 children were abused daily, and more than 50,000 reports of possible child abuse and neglect were reported to child protective services.

### HISTORICAL AND CULTURAL PERSPECTIVE

Cultural differences in attitudes toward child rights, child labor, and corporal punishment (physical

discipline of a child such as spanking, beating, and whipping) contribute to wide cultural differences about what is considered abusive toward children. Wealthy industrialized, technology-based nations hold different perspectives. By such nations' standards, the living conditions, quality, and/or lack of water, food, and shelter for children in developing nations is commensurate with child maltreatment. In some developing nations, cultural rituals involve mutilation of children's genitals (often females only), while male children are sent off to war. The conceptualization of what is child abuse and maltreatment is subject to wide cultural variation.

In the United States, belief in a child's right to humane treatment and adequate care evolved from an initial perspective that children were possessions to be treated as their parents or caregivers saw fit. For example, the Massachusetts Stubborn Child Act of 1654 permitted parents to put stubborn children to death for noncompliance. Throughout the colonial United States, children were virtually enslaved as apprentices or otherwise engaged in hard labor for barely enough money to pay for their own food. In 1870, the Census Bureau reported that one of every eight children was employed. By 1900, the figure had dropped to one in six. Abandoned, runaway, or maltreated children were also sent "out West" as laborers. Child abuse and maltreatment gained focus in 1874 with the case of Mary Ellen Wilson, a child of somewhere between 8 and 10 years of age, who was severely abused by her stepmother. Concerned citizens turned to the Society for the Prevention of Cruelty to Animals because at that time there were no formal organizations to help abused children. This incident led to the birth of child protection groups, and represented a growing shift in the public's perception on the treatment of children. As a result of the Mary Ellen case, the Society for the Prevention of Cruelty to Children was established in New York in 1875, pioneering the development of other advocacy and protective organizations for children across the United States.

## WHAT IS CHILD ABUSE?

Federal legislation provides the basis for the definition of child abuse in the United States, although each state has its own statutes as well. In 2003, the Federal Child Abuse Prevention and Treatment Act (CAPTA) was amended by the Keeping Children and Families Safe Act to define child abuse as "any recent act or failure

to act on the part of a parent or caretaker which results in death, serious physical or emotional harm, sexual abuse or exploitation." A "child" is typically defined as any person under the age of 18 years, although for some state definitions of sexual abuse, the definition of the age of a child is specified otherwise.

Child abuse includes acts of commission or acting upon a child. Mental health professionals typically question any actions by caregivers that result in marks, swelling, bruises, burns, or breaks to the child's skin; obviously even more severe injuries such as bone fractures or internal injuries are considered abusive. Falling within the acts of commission are sexual abuse and exploitation.

Child abuse also includes acts of omission or neglect that involve failure or lack of action by the parent or other caregiver to protect or care for the child. Such acts of omission include, but are not limited to, failure to provide adequately for the child's basic physiological needs such as food, water, clothing, and shelter; failure to provide adequate supervision from harm or failure to tend to a child's medical needs. There are exceptions to what is considered an abusive act of omission. U.S. state statutes often exempt parents who do not obtain medical intervention for their children due to religious beliefs. Cultural values/practices and poverty also cause wide differences in the standards of care set by parents and caregivers across cultures.

## TYPES OF CHILD ABUSE AND NEGLECT

Child maltreatment is a general term used to encompass all types of child abuse and neglect, including physical abuse, neglect, emotional abuse, sexual abuse, and exploitation. Neglect is the most common type of maltreatment, making up about 62.8% of known victims in 2000, followed by 19.3% being physical abuse cases, 10.1% sexual abuse, and 7.7% emotional abuse and neglect.

### Physical Abuse

Physical abuse involves causing bodily injury to a child, including but not limited to hitting, punching, kicking, burning, beating, or shaking. Such actions are considered physically abusive whether or not the parent or caregiver intended to inflict injury. Physical abuse can be deliberate or can be the result of excessive corporal punishment.

Shaken baby syndrome, known medically also as whiplash-shaken infant syndrome, involves injury caused to an infant by shaking a baby by the arms, legs, shoulders, or chest. As a result of the shaking, the infant's head is forced forward and backward, causing the brain to collide with the inside skull. Severe brain injury and death may result. Even mild shaking of an infant can lead to injury or death. The estimated number of cases of shaken baby syndrome is between 600 and 1,400 annually in the United States, although this number may be too low due to underdiagnosis or underreporting of incidents. Babies cannot talk to explain what happened, and parents/caregivers do not readily admit to such conduct.

Munchausen's syndrome by proxy, also called factitious disorder by proxy, is a psychological disorder in which a parent, almost always a mother, lies about their child having physical symptoms or actually deliberately induces physical symptoms, for example, through poisoning or suffocation. The parent does so in order assume the role of concerned parent and to receive attention from the medical community. Such parents are deliberately fabricating or inducing their child's illness for their own psychological/emotional reasons, rather than for financial or material gain (such as disability income.) An estimated 400 to 500 cases are diagnosed annually, although certainly others go undetected.

## Child Neglect

Child neglect can be physical, educational, or emotional. It involves acts of omission. In addition to physical neglect such as the failure to provide for the child's basic needs (such as food and shelter), educational neglect involves allowing a child not to attend school or willfully disregarding a child's special educational needs. Emotional neglect can be the most difficult form of neglect to detect. It involves failure to provide basic levels of nurturing to the child such as verbal or physical affection. Emotional neglect can also involve violence toward a parent in the presence of the child or condoning the child's use of alcohol and drugs.

## Emotional Abuse

Emotional abuse moves from acts of omission to also include acts of commission that result in emotional injury or trauma to the child and/or serious behavioral or mental disorders. Emotional abuse may

involve use of extreme punishments beyond what a reasonable adult would consider appropriate such as locking a child in a dark closet or less florid acts such as repeated scolding and verbally degrading the child, habitual scapegoating (blaming the child for causing any and all problems or stressors in a family), or rejecting the child. This form of neglect is the most difficult to detect because the harm is not physical.

## Sexual Abuse and Exploitation

Sexual abuse and exploitation involve any inappropriate sexual behavior toward the child such as touching a child's genitals, sexual or anal intercourse, incest, rape, oral sex acts performed on the child, or forcing the child to perform them. It also includes forcing the child to watch sexual acts performed by others, exposing a child to sexual material or behaviors, or exposing or otherwise exhibiting one's genitals to the child. Sexual exploitation of children for financial gain involves child prostitution and production of child pornography. Whether the child is physically raped or otherwise touched against his or her will, or, more commonly, when the child is bribed, persuaded, tricked, coerced, or seduced, the activity is considered sexual abuse.

When the sexual abuse is occurring inside the family by an immediate family member such as the child's parent, it is referred to as incest. Unlike physical abuse and neglect, sexual abuse is much more premeditated and planned by the perpetrator. When a child is victimized by either a person in or outside of the family, there are steps that these perpetrators take in order to gain and maintain access to a child. This process is frequently referred to as grooming a child for abuse. Perpetrators of sexual abuse will often try to create a special trust or bond with the child. They strive to convince the child that they are a special or unique friend, and may do so by confiding in the victim or telling the victim of their loneliness and that the child can help. The perpetrator will also give the child gifts or special privileges. Next the pedophile attempts to alienate the child. Alienation is easier to accomplish when the sexual abuse occurs within a family. The child is alienated from the mother and siblings because of special privileges or status afforded by the perpetrator. As the abuser dominates the life of the victim, access to friends, support, and sources of help are minimized, creating dependency on the perpetrator. Next, secrecy is emphasized. The child is either directly

instructed not to tell anyone about the abuse, or the perpetrator is more subtle and convincing about the need for secrecy. The process of committing the actual sexual abuse typically involves progressive boundary violations. For example, first the perpetrator will simply be where they do not belong such as in the child's bed or in the bathroom with the child. Such boundary violations progress to inappropriate touching of the child and so on. The sexual abuse expands from inappropriate looks, conversation, and touching to more and more intense abuse. Specifically, a child abuse accommodation syndrome (CAAS) has been identified among girls who have been repeatedly sexually abused by a male perpetrator over time. This syndrome involves stages of secrecy; helplessness; entrapment and accommodation; delayed, conflicted, and unconvincing disclosure; and retraction. The common experience of the victims recognized by the CAAS include the ideas that sexual abuse is almost always shrouded in secrecy and feelings of helplessness in the victim; fear and ambivalent feelings (especially toward a perpetrator who is a family member) cause victims to disclose abuse in delayed and unconvincing ways and often to recant their disclosure later; and it is common for sexually abused children to show little emotion about the abuse and to delay for long periods of time before disclosing the abuse.

## VICTIMS

Male and female children are about equally likely to experience neglect and physical abuse. Girls are almost five times more likely than boys to be sexually abused. Boys are more likely to be sexually abused by male nonfamily members such as teachers or coaches, whereas girls are more likely to be sexually abused by male family members. Thus, girls and boys have different patterns of vulnerability that should be taken into account for prevention purposes.

No group of children is immune from child abuse, and children of all ages experience abuse. Younger children from birth to 3 years old have the highest rates of victimization; they comprise the largest number of neglect cases (which is the most common form of abuse.) It is theorized that abuse rates drop with older children who are better able to understand what is happening and to disclose the abuse to others. One exception to the decline in abuse rates with age occurs with sexual abuse. The median age for female

sexual abuse victims is 11 years and for males it is 8 years. Half of all victims of abuse or neglect are white, 24.7% are African American, about 14.2% are Hispanic. American Indian/Alaskan Natives make up 1.6% of victims, and Asian/Pacific Islanders account for 1.4% of victims.

## Signs of Abuse

A child may show signs of being abused, including nervousness around adults; avoidance or fear of going home; low self-esteem; aggressive or sexual themes in their art, play, or interactions with others; developmentally inappropriate knowledge of or interest in sex; frequent physical injuries; and poor hygiene and grooming. Having many psychosomatic complaints (such as headaches, stomachaches) and difficulty sleeping, especially nightmares, is also common but in no way unique to abuse.

For physical abuse, injuries that are in the shape of a specific object (such as a belt buckle or a handprint) are suspect, as is a discrepancy between the parent's and the child's accounts of how the injury occurred. For sexual abuse specifically, genital or rectal pain, redness, itching, swelling, and sexually transmitted diseases are all strong indicators of possible sexual abuse. Regressive behavior and the occurrence of accidents after being solidly potty trained frequently signals the onset of some stressor strongly impacting a child.

## Fatalities

The most tragic result of child maltreatment is the death of a child. Annually in the United States, an estimated 1,300 child deaths result from abuse and/or neglect. Fatalities are composed primarily of very young children, with more than 84% being less than 6 years old. The most common age of death is infancy (birth to younger than 1 year), which makes up more than 40% of the fatalities. Fifty-six percent of the deaths are male children, with the remaining 44% female. Neglect and/or the combination of both neglect and physical abuse cause almost all of the fatalities. For 82.8% of the total fatalities occurring annually, the abuse/neglect is perpetrated by one or both parents. Only a small percentage occurs when the child is in an out-of-home placement such as a foster home, group home, or residential treatment setting, although it is not rare for children to be abused and maltreated in such settings.

## PERPETRATORS

### Physical Abuse and Neglect

Maltreatment is linked with poverty and economic disadvantage. Conditions associated with lower socioeconomic status such as limited child care options, crowded and substandard housing, and limited access to adequate health care provide the backdrop for maltreatment. Parents account for more than 78% of all abuse or neglect cases, which is not surprising in that they are the primary caretakers of children. Parents who are physically abusive or neglectful often come from homes in which they also were abused and neglected. This is part of a multigenerational cycle of abuse. Therefore, these parents lack successful, positive parenting role models. On average, most abusive parents are young—in their 20s—near or below poverty level, lack high school education, and have been victims of childhood abuse themselves. These parents lack economic resources and social support and have inadequate coping skills. They are isolated, perhaps living away from or estranged from family and friends. However, it is important to remember that no profile fits all abusers, and abuse permeates across gender, all races/ethnicities, and all social classes. Abusive and neglectful parents generally interact less with their children. They often appear uninvolved or uninterested in the care and well-being of their children. They may also appear overly critical of their children and very rigid about discipline. A major risk factor for violence in any home is active substance abuse by a parent. Forty percent of known cases of child abuse and neglect involve substance abuse.

Physical abuse can be triggered by stresses related or unrelated to the child. Stressors related to the child include excessive crying, such as with a young child or an infant with colic, feeding or potty training challenges, unrealistic expectations of a child, and holding highly exaggerated perceptions of the child's disobedience. Stresses unrelated to the child include economic, housing, or personal problems, loss of a job or a loved one, physical or mental illness of the parent or caregiver, and legal difficulties. In addition to active substance abuse in the home, another major risk factor for child abuse is domestic violence. Children who live in homes where a male caregiver is physically abusive to another adult in the home are at severe risk for being victims of physical abuse as well.

### Sexual Abuse

Perpetrators of sexual abuse are also referred to as child molesters or pedophiles. Sexual abuse is perpetrated more than 90% of the time by males. The vast majority of cases are committed by someone who is known to the child, and as much as 80% of these cases involve a family member such as a father, stepfather, or uncle. Moreover, the child who is sexually abused by a family member is likely to experience repeated and more severe levels of abuse than those children abused by nonfamily perpetrators. As a result of the repetitive and severe nature of the abuse as well as the emotional betrayal of the adult family member who perpetrates the abuse, these cases also tend to result in more serious psychological damage and consequences for the child.

Perpetrators of sexual abuse often have deviant sexual arousal patterns that emerged in adolescence. Many of them have specific gender and/or age preferences for victims. Other than the large majority of sexual abusers being male, no other characteristics such as personality traits, occupation, or age can be used to predict who is an abuser.

## CONSEQUENCES OF ABUSE

### Short-Term Consequences

Child abuse and neglect do not affect all children in the same way. The impact of the abuse on the child depends on the nature, severity, and length of time over which the abuse occurred, as well as the child's temperament, personality, and level of functioning prior to the onset of the abuse. The level of emotional support and assistance received by the victim is also critical. Whether the child has just one positive, consistent, and nurturing relationship with a person in his or her life has been shown to significantly mediate or protect the child from the potential effects of the abuse.

Abuse can seriously interfere with a child's normal development, resulting in emotional and behavioral symptoms in the child. Chronic, repeated abuse, especially by a parent, may interfere with a child's ability to formulate an attachment or bond with a parent. Later, these children have difficulty establishing healthy, reciprocal emotional connections with others.

Children who are abused or neglected also tend to have difficulty coping with their own emotions. They are likely to have inhibited emotional expression and

may engage in unusual, maladaptive, and self-injurious behaviors, such as cutting themselves or abusing substances. Children who are abused are at severe risk for developing a wide array of psychological disorders. Girls who have been abused tend to develop more shame, self-blame, and internalizing disorders such as anxiety and mood disorders. Boys tend to show more problems associated with acting-out behavior such as physical and verbal aggression and defiance and the development of conduct disorders. These girls and boys lack self-esteem and positive beliefs about themselves and their world. Frequently they feel like they are unworthy of love and blame themselves for the abuse.

In general, maltreated children evidence one of two patterns in their peer relationships. The first pattern is one of hostility. Abused children, especially in the case of physical abuse, tend to interpret ambiguous or even friendly behaviors as hostile or threatening. They are more physically and verbally aggressive toward others and tend to have limited social networks, with aggressive and attention-seeking behaviors. The second pattern, associated with neglect, involves withdrawal and avoidance of peers. Such children are withdrawn, passive, and therefore as socially isolated as the children who display the aggressive pattern.

Abuse interferes with a child accomplishing what is developmentally expected of them, including impairing academic achievement. It is common for abused children to have poor grades. A dramatic drop in grades can be a strong indicator of the onset of some significant stressor in a child's life.

### Long-Term Consequences

Not all abused or neglected children develop psychopathology that can follow them throughout adulthood. Yet, all are at increased risk for doing so. The negative outcomes stemming from abuse can be avoided if children receive social support from non-offending family members in addition to other intervention. However, without such support and the opportunity to develop healthy coping and interpersonal skills as well as a renewed ability to trust others who are worthy, these children are at tremendous risk for developing mood disorders (such as clinical depression and even suicidal behavior), posttraumatic stress disorders and other anxiety disorders, dissociative disorders, sexual adjustment problems in adulthood, and criminal and antisocial behavior.

### TREATMENT

Parents and caregivers most in need of treatment because they are perpetrating child abuse are actually the least likely to seek it. Child abusers may feel shame and guilt and fear losing their children. Abusers who are non-family members fear criminal repercussions. Most often, treatment only comes as the result of legal mandate once the abuse is discovered.

Since the 1960s in the United States, a protective, social work approach to child maltreatment has been the prevailing standard. Currently all 50 states and the District of Columbia have mandatory reporting laws that require professionals and other individuals who work or interact with children to report suspected abuse to child protective service (CPS) agencies. False and malicious reporting occurs and is highly problematic.

Many CPS agencies have child protection teams (CPTs). These are multidisciplinary teams that are called into action immediately when a reasonable suspicion of child abuse has come to light. The CPT includes pediatricians who are trained in the medical examination of a possible victim and mental health clinicians who are trained in how to conduct forensic interviews to address the possibility of abuse. Clinical social workers and clinical psychologists on the team coordinate evaluation of parents, treatment planning for the perpetrators and victims, and referrals for all necessary services.

The prevailing philosophical emphasis related to the mandatory reporting legislation and child protective services for within-family abusers is family preservation (maintaining a child in the home rather than removal whenever possible), which is considered to be in the best interests of most abused children (except in extreme, horrific, or treatment-resistant cases) as well as cost effective compared with out-of-home placement of children in foster care, group homes, or other residential settings. More evaluation and research on the outcome of these programs is needed in order to determine their effectiveness in rehabilitation of the abuser and treatment effectiveness with the abused children.

In the United States, family preservation programs are modeled after the Washington State Homebuilders Program. These programs provide individualized treatment plans for each family. Treating abusive or neglectful parents frequently involves counseling multiproblem, complicated families. Counseling interventions are intensive and frequently referred to as "wraparound" services. Treatment for the abusers commonly involves

individual and group counseling, including strong parent education and counseling in relaxation training, stress and anger management skills, cognitive restructuring to assist the parent in interpreting and responding to the child's behavior more appropriately, problem-solving skills, and training in basic child-rearing skills. Parents are provided with exposure to positive parenting models and skills and may practice them through role playing and coaching from a clinician. Abusive parents may also need intensive substance abuse/dependency intervention, assistance with job training, and other social and financial assistance. Neglectful parents also frequently require training in how to manage everyday demands of living such as money management and housekeeping. Neglectful parents need to break a cycle of avoidance of interaction with their children and of daily responsibilities, replacing this with positive parent-child interactions and active care for their children and daily life responsibilities.

Treatment for the victims of abuse is also important. For children who have been physically abused, play therapy, individual therapy, group therapy with other children, and on-site therapeutic interventions at the child's school, day care, and home focus on rebuilding the child's battered self-esteem and self-concept. Related goals include restoring the child's sense of self-efficacy (sense of power or ability to have some control over themselves and their environment) and improving the child's social behavior, cognitive development, and academic achievement.

For sexually abused children, treatment is aimed at helping the child realize that what they experienced was abuse, that it was wrong, and that it was not their fault. These children need to slowly, in a paced manner and safe environment, share and release their memories and feelings about the trauma in order to prevent or extinguish posttraumatic-stress-related symptoms and alleviate guilt, shame, and self-blame. As is the case with physical abuse, rebuilding the child's self-esteem is an important therapeutic goal, as is helping the child to regain a sense of safety. Educating the child about sexual abuse and ways to prevent it from occurring ("I know I can tell my mommy if anyone tries to touch my private parts, or makes me feel uncomfortable") is important.

In relation to the treatment of sexual abusers, unfortunately the outcomes of treatment programs are poor, with very high recidivism rates. Thus, the criminal court systems tend to focus on incapacitation (removing access to victims) and retribution. Research into

treatment options is expanding, as is the availability of prison treatment programs for pedophiles, despite limited treatment success at this time.

## PREVENTION

In the area of prevention of child abuse, prevention can occur at the cultural level. Cultural violence, as evidenced by strong violence in the media, has been linked as a promoter of violence within families. On a cultural level as well, the link between poverty and child abuse has been established. Thus, efforts to reduce cultural violence and poverty are theorized to have a direct impact on the welfare of children.

Breaking the multigenerational cycle of violence is a direct way to prevent future child abuse. Because many abusers were abused themselves, these individuals need specific intervention before or while being parents in order to prevent the cycle from perpetuating. Because substance abuse is also so strongly linked with child abuse, substance abuse prevention and intervention with parents is another way to prevent child abuse.

Prevention and education services aimed directly at future parents have a strong impact as well. Prenatal medical care protects the health of the new mother and allows her to be in a better state to care for a baby. Prenatal programs, family-centered birthing and coaching classes, infant care classes, and parenting classes do everything possible to educate and prepare parents for the demands of caring for a baby, with the goal also of facilitating emotional bonding between the infant and the family. Careful attention by the medical profession and the members of a new mother's support system is recommended, so that postpartum psychological symptoms and disorders can be treated, preventing neglect and maltreatment of the infant, and alleviating the mother's intense suffering caused by these often unrecognized and untreated disorders.

Support groups, parenting education, and community programs can also assist in relieving parental stress. Food banks, shelters, thrift stores, and emergency assistance programs can provide some help to parents. Some communities even offer respite child care services where parents who are on the verge of abusive actions can leave their children temporarily. Schools provide safety education to children (programs on topics such as stranger danger) and teach children what to do if they are being abused. The National Child Abuse Hotline at 1-800-422-4453 is available for all members of the community.

## SUMMARY

Despite increased preventative and intervention services and strong public awareness and concern about child abuse, this problem is far from going away. Only through continued education of parents and changes at all levels of society can the problem of child abuse be prevented and eliminated.

positive socialization, enriches development, and improves social/familial/labor concerns. Child care/day care can simply be described as any service involving care of others' children, but child care is also complex in that it includes a variety of settings, activities, regulations, costs, quality, and types of providers. The three primary types of child care/day care are center-based care, in-home care, and family care.

Center-based child care outside the home is often referred to as day nursery, day care or child care center, nursery school, or *crèches* (French for “cribs”). These terms are often used interchangeably to identify various types of day care for children and for preschool educational programs. In most communities, religious institutions and civic groups also operate child care/day care and preschool facilities. Parents choose center-based child care because they believe that larger groups, multiple caregivers, and government inspections make programs safer for their children and make the arrangement more dependable. Parents respect the reputation of the child care program or the institution sponsoring the program. Many parents believe that more staff, space, equipment, toys, and organized activities provide a better learning environment for their children.

In-home child care is another type of child care, in which an outside caregiver comes into the family home and cares for the child. These caregivers are frequently referred to as nannies, babysitters, or *au pairs* (French: a young foreigner who lives with a family and does child care and light housework). Parents often choose and place trust in a provider based on recommendations from friends or professional services. With an in-home provider, parents believe that their children will be safer and more secure in their own home and that they will have more control over the kind of care their children will receive. Some parents find in-home care is a more convenient arrangement for the family and may provide more flexibility, as they can have all their children in the same location and may find that in-home care is not significantly more expensive than other forms of care.

Family child care is generally based in another person's home and may include children from several different families. Because they want to keep their children in a home-like environment, parents who use this kind of care consider themselves lucky to have a relative, friend, or neighbor to care for their children. Parents believe that these caregivers will provide warmer, more loving care for the child than an

---

## CHILD CARE/DAY CARE

---

Quality child care/day care for families is an important aspect of daily life. At its best, child care provides

institutional-type center and that the child will be more secure. Parents often prefer to relate to a single caregiver and believe that children are healthier, happier, and more secure in smaller groups. Many families choose family child care because they find it closer to home, less expensive, or more flexible. Many parents believe that relatives, friends, and neighbors will be more likely to share their values and thus feel more comfortable entrusting their children to them. Sometimes parents use this type of care because their schedules, budgets, or transportation problems limit other child care options.

While each of these types of child care/day care has many benefits and some detriments, the most important factor in choosing any child care is that parents feel comfortable leaving their children in a safe and quality care environment.

## HISTORY

Child care as a cultural responsibility is as ancient as society itself. Historically, families enlisted the help of relatives or community members to care for small children much as they do today. Tribal, nomadic, and aboriginal cultures consider child care a primary and important function, where children are cared for during their youngest years by the entire group.

Modern child care services to young children and their families, while still paramount in importance, differ from the past in that they are more often provided outside the insular community.

Both the importance and the availability of outside day care increased in the late 19th and early 20th centuries due to the rising proportion of women working outside the home. Institutional child care appeared in France about 1840, and the Société des Crèches was acknowledged by the French government in 1869. Day care centers were established by the government in most European cities and industrial centers during the second half of the 19th century. Great Britain, for example, established the first centers in 1860, and in the United States, these institutions appeared by the 1920s.

By the early 1990s, women made up a significant portion of the workforce worldwide. In East Asia more than 60% of women were working, and in Western Europe and the United States, nearly 50% of women were employed. Without suitable child care arrangements, many of these women would be forced to stay home and forego working.

## SOCIOPOLITICAL STRATEGIES

Successful child rearing is crucial to a healthy society. If children thrive in the earliest years, there is evidence that they become more valuable contributors to society. The pressure of providing quality child care is a universal challenge not only to the family, but to governments as well. To ameliorate these challenges, many developed countries provide infant care and preschool programs as policy. However, there is a good deal of variation across countries in the types of policies that governments use to support child care to families.

In Europe, child care is often provided by the state or by facilities licensed and subsidized by the state. For example, France and Italy include early child care in the regular public school system, Hungary has more than 3,000 state-operated day care facilities, and in Sweden, almost 60% of preschool children are enrolled in state-run child care institutions.

Countries such as Italy and Spain have low female employment rates and a low availability of child care. Countries such as Sweden, Denmark, and Finland have high female employment rates and provide wide access to child care facilities. In countries such as Germany and Austria, where child care services are moderately available, women are more likely to work part-time.

The United States is one of the few industrialized nations that does not have a comprehensive government-funded child care policy. In recent years, the federal government has passed legislation designed to help parents ease the burden of child care costs. This legislation includes allowing workers to set aside part of their income, tax free, to pay for child care; issuance of a child and dependent care tax credit; and state funding that can be used for day care facilities.

## QUALITY, LICENSING, AND REGULATIONS

High-quality child care is the ideal for most societies. How a system achieves that ideal is through licensing and regulations. The goal of licensing is to ensure the safety and developmental well-being of children while in out-of-home care.

In the United States, many individual states follow the licensing curriculum developed by the National Association for Regulatory Administration. The curriculum was designed to ensure that all professionals and paraprofessionals serving infants, toddlers, and their families are adequately trained and provides a baseline of quality below which it is illegal to operate.

In most states, and in Europe, licensed child care/day care facilities require up-to-date immunizations for entrance. These immunizations help to prevent outbreaks of illness since children in child care/day care typically have more severe infectious illnesses than children cared for in the home. Reviewing and monitoring these facilities are essential to ensure compliance.

Current child care regulations are designed to protect children from harm and are key predictors of positive outcomes of both the children and the centers. Many states do not regulate care provided by relatives, friends, and neighbors. A few states require these informal providers to be screened through a criminal history check and/or child abuse and neglect clearance. Several states require minimal training in health and safety. Despite these efforts, unlicensed day care centers continue to operate.

There remains a need for regulations and licensing of child care services that meet the individual needs of children and of their parents. These regulations must be enforced with the goal of ever better outcomes for children and families.

## RESEARCH

A great deal of research has been focused on the effects of care on children. There are numerous studies addressing social and emotional development of children in child care/day care settings. In general, it has been found that having young children in quality care environments is beneficial. Both language proficiency and cognitive function have been found to improve among children who attend day care centers.

Low child-to-staff ratios and staff education have been found to be major factors in positive outcomes in day care centers. Children in day care settings who had better educated teachers recorded higher measures of school readiness and language skills. In addition, Susanna Loeb, PhD, of Stanford University reports that children in day care centers scored better on a variety of tests compared with children who went to family child care homes or who were left with friends or relatives while their mothers worked.

## FUTURE TRENDS

Child care is with us today and will continue to be with us throughout time. Most countries and world organizations are placing child care issues near the tops of their priority lists. The continued rise in

population and, subsequently, women in the labor force are compelling countries to recognize the value of quality early child care. There is pressure on governments for new regulations, facility expansion, quality improvement, and affordable, universal access to child care for all families. The impetus for a better solution to child care needs will continue in all countries, despite variations in approach.

## CHILD CUSTODY

---

The term *child custody* employed here refers to child consequences and parental responsibilities following

separation and divorce. Child custody may also refer to legal terminology related to guardianship and legal authority in the care of a minor child following adoption, loss of parental rights due to abuse or neglect, or other situations. In each case, the concept of “in the best interest of the child” is often applied.

Child custody matters are a central concern among human development experts in the United States due to the high number of divorces. A great deal of research devoted to how custodial and guardianship matters impact child development and outcome have resulted.

Child custody is often determined after legal proceedings that may include a trial, civil mediation, or a hearing involving a state child welfare agency. Mental health experts assist in providing important information for the judge or hearing officer. Clinical social workers often complete a home study or investigation of the future possible home environment, as well as observations and opinions about the fitness and capability of the potential parents/guardians. Psychologists are also involved.

The American Psychological Association has specified the role of psychologists in child custody decisions. These guidelines direct psychologists to take the child’s interests and needs into account as the primary determinant in recommendations to the legal system.

The typical child custody evaluation assesses the capacity of an adult desiring the responsibilities related to caring for a minor child. This is done by interviews, background checks, psychological tests, and structured observations of the adult and child in interaction. Evaluations may also include direct observation of the home environment.

Psychologists are then asked to make recommendations to the court regarding the best interest of the child. Psychologists should take into consideration key variables, including the child’s developmental level, the level of functioning of the child, and a range of variables related to parental fitness in the adults. In addition, the fit or match between the adult(s) and child is also to be taken into account. The range of parental variables will include an assessment of parenting and discipline styles, consistency of behavior, and psychological qualities such as maturity level, freedom from psychopathology, and experience with children.

The psychologist provides expert testimony and opinion. Psychologists and other mental health specialists do not directly determine the final placement of a child—this is the responsibility of the judge or hearing officer.

Child custody issues after divorce are often related to new conflicts or disagreements. If old unresolved issues interfere, counseling is recommended. In addition, these three activities often help minimize conflict:

1. *Trying new ideas out on an experimental basis.*

There arise legitimate disagreements over some issue for which there is no “right” way or solution. Families should try each proposed solution on an experimental basis in order to see what is best for their child. In the example of a dispute about overnight visits during the school week, one way to resolve the matter is to try both solutions for 1 month each and monitor the child’s response in as fair a way as possible.

2. *Asking a trusted third party to help resolve your dispute.* When both parents believe that their position is best for the child, a third party can bring a fresh perspective. This individual should be a professional (a trusted therapist, counselor, or clergy person). Such a competent third party will help both parents see what is best for their child.

3. *Attempting civil mediation to resolve disputes.* Many final divorce judgments include a mediation clause, requiring this alternative in an attempt to limit postdivorce caseloads, which overburden the family court system. It also encourages divorced parents to work out their problems between themselves, which leads to better, more personal solutions. Civil family mediation is intended to help parents reach a cooperative, mutually agreeable solution with assistance from a trained mediator. Much data suggest that families and children fare better when disputes are resolved through mediation because this settlement is family centered and individualized.

## CHILD CUSTODY ARRANGEMENTS AND COPARENTING

Following divorce, a child may be placed in the sole custody of one parent or placed in a joint custody status. States have differing statutory guidelines for these decisions. In Florida, for example, minor children are to be placed in a joint custody arrangement, called shared parental responsibility (SPR), in all cases unless there is good reason to deny either person his or her parental rights and responsibilities. The Florida statutes say that it is the will of the people that children be raised by both parents in an arrangement termed coparenting. SPR is a court-ordered

relationship in which both parents retain full parental rights and responsibilities with respect to their child and in which both parents confer with each other so that major decisions affecting the welfare of the child will be determined jointly. In cases where one parent is determined to be unfit or unable to parent, or is a threat to the welfare of the child, then sole custody is awarded to the fit parent.

Coparenting is based on cooperation and respect between biological/adoptive parents, no matter their marital status, over the lifetime of their child. Coparenting involves (1) keeping the needs of children first and foremost no matter the feelings about the other parent; (2) working out plans that allow each child enough time to maintain and nurture relationships with both parents; (3) sharing responsibility and decision making for the children's care and needs; and (4) developing a means of communication that is straightforward, child centered, and problem resolving in the children's best interest.

The importance of coparenting has been documented in the social science literature. Children who have access to, and are influenced by, two caring involved parents fare best following separation and divorce. With appropriate coparenting, children have the minimum amount of later difficulties. When hostility and conflict interfere with coparenting, those children suffer the most. Level of involvement for each parent varies, but should be determined by the child's needs.

Coparenting is not always easily accomplished because bitterness, anger, and resentment from the divorce may interfere with successful child rearing. The child psychiatrist Richard Gardner has described and identified a pattern termed parental alienation syndrome (PAS). PAS is the opposite of coparenting and is defined as "a disturbance in which children are preoccupied with deprecation and criticism of a parent—denigration that is unjustified and/or exaggerated." PAS is a systematic process involving efforts by the "programming parent" which ultimately creates within the child (without further parental aid) an obsession to maintain his bond with the programming parent at the price of rejecting the other parent.

The hallmark symptom of PAS is the child's complete lack of ambivalence. The "hated" parent is all bad and the "loved" parent is all good and can do no wrong. One powerful way this plays out is when the alienating parent insists on taking a neutral stance, thus empowering the victimized child to make decisions about visitation. But with full knowledge that the alienating parent opposes the contact, the child

refuses visits. Alienation also impacts the child, as when the child feels guilt during a required visit, leaving the programming parent abandoned.

There is some degree of alienating behavior between practically every divorcing parent dyad, which will eventually subside as the parties make their adjustments. It is when the alienation behavior is raised to a very high level, fueled by conflict and anger, that a child becomes endangered by his parents.

Coparents who are making their own positive adjustment will be more likely to be able to identify and respond to their child's needs following divorce. A successful child custody outcome is often dependent on the following four areas:

1. Children's remarks are often stated to elicit a response on two levels. A child complaining about being picked up late from school may also be worried by abandonment fears: "Will I be left alone like dad or mom?"

2. Once a child's concerns have been identified, parents must reassure their child. Making time to be with them without competing activities and seeking outside resources such as therapy, support groups for kids, and time with the school guidance counselor are essential.

3. Children can see that normalcy has returned by introducing new ways of doing family things like celebrations, holidays, and birthdays. In postdivorce situations, the child will need to adjust to alternating holidays and other events with different parts of their family. One should encourage children to come up with new ideas and traditions for the new family configuration.

4. The former in-laws remain relatives to your child after the divorce. Depending on how much contact was usual prior to the separation/divorce, that will be a predictor for what level of involvement is expected and needed by your child. If the child had regular and frequent contact with other relatives, there should be an honest attempt to keep that involvement alive. At all times, respect must be shown for all of the child's kin.

## CHILD NEGLECT

---

There are many children in our society who go through the day without eating or who fail to receive adequate medical services when ill. Others reside in homes without running water or electricity or homes infested with rodents and roaches. At times, young children are left at home without adequate supervision and are often responsible for watching a younger sibling as well. The above scenarios are but a few examples of what is termed child neglect. Child neglect is defined by a broad spectrum of actions that can range from leaving a 5-year-old at home alone for the afternoon to a child not eating for days as her parents are strung out due to heavy drug use. Although child neglect is a serious social problem affecting our society, neglect is often viewed as unfortunate but benign and often goes unnoticed because it occurs in the privacy of a home. Similarly, the issue of child neglect has received limited attention in the research community, studied far less than physical or sexual abuse, despite the fact that it is the most frequently substantiated form of child maltreatment.

According to the U.S. Department of Health and Human Services, approximately half of the substantiated cases of child maltreatment pertain to child neglect. Although the act of child neglect may not be readily apparent as compared with physical and sexual maltreatment, child neglect may do just as much damage to a child's psychological and physical well-being. Contextually, child neglect is conceptualized as acts of omission, and the parent's actions may be either intentional or unintentional. According to Erickson and Egeland, child neglect can be differentiated into subtypes that include physical neglect, emotional neglect, medical neglect, and educational neglect. Of these

different subtypes of child neglect, physical and medical neglect are the most common. Physical neglect pertains to failure to protect a child from harm or danger and not being able to provide for the child's basic human needs such as adequate housing, clothing, and food. This type of neglect is easier to substantiate due to the physical evidence involved (such as when a child attends school in tattered or inadequate clothes). Emotional neglect is sometimes categorized with emotional (i.e., verbal, psychological) abuse and is more difficult to substantiate since the harm that occurs to the child generally does not involve the presence of physical evidence. An example of emotional neglect would be a parent's repetitive lack of response to a young child's cries for warmth, support, and protection. Medical neglect relates to the failure to meet the medical needs of a child such as those procedures that would lead to the prevention or amelioration of disease or injury. Medical neglect also encompasses the failure to meet the mental health needs of a child if the child has serious emotional and/or behavioral disturbances. Finally, educational neglect occurs where a parent or guardian fails to meet the minimal state standards regarding educational needs for their child (e.g., having a child attend school on a consistent basis).

## CONSEQUENCES OF ABUSE

There are numerous negative developmental consequences associated with child neglect. Generally, neglected children are at risk for delays in cognitive and language development, social and emotional withdrawal, anxiety symptoms, aggressive and inattentive behaviors, and lowered self-esteem. Neglected children are often unpopular, have difficulty forming and maintaining close attachments, have diminished capacity for coping with everyday demands, and by adolescence have been diagnosed with one or more psychiatric diagnoses. Academically, neglected children have lower scores on standardized tests, lower grades, and higher dropout rates. Extreme forms of neglect can lead to developmental delays, failure to thrive, and even death for younger and more vulnerable children. Both the short- and long-term consequences of neglect on a child's functioning have been found to be as severe and damaging to a child as other forms of maltreatment. Investigating the consequences of child neglect is difficult, however, because its impact is often compounded by other detrimental influences on child development such as poverty, accidental injury and trauma, and family dysfunction. Furthermore, the

specific physical, psychological, interpersonal, and academic problems that result from neglect are dependent on the specific type of neglect, the chronicity and acuteness of neglect, and the child's age and competence at the time of neglect.

## RISK FACTORS

There is no identifiable single cause that leads to child neglect. Different contextual conditions (e.g., living in poverty, not having access to adequate health care) contribute to but are not consistent indicators of child neglect. Conceptually, risk factors can be categorized into three groups: (1) child risk factors, (2) family risk factors, and (3) social/environmental risk factors. For the child, risk factors related to disability and chronic illness may contribute to child neglect due to the increased needs of the child. Parent factors such as psychological problems (e.g., depression, substance abuse), having low social support, negative parent-child relationships, and high levels of parenting stress may place a child at risk for being neglected. Social and environmental factors such as poverty, homelessness, and lack of or inadequate medical and social services, while not causal, all contribute to an increased risk associated with child neglect. Although these risk factors are nonspecific, they provide useful information from which to develop policy and prevention programs to reduce the risk for child neglect.

## PROTECTIVE FACTORS

Child, family, and social factors have been identified as having a protective quality against child neglect. Children who are in good physical and psychological health are less prone to be neglected. Children with good social, coping, and problem-solving skills are less likely to be the victims of child neglect. Parents who have a warm, caring, and overall positive relationship with their child are less likely to neglect their child. Parents who have a good social support network that allows them to seek support when needed are also less likely to neglect their child. Parents with low levels of stress and good coping skills are also less likely to neglect their child. In the social context, access to adequate housing and medical and social services are factors that decrease the incidence of child neglect. Overall, a supportive environment where the parent is not experiencing physical and psychological problems and has access to adequate medical, school, and social services reduces the probability of a child being neglected.

## INTERVENTION EFFORTS

Identifying families who are at risk for child abuse and neglect is crucial for decreasing the prevalence of child neglect. Reporting suspected child neglect is required by law for many professions. All 50 states have mandatory reporting laws for any individual, regardless of profession, if child neglect is suspected. Suspected cases of child neglect should be reported to your local child protective services agencies. However, it is important to note that the reporting procedures and agency responsibilities may vary to some degree by state. Intervention can occur from one or several different agencies, such as child protective services, criminal justice, and the health-care system. These interventions focus on ensuring the health and safety of the child and removing any threat to the child.

Assessment for child neglect is typically more challenging than for other forms of child maltreatment because there are often no specific physical markers that can be isolated to neglect. Thus, with the exception of extreme cases of neglect, it is difficult to isolate the pattern of symptoms that results from child neglect from that that may result from other health, behavioral, and social factors. Despite this challenge, increasing attention to prevention and early intervention efforts seem to be promising in engaging the family in treatment and reducing risk. School and medical personnel are probably in the best position to identify families at risk for child neglect. Early intervention efforts targeting families who have young children and infants is crucial for future prevention. The current literature, while limited, speaks to the effectiveness of early intervention, showing that approximately half of families respond favorably to treatments that are long term and comprehensive in nature.

## CHILD REARING

---

Few child development experts would disagree that parenting has a significant influence on child psychological and behavioral outcomes. Furthermore, research has reported that the way in which a child is parented not only impacts childhood health, but also shapes the course of adult lives. A problem for parents is that advice from child professionals has periodically changed, ranging from a "spare the rod and spoil the child" philosophy that directs parents to control their children through the use of frequent and harsh discipline, to advising parents to become their children's "pals, buddies or best friends" by adopting a generally permissive style in which discipline is virtually absent.

Human development researchers have indicated more recently that a "roots and wings" philosophy of child rearing, which provides children with a secure base and opportunities for autonomous exploration of their environment, is best. Decades of child development research collectively suggests that children develop best in a variety of domains if parents foster a strong emotional connection with their children while also creating and permitting occasion for their children to experience independent learning.

### HOW DO CHILDREN CONNECT (ATTACH) TO CAREGIVERS?

Attachment is the process through which children develop specific emotional bonds with any person who performs a large portion of the care in their first year of life. John Bowlby proposed that an infant's attachment to their primary caregiver happens as the result of infant signals and the caregiver's responses to them. This synchrony of interaction is characterized by a cadenced, mutually rewarding communication

that occurs in infant-caregiver pairs in the early months of life. If a caregiver is unresponsive to the infant's signals of distress and fails to reward the infant's socializing attempts, attachment may be less secure. Therefore, the ideal infant-caregiver relationship is principally dependent on the infant's trust of the caregiver and the caregiver's protection of the infant during this early stage of their relationship.

Mary D. Salter Ainsworth, a developmental research psychologist, was interested in how infants' connectedness to their primary caregivers influenced infant social behaviors. Her attachment research described five sequential stages in the development of an infant's connection to a caregiver. She linked these stages to the infant's age and therefore its cognitive developmental level. Briefly, Ainsworth suggested that the infant's smiling and cuddling behaviors in the first 3 months were attempts to influence caregiver attachment responses and that throughout the toddler and preschool years children used other age-appropriate methods, such as mimicking the caregiver's actions or helping with household chores, to satisfy their need for connectedness with their parents.

Ainsworth demonstrated the effect of caregiver responsiveness to these infant attempts to garner connectedness by using what she termed the "strange situation." This research procedure exposed infants to a 20-minute period in which infants and caregivers (mothers in this protocol) were placed alone in an unfamiliar room for several minutes, followed by the entrance of a stranger who would attempt to engage the infant with a toy. The caregiver would then briefly leave the room while the stranger continued to distract the infant with the toy. After a brief absence, the caregiver would return to the room and attempt to comfort the infant. The infant's responses during each situation were recorded. Ainsworth found that infant reaction to the return of the caregivers was central to determining whether a secure or insecure infant-caregiver attachment existed, because the reunion indicated whether the infant was attached to a specific individual or if the infant considered its caregivers interchangeable. Four attachment patterns were noted using this research protocol:

1. *Secure Attachment.* These infants actively explored the novel environment and interacted with the stranger while the caregiver was present, and their distress at the caregiver's absence was reduced when the caregiver returned. These infants showed a specific connection to their primary caregiver.

2. *Anxious-Avoidant Attachment.* The infants in this group were indifferent to their caregiver when present, variably distressed when their caregiver left, and soothed equally well by a stranger as by their caregiver. These infants appeared to be uncertain of their caregiver and to less feel confident of her connectedness to them.

3. *Anxious-Resistant Attachment.* These infants can be best described as cautious of both caregiver and stranger. They were distressed when the caregiver left, but were not easily soothed when the caregiver returned. Again, these infants did not appear to have formed a specific connection to their caregivers and did not feel confident in any of the situations.

4. *Disorganized Attachment.* These infants demonstrated seemingly apprehensive behavior, such as moving toward the caregiver but not making eye contact. They appeared confused and sometimes dazed in all three situations. These infants were theorized to have been traumatized by abuse or parental neglect and to represent a minority of infants.

In a secure attachment, caregivers are believed to be more sensitive and appropriately responsive to their infant's signals, such as smiling at their infant when the infant smiles at them, encouraging verbalizations by talking to their infants, and comforting their crying or fearful infant. These responsive caregivers are also more emotionally available to their infants than caregivers in the other three insecurely attached patterns. Accordingly, infants demonstrating stranger anxiety and separation anxiety would actually be indicating that a specific, secure attachment has been made to their caregiver. Infants who appeared avoidant, resistant, or disorganized in their approach to seeking comfort from their caregiver indicate an insecure attachment as a result of caregivers who withdraw from interactions with the infant, are markedly intrusive or overly stimulate the infant, or who are erratically or unpredictably responsive to their infant's cues. In other words, securely attached infants had caregivers who were consistently responsive to their needs and emotionally interactive with them.

## HOW DO INSECURE ATTACHMENT PATTERNS FORM?

There are several factors that may be responsible for the various insecure attachment patterns. A primary influence is the home environment in which the child

lives. Homes that are impacted by instability in the marital relationship, domestic violence, parental unemployment, family poverty, or illness of a parent can disrupt a pattern of attachment. Individual and cultural differences in infants have been suggested as a factor affecting attachment development as well.

Because synchrony depends on both caregiver and child performing reciprocal behaviors, children who are preterm (and thus delayed in social development) or infants who have shy, fearful, or irritable temperaments are at risk for insecurely bonding with their caregivers. Infants born with significant problems such as autism, blindness, or deafness may also have attachment difficulties. These infants are at greater risk for being abused by parents as well, because their neediness, coupled with the delay in (or total absence of) displaying normal infant-bonding behaviors and the development of regular sleep and eating routines, makes parenting them a more intensive process.

Child-rearing practices differ significantly across cultures and subgroups, and any given population's values and beliefs may influence its infant-caregiver attachment patterns. For example, strange situation studies conducted with both Israeli kibbutzim and German children identified more of those children as insecurely attached to their caregivers. Researchers attributed these findings to the inherent child-rearing goals of these cultures, such as the communal parenting responsibilities in the Israeli kibbutzim and the focus on rearing autonomous and undemanding children in German society, rather than on bonding deficiencies. The psychological impact of parent-child connections in non-Western cultures has been recently debated. Some researchers claim that infant-caregiver attachment is paramount to healthy psychological functioning regardless of culture, while others argue that the meanings attributed to infant behavior in the strange situation are insufficient to determine the quality of the infant-caregiver bond in a non-Western population.

Although some researchers have suggested that a child's attachment pattern can be both stable and changeable (depending on the stability of their environment), Bowlby has argued that the pattern of attachment becomes an internal model by approximately age 4 or 5 and is relatively disrupted according to the child's age and characteristics of the parents. Thus, younger children would be more likely to experience a change in their internal model of attachment to a primary caregiver, from a secure to insecure pattern, following a family crisis such as divorcing parents, death of a parent, or abuse by a parent, than would an

older child. Conversely, the attachment of older children would be more resistant to change despite a disrupting event and more likely to generalize to other relationships. Bowlby also suggested that the reliability of attachment is relationship specific, with attachment patterns changing with some individuals but not others. For example, following the divorce of a child's parents, he or she might retain a secure attachment to one parent while shifting from a secure to insecure pattern with the other, depending on the quality of their pre- and postdivorce relationships.

Attachment research has clearly indicated, at least for Western cultures, that attachment patterns are likely internalized, generalized to child, adolescent, and adult relationships, and may persist in subsequent generations. Attachment in non-Western cultures appears to be better determined when the values and beliefs of the respective culture are first considered.

### WHAT ARE THE CONSEQUENCES OF ATTACHMENT?

Attachment patterns in infancy have been linked to adolescent and adult social behaviors, as well as to the style one uses to parent one's own children. Several researchers have reported that infants identified as securely attached to their caregiver tend to be more socially skilled and positive in their adolescent and adult relationships. It is also reported that securely attached children are less clinging and less dependent on parents and teachers, are more emotionally mature in home and school settings, have higher self-esteem, are less likely to be socially aggressive or disruptive, and are more popular with peers. These children also appear to have an academic advantage in that they are more often rated as leaders and tend to get better grades. On the other hand, insecurely attached infants show more disruptive behaviors in adolescence and adulthood, and insecure attachment patterns have been linked to early sexual involvement, riskier sexual behavior, and sexual dysfunction in adulthood. For these reasons, attachment patterns have been implicated in childhood and adolescent social and academic success.

How we parent our children may also be linked to our own early attachment patterns. Developmental researchers have consistently reported that caregivers and infants share the same attachment patterns. That is, caregivers who were classified through testing as securely attached to their parent had infants who were securely attached to them. Conversely, caregivers who showed insecure attachment patterns had

infants who were also insecurely attached to them. Consequently, we not only tend to parent our children as we were parented, but we also pass on an attachment style to our children and, quite possibly, to future generations.

### WHAT ARE PARENTING STYLES AND PARENTING PRACTICES?

Child rearing is the process whereby parents teach their children the rules of the society in which they live, so that their children are prepared for an autonomous adult life. Optimal socialization prepares children to function well as adults and to continue to do so when their parents are no longer available to parent. Child-rearing practices, then, might be an important predictor of whether this socialization was successful.

The terms *parenting styles* and *parenting practices* are sometimes used interchangeably, but they actually refer to different aspects of parenting. *Parenting style* is a descriptor of a parent's attitudes, beliefs, and values regarding how parenting is best accomplished. *Parenting practices* are the specific behaviors, strategies, or methods parents use, based on their particular parenting style. So although the two concepts have different conceptual meanings in the developmental literature, they are intrinsically linked with regard to how parents rear their children.

Various authors have written about differences in parenting styles and practices in terms of their influence on child outcomes and in noting differences across cultures. Outcome investigations, similar to those in the attachment literature, typically use a predictive model to associate various parenting practices with child and adult characteristics such as emotional stability, social skills, academic abilities, and incidence of psychopathology. Cultural difference studies point to how ethnic or cultural values influence diversity in the implementation and meaning of various child-rearing practices, and how culturally shared beliefs guide parenting attitudes and practices. For example, Western cultures who value individualism may see autonomy as an ideal characteristic to shape in children, whereas collectivist cultures who value the common good would be more likely to discourage autonomy as a goal of child rearing. Important to note is that despite cultural differences, some characteristics such as parental warmth and responsiveness appear to be considered important across many cultures.

## HOW DOES PARENTING INFLUENCE CHILD BEHAVIORS?

Diana Baumrind, an influential developmental psychologist, researched a “parenting style” theory that has become important to Western parenting ideology. She suggested that a person’s parenting practices is embedded in their beliefs about how control of their offspring is related to the socialization process. She studied four dimensions of parental functioning: (1) warmth/nurturance, (2) clarity and consistency of rules, (3) level of expectations (maturity demands), and (4) communication between parent and child.

She connected each of these dimensions to various child behaviors. Accordingly, nurturing parents tended to raise more securely attached children and parental warmth was linked to high self-esteem, higher IQs, better school performance, and greater empathy for others. Conversely, parental hostility was linked to poorer school performance, higher rates of delinquency in adolescence, criminality in adulthood, and less socially skilled children.

Likewise, parents who were clear and consistent in their communication, who reliably enforced family rules, and who had high expectations (maturity demands) for their children tended to have children who were less defiant and more socially competent and who showed more empathy for others. Open and regular communication with children has been similarly associated with their emotional and social maturity.

According to Baumrind, these four dimensions occurred in high/low combinations that produced three distinct parenting patterns:

1. Authoritarian parents are low in nurturance/warmth and in communication with their children and high in control and maturity demands. These parents evaluate and attempt to control all behaviors and attitudes of their children. Family rules are typically in accordance with rigid traditional standards, and strict obedience is demanded, while open communication between parent and child is discouraged. These parents generally use punitive methods to discipline their children.

2. Permissive parents are low in maturity demands, communication, and control and high in nurturance. These parents exercise little or no control over their children and typically view themselves as their child’s “friend.” They have few maturity demands, so their children set their own schedules and priorities and learn about life without any kind of structure for such

learning. Discipline in these families is usually absent or inconsistent.

3. Authoritative parents are high in all four dimensions. These parents acknowledge the power differential in the parent-child relationship, but because they believe their children have rights too, consider their children’s point of view. Although they have high expectations (maturity demands) for their children, they use open and regular communication to explain and teach, rather than punitive disciplinary methods to control and stifle their children. They are less likely to stress obedience and more likely to encourage critical thinking and self-responsibility.

Baumrind found that each parenting pattern was associated with a specific pattern of early childhood behavior. Children of authoritarian parents tended to be less socially competent. These children often withdrew from, and would less often initiate, social contact. They were less intellectually curious and lacked problem-solving skills. Children of permissive parents were immature relative to their peers. They tended to have more difficulty with impulse control, independent action, and taking responsibility for their social behaviors. Children of authoritative parents were more self-confident, more self-reliant, more explorative, more self-controlled, and calmer than children in the other two parenting groups. Hence, children of authoritative parents exhibited better socialization skills and greater self-confidence than children who were raised by either authoritarian or permissive parents.

Baumrind’s parenting categories were expanded by Eleanor Maccoby and John Martin, who proposed only two dimensions to categorize families: degree of demand or control (high or low) and amount of acceptance (high or low). They also identified four parenting styles, rather than three: authoritarian (high demand and control, low acceptance); permissive (low demand and control, high acceptance); authoritative (high demand and control, high acceptance); and an additional type, uninvolved/neglecting (low in demand and control, low in acceptance). Child outcomes for these parent types were consistent with Baumrind’s descriptions of the authoritarian, permissive, and authoritative styles. However, they reported that the most consistently negative outcomes were associated with the uninvolved/neglecting parenting type. Children of uninvolved or neglecting parents generally had “psychologically unavailable” caregivers, who often had emotional problems or were substance abusers and who had also had an

insecure attachment to their own parents in infancy. According to Maccoby and Martin, these children had much more difficulty with impulsivity, social relationships, and academic achievement and were more likely to be conduct disordered.

Similar to the attachment research, parenting style research has child-related and culture-specific limitations. The development of a human child is so complex that it is more likely that an interaction between a child's environment (nurture) and their inborn characteristics (nature) influences child outcomes, rather than parenting styles and practices alone.

A child's preexisting temperament may, in part, influence the child-rearing strategies its parents use. Child development researchers have long indicated that children show distinct individuality in temperament in the first weeks of life, independent of either their parents' personality or parenting style. Moreover, these temperamental traits persist into the childhood, adolescent, and adult years. A classic study by Alexander Thomas, Stella Chess, and Herbert G. Birch identified three child temperament classifications based on children's activity level, regularity of bodily responses, reactions to strangers, adaptability to changes in their environment, mood, attention and distractibility, persistence, and intensity of reaction. They identified the following three "type of child" categories:

1. "Easy" children presented few problems for parents because they generally showed regularity in their sleep and feeding behaviors, had low or moderate intensity of reactions, did not withdraw from novel objects or persons, adapted quickly to new situations or routines, and displayed a positive mood. As infants, they were quick to develop routines, were less likely to tantrum as toddlers, and adapted to school and home schedules without difficulty.

2. "Difficult" children, in contrast, were erratic in their development of sleep and eating cycles in infancy, took a much longer time to adjust to routines, and cried more often and more loudly. During toddler and preschool years, these children became frustrated more quickly, engaged in violent tantrums, had more conflict with parents and siblings, and required more consistency and tolerance from parents.

3. The "slow to warm up" child displayed some of both the easy and difficult characteristics. These children usually had a low activity level, tended to initially withdraw from novel situations but would gradually adapt, had a moderately negative mood, but

displayed low-intensity reactivity. As infants, they presented fewer parenting frustrations than the difficult children because they eventually developed regular feeding and sleeping schedules, but were still more problematic than easy children, who quickly established routines consistent with their parent's expectations. As toddlers and preschoolers, slow-to-warm-up children required much more effort by parents to help them adjust to the demands of school, but once acclimated, were not problematic.

According to Thomas, Chess, and Birch, children who fit their easy description may be much easier to parent because they respond positively to most parenting styles and will adapt to environmental changes much more quickly. Conversely, difficult children challenge parents from the outset. Parents experience many more daily battles, which result in the use of more punitive or inconsistent parenting, which in turn can exacerbate the child's negative mood and intense reactivity tendencies. Slow-to-warm-up children require patient parents who allow their child to adapt at his or her own pace while offering encouragement and support for trying new things. When a parental demand "conflicts excessively" with a child's natural temperament, the child will feel extreme distress and will react in a negative fashion. Parents who can recognize their child's temperament pattern and be responsive to it will have less conflict with, and more compliance from, their children. Consistent parenting approaches are essential because a mismatch of parental demand to child temperament will excessively frustrate parents and their children. Parents must acknowledge what their child can and cannot do (given his or her temperament) and adjust their expectations accordingly.

Although authoritative parenting styles and practices appear to best fit most child temperaments, this approach may not be effective for every child. The social skills of a shy child who is inherently reticent to initiate interactions with other people may be harmed by an authoritarian parent who controls his or her social contacts, whereas an overly active or excessively aggressive child may be better parented with the control strategies imposed by authoritarian parents. It is unclear whether authoritative parenting can moderate family conflict and stress, parent psychopathology, and poverty.

Parenting style has not been found to be predictive of the same child outcomes in non-Western cultures as it has in Western societies. Parenting styles and practices tend to differ across cultures due to the different

meanings the culture attributes to specific child behaviors. For example, African American parents view physical punishment as essential to protect their children from social dangers and enforce respect for parental authority, but their children do not show more externalizing behaviors than children of authoritative parents. Similarly, Arab cultures associate “autonomy granting” with “obedience to parents’ wishes” rather than as a method to encourage their children to internalize parental values, and no differences between Arab and Western cultures in terms of child outcomes are reported. Children of authoritarian parents view their practices as normative for their culture, and as an indication of parental warmth and caring. Thus, the cultural meaning parents and children attribute to parenting methods might be more important to child outcomes than a universal parenting style. In fact, only parental warmth has been consistently reported to be a universally positive parenting characteristic in both Western and non-Western cultures.

### HOW DO PARENTS LEARN TO BE PARENTS?

Parents typically enjoy most of their interactions with their children. The “hard work” of parenting occurs when guidance or discipline is necessary to address child misbehavior. How do parents decide how to discipline their children? Generally parents are heavily influenced by how they were parented themselves, because their childhood experiences are their primary, and often only, source of information for child discipline techniques. The relative success or failure, then, of parents’ efforts to guide their children may be solely dependent on what they learned from their parents. If their parents used a limited repertoire of ineffective or inconsistent disciplinary strategies, then repeating this in their own families can result in frustration and poor child outcomes.

There is help for parents who want to go beyond their own family history of parenting. Programs designed to give both child development and child management information have become popular for parents wishing to supplement their parenting knowledge or learn alternate parenting strategies. Research suggests that educational experiences may buffer the effects of problematic parenting and decrease the transfer of risk to subsequent generations. Many of these programs contain content congruent with authoritative parenting ideas and emphasize skill building to help parents successfully provide their child with a sense of security (roots), while appropriately encouraging

their child to explore and learn self-regulation (wings). Collectively, these programs consistently provide the following parenting advice:

1. Parents who are warm, nurturing, and responsive to their children’s needs are more likely to develop a secure infant-caregiver bond and build a positive child-caregiver relationship. It is the parents’ responsibility to provide physical and emotional nurturance for their children, not for children to supply these for parents.

2. Parents who value their children’s ideas and activities by taking time to listen to children’s thoughts, feelings, and experiences foster high self-esteem and better competency skills. Involvement in their children’s daily lives provides opportunities for parents to shape their children’s character and behaviors.

3. Parents need to model caring toward others, rational thought, behavioral self-control, emotional understanding, and social sensitivity in what they say and in what they do. It is important to remember that children say what their parents say and do what their parents do.

4. Parents who directly confront their children’s behavior in a consistently decisive way with clear consequences for noncompliance orient children toward parent-preferred goals while providing stability in their understanding of parental expectations. Consequences should always fit the “crime.” Parents who think before imposing consequences will have greater success in maintaining their resolve than those who impose punishment during an emotionally charged moment. A reasonable consequence will communicate a sense of fairness to children as well. Children learn more about what is expected of them when parents reinforce expected behavior, instead of just punishing disobedience. Positive feedback yields better compliance with family rules, while frequently harsh punishment conditions children to escape, often by lying, from consequences.

5. It is the parents’ job to set standards of conduct for their children by remaining behaviorally focused, rather than attributing child misbehavior to a flaw in the child’s character. Behavioral misconduct implies that change is possible and the transgression is time limited, whereas a defective character is more resistant to modification and more likely to generalize to other contexts.

6. The use of reason and persuasion to gain compliance is more effective than the use of power and manipulation. Parents who are firm, but reasonable, in their parental control and who take time to clearly explain the rules to their children are more likely to have children

who internalize their morals and values than children of parents who are arbitrary in their rule setting, assert their power, or withdraw their love from their children. However, flexibility in setting limits that match each child's individual characteristics is essential. Not all rules are necessarily appropriate for all children at all ages.

7. Parents who encourage their children to be independent thinkers, accept opposing points of view, and encourage verbal give-and-take teach their children to take responsibility for their thoughts, feelings, and actions and to accept differences in others. Reciprocity of thoughts and emotions teaches self-honesty and humility. Children see themselves as having more agency in their lives when parents resist using restrictive control of their children's thoughts and ideas.

8. Parents who do not overly control or restrict their children's experiences permit children to build confidence in their ability to handle varying and complex situations and give them the opportunity for learning about themselves and the world in which they live. The fear of children becoming emotionally or physically harmed is paramount for parents and causes them to worry about a negative outcome from allowing their children too much freedom. The decision about how much autonomy, or freedom of choice, a child should have must be child specific and age based, so that experiences are formative in nature rather than an overwhelming or harmful experience for the child.

## SUMMARY

What is the best advice to parents based on current research? First, infants require parents who are warm and responsive to their physical and emotional needs so that a secure attachment can form. Second, authoritative parenting styles and practices, which encourage children to develop strong emotional bonds with their parents as a secure base for their autonomous exploration of their environment, are linked to optimal development in social and academic arenas and to a positive self-esteem. Third, it is a necessity that parents attend to their child's individual temperament and developmental needs and be aware of the reciprocal nature of the child-caregiver relationship. Fourth, cultural differences must be considered in the use of any parenting style.

## CHILDLESSNESS

---

In its strictest definition, childlessness occurs when people do not biologically bear children. However, this definition is limited and fails to address the complex

psychosocial factors that contribute to its causes and consequences. Most people are childless for large segments of their life and actively pursue not getting pregnant or having children.

In this context, childlessness is a normal human experience. Childlessness is a dynamic process that evokes different emotions and social reactions at different points in time, as well as an outcome. As such, the meaning of childlessness may change throughout the life course of the individual.

The social, psychological, economic, hormonal, and family pressures to reproduce are strong forces that result in childbearing being considered the norm. People who deviate from the norm may not only feel “different,” but “stigmatized” because they do not have children. Childlessness implies not just the physical absence of children, but also strong emotional reactions that may include regret, loss, sadness, failure, grief, depression, embarrassment, or feelings of incompleteness as people do not have desired or expected offspring. From a life course perspective, childless people may feel awkward at times when their friends are pregnant or consumed with childbearing responsibilities, and they may be left out of conversations or events because they do not belong to the social group of “parents.” People without children do not have automatic recipients for their material legacies (including possessions and property) or emotional and historic histories, as do parents, which creates a challenge at the latter stages of life.

This view varies dramatically from people who define themselves as “child-free,” who see the absence of children as a liberating, positive experience. National organizations such as the National Childfree Association or Childless by Choice provide information and support to people who wish to pursue a nonchild lifestyle. People who are childless by choice are not antichild; they may simply not want one of their own. Couples who do not have children have more time to be together and more discretionary money with which to do interesting things, and they report higher levels of relationship satisfaction since they are not burdened with the financial, emotional, and time constraints of parenthood.

Two major forces contribute to people not having children. One is a push force, in which there are obstacles and challenges that prevent people from having children. Push forces are usually negative forces that get in the way of childbearing. These include lack of a mate or having a mate who does not want children, infertility, miscarriage, infant death, feeling that one cannot afford to have children, allowing jobs or education

to take precedence, feeling that one’s partner is not suitable parent material, a history of alcoholism, genetic problems, abuse that adults fear may get passed on to the child, or assumptions that they would not be a good parents. Pull factors are positive forces that encourage the adult into pursuing meaningful activities that are deemed more important and satisfying than parenthood. Pull factors are lifestyle choices that include wanting to go to school or pursue a career path, choosing a partner or relationship over parenthood, travel, recreation, and the active pursuit of goals that people want to accomplish. If people are childless, they may feel pushed into that outcome and have more of a negative feeling about not having children compared with people who were pulled to wanting something other than children. The choice involved with having children or not influences emotional well-being.

## CHILDREN WITH SPECIAL HEALTH CARE NEEDS (CSHCN)

---

Children with special health care needs include those with chronic illnesses (e.g., asthma, diabetes, sickle cell anemia), physical disabilities (e.g., cerebral palsy, spina bifida), and developmental/emotional disabilities (e.g., autism, Down syndrome). Historically, children have been classified as having special health care needs based on whether they have been diagnosed with specific conditions. In the past decade or so, it has been recognized that this classification system is flawed and may exclude children with rare, undiagnosed, or

difficult to define conditions. In 1998, a working group established by the United States' Maternal and Child Health Bureau's Division of Services for Children with Special Health Care Needs published a new definition of children with special health care needs that was designed to be more inclusive of all children currently needing or who are at risk for needing special health or related services:

Children with special health care needs are those who have or are at increased risk for a chronic physical, developmental, behavioral, or emotional condition and who also require health and related services of a type or amount beyond that required by children generally.

This new definition was created to help guide program planning for these children and their families. By not depending on specific diagnoses to classify children, the definition implicitly recognizes that children and families affected by different conditions have many common experiences. For example, many of these families face frequent disruptions of family and social activities and increased financial obligations due to their increased need for a wide array of community and professional services. These services may include frequent physician visits, allied health services, medical or orthopedic devices, and individualized education plans.

In addition to the above common experiences, families of children with special health care needs often have increased challenges associated with optimizing and maintaining the child's emotional development and self-concept. Due to the need for specialized services, or because of physical or academic limitations, children with special health care needs may feel stigmatized or simply "different" from their peers, which may in turn affect their emotional health and well-being. As advances in health care have allowed children with special health care needs to live longer and fuller lives, attention has shifted to focus on understanding their unique developmental and emotional needs.

However, the impact of an illness or disability on a child's cognitive, social, and emotional development varies over time as the child's developmental level changes. In addition, the implications of the illness/disability are different depending on the child's developmental level at its onset and the limitations of the disorder at each level of development. Professionals who work with children with special health needs must keep these changing developmental needs in mind. They must also understand the effects (both negative and positive) of the child's condition on the

family system and how these in turn can affect the child's development. The way that medical treatment, allied health care, and other necessary programs are delivered can have lasting effects on the family's stress associated with the child's condition. Supportive care designed to ameliorate the negative effects of the condition can assist the family in managing the child's care and the burdens associated with it. Support groups for families, parent and child educational training about the condition, home care services, respite care, and other support services can prevent the accumulation of stress that can overwhelm a family's resources or hinder the child's development.

## CHILDREN'S RIGHTS

---

### THE UNITED NATIONS CONVENTION ON THE RIGHTS OF THE CHILD

The United Nations Convention on the Rights of the Child (UNCRC) is the clearest and most comprehensive expression of what the world community wants for its children. The Convention is the most universally accepted human rights instrument in history

(except for the United States and Somalia, it has been ratified by every country in the world) and is the only treaty that puts into legally binding form the entire range of human rights: political, social, economic, cultural, and humanitarian. The UNCRC arose as a reaction to the weakening global humanitarian response to children. During the momentum of the 1979 International Year of the Child, the government of Poland proposed a drafting process for a legally binding human rights treaty, thus taking the first steps in establishing the UNCRC. The United Nations unanimously endorsed the convention on November 20, 1989, and it became international law in 1990.

The 54 articles of the UNCRC can be divided into four main parts: guiding principles, rights articles, monitoring systems, and process of ratification. The four guiding principles are: nondiscrimination, best interest of the child, survival and development, and participation. Articles on rights apply to all children under 18 years of age and seek to safeguard and uphold children's minimal health, civil, humanitarian, and family rights. For example: protection of children against discrimination, abuse and neglect, and armed conflict is outlined in Articles 2, 19, and 38, respectively. Parent-child relationships are protected and defined in several articles (parental guidance, Article 5; parental separation, Article 9; and family reunification, Article 10). It calls on countries to ensure survival of children to the maximum extent (health care, food, and clean water, Article 24; education, Articles 28, 29). It articulates that children should have increasing opportunities to participate in society as preparation for responsible adulthood (name and nationality, Articles 7 and 8). Countries' obligations toward dissemination, implementation, and monitoring are spelled out in Articles 42 to 45. The final set of articles (46 to 54) outline the process of ratification.

The UNCRC focuses on the rights of the child from a developmental ecological perspective. It assumes that the child's overall development is a function of a number of factors (psychological, social, educational, and cultural) and contexts (home, school, community, and country). The UNCRC outlines the legal responsibilities of governments to ensure that children have the family support and resources to grow up to be responsible adults. The Convention reaffirms the fact that children, because of their vulnerability, need special care and protection and consequently has set standards in health care and education and in legal, civil, and social services.

The Convention has served as a vital tool for advocacy and programming. For instance, advocating for the demobilization of child soldiers in war-torn regions, such as Sierra Leone, was possible because of Article 38, which requires "that states parties take all feasible measures to ensure that persons who have not attained the age of 15 years do not take direct part in the hostilities" and further "refrain from recruiting any person who has not attained the age of 15 into their armed forces." A rights base approach to programming is evident in many early childhood intervention efforts around the world. For instance, Save the Children has developed the indicators to assess the quality of early child care programs in central and east Africa rooted in the framework of the UNCRC.

In conclusion, UNCRC has made a vital contribution to recognizing the fundamental dignity of the child by seeking respect for children, highlighting the importance of the family, and establishing clear responsibilities of the larger community (i.e., country) to uphold the rights of all children everywhere.

## CHOMSKY, NOAM (1928–)

---

Noam Chomsky is cofounder of the Department of Philosophy and Linguistics at the Massachusetts Institute of Technology (MIT) and a seminal figure in 20th-century linguistics, anarchism, and radical politics. He was born in Philadelphia, Pennsylvania,

in 1928 to William, foremost Hebrew grammarian, and Elsie (née Simonofsky), a Hebrew teacher also involved with Zionism, the Hebrew language, and Jewish cultural affairs. Since 1955, he has been with MIT, first as a researcher, then as cofounder of the Department of Philosophy and Linguistics, and now an Emeritus Institute Professor of Philosophy and Linguistics. His work contributes to linguistics, cognitive sciences, politics, history, law, and philosophy, and his approach contributes to the study of human development through his philosophy of the mind and his theories of pedagogy and language acquisition.

Chomsky was influenced early on by anarchists and anti-Bolsheviks, and then at the University of Pennsylvania by mathematicians, logicians, philosophers, and linguists, most notably Zellig S. Harris (1909–1992), with whom he shared interests in radical politics and left Zionism. His PhD thesis with Harris (published as “Syntactic Structures and Logical Structure of Linguistic Theory”) was a study of linguistic forms through the arrangement of words and morphemes in sentences. He subsequently violated the norms of the linguistics field by pursuing the Cartesian idea that language is genetically determined, positing the existence of innate representational structures governed by rules, and then searching for discovery methods to identify the logical structure (“deep structure”) that underlies all natural languages. The central insight of Chomsky’s approach, already present in his graduate work, is that human languages can be formally modeled as the infinite sets of strings generated by computational devices with well-defined limited properties. Chomsky’s work on transformational generative grammar had a seminal impact on our understanding of the development of the human mind, and his ideas of language acquisition contrasted with the behaviorism of B. F. Skinner and with Jean Piaget’s views on the development of intelligence. The core notion of cognitive science is that mental processes can be usefully characterized as a set of interacting, formally described computational mechanisms, and Chomsky’s work demonstrated that mental processes could possibly be formally and precisely modeled as computational processes. Chomsky’s interest in characterizing how language was tied into the process of human thought led to his work on determining how human cognitive abilities are organized into a unity of mind and how the brain supports these abilities.

Outside of the language research, Chomsky is also involved in political work and crusaded against the

Vietnam War. As in his seminal work *American Power and the New Mandarins*, he continues to critique American foreign policy. His analyses of the Middle East and Central America, long-standing local and international activism, and studies of the media combine to make him one of the most cited intellectuals in history.

---

## CHROMOSOMES

---

Chromosomes are large pieces of DNA that contain genes, other sequences of DNA, and associated proteins. Genes code for traits, and many of the additional sequences and associated proteins, are used to organize and to regulate the expression of the genes.

A typical human cell contains 46 chromosomes, which if stretched out and laid end to end, would be about 1 meter long. There are 23 different types of chromosomes, each containing a different set of genes. Each person has two copies (one from one's mother and the other from one's father) of each type of chromosome. The two copies contain the same genes in the same order but may carry different forms of those genes (alleles). Thus, any individual may have two identical copies of a gene (homozygous) or may have two different forms of the gene (heterozygous). Since genes are a sequence of DNA, different alleles vary in their DNA sequence. These variations can affect the presence, severity, or intensity of a particular trait in an individual.

The sex chromosomes make up one set of the 23 kinds of chromosomes. There are two forms of the sex chromosome, the X and the Y chromosome. If a zygote receives two X chromosomes, the individual will become female; if a zygote receives one X and one Y chromosome, the individual will become male. The X and Y chromosome pair differs from the other pairs in that they do not contain all of the same genes. The Y chromosome is smaller than the X chromosome and contains genes that determine maleness. Since women have two X chromosomes in their cells and only one is needed for proper functioning, one of the X chromosomes is randomly inactivated in each of the woman's cells.

During reproduction, gametes are formed that contain one copy of each of the chromosome types. This ensures that each new offspring will receive one copy

of each chromosome from each parent. Since males contain one X and one Y chromosome, half of their sperm will carry an X and half will carry a Y chromosome. All eggs carry an X chromosome. The sex of the child is then determined by whether the sperm that fertilized the egg carries an X or a Y chromosome.

Because each parent gives one of each of their chromosomes to each child, there is a wide variety of different combination of genes, and this genetic variability results in the large diversity of people, even those in the same family. Since each child randomly receives half of his or her mother's genes and half of his or her father's genes, siblings share one fourth of their genes in common with each other. The only exception to this is in identical twins, who share 100% of their genes because they arise from a single fertilized egg that splits into two embryos.

Genetic diseases may arise from variant or mutant forms of genes. Many genetic diseases are recessive, meaning that both copies of the gene have to be mutant for the disease to occur. People that have one copy of the mutant and one copy of the normal gene are called carriers, and there is a 50% chance that they will pass the mutant allele to each of their offspring. There are also some dominant diseases that result from a mutation in only one copy of the gene involved in the disease. If a parent has a dominant disease, there is a 50% to 100% chance that he or she will pass this allele to his or her offspring.

## CHRONIC FATIGUE SYNDROME

---

Chronic fatigue syndrome (CFS) is a poorly understood and sometimes controversial illness thought to affect as many as 800,000 Americans. Individuals with CFS often report flulike symptoms with low-grade fever and body aches. CFS is often a diagnosis of exclusion, since other potential medical or psychiatric disorders must be ruled out before a diagnosis of CFS can be made. Currently, scientists use a CFS case definition,

which requires a person to experience 6 or more months of chronic fatigue of new or definite onset that is not substantially alleviated by rest, not the result of ongoing exertion, and results in substantial reductions in occupational, social, and personal activities. To be diagnosed with CFS, individuals also need to have the concurrent occurrence of four or more symptoms that did not predate the illness and persisted 6 or more months since onset (i.e., sore throat, lymph node pain, muscle pain, joint pain, postexertional malaise, headaches of a new or different type, memory and concentration difficulties, and unrefreshing sleep). Some research samples have included a high or low percentage of patients with critical CFS symptoms (e.g., postexertional malaise, memory and concentration problems), further complicating identification of comparable samples. A new Canadian case definition does include these critical symptoms (i.e., postexertional malaise, memory and concentration problems), and use of this case definition might aid in the selection of more homogeneous samples.

CFS came to public prominence in the 1980s. At that time, it was believed to be a rare condition affecting primarily upper-class White women, thus the pejorative term “yuppie flu.” More recent epidemiological research indicates that the illness affects individuals from many different classes and ethnic/racial backgrounds and is more common among women.

The cause of CFS is unknown. Often individuals report a viral infection immediately prior to onset. Others may describe trauma, emotional stress, prolonged overexertion, or no particular precipitant before the appearance of symptoms. The lack of a biological marker has caused some within the medical community to theorize that CFS is a psychogenic illness. However, others adopt a more biopsychosocial explanation. Evidence does exist indicating that when the hypothalamic-pituitary-adrenal axis and sympathetic nervous system become upregulated—possibly due to heightened central nervous system sensitivity to stimuli such as cytokines—secretions of glucocorticoids and catecholamines (adrenalin and noradrenalin) are raised. This could result in an immune response shift, which could impair the body’s defense against viral or intracellular bacterial infections. There might be multiple pathways leading to the cause and maintenance of the neurobiological dysregulations and other symptoms experienced by individuals with CFS. Depending on the individual and subtype, these may include unique biological, genetic, neurological, psychological,

and socioenvironmental contributions. Subgrouping is the key to understanding how CFS begins, how it is maintained, how medical and psychological variables influence its course, and, in the best case, how it can be prevented, treated, and cured.

CFS is a highly stigmatizing illness. Many health care professionals continue to deny its existence. Research has demonstrated that even the name *chronic fatigue syndrome* leads to minimization of the severity of the illness. Individuals with CFS are often told, directly or indirectly, that their symptoms are purely psychogenic and are caused by depression or some other psychiatric disorder. Because the illness is not widely recognized, sufferers have difficulty being appropriately diagnosed and treated.

No specific treatment currently exists for CFS. Medical management consists of treating specific symptoms, such as medication to aid sleep or relieve pain. Comprehensive rehabilitation programs involving multidisciplinary teams might be helpful, and such programs might include cognitive-behavioral therapy, physical and occupational therapy, and even complementary and alternative therapies such as acupuncture and massage.

---

## CHRONIC ILLNESS

---

### WHAT IS CHRONIC ILLNESS?

A chronic illness is any medical condition that has a prolonged course and often interferes with physical and mental functioning. Chronic medical conditions may also be marked by periods of acute exacerbation that require more intensive medical attention. Examples of chronic illnesses include acquired immunodeficiency syndrome (AIDS), asthma, cancer, cerebral palsy, congenital heart disease, cystic fibrosis, hemophilia, insulin-dependent diabetes mellitus, leukemia, sickle cell disease, and spina bifida. Although chronic conditions can be life threatening, increases in medical knowledge and advances in technology have enabled many individuals with these medical disorders to live longer and lead productive lives. The presence of a chronic medical condition affects not only the individual diagnosed with the disease but the person's entire family. Because chronic illnesses are not curable, continual medical management and adherence to treatment regimens are necessary. Frequently, it is necessary for family members and the individual to assume a great deal of responsibility for managing the illness.

### WHAT IS THE FREQUENCY OF OCCURRENCE?

It is estimated that 15% to 18% of school-aged children in the United States have a chronic medical illness or disabling condition, putting the number of children under age 18 with chronic conditions at 12 million (some examples given in Kliewer, 1997; Newacheck & Halfon, 1998).

### CHRONIC MEDICAL CONDITIONS

#### Acquired Immunodeficiency Syndrome

AIDS is a life-threatening condition caused by the human immunodeficiency virus (HIV). HIV affects the body's immune system and interferes with a person's ability to fight off viruses and bacteria that cause disease. This makes the body more susceptible to opportunistic infections, such as pneumonia, meningitis, and certain types of cancers. Worldwide, an estimated 2.5 million children under the age of 15 are living with HIV. Mother-to-child transmission of

HIV has accounted for approximately 91% of AIDS cases reported among children in the United States. Among adolescents, most cases of AIDS are a result of sexual contact with an infected partner or drug use with a contaminated needle. In the United States, it is estimated that two adolescents are infected with HIV each hour. Although there is no cure for AIDS, there are medications that can slow down the HIV virus and reduce the rates of opportunistic infections.

#### Asthma

Asthma is an inflammatory disorder of the airways characterized by difficulty breathing, particularly during an asthma attack. Asthma attacks can vary from mild to life threatening and involve shortness of breath, cough, wheezing, chest pain or tightness, or a combination of these symptoms. Asthma attacks are triggered by allergies, infections like colds or bronchitis, exercise, changes in the weather (from mild to cold), and smoke. Approximately 20 million individuals in the United States have been diagnosed with asthma. Asthma can be a life-threatening disease if not properly managed. Effective medicines such as bronchodilators and anti-inflammatory agents start working within minutes and have few side effects.

#### Cancer

The most common forms of childhood cancers include the leukemias, lymphomas, and those of the central nervous system and brain. It is estimated that 1 in every 330 children will develop cancer before age 19. Although children frequently have a more advanced stage of cancer when they are initially diagnosed and pediatric cancers are the leading cause of death by disease for children in the United States under age 15, many pediatric cancers also respond well to treatment. Recent estimates suggest that the overall 5-year survival rate is almost 75% (National Cancer Institute, 2004). Current treatment regimens are quite intense and often combine a course of surgery, radiation, and chemotherapy.

#### Cerebral Palsy

Cerebral palsy refers to a group of conditions that result when damage to the brain disrupts the brain's ability to control movement and posture. In about 70% of cases, brain damage occurs before birth,

although in a minority of cases it occurs around the time of delivery or in the first months or years of life. The condition affects approximately two to three children per 1,000 over the age of 3 years. Signs of cerebral palsy include difficulty with fine motor tasks, difficulty maintaining balance or walking, and involuntary movements. Some people with cerebral palsy are also affected by other problems that require treatment, including mental retardation, learning disabilities, seizures, and vision, hearing, and speech problems. The symptoms of cerebral palsy range from mild to severe; the disease is not progressive, and most children can significantly improve their abilities with appropriate health care and therapies.

### **Cystic Fibrosis**

Cystic fibrosis is a genetic disease affecting approximately 30,000 children and adults in the United States. The body produces abnormally thick, sticky mucus that clogs the lungs and leads to life-threatening lung infections. These thick secretions also obstruct the pancreas, preventing digestive enzymes from reaching the intestines to help break down and absorb food. People with cystic fibrosis have a variety of symptoms, including salty-tasting skin; persistent coughing, wheezing, or shortness of breath; excessive appetite but poor weight gain; and greasy, bulky stools. Clearing mucus from the lungs is an important part of the daily treatment regimen. The median age of survival for a person with cystic fibrosis is 33.4 years, a significant increase over earlier times.

### **Insulin-Dependent Diabetes Mellitus**

Diabetes is a disease in which the body does not produce or properly use insulin, a hormone needed to convert sugar, starches, and other food into energy. There are two major types of diabetes. Type 1 diabetes, accounting for 5% to 10% of diabetes diagnoses, results from the body's failure to produce insulin. Type 2 diabetes, which accounts for the remaining, results from the body's failure to properly use insulin. Common symptoms of diabetes include frequent urination, excessive thirst, extreme hunger, unusual weight loss, increased fatigue, irritability, and blurry vision. There are 18.2 million people in the United States who have diabetes; unfortunately, nearly one third of these people are unaware that they have the disease. Diabetes management involves

adhering to special dietary and exercise guidelines, as well as receiving insulin daily.

### **Sickle Cell Disease**

Sickle cell disease affects approximately 72,000 people in the United States, mostly those of African descent. An inherited blood disorder affecting red blood cells causes them to become sickle shaped and tend to get stuck in narrow blood vessels, blocking the flow of blood. Complications include pain episodes, strokes, increased infections, leg ulcers, bone damage, yellow eyes or jaundice, lung blockage, kidney damage, blood blockage in the spleen or liver, eye damage, and delayed growth. Sickle cell disease management includes taking folic acid daily to help make new red cells, taking penicillin daily until age 6 to prevent serious infection, drinking plenty of water, avoiding extreme temperatures, and avoiding overexertion and stress.

### **Spina Bifida**

Spina bifida, the most common neural tube defect, affects approximately 1 out of every 1,000 newborns in the United States. Spina bifida results from the failure of the spine to close properly during the first month of pregnancy. Surgery is generally performed on the newborn. In addition to physical limitations, spina bifida can also cause bowel and bladder complications, hydrocephalus (fluid in the brain), and learning disabilities. Taking 400 µg of folic acid every day before and during early pregnancy reduces the risk of spina bifida and other neural tube defects. Most children born with spina bifida live well into adulthood as a result of sophisticated medical techniques.

## **PSYCHOSOCIAL ADJUSTMENT TO CHRONIC ILLNESS**

Research regarding adjustment to chronic illness suggests that children and adolescents with chronically ill conditions are at some risk for psychological problems and psychosocial adjustment difficulties. However, the coping ability and adjustment of a child or adolescent with a chronic illness depends on multiple factors. Risk factors include the degree to which the illness impairs functioning, involvement of the brain, nature of the illness, and type of medical procedures and hospitalization experiences. Risk factors related to the individual include interference with

non-illness-related aspects of life; family functioning; the individual characteristics and internal resources of the child; demographic variables such as age, sex, and social class; and external resources and support systems. Various interventions, including education, cognitive-behavioral strategies, social skills training, remediation and rehabilitation, and family therapy and group work, have been used successfully with children and adolescents with a chronic illness.

## SUMMARY

Recent medical and technological advances have resulted in children and adolescents with chronic medical conditions living significantly longer lives. However, the stress associated with these conditions places individuals at greater risk for psychosocial adjustment difficulties. Health care professionals and parents should recognize the risk factors related to adjustment difficulties and implement appropriate interventions.

—Julie Maikranz and Michael C. Roberts

---

## CHRONOLOGICAL AGE

---

As we traverse the path from birth to death, chronological age (CA) provides a simple and convenient signpost for all that happens along the way. Birthdays have assumed the form of a personal holiday for almost everyone, marked with pleasure in the earlier stages of life, and often with regret and ill humor in the later years as the life span approaches its end point. This CA end point, however, may be considerably lower than

human biological potential. Recent scientific demonstrations of longevity extension in rats through caloric restriction have opened up the future possibility of vastly extended CA limits for humans, raising utopian hopes as well as a host of ethical questions.

Along with sex and race (or ethnicity), CA is a visibly salient attribute of all human beings. This does not imply complete accuracy in identifying individuals on the basis of those attributes. Androgynous-appearing individuals may be difficult to categorize as male or female, and visual cues of race (or ethnicity) are sometimes misleading. In the case of age, it is not the precise CA that is recognizable, but rather the broad age category to which the person belongs (e.g., preadolescent, adolescent, mature youth, middle aged, and elderly). Finer differentiation of such categories almost certainly occurs, with preadolescents divisible into preschool and primary school children, for example, and the elderly readily separable into the young-old and the old-old.

At what point in development do these differentiated age categories emerge? The evidence indicates that preschoolers in the CA range between 3 and 4 years of age link CA to height. This implies that such children would be quite incapable of making age distinctions within the adult range. By age 5, however, almost all children have become sensitized to the physiognomic features associated with aging (e.g., wrinkles and hair color), and their age ranking of photographs of people ranging across the life span closely matches the corresponding ranking of adults. Furthermore, when children have learned to make these CA differentiations, their liking and attractiveness rankings of the photos begin to follow the age rankings, with the more elderly photos found less attractive and least liked. One can discern the beginning of age stereotyping and ageism in these data.

CA is a simple marker for noting the passage of time in a person's life. Yet CA has profound meanings for everyone. These meanings are reflected in the research on age norms—the indication that various important life events are expected to take place within a circumscribed CA range. Events such as formal completion of education, marriage, birth of first child, and retirement elicit relatively narrow CA ranges for being “on time.” The implication is that an event falling outside of the designated acceptable age range is “off time” or deviant, and possibly maladaptive, for the individual concerned.

This idea of CA as a constraint was contested in subsequent research, where it was demonstrated that the effects of being “on time” versus “off time” revealed

few differences. On the basis of such outcomes, Bernice Neugarten (initiator of the tradition of age norm research) advanced the radical proposal that we had become an “age-irrelevant society.” However, more recent replications of the original age norm studies have made it clear that age norms are currently looser (the acceptable CA range for various life events has considerably widened), but there is no indication whatever that age norms have essentially vanished.

Age norms represent but one aspect of the cognition of age. Other aspects include the spontaneous tendency to categorize individuals on the basis of their CA (rather than other attributes of the person) and judgments of the CA onset of the various age stages cited earlier. As research along these lines has proceeded, there has come the realization that age cognitions might well be influenced by gender, both that of the respondent and that of the target person evaluated. The claim that the meaning of CA is moderated by gender was given prominence by the essayist Susan Sontag in an article entitled “The Double Standard of Aging.” Sontag argued that the physical attributes of aging (e.g., wrinkling, graying hair) are positively evaluated as signs of virile maturity in males, but are negatively evaluated as signs of loss of youth and attractiveness in females. These distinctively different evaluations are attributed in part to the mass media subscribing to the values of a patriarchal Western culture. Experimental efforts to test Sontag’s claims with both verbal and photo materials yielded suggestive confirming evidence that CA is a more salient dimension for males than for females when judging others. Furthermore, males exhibit a stronger youth bias, particularly in their affective preferences for females.

Although there is empirical support for a double standard of aging, the interpretation of the phenomenon remains controversial. Arguing against the sociocultural view that the Western media promote the double standard, evolutionary psychologists have examined CA in mate preferences (as well as actual marriage data) in cross-cultural investigations. Comparable effects are observed across Western and non-Western cultures, males preferring females younger than themselves, and females preferring males older than themselves. Interpretation has stressed males’ sensitivity to cues of reproductive value or potential in females (linked to youth) and females’ emphasis on male resources (linked to an older CA). Most dramatic are the CA preferences provided by middle-aged and older males who generally prefer and select mates as much as a generation younger than themselves.

In sum, the implications of chronological age cut across the developmental, sociopsychological, and biological sciences. CA is much more than a simple demographic descriptor.

—Nathan Kogan

## CIRCADIAN RHYTHM

---

Circadian rhythms refer to regular or rhythmic variations in biological and behavioral measures approximately (“circa”) on a 24-hour or daily (“dian”) timing basis. Virtually all biological and behavioral measures taken over time show circadian rhythms. For example, core body temperature normally reaches its highest value in the early evening and lowest value between 4 and 6 a.m.

Our biological circadian rhythms strongly determine our level of alertness and ability to sleep. At our maximum core body temperature, our alertness is greatest. At the minimum body temperature, alertness is diminished and sleepiness is maximum. Night shift workers experience these effects when they have difficulty maintaining alertness on the job at around 4 to 6 a.m., but then have difficulty sleeping during the day. Another example is the difficulty with nighttime sleep and daytime alertness following transmeridian jet travel, known as jet lag.

Our circadian rhythms can drift later or earlier and cause difficulties sleeping at our chosen times. Evening types or “night owls” have difficulty getting to sleep before midnight and difficulty arising early. They will lose sleep if they have to stick to a consistent early wake-up time. Sleep-onset insomnia is associated with late timed circadian rhythms. Morning types or “larks,” in contrast, struggle to stay awake in the evening but then have difficulty maintaining sleep. This can lead to early morning awakening insomnia caused by circadian rhythms timed abnormally early. If the difference between maximum and minimum values in a rhythm (amplitude) is reduced, it can impair daytime functioning and disturb nighttime sleep.

During postnatal development, there is a progressive shift from a 4-hour sleep/wake rhythm toward increasing amplitude circadian rhythms and the consolidation of sleep into the night period. This consolidation is usually well progressed by the age of 6 months and complete by early school years. However, the broken sleep of infants can disrupt parental sleep and be stressful to a family. A common circadian rhythm difficulty in adolescence is a delayed rhythm in which the early evening alert period is delayed, making it difficult to initiate sleep before midnight. Awakening for school at 7 a.m. is doubly difficult due to insufficient sleep and the maximum sleepiness associated with the low body temperature occurring at that time. Attempts to catch up on lost sleep on the weekend by sleeping in late only further delay the circadian rhythms and exacerbate the problem. The middle-aged and older populations more commonly have the opposite problem of early timed circadian rhythms and early morning awakening insomnia. The elderly in nursing homes often have reduced amplitudes of circadian rhythms associated with reduced daytime activity and very disturbed nocturnal sleep.

Circadian rhythms can be retimed and amplitudes enhanced. The best known tool for retiming the rhythms is bright light visual stimulation, particularly light from the blue end of the color spectrum, which can be provided by daylight. In infants and the very elderly, amplitudes of circadian rhythms can be enhanced and timing of rhythms stabilized with increased daylight exposure. The delayed rhythm problems of adolescents can be treated with consistent early morning daylight exposure. The early morning awakening problems in older people can be treated with evening bright light and avoidance of early morning daylight. Where daylight is insufficient in the winter, especially in northern

latitudes, portable light devices have been developed to be of therapeutic benefit.

## CIRCUMCISION

---

Circumcision is the surgical removal of the foreskin from the penis and is practiced by Jews, Muslims, and Coptic Christians. Circumcision was practiced by Egyptians in antiquity and is now prevalent among many African tribes. Among Jews, circumcision is performed on the 8th day after birth and is also required of male proselytes as an integral part of the conversion procedure. If circumcision is delayed for any serious medical consideration, 7 full days must elapse subsequent to the complete recovery of the child before circumcision may be performed.

As recorded in Genesis 17:11, circumcision is a sign of the covenant entered into between God and Abraham. Rabbinic literature is replete with additional suggestions concerning the symbolism represented in the rite of circumcision. Of particular significance is the concept that removal of the foreskin, which constitutes a physical obstruction, is symbolic of the removal of the spiritual barrier which may separate the heart of man from God. An indication of the central role of circumcision in Judaism is the fact that, although letting of blood is generally forbidden on the Sabbath, circumcision

is performed on the 8th day even when it occurs on the Sabbath. It is significant to note that there is no rabbinic source indicating that the purpose of circumcision is avoidance of disease or promotion of health.

In Jewish teaching, circumcision is incumbent not only upon Jews but also upon all descendants of Abraham. Since circumcision is not discussed in the Koran, it is probably that tradition that gave rise to the practice among Muslims. Jewish tradition requires excision of the foreskin and exposure of the corona for all males of Abrahamic descent and, for Jews, removal of the underlying mucus membrane covering the glans as well. Jewish practice also requires that blood flow freely from the wound and employs suction in order to guarantee free flow of blood. For this reason, surgical procedures involving use of a clamp designed to cause necrosis and subsequent sloughing off of the tissue is not sanctioned. Talmudic sources indicate that the requirement for suction of blood is designed to prevent endangerment of the child, that is, the flow of blood cleanses the wound and prevents infection. Some rabbinic authorities permit laser surgery for the circumcision of hemophiliacs.

The attitude of the medical profession toward circumcision has had a checkered history. Circumcision is historically the only example of a prophylactic surgical procedure. Alleged medical benefits include a decrease in the incidence of urinary tract infection and resultant kidney disease, lower susceptibility to sexually transmitted diseases, as well as a lower rate both of cancer of the penis and of cervical cancer in sexual partners. Circumcision among non-Jews in Western countries was uncommon until late in the 19th century, when it became increasingly popular as a health measure. The circumcision rate in the United States reached a height of more than 80% in the post-World War II years. The rate declined subsequent to the finding of the American Academy of Pediatrics in the 1970s that “there is no absolute medical indication for routine circumcision of the newborn.” Strident opposition to circumcision then developed in some circles on the grounds that the procedure constitutes an unwarranted trauma inflicted upon the newborn. In 1989, a task force of that organization found that the procedure did indeed yield some medical benefit. In a 1999 statement, the American Academy of Pediatrics found circumcision to be a significant factor in preventing urinary tract infection but did not find grounds to warrant a recommendation for routine circumcision. Recent studies indicate that circumcised males

may have a diminished risk of contracting syphilis and human immunodeficiency virus infection.

## CLASSICAL CONDITIONING

---

We are constantly making predictions about events that may happen in our environment and actively seeking information with predictive value. Predictability is so important that the signs used to make predictions also acquire affective value in their own right. Classical or Pavlovian conditioning is the mechanism that endows signals with predictive value and transforms them into events with affective significance. Consider the following example involving a change in preference for the ingestion of water. Six-month-old infants consume less water than formula, but this can be altered using a conditioning procedure. In a first stage, a scent is applied to the formula bottle so that the scent becomes a signal for the formula. In technical terms, the scent is called the conditioned stimulus (CS), the formula is called the unconditioned stimulus (US), and the trial is described as a CS-US pairing. In a second stage, the scent CS, now transformed into an appetitive stimulus, is applied to a water bottle and, as a result, infants consume more water than they had consumed before scent-formula pairings. Thus, the scent CS acquired signaling and affective value as a result of classical conditioning. In this example, the scent signals the impending presentation of the formula and also reinforces water consumption.

The distinctive feature of classical conditioning is its response-independent procedure for US administration. Although typically some form of behavior is measured at the time of CS presentation, the occurrence of a response is not required for US delivery. Despite this feature, behavioral changes may still be the result of instrumental learning (i.e., response-US contingency), rather than of the CS-US pairings. This can be clarified by introducing omission contingencies, in which the occurrence of a response cancels the presentation of an appetitive US, itself delivered only when the response does not occur. Unlike instrumental

responses, Pavlovian responses are less modifiable by omission contingencies, occurring reflexively as a result of the predictive and affective value of the CS. For example, approach responses tend to be Pavlovian; thus, in an omission contingency experiment, approach to a CS signaling food or a receptive sexual partner causes the animal to lose the US—yet, these response may occur at relatively high rates.

A proper demonstration of conditioning requires a distinction between the effects of CS-US pairings and the individual effects of the CS and US. The original response to the CS may increase after exposure to the US (sensitization); moreover, the repeated elicitation of a response by the US may cause other stimuli to elicit the same response (pseudoconditioning). Sensitization and pseudoconditioning mimic classical conditioning without being associative phenomena (hence, they are called nonassociative). Controls that eliminate nonassociative effects must be included in demonstrations of classical conditioning. For example, the CS and US may be presented an equal number of times in a control and in an experimental group, but explicitly unpaired from each other in the control group. Most control conditions introduce their own problems. The choice of an appropriate control often depends on the nonassociative effects that need to be eliminated.

Classical conditioning has been implicated in situations involving behavioral changes, changes in the response to drugs, neural-immune interactions, causal judgments, protective reflexes, fear conditioning, the development of attachment in young organisms, and endocrine responses, among others. Although it can be isolated under laboratory conditions, classical conditioning is often embedded into complex contingencies, including instrumental learning and behaviors mediated by language, where it can provide predictive value and regulate the acquired affective significance of stimuli. The elucidation of classical conditioning mechanisms is providing a detailed picture of how the brain acquires, stores, and retrieves information.

## CLUSTER SUICIDE

---

*Cluster suicide* refers to the occurrence of two or more suicides or suicide attempts, or both, that occur closer together in time and geographic space. Of all the different age groups, teenagers are more susceptible to cluster suicide than others, accounting for about 100 to 200 deaths every year in the United States. It has been estimated that about 1% to 5% of all completed suicides among teenagers and young adults occur in clusters. The extent of clustering in suicide attempts however, is difficult to estimate due to the underreporting and misreporting of attempts.

Cluster suicide is more commonly seen among religious cults, prison inmates, marine troops, high school students, college students, and psychiatric inpatients. There are two types of suicide clusters: mass clusters and point clusters. In mass clusters, suicides and suicide attempts follow media portrayal of an actual or fictional suicide or suicide attempt.

Glamorization of death by suicide results in a chain reaction among those who are psychologically vulnerable. Point clusters, on the other hand, occur locally; for example, a suicide of a teenager in the neighborhood triggers a series of attempts or completed suicides by peers. Geographical area is a common denominator in point clusters.

The existence of mass suicide clusters has been documented worldwide following fictional depiction of suicide. There is a general consensus among suicidologists that newspaper and television coverage of suicide has a detrimental effect on suicidal behaviors. There is also evidence of outbreaks of suicidal behavior that occurs in high schools, often reaching epidemic proportions. These point clusters typically occur in institutional settings like schools and psychiatric hospitals, although proximity is not a prerequisite.

Vulnerability to suicide or suicidal behavior increases in the presence of negative life events like the death of a loved one or a traumatic loss. Similarly, having a psychiatric diagnosis, being unemployed, experiencing health crises, and lack of family support are potential risk factors for suicide. A possible explanation for suicide clusters is that humans tend to group together because of similar personal traits and temperamental characteristics. When one member of the cluster becomes suicidal and attempts or commits suicide, it consequently puts the others in the cluster at a higher risk.

Increased risk for cluster suicide among adolescents can be attributed to unintentional glamorization and glorification of suicide by the school system, which makes suicide attractive to vulnerable teenagers. A common environmental stressor sometimes influences clustering of suicide among those who are exposed to it.

It is important to differentiate between imitation suicide or copycat suicide and cluster suicide. In imitation suicide, the phenomenon of contagion impacts those who are in close proximity to the person who commits suicide. For example, studies have documented an increase in both suicide and suicide attempts among adolescents following the suicidal death of a parent. A somewhat rare form of clustering is known as a suicide pact, in which two or more individuals simultaneously plan and commit suicide. Suicide pacts are common among close friends or life partners.

In order to prevent cluster suicides from occurring, it is important to educate parents and teachers in schools and avoid the glorification and media coverage when a suicide occurs in an institution.

Conducting school-based postvention efforts in terms of offering counseling services to students is of vital importance following a campus suicide or suicide attempt. The Centers for Disease Control (CDC) recommends delivering a public response that minimizes glamorization of suicide and glorification of the victims of suicide and conducting timely evaluation and intervention with close friends of the deceased who may be at high risk. Educating family members is also crucial because family support and presence of family strengths mediate the impact of stressors.

## COCAINE

---

Cocaine is a frequently used central nervous system (CNS) stimulant that enhances energy and mood. It is also a dangerous drug of abuse, the subject of much regulatory legislation, and a major target of the “war on drugs.”

## HISTORY

Cocaine is a naturally occurring substance found in the shrub *Erythroxylon coca* that grows in the eastern highlands of the Andes in Bolivia, Peru, Ecuador, and Colombia. Native inhabitants of this region are known to have chewed coca leaves, usually in combination with lime, for at least 5,000 years. In 1551, the Spanish conquistadores condemned this practice as “an evil agent of the devil” but soon discovered that, without the drug, natives could barely work the fields or mine gold (at altitudes of more than 8,000 feet). Thus, crops were cultivated and leaves were distributed to workers three or four times a day in order to ward off hunger and fatigue.

In Western Europe and North America, significant use of cocaine did not emerge until the middle of the 19th century, when the pure alkaloid (cocaine) was isolated. Three men were particularly influential in increasing the popularity of the drug. The first of these, Angelo Mariani, was a French chemist who made and sold many products containing cocaine, including lozenges, tea, and, most notoriously, wine (Vin Mariani).

The second proponent was the “father of modern surgery,” Ward S. Halsted, who administered cocaine to his patients via the newly invented hypodermic syringe to induce local (topical) anesthesia. According to the Controlled Substances Act of 1970, which regulates the supply and distribution of drugs in the United States, this is currently the only legitimate medical use of cocaine.

Finally, Sigmund Freud, another father (of psychoanalysis), advocated the use of small doses of cocaine to combat alcoholism, depression (or, like Sherlock Holmes, boredom), indigestion, and, perhaps most interestingly, to treat the withdrawal symptoms and “cravings” of people who were trying to stop using another addictive drug, morphine. In this respect, Freud resembles contemporary pharmacotherapists who promote the use of methadone, naloxone, or buprenorphine to treat heroin addiction. While such therapies have many benefits (at least in part because they are legal and heroin is not), we are now faced with a new problem—addiction to methadone. Interestingly, heroin was first synthesized (by Bayer, AG) as a potential, nonaddictive opiate, to be used as a substitute for morphine.

By 1885, one pharmaceutical company (Parke, Davis) had marketed 15 different products containing

cocaine. These included cigarettes, cigars, and inhalants. One year later, a Georgia pharmacist, John Pemberton, invented a new beverage, *Coca-Cola*, that, from 1886 until 1906, contained both cocaine and another, less potent CNS stimulant, caffeine. Shortly thereafter, cocaine use spread across the United States to such an extent that, in 1910, President Taft declared the drug to be “public enemy number one.” In 1914, the Harrison Narcotic Act prohibited the inclusion of cocaine (as well as opium) in patent medicines.

The use of cocaine, which was relatively stable from the 1920s to the 1960s (with relatively benign effects), increased dramatically during the 1970s and 1980s (to more than 10 million individuals in 1984) despite additional efforts by the U.S. government to limit its use. Moreover, this increase was accompanied by reports of dependence liability and toxicity. One reason for these developments, although certainly not the only one, is related to the way in which cocaine is administered. South American Indians chewed coca leaves, which contain small amounts of cocaine in a form that is absorbed relatively slowly from the gastrointestinal tract into the bloodstream (and brain). In contemporary North America, however, cocaine is usually self-administered in more concentrated form, either intravenously or, most recently, by smoking “crack.” Each of these routes produces more rapid effects, including psychological and possibly physiological dependence.

## PHARMACOLOGY

Coca leaves typically contain between 0.5% and 2% cocaine. To extract the pure drug, the leaves are soaked and mashed to form a paste, which, after the solvent evaporates, contains 60% to 80% cocaine. The paste is converted to a water-soluble salt, cocaine hydrochloride, which is a pink to off-white powder that can be taken orally, intranasally (“snorting”), or by intravenous injection and is the form that is now exported around the world. While the salt is vulnerable to pyrolysis (heat-induced breakdown), which prevents it from being smoked, the drug can be transformed back into its free base form (“crack” or “rock”) by dissolving it in baking soda and water.

Different routes of administration produce different patterns and levels of cocaine concentration in the blood. Extremely rapid absorption occurs with both intravenous injection and smoking; absorption is slower following oral administration or snorting. Once

in the body, cocaine is widely distributed and metabolized rapidly into two substances, ecgonine methyl ester and benzoylecgonine, both of which are excreted in the urine. However, because the acute effects of cocaine have a rapid onset and relatively brief duration, detection of measurable amounts of either cocaine or its metabolites (and, thus of cocaine use) is difficult.

The local anesthetic properties of cocaine (above) are the result of the drug's ability to block the conduction of nerve impulses within neurons by preventing the influx of sodium ( $\text{Na}^+$ ) ions, which are necessary for the generation of action potentials (neuronal firing). However, the mechanism that underlies most other effects of cocaine, including its stimulant and addictive properties, involves the enhancement of the actions of neurotransmitters (intercellular messengers), such as dopamine (DA), norepinephrine (NE), and serotonin (5-HT), by blocking their cellular reuptake by plasma membrane transport proteins. The mesocorticolimbic or limbic-extrapyramidal DA system appears to play a particularly important role in the acute, CNS effects of cocaine and other reinforcing drugs. The neurons of this system arise from cell bodies in the ventral tegmental area (VTA) of the midbrain and innervate the nucleus accumbens (NAc), ventral caudate-putamen, and the prefrontal cortex (PFC). Other neuronal systems, including those involving both excitatory (glutamate) and inhibitory ( $\gamma$ -amino butyric acid, GABA) amino acid neurotransmitters, might be involved in some of the chronic behavioral effects of the drug, including cocaine "craving."

## BEHAVIORAL EFFECTS

The effects of cocaine are similar but not identical to those of other stimulants such as *d*-amphetamine and methamphetamine ("speed"). In humans, they include mood amplification (both euphoria and dysphoria), heightened energy, sleep disturbances, insomnia, motor excitation, restlessness, talkativeness, hyperactive ideation, increased sexual interest, anger, verbal aggressiveness, mild to moderate anorexia (loss of appetite), and inflated self-esteem. When administered intravenously or smoked, the drug can also produce a "rush" that is sometimes described as being even more intense than an orgasm. Cocaine also has a variety of physiological (sympathomimetic) effects, including increasing heart rate, blood pressure, locomotor activation, and, at higher doses, stereotyped behavior.

Humans and other animals (rats, pigeons, monkeys) can be taught to discriminate between the effects of cocaine (the cocaine state) and the absence of these effects (or the presence of other drug states). These effects generalize readily to other stimulants such as *d*-amphetamine, methamphetamine, and methylphenidate (Ritalin), suggesting that these compounds have similar mechanisms of action.

When humans or other animals are given the opportunity to self-administer cocaine either intravenously or through surgically implanted cannulae directly into regions of the brain such as the VTA, NAc, or PFC, even naïve (nondependent) subjects do so quite readily. This suggests that cocaine is reinforcing and therefore has a high potential for abuse. Unlimited access to the drug may lead to compulsive use accompanied by weight loss, convulsions, and even death.

## COCAINE ABUSE

While cocaine use seems to have "leveled" off in the 1990s and continues to this day at an estimated 1.5 million individuals in the United States, reports of cocaine dependency (addiction) and toxicity continue to increase. In addition, many cocaine users and former users have turned to even more potent and more toxic substances, including methamphetamine ("ice"), mixtures of amphetamines and heroin, and methylphenidate (Ritalin).

As mentioned previously, cocaine users feel an initial "rush" or sense of well-being, of having more energy, and being more alert. However, this effect quickly wears off, leaving the user feeling more "down" or depressed than before he or she took the drug. This feeling leads to more cocaine use, sometimes just to feel "normal." Over a period of time, both the amount of cocaine needed and the frequency of use have to be increased to maintain the "high" (tolerance). When more cocaine is not available, users frequently turn to other drugs such as alcohol; such combinations or synergisms (e.g., alcohol and cocaine) can be more deadly than either drug alone.

Despite a popular myth, cocaine does not enhance performance on the job, in sports, at school, or with a sexual partner. Long-term use can lead to loss of concentration, irritability, loss of memory, paranoia (cocaine psychosis), loss of energy, anxiety, and a loss of interest in sex. Breaking a cocaine habit, which can cost an addict thousands of dollars a week, is not easy. How long and how difficult a task it may be varies from

person to person. Treatment can be costly, and the craving for cocaine may persist for long periods of time.

An alarming statistic that was first reported during the late 1980s and early 1990s was that at least 10% to 15% of infants born in public hospitals had been exposed to cocaine prenatally. While the effects of such exposure are controversial and may have been overestimated by both the press and the scientific community, cocaine-exposed neonates are frequently smaller and have smaller brains than normal babies, perhaps because they are more often born prematurely. The long-term consequences of exposure to cocaine in utero have not yet been fully determined.

## COCHLEAR IMPLANT

---

Hearing impairment is a common disorder, affecting many children and adults. Its severity varies widely among individuals. Mild loss of hearing sensitivity can almost always be treated effectively by

acoustic hearing aids. These devices electronically amplify weak sounds to enable people with hearing loss to hear most sounds comfortably. However, sometimes the degree of impairment in both ears is so severe that no amount of amplification can restore adequate hearing sensitivity. At present, the cochlear implant is the only effective form of treatment when profound hearing impairment results from extensive loss or dysfunction of hair cells. Located in the inner ear (or cochlea), hair cells convert the mechanical vibrations of sound waves into electrical impulses, which travel along specialized nerve fibers to the brain, where hearing sensations are perceived. They are susceptible to permanent damage from various causes, such as infections, exposure to excessive levels of noise, and physical trauma.

Many types of cochlear implant have been developed and evaluated. All are based on the same functional principle: to replace the role of the hair cells by delivering electric stimuli directly to the auditory nerve fibers. The stimuli are small electric currents conducted through electrodes that are placed inside the cochlea during a surgical operation. Most commonly, the stimuli comprise brief pulses of current that produce nerve impulses similar to those resulting from hair cell activity in acoustic hearing.

In a normal cochlea, there are many thousands of hair cells and nerve fibers. Researchers have found that the structures of the cochlea are organized in a regular pattern, such that some nerve fibers respond best to sounds having high frequencies (or high pitch), whereas others are more responsive to lower frequency sounds. Therefore, modern cochlear implants have an array of multiple electrodes that are positioned to elicit hearing sensations that vary in pitch.

In addition to the electrode array, a miniature electronic device is surgically placed under the skin near the implanted ear. This device receives instructions transmitted from an external sound processor that controls how much current should be delivered by each electrode over time to evoke the intended sensations of hearing. Generally, the perceived loudness depends on the current level and the pitch depends on the location of the active electrode, as well as the rate at which the current pulses are presented.

The sound processor is usually worn on the external ear and has a similar appearance to a conventional hearing aid. Its transmitter is magnetically coupled to the implanted receiver so that information is conveyed across the intact skin. The implant also receives

electrical power via this coupling. Thus, the batteries required by the system are located in the external processor, where they may be replaced easily.

The processor picks up sound with a microphone that converts acoustic waves into electric signals. These signals are continuously analyzed by dividing them into separate frequency bands. Typically, the number of bands equals the number of implanted electrodes. The level in each frequency band controls the current level of the pulses delivered by the associated electrode. By this means, the frequency components comprising a complex sound are transformed into a corresponding pattern of electric nerve stimulation. Consequently, the cochlear implant user experiences hearing sensations that have variations of pitch and loudness related appropriately to the original sound.

The performance of cochlear implants has improved steadily since the earliest practical devices were developed in the 1970s. Much of the improvement is a product of progress in sound processor design. With the latest devices, most implant recipients can understand speech and recognize many other sounds, at least in favorable listening conditions. However, performance is poorer in situations with high levels of background noise, and perception of music is often unsatisfactory. Future advances will enable cochlear implants to provide better hearing of all types of sounds to people who obtain insufficient benefit from acoustic hearing aids.

## COGNITIVE DEVELOPMENT

---

“New ideas come into this world somewhat like falling meteors, with a flash and an explosion and

**Table 1** Piaget’s Stages of Cognitive Development

Stage 1.	Sensorimotor period (0–2 years)
Stage 2.	Preoperational period (2–7 years)
Stage 3.	Concrete operations period (7–11 years)
Stage 4.	Formal operations period (11–15 years)

perhaps somebody’s castle like roof perforated.” This quotation by Henry David Thoreau aptly captures the burst of insight that occurs when an infant discovers the link between their internal and external worlds; when a preschool child suddenly masters the notion of symbols; when the school-aged child and adolescent approach problem solving with logic and flexibility; and when the adult supplants reasoning with wisdom. In essence, the quote captures the gist of cognitive development.

For definitional purposes, cognitive development is the process of reasoning, thinking, and problem solving, which changes over the course of the life span.

The first section of this entry begins with a discussion of infant cognition, the second section continues with a focus on preschool cognitive development, the third section covers cognitive development in middle childhood and adolescence, the fourth section discusses adult thinking, and the entry concludes with the fifth section on contemporary issues in cognitive development and directions for the cognitive development in the 21st century.

The theoretical perspective responsible for shaping much of 20th-century discourse, thinking, and scholarship on cognitive development is that of the late Swiss scholar Jean Piaget. As a genetic epistemologist, he was keenly interested in understanding the origins of knowledge. He posited such questions as how does knowledge evolve? And where does knowledge come from? He viewed the acquisition of cognitive development as an active process, where the infant, child, and adolescent organize their experiences with their environment, adapt to their environment, and try to maintain a sense of balance with old and new knowledge. He believed that cognitive development occurred in discrete albeit connected stages encompassing the first 15 years of life. These stages were universal, invariant, and qualitatively different.

Piaget’s theory serves as the framework for much of the discussion on cognitive development in this entry. Table 1 provides an overview of his stages of cognitive development.

## COGNITIVE DEVELOPMENT DURING INFANCY

How do infants come to know their worlds? What rudimentary capabilities are present in infancy? Without the contribution of Jean Piaget, our knowledge of infant cognition would be limited to the behaviorist perspective, which asserts that learning or cognitive development occurs in a stimulus-response mode.

How then does cognitive development progress in infancy? According to the Piagetian perspective, infants “come to know” their world primarily through their senses and motor abilities. These rudimentary motor and sensory abilities lay the foundation for the more complex cognitive skills that will emerge during the latter half of the sensorimotor period and lay the foundation for the cognitive skills that will emerge during the subsequent stages of cognitive development.

This progression of infant cognitive development occurs through six substages of the child’s first stage of cognitive development, referred to as the Sensorimotor Period. Table 2 provides an outline of the substages.

In substage 1 of the sensorimotor period, infants learn about their world through the use of their reflexes. Hence, the infant engages in the world, through sucking, reaching, and grasping. Eventually the use of these reflexes becomes more deliberate and purposeful as the infant progresses to substage 2 of the sensorimotor period. During these 3 months, the infant begins to actively involve his or her own body in some form of repeated activity. Thus the behavior is circular and primary because it centers on the infant’s own body. It is not until substage 3, secondary circular reactions, that the infant begins to engage with objects in the environment. Initially, the contact with external objects (e.g., a crib mobile) is accidental, then with some planning and purpose subsequent contacts are deliberate. These contacts with the external objects become a repeated activity.

In due course, the infant will be able to combine these basic reflexes and use planning and coordination to achieve a particular goal, which is substage 4. For example, an infant sees a red ball under a chair in the living room. The infant crawls, reaches, and grasps the ball, thus coordinating both internal and external activities to achieve a planned goal.

In substage 5, the infant, now considered the “little scientist” begins an active exploration of its world, with a trial-and-error approach. Combining more mature motor behavior with increased planning and

**Table 2** Substages of the Sensorimotor Period

Substage 1.	Reflexes (0–1 month)
Substage 2.	Primary circular reactions (1–4 months)
Substage 3.	Secondary circular reactions (4–8 months)
Substage 4.	Coordination of secondary circular reactions (8–12 months)
Substage 5.	Tertiary circular reactions (12–18 months)
Substage 6.	Beginning of representational thought (18–24 months)

reasoning capabilities, the external world becomes the infant’s laboratory.

The sensorimotor period culminates with substage 6 and the emergence of symbolic or representational thought. The toddler now has a basic understanding that objects can be used as symbols for other objects (e.g., a pillow can be used to represent a doll in play).

A critical attainment during the sensorimotor period is object permanence. Object permanence is the understanding that objects in our environment have a continued existence even though they may no longer be perceptually available. Piaget felt that infants did not fully master this ability until the substage 5 of the sensorimotor period.

There are other cognitive capabilities that begin to emerge during the first 2 years of life. Language is perhaps one of the greatest cognitive achievements.

Table 3 provides a brief summary of language acquisition during the first 4 years of life.

## COGNITIVE DEVELOPMENT DURING THE PRESCHOOL YEARS

The preschool child has now entered Piaget’s second stage of cognitive development, the preoperational period. This period heralds a new perception and understanding of the world, brought on by the attainments of the sensorimotor period.

One major attainment, the ability to engage in symbolic thought, allows the preschooler to participate in a variety of activities. These activities include understanding pictorial representations, engaging in pretend play, and mastering basic numeracy principles.

Understanding pictorial representations (i.e., knowledge that pictures are symbols of real objects) not only reflects the preschooler’s evolving cognitive skills, but also permits the preschooler to engage in varying levels of sophisticated social interaction.

As an example, a child is looking through the family photo album with a parent and turns to a page with a picture of a grandparent; the child labels the person in the picture as grandpa. Thus, the preschool child has established that he is aware that the photograph represents a real person. Given their increasing vocabulary, and their developing pictorial representational ability, preschool children are now able to engage in a variety of learning interactions and activities with their parents.

When children engage in the various forms of pretend play, they are demonstrating their understanding of the multiple, flexible, and complex uses of symbols. For example, a child uses a block to represent a telephone, the child then speaks into the block and carries on a conversation (with another person); the child then hands the block to a playmate and persuades the playmate to engage in conversation with the block. Furthermore, there are elements of creativity present, as well as some rudimentary understanding of the social aspects of pretend play.

Even with the impressive achievement of symbolic thought, Piaget believed that preoperational children experienced some challenges in their thinking and reasoning capabilities, especially regarding issues of quantity. To assess this, Piaget administered his classic conservation of numbers task to the preschool children. The task involved presenting the children with two rows of pennies; one row was then spread out, and the children were asked if the rows contained the same number of pennies. The preschool children frequently stated that the longer row contained more pennies. Thus, Piaget concluded that the preschool children were unable to conserve quantity, and that their performance was due to their inability to focus on relevant aspects of the task (concentration), their inability to mentally reverse the operation (irreversibility), and their inability to understand the difference between transformations and static states. Piaget stated that in order for the preschool children to conserve numbers, they must understand that the two rows are still numerically equivalent despite the differences in the appearance of the rows.

Research by Rochelle Gelman has indicated that preschool children comprehend a great deal about numbers. She observed that preschool children possess two basic concepts about numeracy: number abstraction principles and numerical reasoning abilities. Number abstraction principles include an awareness of rules for counting, knowledge of number labels, and strategies for counting. Numerical reasoning

**Table 3** Milestones in Language Development

<i>Age</i>	<i>Behavior</i>
1–4 months	Coos, makes vowel-like sounds
6 months	Coos, babbling of consonants and vowels
8–10 months	Babbling of two-syllable utterances, understands some words
12–18 months	Imitates sounds, understands simple commands; two-word utterances
24–30 months	Speaks 50 words or more; learning new words
36–48 months	Has a vocabulary of 1,000 words; language is well established

abilities involve rudimentary knowledge of the rules for adding and subtracting quantity.

Memory and language skills and abilities show vast improvement during the preschool period. For example, preschool children have well-developed memories for everyday events that happen in their lives and can articulate those experiences (e.g., what happens when you go to McDonald's?). Language becomes less egocentric, and they are able to engage in various forms of social discourse. Vocabulary development continues, and individual differences in vocabulary and overall language competence emerge during this time period.

## COGNITIVE DEVELOPMENT DURING MIDDLE CHILDHOOD AND ADOLESCENCE

The child in middle childhood has now entered Piaget's third stage of cognitive development, the concrete operations period. Unlike the preschool child, the concrete operations child has now acquired what Piaget referred to as mental operations. Mental operations are the ability to use logic when solving problems. This is evident in such Piagetian tasks as the conservation tasks. Thus, the major hallmark of this period is the ability to conserve not only quantity but other domains as well (e.g., liquid, mass).

The classic conservation tasks described in the previous section discussed the challenges that preschool children encounter with such an activity. Children in middle childhood possess the ability to decenter, to

comprehend transformations, and to engage in reversibility of thought.

In addition to these attainments, children in middle childhood are also able to engage in a variety of classification and categorization activities. That is, they can appreciate that objects and items belong to several categories. For example, preschool children and children in middle childhood are presented with the following classification problem. They are presented with a group of animals consisting of two collies, three great danes, five poodles, and six German shepherds. The children are asked the question, "Are there more German shepherds than dogs?" Preschool children would state there are more German shepherds. On the other hand, children in the concrete operations period would state that there are more dogs than German shepherds, because they are able to understand that shepherds belong to both a general category (dogs) and a subcategory (specific type of dog). This attainment as well as the others discussed below might well account for the interest that many school-aged children have in collecting objects (e.g., bugs) and classifying their classmates (e.g., ranking by looks, niceness).

Concrete operations children are also able to engage in the seriation of objects, which involves sequencing or ordering items according to such dimensions as height, color, size, or shape.

Language and memory abilities also improve during this time period. Vocabulary continues to build, and memory becomes a vehicle for learning. Their metacognitive skills, or their understanding of their memory and learning competencies, improve. Consequently, they are able to use their metacognitive knowledge to improve their learning of academic material.

The adolescent has entered Piaget's final stage of cognitive development, the formal operations period. The hallmark of this period is the ability to think abstractly. In contrast to the concrete operations child, the formal operations adolescent is able to use logic to solve problems, and these problems can be abstract rather than concrete in nature.

Also in contrast to the child in the concrete operations period, the formal operations adolescent can reason about such issues as spirituality, politics, and abortion. In addition to the ability to think abstractly, the formal operations adolescent can engage in what Piaget referred to as hypothetico-deductive reasoning. Hypothetico-deductive reasoning is the ability to generate hypotheses and systematically test each hypothesis.

As an example, a formal operations adolescent wishes to obtain the family car, (e.g., I want to use the car tonight); he generates several hypotheses (e.g., I could ask mom, or I could ask dad); then he can mentally test the hypothesis (e.g., Now if I ask mom she might say no, so dad may be the more reasonable one to ask).

Formal operations adolescents can also envision and speculate about the future, and they can reflect on their own thinking. Thus, programs that encourage discussion of future plans and goals and decision making are often effective in facilitating the cognitive development of adolescents.

Language and memory skills show a dramatic improvement over the language and memory skills observed during the middle childhood period.

## COGNITIVE DEVELOPMENT DURING ADULTHOOD

The formal operations period concludes Piaget's focus on cognitive development. While he acknowledged that cognitive growth and development continue throughout the life span, he felt that adult experiences were too diverse to capture characteristics that would encompass the universality of the experiences of all adults. Nevertheless, his conceptualization of cognitive development has influenced many theoretical perspectives on cognitive development in adulthood.

There is consensus from investigators who study cognitive development in adulthood that adults conceptualize problems differently from adolescents and shift from relying solely on logic to combining logic and "common sense" when reasoning about issues. Furthermore, there is acknowledgement by these researchers that the issues that adults are confronted with differ significantly from the more scientific and academic issues that adolescents have to deal with.

However, there is a great deal of variation in how researchers define adult cognitive development and a great deal of variation in the way in which they frame research questions about adult cognitive development. As a result, the focus on cognitive development in adulthood is multifaceted.

There are researchers who have put forth the idea that the Piagetian stages of cognitive development should be expanded to encompass adulthood. They have introduced the term *post-formal reasoning*. These scholars maintain that both the issues and patterns of reasoning in adulthood are qualitatively different from those of adolescence.

Post-formal reasoning could be classified into the following categories.

1. *Relativistic*: These adults reason with the acknowledgement that the “truth” is relative and that the implication of a situation is related to contextual issues.

2. *Dialectical*: These adults reason with the acknowledgement that the world is a dynamic and changing entity and that the interpretation of a situation should be considered in light of an unstable world.

3. *Problem Finding*: These adults reason with the goal of finding solutions to life’s problems. There are many variants on the characteristics of post-formal reasoning, but this conceptualization captures the common assumptions among those who investigate post-formal reasoning in adults.

In contrast, there are researchers who have operationalized cognitive development as intelligence and investigated which aspects of intelligence remain the same from young adulthood to late adulthood and which aspects change over the life span.

The Cattell-Horn theory of crystallized and fluid abilities is a frequently cited example in the literature on aging and intellectual changes. According to these researchers, intellectual abilities can be classified into two general categories: crystallized and fluid abilities. Crystallized abilities are those abilities that are assessed by vocabulary and creativity subtests of IQ measures, and fluid abilities are those abilities that are assessed by timed reasoning, problem-solving, and math subtests of IQ measures. According to the theory, crystallized abilities increase or remain the same from young adulthood to late adulthood, whereas fluid abilities have been shown to decrease from young adulthood to late adulthood. Recently there has been some debate about whether fluid abilities do in fact decrease. A study conducted in the 1980s found that older adults could be trained to improve their performance on measures of fluid ability. Other research has demonstrated that noncognitive factors may contribute to the observed decline in fluid abilities rather than age per se.

Finally, there are researchers who have examined memory and explored how memory changes from young adulthood to late adulthood. Three aspects of memory have been explored by researchers in the psychological literature. These include episodic memory, which is a person’s memory for personal events (e.g., what was your 5th birthday party like?); semantic memory, a person’s memory for world information

(e.g., what is the capital of France, meanings of words); and cognitive resources (e.g., short-term memory) and noncognitive factors (e.g., health).

Based on findings from the literature, age comparisons suggest that younger people for the most part have better episodic memories than do older adults. On the other hand, there are few age differences in semantic memory, with the exception that younger adults are faster in retrieving semantic information than are older people. There is some evidence to suggest that working memory declines in late adulthood. That is, older adults experience some challenges in retrieving information from working memory. Lastly, such noncognitive factors as health (older people in poor health experience problems with memory) influence the memory performance of older adults.

The general agreement is that there is a great deal of individual variation in adulthood cognitive development. If declines are present, age is sometimes not the sole contributing factor. There is some truth to the saying “Use it or lose it!!”

## CONTEMPORARY ISSUES IN COGNITIVE DEVELOPMENT ACROSS THE LIFE SPAN

During the latter half of the 20th century, cognitive developmental psychologists turned their attention to investigating the following issues and questions.

What is the relationship between brain development and cognitive development? On the one hand, the specific focus has been to identify how brain changes (e.g., structure, function) influence language and other cognitive capabilities. On the other hand, researchers are beginning to explore and specify the brain changes that contribute to intellectual decline in old age. During the 21st century this area has been a hot topic for researchers in cognitive development.

In addition to the focus on brain changes and cognitive development, researchers are continuing to explore the role of social influences on cognitive development. The works of the late Russian theorist Lev Semonovich Vygotsky have contributed to this interest. Researchers are particularly concerned with investigating how social and cultural influences shape cognitive development early in life and how social and cultural influences have a continued effect on cognitive development throughout the life span.

Theory of the mind reemerged in the latter half of the 20th century and the beginning of the 21st century as a topic of interest for cognitive developmentalists.

Such questions as how do children understand the intentions of others and how do children develop an understanding of the critical aspects of human thinking and behavior have occupied a central focus in the area of social cognition in the past decade.

Finally, the area of eyewitness testimony continues to have a prominent place in the field of cognitive development in the 21st century. Researchers are exploring ways to reduce the influence of interviewer suggestibility on eyewitness testimony and to increase the accuracy of eyewitness testimony of both adults and young children.

## COGNITIVE DISSONANCE

---

Cognitive dissonance refers to the psychological discomfort that people experience when there is

inconsistency between their knowledge or beliefs and their behavior. Dissonance is distressing because humans strive to be consistent within themselves. A major category of cognitive dissonance is known as postdecision dissonance. This refers to the distress that occurs after one makes a decision.

Whenever individuals decide between a set of desirable alternatives, their decision will result in dissonance. For example, imagine that a person is considering job offers from company A and company B. Both positions have several positive features that make each of them uniquely appealing. After much consideration, the person selects job A but then immediately begins to wonder if it was the correct decision. This postdecision dissonance occurs because the person knew that job B had many attractive features and yet did not choose it; therefore, the decision is inconsistent with some of the person's beliefs about the characteristics of an ideal job.

Different decisions are associated with varying levels of dissonance. How strongly the postdecision dissonance is felt depends on the importance of the decision, the attractiveness of each decision option, and the amount of similarity between the alternatives. Decisions of higher importance result in stronger dissonance. Therefore, a decision about which home to buy will result in greater dissonance than deciding what to eat for dinner.

Likewise, the more attractive an unchosen alternative is, the stronger the dissonance will be. Returning to the example of job offers, as the number of positive qualities of job B increase, so does the number of factors that are inconsistent with a decision to reject the job. The magnitude of the dissonance is decreased because there is more overlap between the different choices. Dissonance is caused by inconsistency, and because similar alternatives are highly consistent with each other, they will result in less dissonance.

The presence of dissonance results in a motivation to reduce it. There are three ways that postdecision dissonance can be alleviated. First, one can change or revoke the decision. Changing the decision may provide brief relief but will ultimately result in dissonance again because one is simply switching the elements that are consistent and inconsistent. Psychologically revoking the decision can be an effective means of reducing dissonance. One way this is achieved is by admitting that one made the wrong decision. Another tactic is to convince oneself that it was not a free decision. By believing that the decision was applied from the outside

instead of through personal choice, the person has not engaged in any inconsistent behavior. A second way to reduce postdecision dissonance is to change one's cognition about the alternatives. This can be achieved by adding to the consistent characteristics of the chosen alternative or by adding to the inconsistent characteristics of the alternative that was not chosen. One could also focus on reducing the inconsistent characteristics of the chosen alternative or reducing the consistent characteristics of the unchosen alternative. Finally, cognitive dissonance can be reduced by creating cognitive overlap between the alternatives. By picking aspects of each alternative and applying them so that they will lead to the same result, one can eliminate the inconsistency.

Cognitive dissonance is an unavoidable side effect of decision making. Depending on the characteristics of the alternatives, the strength of the dissonance will vary. Because the experience of cognitive dissonance is unpleasant, individuals will try to reduce the dissonance by changing their thoughts about the possible choices. This is done by increasing the attractiveness of their selection, decreasing the attractiveness of the other alternatives, creating overlap between the alternatives, or psychologically revoking the decision.

## COGNITIVE EQUILIBRIUM

---

Cognitive equilibrium refers to a state of balance between an individual's mental schemata, or frameworks, and his or her environment. Such balance occurs when our expectations, based on prior knowledge, fit with new knowledge. Swiss psychologist Jean Piaget (1896–1980) developed the concept of equilibrium to describe one of four critical factors in cognitive development, along with maturation, physical environment, and social interaction. Piaget described equilibration as an ongoing process intended to refine and

transform mental structures, which is the basis of cognitive development. More equilibration action tends to occur as an individual is transitioning from one major developmental stage to the next.

Equilibration also explains individuals' motivation for development. Individuals naturally seek equilibrium because disequilibrium, which is a mismatch between one's way of thinking and one's environment, is inherently dissatisfying. When individuals encounter new, discrepant information, they enter into a state of disequilibrium. In order to return to a state of equilibrium, individuals can ignore the information or attempt to manage it. One option for managing discrepant information is called assimilation, and the other option is called accommodation.

Assimilation is the process of modifying discrepant information so that it matches current schemata. For example, a child visiting a petting zoo may encounter a pony for the first time. The child recognizes some of the features of the animal, so the "dog" schema is activated and the child says, "Dog!" As a second example, a student who knows that the area of a rectangle can be calculated by multiplying the length by the width may attempt to calculate the area of a triangle by multiplying two sides together. In each example, individuals' assimilations lead to error; however, errors do not always follow assimilations. If the child said, "Dog!" upon seeing a poodle for the first time, or if the student applied the formula for the area of a rectangle in order to calculate the area of a parallelogram, they would be assimilating the new information without error. Erroneous or not, assimilation does not produce cognitive change (which Piaget considers the source of development) because the schemata are unchanged.

Cognitive change, and thus cognitive development, can only be achieved through accommodation. Accommodation is the process of modifying current schemata so that it matches discrepant information. For instance, in the previous example of the child at the petting zoo, the child's caretaker might have said, "No, that's not a dog; that's a pony." In this case, the child's old schema did not work so the child must reevaluate the "dog" schema. To do so, the child must determine whether the "dog" and "pony" schemata might both fall under a larger "four-legged animal" schema, whether they can both exist separately from each other, and which characteristics differentiate two animals. The child's slightly modified "four-legged animal" schema is now less vulnerable to disequilibrium due to discrepant information and is therefore more stable.

While cognitive equilibration is an ongoing process that utilizes the dual processes of assimilation and accommodation, there are certain instances when one of the equilibration processes is more likely to occur than the other. Accommodation is more likely to occur when new information only slightly diverges from current schemata and when an individual is transitioning from one developmental stage to the next. Assimilation is more likely to occur when new information is vastly divergent from current schemata and as a precursor to accommodation. When new information matches existing schemata exactly, the individual remains in a state of equilibrium. It is this state of equilibrium that creates the basis for the disequilibrium and accommodation that propels individuals to subsequent developmental stages and higher levels of adaptability.

—Anne S. Beauchamp

## COGNITIVE STYLE

---

Predicting school achievement as well as traditional psychometric measurements of intellectual abilities, cognitive styles are not abilities themselves but rather preferred ways of applying the abilities one has. Typically, *cognitive styles* refers to the manner in which individuals receive, process, and apply information. Unlike individual differences in abilities that often are arranged by descriptions of peak performance, styles describe a person's typical mode of thinking, remembering, and problem solving. Furthermore, styles are theorized as bipolar dimensions, whereas abilities are unipolar (ranging from zero to a maximum value). Having more of a particular ability is usually considered beneficial, while having a particular cognitive style simply designates a tendency for one to behave in a certain manner. Cognitive style

is usually described as a personality dimension that influences attitudes, values, and social interaction. Cognitive styles dominate the preferences for how people process information, and while many paradigms have been hypothesized, two basic dimensions appear most readily in the research literature: holistic/analytic and verbal/imagery. The former encompasses a tendency to organize and rearrange information into categorical segments of "wholes" and "parts." The latter embraces a tendency to represent information verbally and/or through mental images. Cognitive style is an independent construct or psychological schema that is not apparently related to intelligence, personality, and gender. As such, it is an important component of individual differences and has profound implications for accommodations in educational and workplace arenas. It is related to a range of behaviors, including learning performance, social responses, and occupational stress. Cognitive style appears to be fairly fixed, with a probable physiologic basis and, as such, is distinct from learning strategies that can be taught and acquired through instruction. A collection of cognitive styles has been isolated and examined over the past few decades, starting with the cognitive styles movement in the 1950s and 1960s. Among the most well-known cognitive styles are those related to handling one's environment: field independence versus field dependence. This bipolar cognitive style refers to a tendency to approach the environment in either an analytical or a global fashion. At a perceptual level, field-independent personalities are able to distinguish figures as discrete from their backgrounds compared with field-dependent individuals, who experience events in an undifferentiated way. Field-dependent individuals have a greater social orientation relative to field-independent personalities. Several studies have identified a number of connections between this cognitive style and learning. For example, field-independent individuals are likely to learn more effectively under conditions of intrinsic motivation (e.g., self-study) and are influenced less by social reinforcement. Another well-known cognitive style related to the way people tend to approach and handle tasks is that of impulsivity versus reflectivity. An impulsive student works fairly quickly but makes many mistakes. In contrast, a reflective student works much more slowly but with much greater accuracy. Similar to the field independence–field dependence cognitive style, impulsive and reflective cognitive styles are not substantially related to intelligence

within the normal range. Some studies of the impulsivity-reflectivity cognitive style found that this style is stable over time and tasks, whereas other studies found that, as children progress through school, they generally become more reflective, and as a result, their academic performance may improve. Several other cognitive styles have been proposed, which are only listed here: equivalence range, category width, compartmentalization, conceptual integration, tolerance for unrealistic experiences, and scanning. It is generally agreed that accepting the concept of cognitive style has implications for how we view the teaching and learning process. With the dramatic changes in the means of communication (e.g., an increasing and widespread use of electronic media), educators need to adjust the means of providing service to students. These adjustments need to take into account students' preferred cognitive styles to maximize and optimize learning for all students.

## COHABITATION

---

The trends in romantic relationships have been changing dramatically over the past few decades in the United States. Divorce rates increased steadily over the past 40 years and are finally leveling off at just less than 50%; marriage rates have similarly declined, with

the average age of first marriage increasing; and the number of cohabiting couples has increased sharply. Census data from 2000 indicated that 5.5 million households (4.9 million different-sex couples and 0.6 million same-sex couples) identify themselves as unmarried relationship partners living together, representing more than 5% of all households in the United States. Although this arrangement may seem to represent a small proportion of households in the United States, the number of cohabiting couples has increased 1,000% since 1960 (while the general population increased by around 60%). More than 40% of women have lived with a romantic partner without marriage at some point in their lives, and the majority of married couples today lived together before marriage.

### WHO COHABITS?

Cohabiting couples tend to be younger, more likely to be employed, and more racially diverse than married couples living together. Relationships between partners of a different race are uncommon for both unmarried and married partners living together, but this arrangement represents about twice as many cohabiting households as married households. People who enter cohabiting relationships are more likely to be in college, have divorced parents, and have parents with higher education than those who do not enter cohabiting relationships. Frequent religious attendance is a negative correlate of cohabitation. Finally, cohabiting couples are slightly less likely than married couples to have children younger than 18 living in their household.

Similar to the general population distribution, cohabiting couples are much more likely to live in or near an urban area than a nonmetropolitan area, with nearly 60% of cohabiting couples living in the Southern and Western United States. Alaska has the highest proportion of cohabiting couples of the 50 states (primarily due to the high Native American population in the state), with San Francisco, California, and Fort Lauderdale, Florida, having the greatest proportion of cohabiting couples among major U.S. cities.

### FACTORS AFFECTING COHABITATION TRENDS

On an individual level, people cohabit for a number of reasons. Cohabitation may make the most financial sense for a dating couple strapped to pay for separate

living arrangements. Cohabitation may be a matter of convenience for couples. Cohabitation may serve as a trial marriage for couples and allow for easier dissolution if the relationship ends. Cohabitation may be an alternative to marriage for couples that do not believe a more formal arrangement is necessary or optimal. Finally, unmarried cohabitation is the only option for homosexual couples in many states although gay couples in Massachusetts, parts of Canada, and some European countries can be legally married. But it is yet unclear as to who can fully enter into a legal married union. These reasons, though, do not address the growing trend of cohabitation.

Although it is difficult to point to any one factor causing the societal boom in cohabitation, the improved status of women certainly plays a role. Before the 1960s, few women in the United States worked outside of the home and marriage was the primary means of economic subsistence for women. Today, 95% of women will work outside of the home at some point in their lives, 60% of women at any given time are working for pay, and nearly 60% of college entrants are women. Marriage is no longer the only option for financial security for women (and their children). Further easing the pressure toward marriage for women is the availability of reliable contraception and the subsequent demise of the “shotgun” marriage. Cohabitation may be seen as a comparable alternative to marriage for women who do not need the security that a more formal union may have provided in the past. Cohabitation may also be seen as an acceptable precursor to marriage while one finishes school or establishes a career.

Another explanation for the increase in cohabitation and decrease in marriage is that the social mandate for marriage has weakened. In 1950, 67% of men and women over 15 were married; in 2002, only 55% of men and women over 15 were married—and this percentage typically reflects an older segment of the population. Only 7% of American households represent the “traditional” family of a married heterosexual couple with children.

There is a general sense among adult men and women that marriage is not necessarily the culmination of a long-term dating relationship. Religious doctrine has been the long-standing force against unmarried cohabitation (primarily due to sanctions against sex outside of marriage). As attitudes in the United States shift toward greater adherence to individual desires than religious teachings, attitudes toward premarital sex

and cohabitation have become more permissive. Fifty percent of college students say that they would live with a romantic partner under the right circumstances (and 25% already do).

## COHABITATION AND CULTURE

Attitudes about cohabitation have varied greatly over time and across cultures. Today, trends similar to those in the United States can be seen in other industrialized nations. Cohabiting couples represent about 7% of households in the Netherlands, 13% of households in France, and 25% of households in Sweden. Relationships in Sweden may have moved the farthest of any industrialized nation from the “traditional” nuclear family (with 55% of 25- to 34-year-olds cohabiting). However, cohabitation may have different meanings in these European countries. In Northern European countries, cohabitation may represent an alternative to marriage, whereas cohabitation is more likely to act as a precursor to marriage in Western Europe. In Southern Europe and Ireland, cohabitation is much rarer than in other areas of Europe.

Although the cohabitation trend is more noticeable in industrialized nations than in the developing world, there are some notable exceptions. Economically, Japan is very similar to Western industrialized nations, but cultural differences (e.g., importance of the traditional family) translate into different practices as far as marriage and cohabitation are concerned. Although noting similar increases in divorce and later marriage as many Western countries, Japan has not had a comparable increase in cohabitation, with less than 2% of households in Japan made up of cohabiting couples.

In the developing world, cohabitation rates vary greatly depending on cultural norms. In Latin America and the Caribbean, where cohabitation is more normative, 54% of women are in unmarried cohabiting partnerships. However, in Arab cultures, societal and religious norms strongly sanction any type of relationship that suggests premarital sex. Similarly, in South Asia, cohabitation is very rare and trends do not seem to mirror those in Western cultures.

The impact of culture is notable even within the United States. More than 17% of Native American households are cohabiting couples compared with 4.6% of Latino households, 4.1% of Black households, 3.6% of White households, and 3.1% of Asian American households.

## RELATIONSHIP SATISFACTION, MARRIAGE, AND DIVORCE

Changing trends in an institution as ingrained as marriage lead to questions about the quality of cohabiting relationships. For years, well-meaning parents have warned their children against the evils of cohabitation, citing the oft-reported finding that people who cohabited (not necessarily with their eventual marriage partner) were 50% more likely to get a divorce than noncohabitators. The problem with this correlation is that it is often misrepresented as a causal association. People with nontraditional attitudes are more likely to cohabit and more likely to have permissive attitudes about divorce. Furthermore, research has shown that cohabitation changes a person's attitudes in favor of nontraditionalism, so it is not cohabitation but rather the more favorable attitudes toward divorce that lead to divorce. Suggestions that people who enter into cohabiting relationships are simply less likely to be successful at relationships in general have not been supported by research.

Fifty percent of different-sex cohabitators get married within 5 years of moving in together, 40% break up within 5 years, and around 10% remain in unmarried relationships for more than 5 years. The difference in relationship satisfaction between cohabitators who plan to marry and those who do not is significant, with those who plan to marry having greater relationship satisfaction than those who do not plan to marry and having essentially the same relationship satisfaction as those who are married. Those who cohabit and go on to marry their cohabitation partner have marriages that are of comparable length to those who do not cohabit before marriage. It is important to note that cohabitators are no less likely to get married than noncohabitators. They are just not necessarily going to marry the person with whom they currently live.

Cohabiting couples who do not officially marry sometimes enter into a common law marriage (by choice or circumstance). Formally recognizing cohabiting relationships has been common practice for hundreds of years. In pioneer times, when formal marriage was precluded by poverty or an unavailable officiant, the idea of common law marriage was born. Fifteen states currently recognize common law marriages (although a number of states specifically outlaw common law marriages). Common law marriages are usually defined by a couple's prolonged cohabitation and presentation of themselves to others as a married

couple. Common law marriage typically affords a couple all of the rights of marriage (including necessitating a divorce upon dissolution). It should also be noted that, although rarely enforced, seven states currently outlaw cohabitation of unmarried relationship partners.

## SUMMARY

As relationship freedom expands for men and women and the stigmas against cohabitation break down, more couples are opting to enter into unmarried cohabiting relationships. Cohabitation allows many of the once exclusive perks of marriage—convenience, increased time spent together, legitimized sex, financial savings—to couples who are not ready for, interested in, or are barred from marriage.

## COHORT

A cohort refers to a group of individuals who have common characteristics such as age, experience, location, or generation. Historically, the term was used to describe a Roman military unit. Currently, the term is used more loosely, and the grouping characteristics of a cohort can be quite varied. The most typical type of cohort in developmental psychology is referred to as an age cohort or birth cohort and can include either a particular year of birth (e.g., 1990) or a span of years such as the “baby boomer” or “generation X” generations. These age or birth cohorts are likely to share common cultural, historical, and social influences. However, time of birth is not the only grouping characteristic of a cohort. Other types of cohorts include groups of individuals who have experienced a significant life occurrence such as 9/11 or a group of individuals who started medical school at the same time. Overall, cohorts are of concern in many areas of research other than developmental psychology, such as economics, health, and sociology, and are also of concern to demographers.

In developmental psychology, cohorts represent a methodological concern because age and cohort can be confounding variables. Thus, in many studies there is a risk of a cohort effect. A cohort effect occurs when the results are affected by the particular cohorts used in the study rather than representing true age effects. For example, in life span studies of intelligence, age and cohort are often confounded because older adults are typically less educated than younger adults, so although differences in intelligence are found across the life span, these differences do not reflect true age-related effects. In general, most developmental studies use the traditional cross-sectional or longitudinal designs, and both of these designs are susceptible to cohort effects. In the cross-sectional design, groups of different ages are included, but differences that are seemingly age related may in fact be due to unique experiences to one or more of the age, or cohort, groups. For example, in a study of reading development in 6-, 8-, and 10-year-olds, a new reading curriculum may have been implemented just as the 6-year-old group started school, and therefore their reading scores are as high as those of the 8-year-old group. It would then be erroneous to conclude that there are no age-related changes in reading development between the ages of 6 and 8 because a cohort

effect may have occurred. In the longitudinal design, data are collected from one group across time, but that group may have had unique experiences such that conclusions from the study are not generalizable. In an ongoing study of computer literacy, for example, the study began in 1980 with a group of 10-year-olds tested at regular intervals. This study would yield data on 20-year-olds from 1990 that would not necessarily be reflective of the typical computer literacy of individuals who turned 20 in 2004. Once again, a cohort effect may have occurred because the data from the study are not applicable to the present day.

To control for effects of cohorts, several research designs are available, but the issue of which design is most appropriate in developmental psychology is contentious. Sequential designs are a common type of research design used to control for cohort effects. In sequential designs, a combination of cross-sectional and/or longitudinal designs is used. The cohort-sequential design utilizes two longitudinal designs with data collection starting at two different times. The time-sequential design utilizes two cross-sectional designs with data collection at two different times. The cross-sequential design utilizes a longitudinal and cross-sectional design that includes groups of different ages that are followed longitudinally. All of these designs can be used to try to control for cohort effects.

## COLIC

---

*Colic* and *colicky* apply to crying behaviors in otherwise healthy infants who, despite their caregivers' attempts at soothing, cry inconsolably. Colic has been defined as inconsolable or excessive infant crying for which no physical cause can be found and which lasts a minimum of 3 hours of total crying per day, at least 3 days a week, for at least 3 weeks throughout the infant's first 3 months of life [Wessel's Rule of Three (1954)]. The incidence of infant colic, thus defined, is estimated to affect approximately 20% of infants. Colic is an anomaly, not a disease that can be cured. Infant crying is a universal phenomenon. It begins shortly after birth and increases thereafter with the peak amount of crying occurring at about 4 to 6 weeks of age. Crying then decreases in amount until about 3 months of age. It has been reported that all infants during this time cry an average of 2¾ hours per day, with colicky infants crying considerably longer.

Colic has been thought to be a problem originating in the gastrointestinal (GI) tract of infants, resulting in flatulence or "gas," cramping, or intestinal pain. Little, if any, scientific evidence supports this connection. In addition to similarities in GI function, research comparing colicky infants with normally crying infants has shown no differences in sex distribution, birth order or parity, birth weight or weight gain, feeding practices (breast, bottle, or mixed feeding), infant allergies or eczema, or family history of allergy. There also has been little evidence of related factors such as maternal age or education or maternal illness during pregnancy. Some evidence supports an association of colic with maternal emotional state or family tension. However, these studies were done retrospectively after parents' experiences with their colicky infants, making it difficult to determine the direction of causality. It is possible that the increased anxiety and/or family tension was the result not the cause of the colic. Some evidence exists that colic may run in families.

Research on infant crying has shown similarities between normal crying and colic. First, both colicky and normally crying infants appear healthy with no physical cause for their crying. Second, both normal crying and colic show the same diurnal pattern, that is, most crying occurs during the evening. While crying bouts can occur at any time during the day, they seem to be most common during the later hours of the day.

Third, both normal crying and colic show the same developmental course over weeks.

Colic most often has its onset during the 2nd or 3rd week of life, with the severity of symptoms and the proportion of infants reported as colicky increasing until the 2nd month of life and decreasing thereafter. Inconsolable crying usually ends at 9 to 16 weeks of age. In populations of normal criers, a similar developmental course of increase and subsequent decline in amount of crying has also been reported. Hence, normal crying and colic differ from each other quantitatively but not qualitatively.

There is no cure for colic. However, colic will usually resolve on its own by about 3 to 5 months of age. In the meantime, colic can be managed by soothing techniques that have proven helpful. These include swaddling, non-nutritive sucking (pacifiers), auditory stimulation, and rocking. All four classes of soothers can be provided simultaneously to the infant who is carried by and in close contact with his or her caregiver. Experimental research has shown that combinations of these soothers are more effective in calming crying infants than a single soothing technique used alone. Infant massage has been shown to be no more effective than other soothing techniques such as carrying, but when used in combination with supplemental carrying, for example, has proven helpful.

Caregivers need to remind themselves that they are not the cause of their infant's colic. First, changing feeding methods has not helped to reduce the colic. Since colic is not indigestion, stopping breast-feeding does not necessarily reduce the colic nor does changing formulas or offering solid foods. A number of herbal or nonprescription remedies exist that are unlikely to reduce the colic and which may even be harmful to the infant.

Because of the challenges presented by a colicky infant, caregivers need respite time in order to attend to their own sleep and social needs. They also need reassurance that this difficult and frustrating time coping with their infant's colic will improve with the passage of time when they will enjoy their happier infant.

## COMMON LAW MARRIAGE

---

Common law marriage is a form of marriage that is recognized without legal and civil formalities such as a marriage license or a ceremony and includes all of the rights, privileges, and duties of formal marriage. This form of marriage was an important recognition of rights for early settlers in the United States, where access to "legal" marriage was limited simply by the distances one would have to travel to be formally married by a member of the clergy or state official. However, the legal concept of common law marriage in the 20th century has almost completely died out through legislative changes and the relative ease of getting married in our increasingly mobile society. It is a legal concept entirely created in law and is generally determined by a court of law and rarely defined by statute. Only a handful of states still recognize it as a valid form of marriage. The reasons for abolishment of the recognition of common law marriage in most states range from religious beliefs to beliefs by legislatures that the recognition was no longer necessary.

Common law marriage has its roots, like so much of American law, in English law. It began as a type of marriage entered into *sponsalia per verba de praesenti* (by present words and not ceremony) in ecclesiastical law. Common law marriage in England could be accomplished in two ways, as above, through mutual assent in words of the present tense, or through

mutual assent to marriage in the future, followed by sexual intercourse (*sponsalia per verba de futuro cum copula*). Common law marriage continued in England until the passage of Lord Hardwicke's Act in 1753, which enacted certain formal requirements essential for recognition of a valid marriage. The institution of common law marriage followed the first English and European settlers to America.

The most common myth concerning common law marriage is that a couple has to live together for 7 years. Common law marriage has no requirement of living together for a certain number of years. The specific requirements for a valid common law marriage vary from state to state. In Kansas, for example, there are three requirements: (1) that the parties have the capacity to marry; (2) that the parties hold out each other to the public as husband and wife; and (3) that the parties have a present agreement between them to be married. Other states that recognize common law marriage have similar requirements.

While legal definitions differ from state to state, capacity to marry includes having the requisite mental or physical capacity to marry, not already being married to someone else, not being too closely related to the person, and being of a sufficient age to marry.

Evidence of many different activities can constitute holding out to the public as husband and wife. These activities can include living together, using the same last name, having joint bank accounts, filing joint tax returns, owning property jointly, introducing each other as husband and wife to friends, family, or the public, and many other marital behaviors.

Determining whether a present agreement to be married exists is the most difficult of the requirements for common law marriage to prove. The manifestations of someone in a relationship and the interpretation of those manifestations is what creates the difficulty in discovering if the parties had a present agreement to be married. Generally, consent to cohabit or a promise to get married in the future does not establish a sufficient present agreement to be married. Some courts have allowed the agreement to be married to be implied from the couple's actions and circumstances. This fact-intensive analysis is what makes analyzing common law marriage cases difficult.

There is no statutory common law divorce. The parties, once they have entered into a valid common law marriage, generally must go through divorce or annulment as dictated by state statute. However, no analysis of the above requirements comes into the courts until

there is an issue between parties arising in contexts as varied as intestacy or probate, divorce, marital privilege, criminal prosecution, worker's compensation, or termination of alimony.

---

## COMORBIDITY

---

A disorder reflects a set of symptoms (mental or physical) that causes significant impairment or distress. Comorbidity is the simultaneous presence of two or more disorders within a person. For example, a person diagnosed with generalized anxiety disorder and major depressive disorder may experience symptoms of the former condition, such as chronic, uncontrollable worry, as well as symptoms of the latter condition, such as negative mood or thoughts of suicide. Comorbidity is common among people seeking mental health services, and it increases the risk for more severe symptom development if left untreated. Accordingly, an understanding of the causes and consequences of comorbidity is recognized by mental health clinicians and researchers as critical to the classification, development, diagnosis, and treatment of mental disorders.

Comorbidity can often be a product of how disorders are classified. For example, a classification system that splits symptoms into a greater number of diagnostic groups is likely to produce increased comorbidity estimates, whereas a classification system that lumps symptoms into a fewer number of diagnostic groups is likely to produce decreased comorbidity estimates (but as a result may miss important distinctions). Furthermore, the more symptoms two disorders have in common, the more likely it is that both disorders will be diagnosed.

When comorbidity is present in an individual, researchers and clinicians distinguish between primary disorders and secondary disorders. The primary disorder is the disorder that is most severe and debilitating, and the other disorders are secondary comorbid disorders. Therefore, the rate of comorbidity between two disorders depends on which disorder is considered to be primary. This distinction is important because it may form the basis for treatment recommendations. For example, an individual who has a primary anxiety disorder and secondary major depressive disorder may benefit more from treatments that reduce anxiety symptoms than those that reduce symptoms of depression. Finally, in some classification systems, such as the *Diagnostic and Statistical Manual for Mental Disorders (DSM)*, a diagnosis cannot be assigned when symptoms do not meet criteria for a given disorder. It has been argued that much potentially useful information about symptom comorbidity is lost by disregarding additional symptoms that do not meet criteria for a comorbid disorder. However, the current system helps ensure that diagnoses are only assigned when sufficient symptoms are present to indicate a disorder.

The study of comorbidity may also provide information about processes that give rise to different mental disorders. This is the case with certain disorders that are associated with increased risk for the development of other disorders. Disorders A and B may be highly comorbid, such that people with disorder A are at increased risk for the development of disorder B, and vice versa. This pattern of comorbidity may reflect a shared genetic or psychological vulnerability between the disorders. However, many alternative explanations would need to be ruled out before one could conclude that a single vulnerability causes disorders A and B. For example, the comorbidity may be due solely to a greater tendency in individuals with both disorders to seek treatment than in individuals with only one of the two disorders.

Finally, comorbidity is an essential concept in treatment. Compared with individuals who have only one disorder, individuals with comorbidity have poorer overall functioning and poorer response to a variety of treatments. As a result, comorbidity is an important consideration when clinicians are planning treatment. Because most available treatments are designed to treat a single disorder, clinicians may focus on treating the symptoms of the primary disorder while addressing comorbid disorders indirectly. For example, clinicians may try to improve treatment

response by targeting symptoms common to both disorders, which may share a common cause.

Much remains to be learned about comorbidity. A better understanding of the specific ways in which different approaches to classification, such as splitting or lumping symptoms into diagnostic categories, influence comorbidity will be crucial to future revisions of widely used diagnostic manuals. In addition, research is needed to clarify the complex relationships between basic developmental processes and comorbidity. Finally, the study of comorbidity may inform the development of new treatments that directly target the occurrence of multiple disorders.

## COMPETENCE VERSUS PERFORMANCE

---

The concept of competence versus performance is fundamental to the study of language. This distinction recognizes that the “mistakes” people make when speaking (performance) may not accurately reflect what they actually know (competence). We all have made “slips of the tongue,” where we substitute a word or sound for another or use a different grammatical form than intended, with sometimes humorous results. For example, you might say you need to go “shake a tower” instead of “take a shower,” ask someone to be “pacific” rather than be “specific,” or accuse someone of telling a “lack of pies” rather than “pack of lies.” Performance errors can also be found in comprehension, such as mishearing “just a position” for “juxtaposition.”

These kinds of mistakes do not mean that we have an inaccurate knowledge of language. Rather, a variety of conditions, both internal to the individual (i.e., memory limitations or fatigue) and external (i.e., distractions or interruptions) can cause a difference between what people know about their language and how they apply that knowledge in real situations.

Noam Chomsky defined competence as the underlying knowledge each speaker-hearer has about the language of his or her community. As such, competence is an ideal, which presupposes a “completely homogeneous speech-community.” It is hypothesized as a psychological or mental property or function and therefore cannot be directly observed. In contrast, performance refers to an actual communicative act of speaking or hearing. In this distinction, performance is an incomplete and inaccurate demonstration of what an individual knows about his or her language.

The competence-performance distinction is an important one in linguistics. One of the major goals of linguistic research is to discover how children develop language. Another is to understand how language functions within the human brain. One difficulty in conducting these types of language research is that actual speech contains errors. In 1965, Noam Chomsky argued that the focus of linguistic theory must be on the underlying language system (competence), not the act of speaking (performance). While performance errors may illuminate how language is perceived and organized in the brain, the goal of a theory of language is not a description of what people actually say. Rather, it is to describe the cognitive mechanism by which humans can produce an infinite number of sentences, many of which they have never heard, from a finite number of words and grammatical structures. Therefore, it is crucial to differentiate between competence and performance.

Chomsky’s distinction between competence and performance has undergone some criticism, such as for the emphasis on grammar in his definition of competence. Subsequently, Dell Hymes and others have introduced the concept of “communicative competence,” which refers to an individual’s knowledge of how to use language appropriately in different social and communicative contexts. The focus on language use has emerged in recent years in a variety of areas, including language socialization research. This type of study examines how children from different backgrounds are socialized to use language in culturally appropriate ways and how they develop understanding of the social organization

and worldview of their cultural group through the development of their community's language.

The distinction between competence and performance remains important to many areas of study (i.e., artificial intelligence and second language acquisition) and is widely applied. Nonetheless, as with the theory of language for which this distinction was originally proposed, many questions and controversies remain. Yet, for many, this is a useful heuristic device that allows us to consider and explain how in terms of our language abilities, as in many other areas of human cognition, we may know more than we can demonstrate through our actions in daily life.

## CONCRETE OPERATIONAL PERIOD

---

The concrete operational period is the third period in Jean Piaget's theory of cognitive development. Piagetian periods occur in invariant order. Thus, a child must pass through the sensorimotor and pre-operational periods before entering the concrete operational period and must pass through the concrete operational period before entering the formal operational period. Although exact ages of acquisition are not central to Piaget's theory, he proposed that children in the concrete operational period are between the ages of 6 and 12. Contemporary research has found that both younger and older individuals may engage in thought that is characteristic of the concrete operational period.

Each Piagetian period is characterized by qualitative changes in the nature of children's thought. Entry

into the period of concrete operations is marked by the child's mastery of operations. Operations can be defined as the mental representation of transformations. Using operations, children in the concrete operational period are able to reason logically about real situations. Children in this period are still unable to reason logically about hypothetical situations or to reflect upon their own thoughts.

Entry into Piagetian periods is marked by success on Piagetian tasks designed to assess the quality of children's reasoning. Typically, conservation tasks are mastered by children during the concrete operational period. Conservation can be defined as the realization that changes in appearance do not cause changes in quantity. Conservation is tested in the domains of number, length, liquid, mass, area, weight, and volume. In the conservation of mass task, a child is shown two identical balls of clay. The child is asked if the two balls have the same amount of clay. If the child believes that one of the balls contains more clay than the other, adjustments are made until the child believes the two balls have equal amounts. One of the balls is then flattened while the child watches. Again, the child is asked if the two balls have the same amount of clay. Children in the pre-operational period believe that the flattened ball has either more or less clay than the rolled ball. Children in the concrete operational period understand three concepts that help them to realize that the amount of clay is unchanged: (1) Identity: An item's appearance can change without changing its identity. Using identity, the child reasons that only the shape of the clay has changed, not the amount. (2) Reversibility: The effects of actions can be reversed. Using reversibility, the child reasons that because the flattened clay could be rolled into a ball again, the amount has not changed. (3) Decentration: A change in one dimension can be compensated for by an opposite change in another dimension. Using decentration, the child reasons that although the flattened clay covers a wider area, it is also thinner than the rolled clay and that therefore the amount has not changed.

In general, Piaget believed that advances in reasoning are domain general, meaning they occur in all areas of knowledge. However, in the case of conservation, Piaget recognized a decalage. Decalage can be defined as instances in which children show more advanced forms of reasoning in one domain than in other domains. For example, children typically conserve number, length, liquid, and mass before they conserve area and weight and conserve area and weight before they conserve volume.

When Piaget's tasks are exactly replicated, his results have been widely validated both cross-culturally and across different cohorts. However, contemporary research has found that children show earlier evidence of identity, reversibility, and decentration when the traditional tasks are simplified.

## CONDUCT DISORDER

---

*Conduct disorder* (CD) is defined by the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition/text revision (*DSM-IV-TR*), as a repetitive and persistent pattern of behavior that violates the rights of others or violates major age-appropriate societal norms or rules. These behaviors fall into four main categories: (1) aggressive conduct that threatens physical harm to people or animals, (2) nonaggressive conduct that causes property loss or damage, (3) deceitfulness and theft, and (4) serious violations of rules. *DSM-IV-TR* also makes the distinction between children who begin showing severe antisocial and aggressive behaviors before age 10 (i.e., childhood onset) and those who do not show severe conduct problems before age 10 (i.e., adolescent onset).

Research on the development of conduct problems has uncovered a large number of risk factors associated with CD. These risk factors include dispositional characteristics located within the child (e.g., biological abnormalities, predisposing personality traits, cognitive deficits), as well as factors involving the child's social context (e.g., dysfunctional parenting practices, peer rejection, impoverished living conditions). Research suggests that risk factors have a cumulative effect on the development of problem behavior, with risk increasing in a linear manner from the presence of no risk factors to the presence of six or more risk factors.

Research has also suggested that not all children with CD develop their behavioral problems due to the same causal factors. For example, children in the childhood-onset group are characterized by a number of dispositional risk factors such as difficult temperament, impulsivity, low intelligence, and other cognitive deficits that act to exacerbate existing contextual risk factors (e.g., family dysfunction, impoverished living conditions) to place them at a greater risk for later maladjustment. Recent research also suggests that childhood-onset children can be further divided into (a) those who show a deficit in conscience development and are characterized by a callous and unemotional interpersonal style and (b) those who show very impulsive and emotionally dysregulated behaviors without a callous and unemotional style.

In contrast, youth in the adolescent-onset subgroup do not consistently show these risk factors. The conduct problems of adolescent-onset children are thought to be an exaggeration of the normative developmental process of identity formation that takes place in adolescence. If they do differ from other children, it seems primarily to be in showing greater affiliation with delinquent peers and scoring higher on measures of rebelliousness and authority conflict. The distinction between childhood-onset and adolescent-onset trajectories to CD is a very influential model for explaining the different pathways through which children may develop severe conduct problems. However, it is important to note that clear differences between children in the two pathways are not always found, and the applicability of this model to girls requires further testing.

Reviews of the treatment outcome literature have documented four treatments with proven effectiveness for reducing conduct problems in youth: (1) contingency management programs, (2) parent management training (PMT), (3) cognitive-behavioral programs, and (4) use of stimulant medication. Although each of these four interventions has proven to be effective in reducing conduct problems, even these treatments have a number of substantial limitations. These limitations have led researchers to propose the use of comprehensive and individualized treatments that take into account the different developmental pathways that children with CD have been shown to follow. Recognizing these developmental pathways can aid the clinician in determining which causal processes may be involved in the development of CD for a particular child and can guide decisions as to the most

important targets of interventions. Furthermore, knowledge of the developmental course of CD allows for the implementation of interventions as early as possible in the developmental sequence.

## CONFLICT

---

Conflict and development are bound together: Conflict both fosters maturation and is a product of it. Two distinct forms of conflict may be identified: intrapersonal conflict and interpersonal conflict. Each plays a different role in human development. Intrapersonal conflict denotes internal strife, the resolution of which may prompt social, cognitive, or emotional maturation. Interpersonal conflict signifies overt disagreement between individuals or groups that, depending on how it is managed, may either promote social skills and improve relationships or hinder social competence and disrupt relationships. Both forms of conflict appear to have a curvilinear relationship with developmental outcomes: Some conflict is necessary for optimal growth, but too much is counterproductive.

### THE NATURE OF CONFLICT

*Conflict* is a broad term, widely invoked in the common vernacular and in the scientific literature to suggest a state of disagreement or opposition. The term carries

different connotations depending on how it is experienced and who experiences it. Intrapersonal conflict describes a state of emotional turmoil, intellectual dissent, or motivational equiponderance that occurs within an individual. To be conflicted is to be consumed by internal rivalries and contradictory demands. Interpersonal conflict describes a form of social interaction involving two or more people, characterized by opposing goals and behaviors. The state of interpersonal conflict encompasses a broad category of events, from individuals exchanging opinions to armies engaged in mutual destruction. The earliest known English language use of the word conflict dates to the 15th century; both forms of use have common roots in the Latin *conflictus*, meaning throw or strike together, clash, contend, or fight. This shared etiology muddies fundamental distinctions between these two distinct forms of conflict.

### Intrapersonal Conflict

Intrapersonal conflict encompasses four broad domains. At the emotional level, conflict reflects competing desires or impulses. Sigmund Freud attributed these base tendencies to aggressive and sexual proclivities with origins in the id (the unregulated physical self), which give rise to irreconcilable differences with constraints that are imposed by the superego (the social mores conveyed by family and culture). At the cognitive level, conflict reflects dissonance produced by incongruent facts, opinions, or modes of thought. Jean Piaget attributed these tendencies to equilibration, the innate human tension between a preference for stability and a drive to master the environment. Assimilation encourages stability by incorporating new information into existing mental schema. Should this prove insufficient for mastering the environment, accommodation is required to alter the mental scheme or, in extreme cases, the mental structure itself, in a manner consistent with the information available. At the level of the ego, conflict reflects developmental challenges. According to Erik Erikson, each life stage is defined by a distinct crisis that must be resolved. These crises represent choice points that collectively contribute to ego development and self-representations. At the motivational level, conflict reflects the need to choose between options perceived to be relatively equal in valence. Kurt Lewin identified three distinct forms of motivational discord. Two equally attractive options are described in contemporary terms as approach-approach conflicts. Two equally unattractive options are referred to

as avoid-avoid conflicts. Options that contain both attractive and unattractive elements are considered approach-avoid conflicts.

Intrapersonal conflict is by definition a private experience. It cannot be observed, and it has no clear, reliable metric. Early scientific psychologists relied on introspection to glean insight into thoughts, a practice modified and popularized by psychodynamic psychologists to probe unconscious emotional states. Subjective experience as a topic of study fell out of favor with the behavioral revolution. Reaction times, physiological cues, and projective responses were employed as proxies for inner conflict, but poor reliability and the absence of face validity undermined these efforts. Field theorists attempted to resolve the dilemma by quantifying motivational forces present in the environment. This visionary effort failed to attract a significant following because it proved cumbersome and ill suited for the methodological and analytic tools of the day. With the cognitive (counter) revolution, new introspective methods gained legitimacy as advances in measurement and instrumentation were applied to mental processes. Scholars began to focus on the diverse experiences of different cultural and ethnic groups, and in so doing it became apparent that scientific inquiry into intrapersonal conflict cannot proceed in the absence of valid and reliable self-report data.

## Interpersonal Conflict

Interpersonal conflict may take place at the level of the dyad or the group. Dyadic conflict is a social episode marked by overt behavioral opposition. The function of a disagreement and the manner in which it unfolds varies according to characteristics of the participants and their relationship, the issue and context, the strategies employed, and their consequences. Group conflict refers to negative or incompatible attitudes and behaviors directed by members or representatives of one group toward those of another group. The nature and significance of intergroup conflict varies according to leadership styles and prevailing norms, member cohesion, resource availability, and the individual and collective talents and experiences of each group.

Interpersonal conflict is a quantifiable, often public event. It consists of a sequence of easily recognized and well-defined components including the initial opposition and the tactics, resolution, and outcome. The ease with which components of conflict may be identified has not engendered a common approach for

quantifying experiences, however, and empirical studies of dyadic and group conflict suffer from inconsistent operational definitions. Conflict measures differ in terms of whether they assess oppositions defined by unilateral (one-sided disputation) or mutual (reciprocal contention) behavior and in terms of whether the frequency of an event is distinguished from its affective intensity. Distinct patterns of interpersonal conflict emerge when considering reciprocated as opposed to unreciprocated disagreements and when angry disputes are examined apart from the mundane. The earliest work on the topic involved labor-intensive observations of young children, but this soon gave way to laboratory studies of dyads and groups in experimenter-contrived conditions designed to elicit disagreements. Concerns about the ethical treatment of participants and a lack of generalizability prompted a renewed focus on ecological validity; unobtrusive observations in natural settings have been integrated with running assessments of psychophysiological states and moment-by-moment accounts of participant cognitions and affect. The significance of self-reports increased with the realization that participant views of conflict differ not only from one another but also from those of observers, suggesting that what was once considered measurement error may in fact represent systematic differences in how conflict is perceived and experienced. The nature of the relationship and the role one occupies tend to dictate individual conflict behaviors and shape each participant's interpretation of events.

## THE ROLE OF CONFLICT IN HUMAN DEVELOPMENT

Conflict is inherent in growth. It follows that human development cannot proceed without conflict. Scholars agree that interpersonal and intrapersonal conflict shape developmental trajectories, but there is little consensus as to the exact mode of transmission. Developmental effects appear to be limited to specific domains of influence circumscribed by individual timetables and characteristics of the disagreement. There is evidence that wisdom, emotional maturity, and social skills are tied to a series of age-related tasks and the conflicts specific to each.

## Intrapersonal Conflict

Intrapersonal conflict is instrumental to the attainment of several important developmental milestones.

First, conflict may prompt alterations in mental constructs and cognitive structures. Intellectual maturation and improved perspective-taking skills provide an impetus for change: A child confronted with a difficult moral dilemma may be forced to disregard notions previously held dear in order to objectively consider different viewpoints and reach a fair solution. Conflict may also give rise to changes in perceptions and priorities. Cognitive dissonance typifies this mechanism: A child forced to select a single partner for an outing may find that the esteem for one friend has been enhanced at the expense of others. Finally, conflict may alter affect and impulse control. Emotional regulation is central to this ability: A child who delays gratification to maximize rewards will learn to succeed by cultivating strategies that reduce emotional arousal and divert attention from proximate stimuli.

Theory concerning the ontogenetic significance of intrapersonal conflict has outpaced research on the topic. Much remains to be done, especially in the area of emotional development. As the empirical literature grows, so does confidence in the assertion that the influence of intrapersonal conflict is determined by the problem confronting the individual and the cognitive or affective domain invoked. Recent scholarship suggests that effects are further qualified by developmental timetables. The likelihood that some age periods are more susceptible to alterations than other age periods leads to the provocative suggestion that intrapersonal conflict is neither a necessary nor sufficient condition for development, but rather a factor that may, at certain times, facilitate advances in the specific emotional or cognitive arena in which it arises.

### Interpersonal Conflict

Social competence and social development are inextricably entwined with interpersonal conflict. Disagreements, especially those in close relationships, are one of the primary means whereby individuals define themselves and delimit their interactions with others. Three influence pathways merit mention. First, conflict may prompt changes in self-understanding and self-evaluation. Significant disagreements force participants to reevaluate goals and tactics, offering opportunities to hone social perspective-taking and interpersonal negotiation skills. Second, conflict helps to determine patterns of social interaction that may impact developmental outcomes. Angry, coercive exchanges tend to be self-perpetuating and, once

started, they interfere with the dividends that normally accrue from close relationships; in contrast, constructive conflict management fosters a climate of warmth and problem solving that facilitates connectedness and affective sharing. Third, conflict may define and alter expectations about individuals and relationships. In some cases, roles and responsibilities are negotiated directly over the course of a dispute, but it is more often the case that participants evaluate their own behavior and that of their partner for clues as to whether current expectations are consistent with the capabilities of the relationship and the demands of the situation. Regardless of the influence pathway, successful conflict management is widely considered to be an important marker of developmental maturation.

There is considerable support for the premise that the developmental significance of conflict depends on the relationship in which it arises. Three relationship properties are germane: power, closeness, and permanence. Power describes the degree to which dominance shapes the relationship. Disagreements in horizontal relationships provide fertile ground for improved social skills because when power is shared, negotiation is necessary for a mutually satisfactory resolution; in vertical relationships, resolutions are more often the product of power differentials than negotiated settlements. Closeness describes the extent to which participants' lives are interdependent. Disagreements in close relationships have the potential to profoundly alter developmental trajectories because the interconnections that serve to maintain closeness also promote mutual influence; disagreements in other relationships rarely, if ever, shape the course of individual development. Permanence describes the stability of the relationship. Among close relationships, disagreements in voluntary affiliations are more likely to bring about individual change than those arising in obligatory affiliations; in contrast to conflicts with family members, who worry little about the dangers of relationship dissolution, disputes with friends and romantic partners are particularly salient because participants are normally expected to behave in a manner that promotes mutually satisfactory outcomes. Variations in relationship properties notwithstanding, developmental shifts in conflict management may be identified such that coercion is gradually replaced across childhood and adolescence with withdrawal and negotiation; subsequent life span trends in conflict behaviors remain to be explicated.

## THE COSTS OF CONFLICT

Conflict is not inherently detrimental. The costs of conflict depend on the frequency with which it arises and the manner in which it is resolved. Excessive, poorly managed conflicts exact a steep toll. Some costs take the form of developmental delay; disagreement may interfere with establishment of important relationships and the acquisition of essential social skills. Destructive costs are more readily apparent; conflict spawns emotional turmoil, mental illness, relationship dissolution, and violence. No one is immune from the costs of conflict, but some suffer disproportionately, especially those who lack constructive strategies for coping with dissent.

### Intrapersonal Conflict

The notion that intrapersonal conflict may inhibit development is not new. Some theorists believe that development is contingent upon a dialectic involving opposing psychological functions. Too much conflict, it is argued, could hinder normal development or even prompt a temporary state of regression. These principles have proven difficult to quantify at the global level, but they have received support in specific developmental arenas. The first instance arises early in life, when an insecure attachment relationship may give rise to avoidant or resistant internal working models characterized by anxious or oppositional worldviews. Inner struggles to reconcile the self with the environment are manifest in behaviors that interfere with the establishment and maintenance of supportive parent-child and peer relationships. Another instance arises during middle childhood and early adolescence. Improved cognitive and perspective-taking abilities enable youth with low self-esteem to obsessively ruminate about their behavior and their relationships, creating a vicious cycle of worry and apprehension that may interrupt critical developmental tasks in the educational, psychological, social, and occupational spheres. In both cases, inner conflict interferes with coping strategies, increasingly limiting healthy developmental pathways.

The costs of intrapersonal conflict extend far beyond missed opportunities and stunted growth. One specific form of inner conflict, anxiety, is a pernicious factor in a diverse collection of human maladies. Anxiety and anger have been linked directly to cardiovascular disease and hypertension and indirectly to

debilitating changes in the immune and endocrine system. Chronic inner turmoil increases blood pressure, heart rate, and sympathetic arousal, amplifying risks from contagion and infection, and elevating rates of morbidity and mortality from cancer, human immunodeficiency virus, and viral illness. In addition to being a disorder in its own right, anxiety also features prominently in internalizing difficulties. Three forms merit mention. First, substance abuse may have origins in efforts to reduce anxiety. Second, heightened anxiety typically precedes and accompanies depressive episodes. Third, inner conflict is endemic among those who attempt and commit suicide. It should also be noted that the consequences of inner conflict are not limited to those who harbor the ill feelings. Conflicted individuals make poor company and poor decisions. Intrapersonal conflict often accompanies abuse, infidelity, and divorce among lesser mortals; starvation, dislocation, and war have been attributed to inner strife among the leadership elite.

### Interpersonal Conflict

Developmental disadvantages may be traced to the disruptive influence that interpersonal conflict has on socialization processes. Chronic discord interferes with opportunities for social skills training in close relationships. Children who adopt coercive conflict management strategies early in life miss out on the crucial experience of negotiating resolutions and, as a consequence, fail to keep up with their peers in the development of empathy and role-taking skills. Social skills suffer, which may compromise sibling relationships and interfere with the establishment of friendships. The absence of constructive peer experiences may promote an information-processing bias that leads children to attribute hostile intentions to benign actions. This further diminishes positive contacts with peers and reduces the likelihood that children will gain the experience necessary for advanced levels of social perspective taking.

The costs associated with an inability to manage interpersonal conflict are significant. Delinquency and criminality appear to have origins in destructive conflict management skills acquired in coercive families. Young children inadvertently rewarded for noncompliant behavior learn to control their social environment such that the slightest opposition provokes an aversive outburst. Unable to constructively address disagreement, these children experience school failure

and peer rejection, which leaves them isolated and restricts their interpersonal world to all but the antisocial. Divorce and child adjustment difficulties may be traced to interparental conflict. Disagreement, in and of itself, does not promote marital instability; conflict is common in all marriages. Instead, divorce is best predicted by the regulation of conflict; satisfied couples maintain a ratio of at least five positive interactions for every negative one. When the balance tilts toward discord, a demand-withdrawal pattern emerges: Complaints by one partner elicit contempt, which prompts the other partner to react defensively and retreat by stonewalling. A family climate of hostility and unregulated conflict has significant adverse consequences for children. Negative affect between parents spills over onto children who experience similar emotions but are powerless to address their source. Prolonged exposure to angry, unresolved marital disagreements has been linked to delinquency, school adjustment problems, and depression. Furthermore, children model the resolution practices they witness: Youth from distressed households display markedly deficient conflict management skills.

### THE PARADOXICAL INFLUENCE OF CONFLICT

Conflict is often unpleasant and aversive. Given the option, most people choose to avoid it. Research on conflict, especially interpersonal conflict, invariably focuses on adverse outcomes; benefits are rarely considered. The costs of conflict are well documented and widely appreciated. For this reason, it is commonly assumed that the consequences of conflict are uniformly negative and that disagreements provide little or no advantage. This assumption has been challenged conceptually on grounds that linear models overlook the beneficent role that conflict may play in maturation. A curvilinear model of influence captures this alternative perspective: Too little conflict limits the potential for growth and too much conflict overwhelms coping mechanisms, but moderate conflict may provide experience necessary for optimal development.

This curvilinear model of conflict influence remains largely untested, although there are instances in which it provides a good fit to the data. Intrapersonal conflict is a necessary prerequisite for the establishment of a healthy ego identity. Too little internal struggle over identity produces foreclosure or diffusion, too much results in an extended moratorium. Moderate levels of interpersonal conflict may

also be proscriptive of family well-being. Families that suppress conflict demonstrate unhealthy levels of enmeshment that inhibits individuation; families that are demonstratively engaged in running combat tend to be isolated and alienated. Relationship quality may moderate this dynamic such that the potential benefits of conflict are realized only in the context of a history of supportive interactions: Disagreements that arise in warm, caring relationships with friends and parents have been found to promote identity development, role-taking skills, positive self-esteem, social problem solving, and school grades. Thus, conflict may be beneficial, detrimental, or benign; the consequences depend on how often it occurs, with whom it is experienced, and the way in which it is managed.

### INTERVENTION EFFORTS

Strategies for reducing conflict and mitigating its adverse consequences have targeted individuals, relationships, and groups. Intervention approaches aimed at the individual have met with limited success. Some are designed to reduce overall levels of conflict, whereas others aim to improve conflict management skills. Interventions devoted to anger and anxiety management have demonstrated promising short-term reductions in internal strife; studies currently under way should clarify the long-term efficacy of these approaches during different developmental periods. Efforts dedicated to the reduction of interpersonal conflict fall into two camps. Some programs target characteristics of individuals that may predispose them to frequent or angry disagreement. These training programs have proven more successful at limiting impulsivity than aggression, but neither has enjoyed reliable success at minimizing conflict or improving conflict management skills. Other programs target the development of social competence and problem-solving skills as a means to reduce conflict and better manage those that do arise. Social problem-solving procedures assist children in the management of interpersonal difficulties. Social skills training programs implemented in schools across North America provide some immediate reductions in problem behavior, but commensurate improvements in conflict management remain to be documented.

Considerable attention has been given to the problem of dyadic and group conflict. Yet despite the diversity of therapeutic approaches for dealing with family discord, few models have received rigorous empirical

scrutiny. One of the earliest programs specifically designed to reduce conflict between parents and children has proven to be one of the most effective: Problem-solving communication training, an integration of family systems and cognitive-behavioral approaches, encourages constructive parent-child communication in a manner that reduces the escalation of a conflict. Dyadic approaches are more commonly applied to marital conflict. Many of these techniques focus on the twin goals of supplanting negative attributions with positive ones and adopting constructive discourse strategies that enhance communication and limit negativity. Short-term successes are well documented, but persistently high rates of divorce are a testament to the fact that long-term solutions remain elusive. Peer conflict has also received considerable attention. There is evidence that the peer mediation programs adopted by many North American schools to address rising levels of violence are successful in teaching children constructive strategies for conflict resolution and in training peacemakers to intervene in disputes. These efforts tend to offer modest reductions in serious peer conflict and reports of improved conflict management practices. Finally, although much ink has been spilled over the goal of averting conflict between groups, a cursory glance at the daily news suggests that success remains elusive. Initial work on the topic proved encouraging. Experimental studies revealed that animosity could be manipulated through competitive and cooperative activities. In-group and out-group biases, a source of considerable discord, are susceptible to exposure and information exchanges. Unfortunately, progress in understanding the origins of intergroup conflict have not translated into progress in averting and minimizing strife.

## CONCLUSION

Research on conflict typically focuses on its potential for adverse consequences. Yet the nature of this research is such that it is impossible to determine whether maladaptation is the cause or the consequence of disagreement. Intervention efforts aimed at mitigating adverse outcomes are hampered by a lack of research that makes a full and nuanced account of the dynamic interplay between conflict and adjustment. Critically needed are accounts that specify how conflict may be beneficial to human development and when conflict should be viewed as a symptom or by-product that signals difficulties in other arenas.

## CONGESTIVE HEART FAILURE

---

Heart failure is a chronic condition in which the heart is unable to pump a sufficient volume of blood to supply the body's oxygen needs. High-output failure results from intolerable increases in oxygen demand, often resulting from thyrotoxicosis, beri-beri, and other conditions and does not reflect underlying heart disease. It will not be further discussed in this article. Low-output failure, or congestive heart failure (CHF), results from various cardiovascular diseases.

CHF is a disease of the elderly; failure in infancy and childhood is almost always the result of the obstruction of efficient outflow of blood from the heart because of diseased valves, whereas in adults intrinsic heart disease is the most frequent finding. Mortality in heart failure shows a bimodal age distribution, with a peak around age 1 year and a continuous rise after age 50. The gap between these peaks reflects the fact that young children either die or have the defect repaired surgically, and patients between 1 and 50 years old are in early stages of disease.

After the initial insult, the inability of the heart to pump blood forward adequately results in the accumulation of blood in the venous circulation (congestion), hence the term *congestive heart failure*. Venous congestion also occurs in the vessels of the lungs, resulting in pulmonary edema. Fatigue, reduced exercise tolerance, shortness of breath, and generalized hypoxia are the inevitable consequences.

The primary defect is unknown, but viral infections and exposure to toxins such as alcohol are thought to

be the cause in some cases. Other known causative factors are ischemic heart disease and myocardial infarction (direct myocardial cell injury) and hypertrophic changes resulting from uncontrolled high blood pressure. Recent research has focused on the role of apoptosis secondary to genetic damage and reversion of energy-generating and contractile proteins in the myocardium to less efficient, fetal forms resulting from the secretion of endogenous growth factors. A weakening of the heart's force of contraction during systole (systolic dysfunction) may result from one or several of these factors.

Whatever the underlying defect, once pump function falls behind demand, the progression of the disease is almost entirely the result of compensatory mechanisms triggered by physiologic perception of low-volume status. The low-volume status is perceived because the bulk of blood volume is in the venous circulation, waiting to be pumped forward by the failing heart, whereas the body's volume and pressure sensors are located chiefly in the arterial circulation, downstream from the heart. These compensatory events would be beneficial in a short-term, low-volume situation, but are maladaptive in a long-term situation.

The first compensation is an attempt to maintain blood pressure by raising myocardial pumping force and arterial vasoconstriction through stimulation of the adrenergic division of the autonomic nervous system. In acute blood loss this would be effective, but in the chronic failure situation, the prolonged exposure of the heart to adrenergic neurotransmitters (epinephrine and norepinephrine) results in direct myocardial toxicity, and the prolonged vasoconstriction increases the work the heart must perform in order to overcome the increased resistance to blood flow caused by arterial vasoconstriction. The body attempts to increase blood volume through activation of the kidney-based renin-angiotensin-aldosterone system (RAAS), the effect of which is to generate circulating angiotensin II (a powerful vasoconstrictor) and aldosterone (a mediator of sodium and water retention). The chronic effects of vasoconstriction are the same as those of the activated adrenergic system, but of no less importance is the role of angiotensin II and aldosterone as myocardial growth factors that promote hypertrophy and remodeling of the cardiac muscle mass. Additionally, renal secretion of vasopressin (antidiuretic hormone) is stimulated, resulting in vasoconstriction and conservation of water by the kidneys. A vicious cycle is entered, wherein perceived low blood volume triggers

water retention and increased vascular resistance, both of which increase the work of the heart required to move blood. An inexorable deterioration of pump function ensues.

Reduced pump function may also occur as a result of the inability of the heart to relax completely during diastole, which results in incomplete filling for the next pump cycle (diastolic dysfunction). Regardless of the mixture of systolic and diastolic dysfunction, the compensatory changes directed toward maintenance of blood volume are the main forces driving disease progression.

Without treatment, mean survival is 5 years from diagnosis. Progressively worsening pump function and global hypoxia account for 50% of CHF deaths; the other 50% are the result of fatal cardiac arrhythmia provoked by hypoxia, electrolyte disturbances (resulting mainly from activation of the RAAS), and cardiac enlargement.

CHF is the most frequent diagnosis-related group occurring in hospital admissions and accounts for a major portion of patient drug and hospital expenditures and public assistance for medical care. The vast majority of heart transplant surgery is occasioned by advanced CHF. Patients with advanced disease suffer from discomfort, limitation of activity, reduced employment, and early death.

Treatment is presently not directed toward the fundamental defect, since this is unknown in the majority of cases. Older therapies include diuretics to reduce the volume overload and inotropic agents, such as digoxin, that increase the force of myocardial contraction, neither of which has affected mortality. Recently, drugs that interrupt the events of the RAAS (angiotensin-converting enzyme inhibitors such as captopril and enalapril) have not only yielded improved quality of life, but are shown to prolong survival. Beta-adrenergic blockers such as propranolol, metoprolol, and carvedilol have also resulted in extended survival. Both classes of drugs lower blood pressure and so are not tolerated in all patients. Lastly, spironolactone, a competitive antagonist of aldosterone, has recently been shown to improve survival. Present therapy includes all three classes as tolerated, plus diuretics if volume overload is evident, and digoxin if these therapies fail to achieve the desired effect. Future treatments will likely involve genetic manipulation directed toward apoptosis and contractile protein subtypes.

## CONGREGATE HOUSING

---

While the majority of older adults live in independent, free-standing housing throughout their lives, advanced age necessarily increases the likelihood that an individual will benefit from an enriched supportive living environment. Congregate housing responds to the needs of persons 65 years and older who wish to have a limited set of support services available to them in their own separate apartments. Congregate housing, as conceived of here, is noninstitutional and should not be equated with nursing home care or homes for the aged, which represent settings in which more intensive services, health and medical in particular, are required because of an individual's level of functional impairment.

The underlying philosophy reflected in the congregate housing concept is that the older individual or couple should be able to have a range of services and amenities available while still maintaining substantial independence and autonomy. Such housing is meant to be comfortable, clean, safe, and affordable.

Congregate apartments may be rental or ownership units. Also called enriched housing, clustered housing, or sheltered housing, congregate housing has been shown to result in substantial cost savings as compared with the expense of nursing home care. It has also been argued that this type of housing can help prolong independence, provide companionship, and otherwise buttress an older adult's personal support network, thus reducing isolation and increasing opportunities for socialization.

Congregate care can be offered under public or private auspices and may be subsidized by government programs such as Section 8 of the Federal Housing Authority. The congregate housing concept first surfaced in 1963 as a specific recommendation made by President Kennedy to Congress. It was not until 1970 that Congress included construction funds for congregate housing as part of the 1970 Housing and Community Development Act. Legislative support was further affirmed in Section 7 of the Housing and

Community Development Act of 1974. In 1978, federal legislation authorized the Congregate Housing Services Program (CHSP) as Title IV of the Housing and Community Development Amendment. That legislation authorized contracts with local public housing agencies and nonprofit corporations to provide congregate independent living service programs. The CHSP program was the largest experiment ever undertaken by the federal government aimed at integrating housing environments and social and human services. Substantial impetus arose from the belief that individuals should have a range of options available to them in terms of housing choices. The promise that such housing would represent a low-cost alternative to institutional care represented an additional factor in driving this legislation.

There are usually income eligibility guidelines in public congregate care whereby residents are able to reside in such buildings for approximately 30% of their income, including rent, utility, and services. If it is a private, for-profit facility, depending on the services offered and the region of the country, monthly rent could range from \$700 to as much as \$2,500.

Congregate housing is an appropriate option for individuals who are relatively independent but would benefit from any and all of the following services: built-in safety features; laundry service; building security; transportation to shopping areas and medical appointments; housekeeping services; social, health promotion, and recreational programs; meal programs (the availability of one, two, or three centrally delivered meals a day); emergency call systems should a medical crisis arise; and social services in general. While health care is not a congregate housing option, individual residents often are able to pay for their own home health visiting nurse or aide.

## CONSCIENCE

---

Conscience is the set of faculties that allows one to participate in the social world by balancing one's needs and desires with those of others. Conscience is evident in behavior that is consistent with an individual's own moral standards. Often, at the core of these standards is a value of the rights and welfare of others. Conscience is expressed both through doing (e.g., giving one's bus seat to someone who looks tired) and not doing (e.g., not taking a friend's toy). A key feature of conscience is that it sustains moral functioning independent of external intervention (e.g., by parents, police). Current understanding of conscience has roots in Sigmund Freud's theory of the struggle between superego and id and Emile Durkheim's description of internalized morality as self-restraint, the precedence of social engagement over egoism, and autonomous reflection based on standards of conduct.

Conscience integrates capacities for emotional arousal, mental representation, and behavioral self-regulation. The emotional features of conscience include self-focused and other-oriented arousal that reinforces and motivates acceptable behavior and punishes and inhibits inappropriate behavior. Self-focused emotion includes negative (e.g., guilt) and positive (e.g., pride) arousal, dependent on whether one's behavior contradicts or promotes internal standards. For example, violation of one's principles results in guilt and remorse that is unpleasant. This negative emotion discourages future violations and may be assuaged through corrective action. Importantly, the self-focused emotion component of conscience does not depend on immediate external consequences and thus differs from, for example, the fear of being caught. Other-oriented emotional arousal, coupled with the ability to take others' perspectives, is another feature of conscience. This empathic component prompts awareness of the effects of one's actions on the feelings of others and elicits emotional arousal (e.g., concern), both of which influence behavior choices.

The mental representation component of conscience allows one to store and reference prototypes of moral conduct. Such representations are based on direct articulation and modeling of values and appropriate behavior (e.g., by parents). These also are gleaned from experiences with, for example, misbehavior, altruism, disciplinary encounters, and associated

emotional arousal. In this way, conscience formation is unique to one's particular assimilation of life experiences and socialization.

A central component of conscience is the capacity for impulse control, attention, and sustained effort, known as behavioral self-regulation. This capacity reflects executive brain functioning, rather than the popular notions of simple motivation or self-control. Without adequate self-regulation, the other components of conscience may not be consistently expressed in moral behavior. Such has been found in some studies of aggressive children, who did not differ from nonaggressive children on knowledge of rules or capacities for empathy or guilt. Instead, some of these children's difficulties were explained by less mature executive functioning that seemed to thwart the expression of their more mature faculties.

The features of conscience work in concert: A failure to regulate a selfish impulse may injure a friend, activating empathic concern, awareness of a standard violation, and self-censure through guilt. The process of development in these features is captured by the term *internalization*. This includes an inward transition of behavioral control from external to internal regulation, a growing sense that standards governing behavior are self-generated rather than externally imposed, and increased attribution of anxiety associated with rule breaking to internal rather than external causes. Notably, the development of conscience is undermined by some discipline strategies, such as physical punishment, that focus children's attention on external causes of emotional discomfort and reasons for compliance. Conscience is best fostered through discipline that teaches the reasons for moral behavior and the consequences of one's behavior for others. For example, the reason that lying is wrong is because it takes advantage of others and hurts friendships, not because it results in a spanking. Positive parenting practices support the development of conscience and sustain moral functioning in the absence of external forces—that is, when no one is looking.

## CONSERVATION

---

Conservation refers to the knowledge that the quantitative properties of objects are not changed by a mere change in perceptual appearance. As adults, we take such knowledge for granted. We do not believe that the amount of juice changes if it is poured into a different-shaped container, nor are we concerned that we have less to eat if a cookie arrives in three small pieces rather than one large one.

Children, it turns out, think differently. One of the most influential discoveries in the history of child psychology was the demonstration by the Swiss psychologist Jean Piaget that young children do not at first understand principles of conservation. Across a dozen or so books and scores of experiments, Piaget and his co-workers explored just about every form of conservation imaginable: conservation of number, mass, and quantity; of length, weight, and area; of time, speed, and movement. The general approach was similar across tasks: presentation of two stimuli equal on some quantitative dimension, followed by a transformation so that the stimuli no longer looked equal. Whatever the content area, children younger than 5 or 6 consistently judged that the quantity had changed when the appearance changed. Thus, young children really seem to believe that spreading out a row of candies increases the number or that rolling a clay ball into a snake changes its weight.

In Piaget's theory, such nonconservation responses are a characteristic of the preoperational period of development, the period between roughly 2 and 6 when children have not yet developed logical operations and are therefore easily fooled by misleading appearances. Conversely, the gradual mastery of conservation (and some forms, Piaget showed, are slower to develop than others) is a hallmark of the concrete operational period—the period of middle childhood during which a

set of mental operations evolves that allows children to solve a wide range of logical and physical problems, including the various conservation tasks.

The conservation phenomenon was the subject of hundreds of studies in the decades of the 1960s, 1970s, and 1980s. In general outline, these studies confirmed Piaget's claims: Young children fail conservation tasks, success emerges only gradually across the childhood years, and some forms of conservation are more difficult than others. At a more specific level, however, the later work revealed a number of discrepancies from the original Piagetian account. Piaget's assessment procedures were often unduly complicated; when the procedures were simplified in various ways, success was often evident at younger ages. Furthermore, the variability in response across different forms of conservation proved to be even greater than that reported by Piaget. Children might succeed on some conservation tasks by age 4, whereas other tasks would continue to baffle them well into adolescence. Findings such as these were a major contributor to the declining popularity of general-stage theories of development, most notably Piaget's theory of concrete operations.

Conservation is no longer the subject of concentrated research effort, a fate that has befallen many once popular topics in the history of psychology. In large measure, however, the decline in interest reflects the success of the earlier wave of studies. Despite some differences in detail and some unresolved questions, Piaget's general conclusions regarding conservation—including the existence of an apparently universal initial phase of nonconservation—rank among the most solidly established, and important, findings in child psychology. In addition, the general Piagetian emphases that are evident in the study of conservation—the focus on basic forms of knowledge, the interest in qualitative and not merely quantitative changes with development, the demonstration of surprising gaps in young children's understanding—live on in contemporary work in cognitive development, most notably the burgeoning research area known as theory of mind.

## CONTINUITY AND DISCONTINUITY IN DEVELOPMENT

---

Arguably, the key task of developmental scientists is to describe and explain developmental change. Changes may occur within an individual across the life span, and there may be between-person differences in such intraindividual change. The description and explanation of intraindividual change involves the concepts of developmental continuity and discontinuity, whereas the description and explanation of interindividual differences in intraindividual change involves the concepts of stability and instability.

In regard to continuity and discontinuity, descriptions or explanations of development can involve quantitative or qualitative changes. Descriptively, quantitative changes involve differences in how much (or how many) of something exists. For example, in adolescence, quantitative changes occur in such areas as height and weight since there is an adolescent growth spurt, and these changes are often interpreted as resulting from quantitative increases in the production of growth-stimulating hormones.

In turn, descriptive qualitative changes involve differences in what exists, in what sort of phenomenon is present. The emergence in adolescence of a drive state never before present in life—that is, a reproductively mature sexual drive—and the emergence in adolescence of new and abstract thought capabilities not present in younger people—that is, in Jean Piaget's terms, formal operations—are instances of changes interpreted as arising from qualitative alterations in the person. It is believed that the person is not just "more of the same"; rather, the person is seen as having a new quality or characteristic.

Explanations of development also can vary in regard to whether one accounts for change by positing quantitative changes (e.g., increases in the amounts of growth hormone present in the bloodstream) or by positing a new reason for behaviors (e.g., an infant's

interactions in his or her social world are predicated on the need to establish a sense of basic trust in the world, whereas an adolescent's social interactions involve the need to establish a sense of identity, or a self-definition). In other words, it is possible to offer an explanatory discontinuous interpretation of development involving either quantitative or qualitative change.

For instance, when particular types of explanatory discontinuous qualitative changes are said to be involved in development, the critical periods hypothesis is often raised, as in Erik Erikson's work. The point is that on the basis of adherence to a particular theory of development (e.g., what has been termed, in the scholarship of Gilbert Gottlieb, a predetermined epigenetic, or natural one), qualitative changes are believed to characterize ontogeny, and because of this, discontinuous explanations of change are needed.

Thus, virtually any statement about the character of intraindividual development involves, explicitly or implicitly, taking a position in regard to three dimensions of change: (1) descriptive continuity-discontinuity, (2) explanatory continuity-discontinuity, and (3) the quantitative versus the qualitative character of one's descriptions and explanations—that is, the quantitative-qualitative dimension pertains to both description and explanation. In essence, then, one may have descriptive quantitative discontinuity coupled with explanatory qualitative continuity, or descriptive qualitative continuity coupled with explanatory quantitative discontinuity, and so forth.

For example, a feature of personality (e.g., a component of temperament, such as mood) may remain descriptively the same over time. It may be represented or depicted isomorphically at two different temporal points (e.g., positive mood may be represented by the percentage of facial expressions per unit time that are scored as indicative of smiling). Such cases therefore may be an instance of descriptive, qualitative continuity. However, more of this qualitatively invariant phenomenon may exist at time 2 (e.g., there may be more smiles per unit time), and thus descriptive quantitative discontinuity may be coupled with descriptive qualitative continuity.

Moreover, both descriptive quantitative discontinuity and descriptive qualitative continuity may be explained by the same ideas, such as by continuous explanatory principles. For example, smiling may be assumed to be released across life by biogenetically based physiological mechanisms. Alternatively, descriptive continuity or descriptive discontinuity may be

explained by different ideas, such as by discontinuous explanatory principles. For instance, smiling may be assumed to be biogenetically released in early infancy and mediated by cognitively and socially textured processes across subsequent developmental periods. Indeed, if different explanations are, in fact, invoked, they may involve statements that constitute either quantitatively or qualitatively altered processes.

In short, the particular couplings that one posits as involved in human life will depend on the substantive domain of development one is studying (e.g., intelligence, motivation, personality, or peer group relations) and, as we shall see, primarily on one's theory of development. That is, any particular description or explanation of intraindividual change is the result of a particular theoretical view of development. This implies that commitment to a theory that focuses only on certain variables or processes will restrict one's view of the variety of changes that may characterize development. Indeed, theory, not data, is the major lens through which one "observes" continuity or discontinuity in development.

## THE CONTRIBUTIONS OF HEINZ WERNER

Heinz Werner believed that considerable confusion existed among human developmentalists over the continuity-discontinuity issue and that at the crux of this confusion was a lack of understanding about two different aspects of change (i.e., quantitative and qualitative). He argued that these two aspects of change must always be considered in discussions of descriptive and explanatory continuity-discontinuity. However, Werner explained the superordinate conceptual importance of the qualitative-quantitative dimension of change.

### Quantitative Change

In regard to the quantitative aspect of development, we have noted that there is change in a feature of development in regard to how much of something exists. Quantitative change is an alteration in the amount, frequency, magnitude, or amplitude of a developmental variable or process. For example, imagine that a person's weight has been measured at the same time during each of his 8th through 13th years. He weighed 125 pounds when he was measured at 8, 9, 10, 11, and 12; but he weighed 150 pounds when he was measured at 13. Thus, a quantitative change occurred in how much weight existed between the times of measurement occurring at ages 12 and 13 years.

Alternatively, the child's change in weight could have been gradual. By gaining 5 pounds per year, the child gradually goes from 125 to 150 pounds between his 8th and 13th years. With gradual quantitative changes, the rate of change stays the same—is continuous—from one measurement time to the next. This is quantitative continuity.

Thus, quantitative change may be abrupt. There are no intermediate steps by which the person's weight gradually moved from one level (amount) to the next. In measuring this change, there is a gap between one point in the measurement curve and another; that is, a curve representing the different measurements is not smooth but has an abrupt change in its direction. There is a "gappiness" in the curve—a lack of an intermediate stage between the earlier and later levels of a variable. The occurrence of an abrupt change is quantitative discontinuity.

### Qualitative Change

The second aspect of change that Werner specifies is the qualitative one. Here we are primarily concerned not with how much of something exists but with what exists—what kind or type of thing exists. Thus, we are concerned with whether or not a new quality has come to characterize an organism, whether something new has emerged in development. When we are considering qualitative change we are dealing with epigenesis, or emergence.

In distinguishing between quantitative and qualitative aspects of change, Werner highlights a core conception of the organismic position. Some of the types of changes that comprise development are emergent changes. These are changes in what exists rather than in how much of something exists. Something new comes about in development, and because it is new—because it is qualitatively different from what went before—it cannot be reduced to what went before. Hence, if at time 1 we can be represented by 10 oranges and at time 2 we can be represented by a motorcycle, we cannot reduce our time 2 motorcycle status to our time 1 orange status.

To take another example, before puberty a person may be characterized as being (in part) composed of several drives—for example, a hunger drive, a thirst drive, a drive to avoid pain, and perhaps a curiosity drive. With puberty, however, a new drive emerges (or, at least, emerges in a mature form)—the sex drive. With this emergence the adolescent begins to have

new feelings, new thoughts, and even new behaviors which, according to Anna Freud, may be interpreted as being a consequence of this new drive. The emergence of this new drive is an instance of qualitative discontinuity. The sex drive cannot be reduced to hunger and thirst drives, for instance.

Hence, qualitative changes are by their very nature discontinuous. A qualitative, emergent, epigenetic change is always an instance of discontinuity. Moreover, not only is an emergent change an irreducible change, but it is a change characterized by gappiness. As indicated above, developmental gappiness occurs when there is a lack of an intermediate level between earlier and later levels of development. It should be clear that gappiness must also be a part of an emergent change. The presence of an intermediate step between what exists at time 1 and the new quality that emerges at time 2 would suggest that the new quality at time 2 could be reduced through reference to the intermediate step. Since we have just seen that an emergent change is defined in terms of its developmental irreducibility to what went before, it is clear that gappiness must also be a characteristic of any emergence.

### CONCLUSIONS

The characteristics of emergence and gappiness are needed to describe qualitatively discontinuous changes in development; on the other hand, the characteristic of gappiness (abruptness) alone seems to suffice for characterizing quantitatively discontinuous changes. Thus, to quote Heinz Werner:

It seems that discontinuity in terms of qualitative changes can be best defined by two characteristics: "emergence," i.e., the irreducibility of a later stage to an earlier; and "gappiness," i.e., the lack of intermediate stages between earlier and later forms. Quantitative discontinuity on the other hand, appears to be sufficiently defined by the second characteristic. . . . To facilitate distinction and alleviate confusion, I would suggest substituting "abruptness" for quantitative discontinuity, reserving the term "discontinuity" only for the qualitative aspect of change. (p. 133)

What Werner has provided us with, then, is a clarification of the concepts involved in appropriately considering the continuity-discontinuity issue. He has given us the conceptual means with which to discriminate between quantitative continuity-discontinuity

and qualitative continuity-discontinuity in developmental change.

## CONTRACEPTION

---

Procreation and sexual behavior are two of the most important of human behaviors. Without sex and procreation the species would not continue. Unfortunately, these behaviors are not well studied due to both methodological challenges and cultural taboos. There are, however, a few basic facts and distinctions that can be identified. According to Warren B. Miller, *proception* (those behaviors engaged in to produce offspring) can be distinguished from *contraception* (behaviors designed to prevent unintended pregnancies while engaging in sex). And, although contraception is the focus here, note that there are many issues to consider regarding proception, especially given the fact that about 15% of all couples suffer infertility problems when desiring to conceive a child.

Sexual behavior typically begins during the adolescent years. The term *sexual debut* has been used to identify the transition from virginity to nonvirginity status. By the age of 16, more than 60% of both U.S. males and females have experienced this debut. According to Robert Hatcher and his colleagues, “most adolescents who have intercourse do so responsibly. The majority of adolescents use contraceptives as consistently and effectively as most adults.” Comparing 1979 statistics with 1990 statistics, those using a contraceptive at first

intercourse jumped from less than 50% to more than 70%. The problem is that contraception is not used consistently and correctly, even by most adults. Two of the largest risk factors for women’s health are unintended pregnancy and exposure to sexually transmitted infections (STIs). Contraceptive use is designed to prevent unwanted pregnancies. Some (but not all) contraceptive methods also protect against STIs. These cases provide “dual protection.” Unfortunately, it is still the case that approximately one half of all pregnancies in the United States are unintended and for every 1,000 women 15 to 19 years of age, 71 have an unintended pregnancy—a rate only exceeded by those 20 to 24 years of age, at 96 per 1,000. Contraceptive use is not what it should be.

Two distinctions relevant to contraceptive behavior are important. The first of these is the fact that although it is possible to identify the theoretical efficacy of differing methods of contraception (often labeled “perfect use”), humans are not perfect, and use of contraceptives is often impacted by circumstances, such as the dynamics of the relationship, the cultural context, and the “heat of the moment.” Hence, the actual efficacy of methods is labeled “typical use” and is a lower rate than the theoretical estimate. Consequently, even though a method might be described as 99% effective, when used inconsistently, incorrectly, or tentatively, the observed efficacy may be much less than this, perhaps even in the 70% to 80% range. The second distinction involves the fact that some methods, known as natural family planning methods (NFP), do not depend on the use of products or artificial hormones. Examples of these methods include abstinence, calendar rhythm, withdrawal, and monitoring of a woman’s mucus. Alternatively, methods using barriers and/or hormones are often labeled “modern methods.” Natural and modern methods have varying arguments for their use, demonstrate varying degrees of efficacy, require varying degrees of sophistication by those using the methods, and evince differing gaps between perfect and typical use rates.

### MAJOR METHODS

The major methods used around the globe vary dramatically as a function of culture and expense. Natural methods used by women depend on an understanding of the female’s body and the functioning of her menstrual cycle. Many women have cycles that are just less than a month in duration. Natural methods depend on estimates of the time of ovulation—typically toward

the middle of this cycle. Intercourse is avoided prior to and during ovulation. In a related fashion, a female's mucus changes consistency and feel prior to ovulation, and thus can be used to estimate the time of ovulation—and intercourse is avoided. A more recent NFP technology is available in Europe (Persona) that identifies the shifts in a woman's hormones, predicts and identifies her days of ovulation, and can assist in training a woman to understand her own cycle. This product offers an educational opportunity to adolescent women, but is rather expensive. In the United States, less than 10% of all women utilize natural methods for contraception.

Major modern methods throughout the world include barrier and hormonal approaches. Barrier methods include the condom, female condom, and diaphragm. Hormonal methods include the pill, injectables, and the intrauterine device (IUD). Recently, patches have been approved for use, mostly in the United States. It is important to distinguish those couples that intend to have more children from those who do not. In the United States, those not wanting more children depend on female sterilization (46%) and male vasectomy (18%) more than any other methods. Note that there is no protection from STIs with these methods. For those intending to have more children, 51% use the pill and 32% use the condom. In countries such as France and Egypt, the IUD is one of the most popular methods.

## NEW METHODS

Of particular importance to adolescents are some of the more recent contraceptive methods approved for use. These include emergency contraception (EC), patches, injectables of varying duration, and Mirena. Emergency contraception has actually been available for decades, but has just recently been made available by manufacturers and physicians. Simply put, the hormones used in many oral contraceptives (pills) will prevent conception if taken in larger doses immediately after intercourse (perhaps up to 3 days but more effectively if taken sooner). EC is especially recommended for those experiencing an unanticipated, unwanted, or forced sexual experience, or one during which another method has failed, such as a broken condom. Patches that adhere to the woman's skin in a fashion similar to an adhesive bandage contain hormones similar to those contained in pills. Patches are worn for varying lengths of time, depending on the brand, and not during menstruation. They do not need

to be remembered every day, as do pills. Similarly, manufacturers are developing injections (again containing hormones) that prevent pregnancy for varying lengths of time (1, 2, or 3 months). They may become more popular than multiple year injections. Mirena is a product similar to the IUD that not only prevents pregnancy, but also seems to have many reproductive health benefits, such as preventing fibroid growth and reducing the risk for cervical cancers. Mirena has become extremely popular in England, where IUDs are more popular than in the United States. Lastly, researchers are confident that a number of new methods will be developed in the next 10 years. They include a male pill, an externally applied spray (spray-on) for either men or women, and topical microbicides (gels) that might provide dual protection.

## GENDER, NEGOTIATION, AND RELATIONSHIPS

It is difficult to understand behavior related to contraception without attention to gender. In fact, most methods are identified as either male methods (e.g., condoms, vasectomy) or female methods (sterilization, pill, IUD, diaphragm, patches, EC). Furthermore, choice and use of a male or female method are often determined by whether the male or the female member of the couple is making the choice.

Clearly, the nature of the couple relationship also influences choice of method. Only one half of U.S. adolescent couples actually talk about contraception prior to sexual debut. Many methods require some type of negotiation, and all too often it is the young woman who is not in a position to negotiate. Too often sexual behavior is impacted by force, coercion, and power differentials (both gender and gender's interaction with economics are at play here). Some research suggests that the individual most committed to the relationship actually wields the lesser power, going along with the other's opinion so as to not scare the partner away from the relationship. The clearest example of differential power involves transgenerational sexual activity. In many African cultures the practice of "sugar daddies" is popular, and increasingly "sugar moms" are as well. In these cases, an older man provides economic incentives (including food, clothing, schooling, etc.) to a young woman (not his wife) for sexual favors. The young woman stays in the sugar daddy relationship for the economic benefits, while also having a same-aged boyfriend for "love."

On a more positive note, many couples choose among contraceptive methods for the impact that they may have on their intimate relationship. In many cultures, men have criticized the condom as they argue that pleasure is diminished, in spite of data questioning that argument. Some methods are better than others in not disrupting the heat of the moment (pills, injectables, etc.) or requiring one to plan ahead (diaphragms, having condoms handy, etc.). Conversely, new methods such as microbicides or spray-ons may provide extra lubrication, thereby making intercourse more pleasurable. The commercial success of similar feminine hygiene products suggests that the creation of contraceptive methods that actually make sexual activity more fun is possible. Such methods might be especially popular with adolescents and those beginning their sexual behavior.

Most importantly, the field of contraception research has much to address. Basic questions remain regarding how we can help people engage in healthy reproductive behaviors and have planned pregnancies, avoid unwanted pregnancies and STIs, access contraceptives in a dignified manner, and use contraceptives safely, consistently, and effectively.

—Lawrence J. Severy

## CONVERGENT THINKING

---

The term *convergent thinking* is defined as the process of finding the single best solution to a problem or question, such as arriving at the answer to a multiple choice question or figuring out how to program your VCR. Coined by J. P. Guilford in 1950, convergent thinking is a process that seeks out the right or best possible solution from many possibilities. Some types of questions that require convergent thinking are multiple choice tests, logic puzzles, and text comprehension questions. Convergent thinking questions often require the subject to resolve, explain, identify, or define.

Convergent thinking is usually contrasted with divergent thinking, which is defined as searching for a variety of relevant solutions to problems that have many possible answers, such as when one is brainstorming for topics to write about for a poem. Some examples of questions that tap divergent thinking include predicting what may happen if the stock market crashes or imagining the possible outcomes of different marketing campaigns for a new product. Divergent thinking questions often require the subject to predict, imagine, compose, or create. Divergent thinking incorporates the ability to generate multiple ideas from a single starting point. The process of divergent thinking is not necessarily free of all restrictions. When writing a poem, one may follow the precise rules outlined for a sonnet or haiku and still engage in divergent thinking. Convergent thinking is usually tested by performance on tasks requiring analytic and reasoning skills, whereas tests that measure divergent thinking are thought to reflect creativity.

Developmentally, many educational psychologists believe that the current education system tends to emphasize convergent thinking over divergent thinking and that this emphasis encourages children to refine related skills and traits over others. Students are often encouraged to memorize facts and algorithms rather than to engage in creative projects. Most of the

usual testing formats, such as multiple choice, true/false, and fill-in-the-blank questions are designed to reflect convergent thinking processes. Additionally, most standardized achievement tests also reflect convergent thinking. Recently, some researchers have advocated an approach to education that recognizes and encourages divergent thinking skills in addition to convergent thinking.

There are some personality differences between individuals that possess a more convergent thinking style versus those that possess a more divergent thinking style. Convergent thinkers tend to be more intolerant of ambiguity compared with divergent thinkers, and thus tend to be uncomfortable in areas that do not emphasize correct answers such as philosophy or art. Also, individuals with a convergent thinking style tend to be more introverted than divergent thinkers. Finally, convergent thinkers tend to have an external locus of control compared with divergent thinkers. Although these studies are correlational in nature, they provide an idea of individual differences associated with each thinking style.

In summary, convergent thinking is the process of finding the single best possible solution to a problem. It is contrasted with divergent thinking, which is defined as searching for a variety of answers to a single problem. Convergent thinking is emphasized throughout the life span; however, divergent thinking skills are also thought to be developmentally important.

## COOPERATIVE LEARNING

---

Cooperative learning refers to instructional methods in which students work in small groups to learn academic content. Cooperative learning methods vary widely. Group sizes may range from pairs to groups of four or more. Children may be asked to work on projects, to tutor each other, or just to help each other as needed. Each group member may be responsible for a unique part of a task, or all may have the same assignments.

There are four major theoretical traditions that attempt to explain why cooperative learning should improve student learning. Each envisions and recommends different forms of cooperative learning.

Motivational theories of cooperative learning focus on the reward structure surrounding group work. Motivational theorists advocate the use of cooperative learning methods in which there is a group reward (such as recognition for successful groups) that the group can achieve only if all group members learn the academic content. For example, in “student teams—achievement divisions,” or STAD, children work in four-member teams to help each other master a well-defined objective, such as adding fractions, using commas correctly, or balancing chemical equations. Each week, group members take a brief quiz and teams whose members show the greatest gains receive certificates or other recognition. The only way the team can succeed is for the group members to learn, so this is where the group's energies are focused. A key element of such methods is individual accountability, which means that the group is rewarded based on the sum or average of individual children's performance, not on an overall group task. The rationale is that if there is one group task (such as solving a single problem or completing a common project without distinct roles), some children may do the thinking part of the work while others watch or do clerical or art work (as when one child makes a bar graph and teammates color it).

The evidence favoring cooperative learning methods that use group goals and individual accountability is strong. A 1995 review identified 64 studies of at least 2 weeks' duration that evaluated programs incorporating group goals and individual accountability. These studies involved grade levels 2 through 12 and a wide variety of academic subjects. Fifty of these studies found significantly positive effects, and the remainder found no differences, for an effect size of +0.32. In contrast, studies of programs that did not use group goals and individual accountability found few differences, with an overall effect size of +0.07.

A second major perspective on cooperative learning is social cohesion theories, which emphasize the idea that because students identify with their group and want each other to succeed, they will work effectively to help their groupmates learn. A hallmark of such methods is an emphasis on team-building activities to create an "esprit de corps" within groups, but a de-emphasis on the use of external rewards.

Evidence for achievement outcomes of programs based on the social cohesion perspective is mixed. Such methods can be effective if they provide well-structured individual tasks within a group project.

A developmental perspective, based on theories of Piaget and Vygotsky, holds that interaction among peers enhances their mastery of critical concepts, and theorists in this tradition recommend against rewards or structure. There is much evidence from brief laboratory studies to support the idea that cognitive change can come from interaction itself, but longer-term evaluations in classroom settings have been rare and inconclusive.

A related perspective is called cognitive elaboration, which posits that cooperative learning enhances achievement by giving children an opportunity to master information by summarizing and restating their current understandings in working with peers. Methods in this category often involve pairs of students taking turns teaching each other discrete skills or content. Methods based on this theory, such as reciprocal teaching, cooperative scripts, and reciprocal peer tutoring have strong evidence of effectiveness.

Cooperative learning can be broadly applied to improve student learning, but research supports the idea that to be effective, cooperative methods should incorporate group goals, individual accountability, and task structures to emphasize cognitive elaboration of academic content.

---

## COOPERATIVE PLAY

---

Children of all ages play and enjoy playing. Psychologists have found that play is important for children not only because they enjoy it so much, but because it also plays an important role in promoting social, emotional, and cognitive development. During play, children learn skills that help them interact with other children and adults, and they also gain knowledge about the world around them. Psychologists have studied the types and amount of play that are evident in children at different ages.

Children have been noted to engage in four different types of play during the preschool years. Early in life, infants play alone and engage in what is called solitary play. Later, between 2 and 3 years of age, parallel play emerges as children begin to play alongside other toddlers with similar materials, but without influencing each other much. Next, associative play begins to include true social interactions when children engage in a common activity and exchange toys and comment on the behavior of each other. Finally, at around 5 years old, cooperative play emerges, when children begin to work together and assume reciprocal roles while pursuing shared goals during their play. For example, children take leadership roles, discuss rules, and negotiate responsibilities. This cooperative play is social play of the most complex type. Cooperative play is especially important because it allows children to learn social rules such as sharing, turn taking, cooperation, and dealing with disagreements. Also, this type of play leads to the development of meaningful friendships.

While more complex types of play develop as children grow older, the less mature forms of play may still be present but are less common. Parallel play should be less frequent as children grow older and will be largely replaced by cooperative play. Psychologists often observe young children's play activities to assess their level of development. If a child does not begin to engage in cooperative play by about 5 years of age, this may be seen as an indication of an underlying cognitive or social-emotional deficit. For example, the inability to engage in fantasy or social play is a common feature of children with autistic spectrum disorders.

Cooperative play not only becomes more frequent as children develop socially, cognitively, and emotionally, but it also becomes more complex. When children begin to enter into cooperative play episodes, they are often quite simple interactions, such as two children working on a puzzle together. As children get better at this type of interaction, the play gets more complex. For example, an older child may engage in a fantasy play episode of "cops and robbers" with a group of children. This complex type of cooperative play is often called sociodramatic play. It is more complex and provides children with experiences rich in cognitive and social challenges. It is important that children master sociodramatic play because here they act out and respond to one another's pretend feelings. They explore and gain control over fear-arousing situations when their pretend play involves such things as monsters or doctor visits. Also, while involved in such play interactions, children must create and manage complex plots and resolve disputes via negotiation and compromise.

Finally, there are clear connections between the complexity of preschoolers' play and social competence with peers. Preschoolers who play in cognitively complex ways are less likely to be aggressive or withdrawn around their peers and are more outgoing than children with impoverished play. Also, the complexity of preschoolers' play can help predict how socially and academically successful children will be during early elementary school.

## CORPORAL PUNISHMENT

---

Corporal punishment refers to intentional application of physical pain as a method of changing behavior. Youth in the United States experience various forms of corporal punishment in two primary places: their homes and their schools. When corporal punishment occurs in the home, it can be thought of as a form of family violence. The most severe forms of corporal punishment occur with very young children, pregnant teens, and adolescent males between the ages of 15 and 17. Spanking is the most common form of corporal punishment used by adults to discipline children. The use of spanking as a disciplinary method is controversial. Parents often consider the use of spanking as a helpful and effective method of child rearing that teaches morals and values to a growing child. However, rather than being employed as an effective disciplinary intervention that is metered out in proportion to the misdeed, parents or teachers are more likely to administer the timing, intensity, and frequency of corporal punishment according to their parental or teacher mood than the child's actual misdeeds.

### HISTORICAL PERSPECTIVE

Corporal punishment against children has been an acceptable form of discipline for thousands of years. Adults have often interpreted legal and religious doctrines to support the use of physical discipline as essential to the rearing for obedient, respectful, well-controlled children who learn appropriate appreciation for authority, develop better social skills, have improved moral character, and learn to better discipline themselves.

Children have been whipped, caned, paddled, spanked, slapped, switched, shoved, choked, punched, and kicked in the United States since colonial times.

### CORPORAL PUNISHMENT AS A FORM OF VIOLENCE

Violence in this context is the act of harming or damaging a human. Corporal punishment is a form of

violence or human aggression. The most extreme outcome of violence is death. Examples of other extreme outcomes of corporal punishment include sexual violence, sexual assault, rape, physical abuse, physical assault, violence committed with a weapon, murder, and homicide. Any and all forms listed above can include acts of hitting, kicking, scratching, biting, pushing, shoving, slapping, pinching, squeezing, punching, or using an object to inflict harm. Those objects can be used to inflict damage through stabbing (knives and other sharp objects), shooting (guns and bows and arrows), or hitting with a stick, belt, switch, board, paddle, rock, and so forth.

### **Supporters of Corporal Punishment**

Advocates of corporal punishment include most American parents, many teachers, organizations such as the National Association of Secondary School Principals and the American Federation of Teachers, some religious organizations, and the majority of family physicians and pediatricians. The majority of American parents spank their small children (under 5 years of age). Advocates of corporal punishment do not just contend that children should be physically punished for every misdeed. They also advocate other methods be tried first or paired with physical punishments and that the actual spanking or hitting of children be used only as a last resort. Supporters of corporal punishment further contend that the research that finds against corporal punishment only refers to severe forms of physical punishment and does not apply to what happens in most homes and schools.

### **Opponents of Corporal Punishment**

Opponents contend that any form of physical punishment is a form of violence, is an ineffective method of discipline, and has major deleterious effects on the physical and mental health of its victims. Opponents also find that there is no empirical evidence that physically punishing children enhances moral character development, increases respect for teachers or other authority figures in general, or creates better controlled individuals. Youth under the age of 15 are at greatest danger of being victims of violence in the form of corporal punishment in two primary places: their own homes at the hands of their parents or caregivers and their schools at the hands of their teachers, counselors, assistant principals, and principals. Individuals who

are exposed to more severe forms of corporal punishment in their homes are at increased risk for physical and emotional abuse, disability, and death. Children who grow up in violent homes are at risk for learning several early and powerful lessons: (a) violence is an inherent part of a “loving” relationship; (b) violence is an acceptable way to assert one’s views, get one’s way, and resolve conflict between partners; and (c) violence is an acceptable method to discharge stress.

Youth who are severely physically punished become more rebellious and are more likely to demonstrate vindictive behavior and seek retribution against parents, school officials, and others in society. The use of severe corporal punishment can result in what is termed operant aggression. In this form of aggression, the victim uses the same physical intervention that was used against him or her on the parent or adult who was administering discipline. The victim retaliates to destroy or immobilize the parent or teacher to prevent delivery of further punishment. Elicited aggression can also result from the punishment in which the victim physically attacks others in the environment, even those who are not the source of the original punishment. The victim simply wants to destroy or immobilize anything that might cause delivery of additional punishment.

Children who grow up in coercive families may become aggressive and further initiate aggressive interchanges that they have learned from their parents or teachers. Children who are victims of corporal punishment in their homes or schools are seen in doctor’s offices and emergency rooms every day. Injuries from these medical visits include abrasions, severe muscle injury, extensive hematomas, whiplash damage, life-threatening fat hemorrhage, and others (including death).

When corporal punishment is used in the school system, it can produce an environment that is unproductive, nullifying, and punitive. Rather than providing an atmosphere of opportunities to learn academically and socially, children who are physically punished become victims, and trepidation is introduced to all students in such a classroom. The victim and witnesses of such abuse can develop low self-esteem, magnified guilt feelings, and various anxiety symptoms, which may have negative results on the psychosocial and educational development of these students.

The student does not learn to adopt societal values and attitudes as his or her own and is not motivated by intrinsic or internal factors; rather, the child or adolescent

learns to elude detection and to use violence as a means to influence others

During the 1970s, organizations that opposed violence against children in our school systems included the American Civil Liberties Union (ACLU), American Orthopsychiatry Association, American Psychological Association, National Center on Child Abuse Prevention, American Academy of Pediatrics, American Bar Association, American Medical Association, Parent-Teacher Association, National Education Association, and Society for Adolescent Medicine. These and over 20 other groups united to ban the practice of physically punishing children and youth in school. Currently 75% of states in the United States have legally banned corporal punishment in schools.

## CORRELATION

---

Does high school grade point average (GPA) predict college performance? Does reading to a child help future school performance? Researchers, legislators, business people, teachers, and parents are all interested in how variables are related. This relationship is the general way in which different values of one variable are associated with different values of a second variable. The degree of relation permits us to predict future behavior and performance. Correlation can refer to either the statistic used to represent the degree of relation between two variables or to the correlational level of interpretation in research methods.

The correlation coefficient, often denoted as  $r$ , is a statistic that describes how strongly variables are related. The correlation coefficient ranges from  $-1.00$  to  $+1.00$ . It provides two important pieces of information about the relationship between two variables. The strength describes the degree of relation in numerical terms. The closer to  $1.00$ , the stronger the degree of relation. When describing the strength of the correlation, the sign, either positive or negative, is ignored. Zero indicates that the two variables are not related. In other words, knowing variable A does not tell you anything about variable B. Knowing a person's shoe size tells you nothing about his intelligence. In contrast, a correlation of  $1.00$ , either positive or negative, would allow you to perfectly predict changes in variable B from changes in variable A. Most correlations fall somewhere between zero and  $1.00$ . The correlation between high school GPA and first year college success is about  $+0.5$ . This means that about 25% of the variability in first year college success can be explained by high school performance. The percentage of variability explained is obtained by squaring the correlation.

The sign of the correlation provides information about the direction of the relationship between the two variables. A positive correlation indicates that the variables change in the same direction. In other words, when the values of one variable increase/decrease, the values of the second variable increase/decrease in the same direction. For example, on average, the more a person studies for a test the better their grade tends to be. Both variables change in the same direction.

A negative correlation indicates that the variables changed in opposite directions. In other words, when the values of one variable increase/decrease, the values of the second variable increase/decrease in the opposite direction. For example, there is less hot chocolate consumed in the summer than in the winter. Therefore, the relation between amount of hot chocolate consumed and outside temperature is negative.

Correlational designs, nonexperimental designs that seek to describe relationships between variables without directly manipulating the variables, are useful for prediction. The major problem with the use of findings from correlational designs is that they are often interpreted in a causal manner. Correlations can be used in research involving both experimental and nonexperimental methods. It is important to note that causality cannot be inferred from correlational analysis when working with the nonexperimental methods. Without proper experimental control, researchers cannot determine the direction of cause and effect. For example, in a bivariate relationship, the change in variable X could cause the change in variable Y. However, it is also conceivable that variable Y is causing the change in variable X. When a nonexperimental method is used, there is also the danger that no direct causal relationship exists between the two variables. Instead there may be a relationship between the two variables because some other variable causes them both. This third variable limits the ability of the researcher to identify the cause of changes in the variables.

## COSLEEPING ARRANGEMENTS

---

Cosleeping is generally characterized by caregivers and their children sleeping in close proximity, either with the caregiver and child sharing a bed or the child

sleeping in the same room as the caregiver but in a separate location, such as a bassinet or crib. Cosleeping can entail children and caregivers sharing sleeping locations for all or part of a night for all or just some nights.

Cosleeping has been identified as the predominant sleeping pattern for families across the world. Despite this widespread use of cosleeping, questions concerning potentially negative outcomes associated with cosleeping abound, particularly in the United States and other Western-based cultures. Negative outcomes have focused on the likelihood of increased night wakings for cosleeping infants in comparison with infants who sleep separately from caregivers and soothe themselves back to sleep upon waking.

A review of what is known regarding children's sleep suggests that night wakings and needs for parental attention are normative across all sleep types, recede over the course of development, and may not be problematic for cosleeping families. For example, the night wakings associated with cosleeping infants are identified as problematic by families engaged in reactive cosleeping (i.e., cosleeping in response to infant sleep problems), but not by families engaged in cosleeping by choice. Furthermore, reports of sleep problems associated with cosleeping arrangements tend to vary based on families' cultural backgrounds, children's or mothers' temperament, or other environmental factors and thus may reflect questions of caregivers' expectations for sleep and socialization goals.

Physiologically, cosleeping leads to lighter infant sleep, in comparison with solitary sleeping patterns characterized by greater periods of quiet sleep. During cosleeping, infants' and caregivers' breathing patterns and sleep cycles become synchronous. These physiological characteristics of cosleeping children, as well as the higher level of parental monitoring associated with cosleeping, may guard against sudden infant death episodes, which can occur when infants fail to continue breathing during sleep.

In regard to social development, caregivers' attention to infants' waking during the sleep routine may help to build a strong attachment between caregiver and infant and thus help form the basis for children's development of a secure attachment and the associated positive social outcomes. In addition, cosleeping may contribute to the likelihood of breast-feeding, which is associated with psychological and health benefits for infants. Despite these potential benefits, some

concerns have been raised that cosleeping, in comparison with solitary sleeping arrangements, may compromise children's development of independence and children's ability to separate from parents. Empirical support can be found for positive social outcomes associated with both cosleeping and solitary sleeping arrangements. Furthermore, a preliminary research report has associated children's positive social development with caregivers' comfort with their chosen sleeping arrangements, but not caregivers' and infants' engagement in one specific type of sleeping pattern.

Cosleeping has been cited as putting infants at risk for suffocation by overlaying or wedging between the caregiver and bedding. In light of these concerns, solitary sleeping arrangements have been identified as safer for infants and often proposed as the preferred sleeping arrangement. However, some research studies report that cosleeping is not more risky unless caregivers smoke cigarettes, are overweight or overly fatigued, use soft bedding, sleep in arrangements where infants became overheated, or use drugs or alcohol.

Given the varied outcomes associated with cosleeping and other types of sleep patterns, and given the universal acceptance of cosleeping, this sleeping pattern represents a viable and important sleep option for parents and professionals to consider when addressing infant and toddler sleep needs. The viability of cosleeping as a sleep option is further supported in that neither cosleeping nor other types of sleep arrangements have been associated with definitively fewer sleep problems for infants or toddlers or with better sleep habits at later developmental stages.

## COURTROOM TESTIMONY

---

In the courtroom, it is often the testimony of a witness that determines whether an alleged perpetrator will be convicted of a crime. Courtroom testimony from a witness in a civil case can determine how that case is resolved. When crimes such as murder or rape occur (or, in the realm of civil law, when an accident occurs), there are two primary types of evidence: eyewitness accounts and physical evidence. In many cases, the courtroom testimony of the eyewitness is the primary or only evidence that the alleged perpetrator committed the crime or that an accident unfolded in a particular way. Yet, there is reason to believe that eyewitnesses are not always accurate. In the past decade, in cases where prisoners have been released because new DNA evidence has conclusively proved their innocence, mistaken eyewitness identification has been shown to be the most common cause of what we now know were wrongful convictions. In addition, new research on child witnesses and acquittals in several highly publicized child abuse day care cases have raised questions about children's ability to testify.

## WHAT IS COURTROOM TESTIMONY?

Courtroom testimony is oral evidence given under oath by a witness in answer to questions posed by attorneys at trial or at a deposition.

## WHO GIVES TESTIMONY?

There are three basic types of witnesses: lay witnesses (or eyewitnesses), character witnesses, and expert witnesses. Lay witnesses are people who perceive an event (by seeing, hearing, smelling, or other sensory perception) related to the trial. Character witnesses are people who testify in a trial on behalf of a person (usually a criminal defendant) as to that person's ethics and morality both by the personal knowledge of the witness and the person's reputation in the community. Such testimony is admissible (1) when the guilt of an accused party is doubtful and the character of the defendant is involved in the question; (2) to affect the damages in civil cases, where their amount depends on the character and conduct of any individual; and (3) to impeach or confirm the veracity of a witness. Finally, expert witnesses may testify when knowledge of a technical subject matter might be helpful to a judge or jury. People with special training or experience in technical fields are admitted as expert witnesses and are permitted to state their opinion concerning those technical matters, even though they were not present at the event.

## HOW ACCURATE IS EYEWITNESS TESTIMONY?

A number of general statements can be made about eyewitnesses:

1. People remember more about central components of an event than details, and the more stress someone is under, the fewer details they will remember. For example, a witness is more likely to remember the actions and speech of a person than to be able to describe the room or the perpetrator's shoes. An extension of this concept is that when a weapon is present, witnesses tend to focus on the weapon more and on the person wielding the weapon less. In this scenario, the weapon becomes a more central component of the event (and thus remembered) and the wielder of the weapon becomes a less central component of the event (and thus less remembered).

2. People can confuse pieces of several true events to the extent that they believe that people or events in

one situation were present in a different situation. For example, imagine that after a bank robbery a person runs outside and bumps into a news vendor. Later this witness is shown a lineup that does not have the robber in it but does have the news vendor in it. The witness may accidentally identify the news vendor as the robber from the lineup because the face of the news vendor is familiar and the witness assumes the face is familiar because of the robbery.

3. We know that in most situations younger witnesses, particularly preschool-aged children, provide less information than adults; more of the information they do provide is inaccurate; and they are more likely than adults to succumb to pressures to change their reports. This is an important problem for the prosecution of child abuse because children are often the only witnesses to the crime.

4. Other known facts are that witness confidence is not necessarily related to accuracy even though jurors tend to believe that more confident witnesses must be correct and that even subtle and unintentional suggestions from authority figures, such as the police, can cause witnesses to distort their reports.

## HOW DO JURORS PERCEIVE WITNESSES?

Eyewitness testimony has a powerful effect on jurors' judgments. Jurors are more likely to convict a defendant if an eyewitness identifies him as the perpetrator than if there is only circumstantial evidence linking him to the crime. Identifications from eyewitnesses influence jurors' decisions even when the eyewitnesses are discredited, for example, by admitting that their vision is very poor. Eyewitness testimony influences jurors' decisions irrespective of the witness's viewing conditions. However, jurors tend to put less weight on the testimony of a child who has witnessed an event than on the testimony of an adult eyewitness. Still, in sexual abuse cases, younger victims are viewed as more credible than adolescents or adults, perhaps because jurors suspect that younger children lack the sexual knowledge to fabricate such allegations.

Testimony from an eyewitness influences jurors' perceptions of a defendant's culpability (or, in a civil case, of the manner in which an accident occurred) because many jurors assume that the witness's memory is accurate. As mentioned previously, for central items, a witness's memory is likely to be accurate. But in the aftermath of a crime or an accident, gist

memory may be insufficient. In these situations, precise details about how the defendant looked or about how an accident occurred are necessary. Unfortunately, eyewitnesses to crimes often have poor memories of the precise details that would implicate one defendant and exculpate another.

Jurors can be sensitized to the factors that influence the reliability of eyewitness identifications. Courtroom testimony from an expert witness for the defense can educate jurors about the difficulty of cross-racial identifications, the influence of a weapon, and the effects of lineup suggestiveness on eyewitness memory, among other things. This expert testimony increases jurors' sensitivity to the effects of a witness's viewing conditions. Specifically, jurors who hear this testimony deem the defendant more culpable when the eyewitness identification was made under good witnessing conditions than when the identification was made under poor conditions.

## SPECIAL ISSUES IN EYEWITNESS TESTIMONY

### The Suggestibility of Children

An increase in the reporting of child abuse and the consequent rise in child courtroom testimony has encouraged research in the area of child witnesses. In cases of child abuse, often the only witness to the event is the child. One major area of study within the field of child witnesses is the influence of adult interviewers on child witness competency. Researchers have established that neutral interviewing techniques such as open-ended and free recall questions elicit the highest rates of accuracy but fewer details in the youngest children. On the other hand, more suggestive interviewing techniques such as close-ended and repeated questions have been found to increase details provided by the child by increasing both accurate and inaccurate details. Furthermore, leading questions, particularly when repeated over time and paired with other suggestive techniques (e.g., stereotype induction) can cause some subset of children to describe events that never occurred.

### Types of Lineups and Cross-Race Identification

Recent research on the issue of photographic lineups has shown that the "typical" method of showing the witness six photographs or six people (i.e., showing all of them at once, called a simultaneous lineup) leads to

less accurate suspect identification than showing witnesses one photograph or person at a time and asking them if this person is the suspect (called a sequential lineup). The idea is that if people view photos all at once they start to rely on relative judgments (i.e., which person looks most like the robber) rather than absolute judgments (i.e., is this individual the robber). People make more errors in relative judgments about photographic lineups. An additional twist is that we now know that witnesses make more errors when they are making identifications of suspects of a different race from their own. For example, a witness of African heritage will make more errors when trying to identify perpetrators of Asian heritage than when trying to identify perpetrators who are also of African heritage.

## SUMMARY

Witnesses are a primary component of Western systems of justice, and there are three basic types: eyewitnesses, expert witnesses, and character witnesses. Eyewitness accuracy is significantly degraded in a variety of common witnessing conditions (e.g., in stressful situations, after long time delays, when identifying someone of a different ethnic background). Despite these mitigating factors, jurors tend to believe in the accuracy of eyewitness testimony and generally do not attend to the types of conditions that are known to cause inaccurate testimony. However, jurors tend to put less weight on children's eyewitness testimony than adults' eyewitness testimony, which is consistent with the knowledge that child witnesses are more susceptible to suggestive interviewing techniques than adults.

## CRACK BABY SYNDROME

---

With the arrival of the relatively inexpensive and smokable crack form of cocaine, the rate of newborns exposed to cocaine in utero rose dramatically in the early 1990s. In the mid-1990s it was estimated that 1.1% of pregnant women used crack cocaine. Early reports of neonatal behavioral abnormalities led to the label “crack baby syndrome” and were followed up with several large, longitudinal studies. Crack cocaine-exposed neonates were demonstrated to be more jittery and less likely to modify their attentional behavior based on their arousal state. During the first year, infants exposed prenatally to crack cocaine are rated as having more attentional abnormalities and being less successful at remembering stimuli in their environments. However, the term *crack baby syndrome* is now generally recognized as inappropriate beyond the early neonatal period, after which time the behavioral differences are more subtle and do not constitute a distinct syndrome.

Several large-scale studies were funded to follow crack cocaine-exposed babies over time. They found that the mothers who had used crack cocaine during pregnancy were different from pregnant women recruited from similar economic and ethnic/racial groups. The mothers of the cocaine-exposed infants were (1) more likely to have used alcohol, cigarettes, and marijuana during pregnancy; (2) were more likely to continue to use alcohol and drugs of abuse postnatally; and (3) were more likely to have symptoms of psychiatric distress prenatally/postnatally. These polysubstance use and psychological characteristics of crack cocaine-using women have been repeatedly documented and found to have their own negative effects on child development.

One question addressed by these studies is to what degree are any persistent difficulties seen due to the cocaine exposure itself, not the other risk factors. In regards to overall mental functioning in early childhood, some studies found small effects of the cocaine specifically and others found no effect. However, specific effects of cocaine exposure on global functioning reported in infancy were no longer detectable, or subtle, by school age.

However, several studies have shown that cocaine exposure is associated with disruptions in attention and inhibition that could not be attributed to differences in maternal functioning and exposure to other substances. These independent relations of cocaine exposure on attention and inhibition have been confirmed in animals and persist into school age. In particular, the difficulties seem to be in paying attention to the information that is important in the moment and using that information to reach goals, as opposed to acting impulsively. Unfortunately, the attentional and planning abilities that are particularly sensitive to crack cocaine are also vulnerable to alcohol, cigarette, and marijuana use during pregnancy. So although the specific effect of the cocaine may be small, crack cocaine-exposed children usually are exposed to multiple substances that all impact on the same system.

Although it may not ameliorate the effects of cocaine on attention, positive environments have been shown to reduce the rate of mental retardation and increase verbal IQ in cocaine-exposed children. The hopeful findings of researchers is that providing a home life supportive of mental development makes a substantial impact on how crack cocaine-exposed children are doing as they enter school age.

## CRAWLING

The onset of crawling is a major milestone in infant motor development that also heralds a dramatic and pervasive set of changes in psychological functioning. Crawling represents the culmination of a long and complex struggle to overcome and then exploit the effects of gravity from the prone position. Once acquired, independent mobility offers many new opportunities to act on one's intentions, to explore the world, and to profit from the numerous encounters that are now possible with that world.

The terms *crawling* and *creeping* are often used interchangeably, although each refers to a distinct pattern of limb motions. Crawling is a pattern of prone locomotion in which the abdomen is in contact with the surface of support, whereas creeping is a pattern of prone locomotion in which the abdomen is above the surface of support and the weight of the body is supported by either the forearms and knees, the hands and knees, or the hands and feet. The term *creeping* is not particularly fashionable in the contemporary literature. Researchers prefer to use the terms *belly crawling* and *hands-and-knees crawling* to refer respectively to patterns of prone locomotion in which the abdomen is either in contact with the surface of support or not in contact with the surface of support.

The development of crawling is a complex process that involves qualitative shifts in the patterns of interlimb coordination used to propel the body and quantitative improvements in speed and efficiency. As many as 23 stages have been identified in the development of prone locomotion, and 25 patterns of interlimb coordination have been identified for propulsion. Although there are large individual differences in the rate at which crawling develops and in the patterns of limb motion used while on the belly, once infants adopt the hands-and-knees posture, they quickly converge on a diagonal gait in which the contralateral arm and knee move together (e.g., left arm–right knee followed by right arm–left knee). The diagonal gait is thought to be the most biomechanically efficient and stable way to move on four limbs because it ensures a wide base of support and minimizes medial-to-lateral and

forward-backward shifts in the center of gravity. It should be noted that even though the diagonal gait is thought to be the most efficient form of prone locomotion, moving in the prone position is mechanically and metabolically less efficient than moving in the upright position, although the differences between the two modes of locomotion are larger for adults than for children.

Researchers once thought that the development of crawling was predominantly a function of neuromuscular maturation. However, it is now recognized that many factors, particularly opportunities for practice, play an important role in crawling acquisition. For example, the age at which crawling is achieved is influenced by season of birth (with infants born in the winter months tending to crawl earlier than infants born in the summer months), the extent to which infants are wrapped in heavy bedclothes, the amount of time infants spend in a prone or supine position, and the degree to which a particular cultural group values the onset of crawling. With respect to the latter factor, infants reared in cultures that promote upright postures tend to crawl later (or not at all) compared with infants raised in Western cultures, and in some cultures crawling is prohibited because it is viewed as primitive and demeaning. In contrast, the onset of crawling is accelerated with training in cultures that value independence from the mother.

Finally, the onset of crawling has been linked to major changes in psychological functioning, including the emergence of wariness of heights, the ability to search for hidden objects, the use of more sophisticated strategies to code one's position in space, the ability to use more spatially delimited patterns of optical flow for postural control, and the ability to understand the referential gestural communication of others. Researchers are now attempting to determine whether the acquisition of crawling is causally related to these phenomena or whether it is simply a maturational forerunner of these important psychological changes.

## CREATIVITY

---

A kindergartener's finger painting, a composer's sonata, a scientist's discovery—many seemingly disparate acts can be labeled “creative.” While creativity has been widely valued both in children and adults, the concept of creativity has varied greatly in its definition. Creativity is conceptualized by some as a desirable trait that a person is either gifted with or lacking, while others believe that a person's creativity, like many other complex behaviors, can be promoted given the right environment.

### WHAT IS CREATIVITY?

Process, person, or product—what is creativity, and where is it to be found? Creativity is thought by some to be a mysterious inner process that can be neither tested nor taught. Some consider creativity to be part of the person, describing a woman as creative as readily as they would describe her tall. Still others find that creativity can be attributed to the product itself and describe ideas, painting, and songs as creative. At its simplest, creativity is the behavior of producing something new, whether it is an idea or a product.

In 1959, Joy Paul Guilford explored the relationship between intelligence and creativity. He hypothesized that the link was problem solving. Guilford detailed two kinds of problem solving: convergent thinking and divergent thinking. Convergent thinking, the type most often reinforced in academic settings, is a manner of problem solving in which the problem solver narrows all of the possible answers down to one single solution. Divergent thinking is a mode of problem solving in which the problem solver creates a number of solutions for one problem. Guilford believed that divergent thinking was at the heart of creativity, and he, like many others, found the educational system to promote almost exclusively convergent

thinking. It is now widely recognized that both convergent and divergent thinking play their own part in creativity, because divergent thinking enables the problem solver to come up with a number of possible solutions while convergent thinking leads to a course of action chosen from those many and varied ideas. In Guilford's theory of creativity there are several components of divergent thinking: originality, fluency, flexibility, and elaboration.

### ASPECTS OF CREATIVITY

People are said to be behaving creatively when they produce a product or an idea that is original or different. The product or idea may be different in relation to others produced by the individual, by others in their peer group, or in relation to the society in which they live. It is generally held that to be creative an idea or product must be not only new but also useful or appropriate. A student who throws blocks at his teacher rather than building with them might be said to be engaging in a new or different behavior, but it would be unlikely to be judged creative.

A trait that is often deemed a necessary ingredient of creativity is fluency. Fluency is shown when a person generates many different yet suitable responses to a stimulus within a set amount of time. It is thought that a person who is able to come up with a large number of responses has a greater chance of producing a creative response. Most common in creativity testing is ideational fluency, the ability to name things that belong to a given class. A person might, for example, be asked to name as many things as they can in 1 minute that are long. While initial responses such as “pole” or “stick” may lack in originality, ideas produced later in a sequence are often more original, such as “a frog's tongue.” Other types of fluency include word fluency, the ability to easily state a large number of words containing a given letter, and associational fluency, the ability to easily state synonyms for a given word.

Flexibility is the ability to shift approach when addressing a problem. For example, in the above problem of listing things that are long, answers such as “pole,” “stick,” and “frog tongues” are all items that are measurable with a ruler. Showing flexibility in answering would be additionally listing answers such as “geometry class” or “the wait for a bus on a cold day.” Spontaneous flexibility is shown in the above example, while adaptive flexibility is demonstrated when a problem solver who has headed down the

wrong path on a problem can effortlessly take a new tack. Both increase the probability of solving a problem by allowing the problem solver to come up with a number of different approaches and easily “switch gears” when it is discovered that they have proceeded in the wrong direction.

Elaboration is filling in the details of an idea or product. This procedure extends the response, supplementing the original to make it clearer or better. The process of elaboration completes an idea or product and may describe how it may be constructed, used, improved, or how it may impact others.

## TESTING FOR CREATIVITY

Once the components of creativity are broken down into observable, measurable units of behavior, creativity testing is possible. Although there are countless tests for creativity and they vary a great deal in their content and structure, creativity tests generally center on the idea of divergent thinking, and most test for the above components of flexibility, fluency, originality, and elaboration. Creativity tests tend to have questionable predictive validity, meaning that results are unlikely to accurately predict whether or not a student will behave creatively or become a creative adult. However, most creativity tests have been found to be fairly reliable in the sense that a person’s scores change very little upon repeated testing.

The most widely used test of creativity is the Torrance Test of Creative Thinking. Both a verbal and a nonverbal component make up this test. The verbal Torrance Test for Creative Thinking consists of six word-based activities in which students are asked to perform tasks, including considering alternative uses for common items, answering hypothetical what-would-happen-if questions, generating questions, and improving products. The nonverbal or figural Torrance Test for Creative Thinking is composed of three picture-based activities in which students are asked to draw as many pictures as possible given a repeated shape, take forms and make them into pictures by adding lines, and complete a picture through drawing.

Both components are scored for fluency, flexibility, and originality. Additionally, the nonverbal component is also scored for elaboration. The Torrance Test has excellent content and construct validity compared with most other creativity tests and has scored higher than other tests on a number of predictive validity measures.

Is creativity, like IQ, something that remains relatively static throughout one’s life, or can a person’s creativity be improved? There are a number of curricula available that are designed to increase aspects of creativity. Most equate creativity to divergent thinking, deriving multiple solutions to a single problem, and work to increase that aspect of creativity. The methods of training in these curricula are varied, including audiotapes, comic books, workbooks, and direct teaching of skills. Most procedures include instructions as to the importance of creative thinking and include skill practice as the primary activity in training.

Some research regarding the effectiveness of these training programs shows an increase in students’ scores on tests of divergent thinking. Although these results may seem promising, students are generally tested using materials that are very much like the training materials. There is little research to show that the positive effects of training generalize beyond these materials.

The most successful results to date come from interventions designed to increase individual aspects of creativity through reinforcement. A number of studies conducted in the 1970s increased diverse and novel behavior by praising behavior that had not previously been seen in the student within the session. Some of the behaviors increased were block building, drawing, constructing tools, creative writing, and painting. Through descriptive social reinforcement, novelty and diversity of behaviors increased substantially. In 1976, Glover and Gary increased each of the four aspects of creativity listed above: originality, fluency, flexibility, and elaboration in a group of fourth- and fifth-grade students. When points were given for fluency, that aspect of students’ writing improved. As each aspect of creativity was systematically rewarded, that aspect and only that aspect of students’ writing improved. As with the broader, multicomponent curricula, the generality of these effects is largely unknown.

## SUMMARY

Creativity has been defined a number of different ways. Most commonly, though, it has been identified with the novelty and originality born of problem solving through divergent thinking. Divergent thinking has been further broken down into four components: fluency, producing a number of responses within a given time; flexibility, producing different types of responses; originality, producing responses that differ from peers, society, or individual history of responding;

and elaboration, producing responses that are sufficiently complex and multifaceted.

Once creativity has been broken down into observable behaviors, it becomes possible to test for this performance and to train individuals and groups to increase the behaviors determined to be creative. From early preschool and into adulthood, it is clear that creative behavior can be influenced by the environment. The challenge of tomorrow will be designing classrooms and work environments that will promote creativity in our daily lives.

## CREUTZFELDT-JAKOB DISEASE

---

Creutzfeldt-Jakob Disease (CJD) is a rare, devastating, degenerative, and mostly fatal brain disorder. It is part of a group of diseases called prion diseases that occurs in humans and certain animals. The leading scientific theory at this time maintains that CJD is caused by a type of protein called a prion.

This group of diseases first came to the public attention in the mid-1980s as a result of the outbreak of bovine spongiform encephalopathy (BSE) in the United Kingdom. BSE is a prion disease in cattle. Tissue from infected animals may have been used in animal feed, leading to the spread of the disease and growing concern over whether this disease could pass to humans.

In humans, the most widely known of the prion diseases is CJD, which affects around one person per million per year. In the United States, around 250 to 300 new cases are reported per year. There are three major categories of CJD: inherited, sporadic, and acquired. These categories mainly refer to the way the disease was acquired rather than the symptoms that accompany the disease. One of the variant types of

acquired CJD observed in younger populations (ages 16–39), variant Creutzfeldt-Jakob disease (vCJD), has been associated with the consumption of beef and beef products from animals infected with BSE. In an animal infected with BSE, prions are concentrated in two areas of the body: the nervous system tissues, including the brain, spinal cord, and eyes, and the lymphatic tissues, such as the lymph nodes, bone marrow, and spleen. The greatest risk according to the Mayo Clinic for acquiring vCJD is associated with ingesting these tissues from BSE-infected cattle. At this time, there is no evidence that milk products from a BSE-infected animal pose a risk to humans. However, according to the Centers for Disease Control and Prevention, there is no precise method for determining the risk for acquiring this variant form of CJD from eating beef and beef products from cattle in countries that have reported confirmed cases of BSE.

There is no single diagnostic test for the diagnosis of CJD at this time. The only way to conclusively diagnose CJD is through a brain biopsy or autopsy. A brain biopsy is a highly invasive procedure and involves removing a small piece of tissue from the patient's brain so that it can be examined by a neurologist. Due to the invasive nature of this procedure coupled with the fact that a correct diagnosis of CJD does not help in the treatment or prognosis of the disease, a brain biopsy is discouraged. When autopsies have been performed on individuals that suffered from CJD, the brain tissue looks “spongy” because it is punctured by many tiny holes where cells have been damaged.

With CJD, typically the symptoms begin between ages 45 and 75. In the early stages of the disease, patients may have significant memory problems and may demonstrate changes in their behavior, lack of coordination, and visual disturbances. As the illness progresses, mental deterioration becomes the primary symptom, with observed involuntary movements, blindness, weakness of the extremities, and possibly coma. As mentioned above, this disease is fatal and about 90% of patients die within 1 year.

What can be done for individuals suffering from CJD? Currently there is no treatment or medication that can cure CJD. Most treatments are aimed at alleviating the symptoms experienced and helping the patient feel as comfortable and pain free as possible. Opiate drugs are frequently used because they can help relieve the pain, and the drugs clonazepam and sodium valproate may help relieve involuntary muscle jerks.

In conclusion, CJD is a very potent and fatal brain disorder thought to be caused by proteins called prions. It affects mainly individuals between 45 and 75 years of age, but the newest variant of the disease (vCJD) has been observed in younger individuals (ages 16–39). There is no specific procedure to diagnose CJD other than a brain biopsy or autopsy. Since this disease is not curable, treatments center around making the patient more comfortable and reducing the pain.

## CRITERION-REFERENCED TESTS

---

Whether it is in a classroom setting, a requirement for college admission, or to acquire something as simple as a driver's license, few individuals in today's society can avoid the necessity of taking tests. The scores received on these tests say something about what we know. Our knowledge level, as measured by the test, can either provide comparison with other individuals as a relative standard or with an absolute or predetermined standard. When an individual's performance on an examination is compared with a predetermined or absolute standard, it is called a criterion-referenced test.

Although the notion of taking a test has not changed, the way we develop and interpret tests has changed drastically over the past 40 to 50 years. One of those drastic changes began taking shape in the early 1960s, when a gentleman named Robert Glaser coined the phrase *criterion-referenced measurement* and wrote about the distinction between a norm-referenced and criterion-referenced measurement. Up until that time, the use of

norm-referenced tests, which compare examinees with a relative standard, was the customary model. Since the early 1960s, when criterion-referenced measurement was introduced, the procedures associated with development and use of criterion-referenced tests have been refined into well-accepted practice.

The purpose of a criterion-referenced test is to measure an individual's level of skill or mastery over a specific body of knowledge being represented by the test. As a result, there are certain design characteristics that must be considered when developing criterion-referenced tests. First we must consider what material the examination should cover. Because we want to be able to make inferences from test performance about mastery, subject matter covered in a criterion-referenced test needs to be dictated by specific goals, instructional objectives, or outcomes that accurately and narrowly define the domain. The format and number of items written for the examination must be a representative sampling from the content area over which we are determining mastery. The final piece in the development of a criterion-referenced test involves setting the performance standard or cutoff score. There are many descriptive phrases associated with criterion-referenced test results that categorize examinees. Examples include, pass/fail, mastery/nonmastery, certified/not certified, licensed/not licensed, and proficient/not proficient. The setting of the performance standard, or cutoff score, allows us to know at exactly what point that decision should be made for the individual test taker.

Criterion-referenced tests are useful when we want to make inferences from test performance about what a person can do. Success on a criterion-referenced test does not imply perfect knowledge; rather, it implies that an individual has met the established performance standard. The examinee, at this point, has demonstrated an acceptable level of the skills and abilities required to be considered a master, proficient, or certified.

Everyday examples of criterion-referenced tests abound. During the elementary school years, there are tests to determine something as simple as whether or not students can tell time or whether or not they know foundational mathematical concepts such as multiplication tables. A few years later, most people take a criterion-referenced test to obtain a driver's license, demonstrating that they have the acceptable skills to safely operate a vehicle on the roadway. Upon entering the workforce many members of our society are required to pass a criterion-referenced test in order to

enter their chosen profession, such as physicians proving that they are capable of caring for and treating patients appropriately.

Few stages of life are exempt from criterion-referenced testing in one form or another. Due to the increased demand for testing in general, and the immense practicality of criterion-referenced testing, its place in the measurement arena is guaranteed.

—Dawn B. Clayton

## CRITICAL PERIOD

---

Critical and sensitive periods are times when development of a particular area may be most influenced by environmental factors. The terms may be confusing, particularly when applied to behavior, because they do not have commonly accepted meaning and the research designs required to demonstrate them behaviorally can rarely be conducted. Strictly, critical periods are relatively brief and discrete times when particular experiences have irreversible effects regardless of subsequent experience. Effects may be due to the absence of normal, or presence of abnormal, experience. Originating in embryology, they have been applied to numerous areas of human development, including socialization, personality, language, and cognition. The concept is closely related to claims that early experience, as opposed to merely prior experience, has lasting impact on the organism. Critical/sensitive periods are often viewed as “windows of opportunity.” Only when the windows are open can environmental factors influence development. However, as Bateson suggested, such

“opened or closed” views of the effects of timing of experience on development are oversimplified when applied to complex behavior.

### HISTORICAL OVERVIEW

The embryological critical/sensitive period concept originated in two classic research programs in the 1920 and 1930s:

1. Working with fish embryos, Stockard (1921) found that physical and chemical agents created “monsters” if presented during rapid cell proliferation and differentiation, but had essentially no effect if presented earlier or later. Permanent damage occurred when an agent interrupted normal development during “sensitive periods” or “critical moments.”
2. Studying differentiation in amphibian embryos, Spemann (1938) transplanted cells at various times from their original donor site to a different host site. Cells transplanted early developed appropriate to the host site, whereas those transplanted later developed appropriate to the donor site. Equipotential development was followed by determined development. Spemann viewed differentiation as a process of “cellular induction” occurring during a “critical period” in normal development.

The critical period concept quickly became applied to behavior. Lorenz apparently first used it in 1937 in his account of imprinting, the process through which newly hatched precocial birds presumably develop filial attachments and species identification (but see Gottlieb for an alternative approach). He suggested that imprinting’s “two chief characteristics,” restriction to a narrow time period and irreversibility, were “in common with Spemann’s inductive determination. . . .” In 1962, Scott stated, “Critical periods determine the direction of social, intellectual, and emotional development.” For Scott, experience during such periods influenced development in at least two ways: (1) acting at a “turning point” leading toward normal or abnormal development, and (2) producing an irreversible effect that subsequent experience cannot modify. Essentially, experience at a critical time directed the organism down a particular one-way developmental path. Scott’s general principle of organization suggested that as any system becomes organized, from differentiating embryonic cells to developing behavior patterns of young animals, reorganization of the system becomes progressively more difficult. That is, “organization inhibits reorganization.”

Indeed, he claimed that major modification can occur only during organization.

Other mid–20th century factors brought critical periods to wide attention. Consider:

1. They fit with Freudian psychodynamic theory's emphasis on the role of early experience in determining personality, then dominant in many areas of psychology and psychiatry.

2. In his influential 1951 review of maternal deprivation, Bowlby stated that depriving young children of maternal care for a prolonged period may have lifelong adverse consequences: "[I]t is a proposition exactly similar in form to those regarding the evil after-effects of rubella in foetal life. . . ."

3. Hebb's theory proposed that first learning was necessary for optimal brain development and functioning.

4. Lenneberg (1967) proposed a critical period for language acquisition. Its beginning owed to lack of maturation, and its end apparently "related to a loss of adaptability and inability for reorganization in the brain. . . ."

5. A variety of experimental nonhuman research supported the apparent existence of critical periods. For example, infant rats reared in enriched environments had larger brains and better problem-solving abilities than those raised in restricted environments, female goats needed contact with their newborn kids to develop maternal attachment, Harlow's infant monkeys deprived of maternal care showed aberrant social behavior, young songbirds needed particular early experience to develop normal song, and early hormone manipulation permanently modified sexual behavior in rodents. The latter is of particular interest because it clearly demonstrated the importance of timing: Testosterone injections in newborn female rats or castration of newborn male rats produced opposite-sex behavior (with appropriate hormone replacement) in adulthood, whereas similar manipulations even in later infancy had no such effect. Some of this research is reprinted in books of readings edited by Denenberg and Scott.

## CURRENT EMBRYOLOGICAL CONCEPT

Critical/sensitive periods are associated with the development of virtually all organ systems. In this section, *critical period* and *sensitive period* refer to times when teratogens may cause major morphological damage and minor morphological/functional damage, respectively, as suggested by Moore and Persaud, who have an excellent figure of human critical/sensitive periods. The

embryonic period in humans is often described as "*the critical period*" since most organogenesis and severe effects of teratogens occur then. Such a description is oversimplified, however, because critical periods for various organ systems have different onsets and durations. The longest, for the central nervous system (CNS), extends to the 16th week of pregnancy, well into the fetal period. Sensitive periods for four systems—CNS, eyes, teeth, and external genitalia—extend for years after birth, resulting in potential adverse effects of abnormal environmental influences or positive effects of supportive environmental influences well into childhood or adolescence. Examples of adverse effects include effects of tetracycline in infancy/early childhood on mottling of permanent teeth and of heavy metals and infections on CNS development. Examples of positive effects include early surgical removal of congenital cataracts on visual acuity and depth/pattern perception and a low phenylalanine diet in infancy on CNS development of those with phenylketonuria.

Critical periods for components of organ systems are more circumscribed. Perhaps most dramatically, thalidomide's teratogenic effects were limited to 34 to 50 days past the last menstrual period. Ingestion at 34 to 38 days was associated with absence of external ears, whereas ingestion at 38 to 48 days was associated with a complex of malformations, including absence or severe shortening of arms and legs (phocomelia), malformed ears, and hip dislocation. Differing critical periods can make diagnosis of teratogenic syndromes difficult. For example, fetal alcohol syndrome (FAS) is classically diagnosed through a triad of characteristics: facial abnormalities, growth retardation, and CNS dysfunction. Since the critical period for facial features is far shorter than that for the CNS, children whose mothers drank heavily after the end of the critical period for facial features may show serious cognitive and behavioral deficiencies but normal facies. Such children may not meet FAS diagnostic criteria.

## CURRENT BEHAVIORAL CONCEPT

Many researchers question the value of applying a strict critical period concept to behavioral development. Some supposed critical periods are neither as circumscribed nor as irreversible as originally claimed. Lorenz, Scott, and Bowlby and others appear to have overstated the parallels between the effects of timing of experience in embryogenesis and those on behavioral development. For example, under certain experimental conditions, imprinting can occur well beyond the

normal end of its “critical period” and can be reversed from one object to another. A critical period for development of human attachment has been questioned both by methodological criticism of early research and by recent findings that some children adopted after extensive early deprivation develop appropriate attachment and social behavior. Little evidence supports the claim that the first 3 years of human life are truly critical for later development, although of undoubted importance. Thus, numerous authors, including Bailey, Bruer, Symons, and Lichtman; Bateson; Bornstein; Bruer; Huttenlocher; and Shonkoff and Phillips, have suggested that *critical period*, implying discrete length and irreversibility, be replaced with the more flexible *sensitive period* to describe effects of timing on behavior.

Direct and indirect evidence supports important roles of such sensitive periods in human development. Noninvasive methods of studying brain structure and function are revealing a variety of periods of rapid postnatal brain development and synaptic pruning, particularly experience-expectant ones. Behavioral as well as neurological evidence exists for sensitive periods in development of components of sensory systems, first language learning, motor behavior, and other areas associated with early brain plasticity. Furthermore, aberrant early relationships and other experiences can have broad adverse long-term effects on children, although the underlying processes are not well understood. The complex effects of early experience can be seen in ongoing publications of the NICHD Study of Early Child Care and Youth Development (<http://secc.rti.org/home.cfm>). As Bateson suggested, no single window of opportunity applies to timing of environmental influence. Critical/sensitive periods are of different types, lengths, rates of onset and offset, and underlying processes. Bornstein thoughtfully reviews and analyzes these issues. They are also subject to individual differences and different environmental conditions.

## CROSS-CULTURAL DEVELOPMENT

---

Everyone is born into a cultural environment. Cultures vary widely in belief systems, settings, languages, and processes of transmission, such as child socialization and teaching. Culture also provides a set of “rules” for interaction and a kind of blueprint for human development. The study of cross-cultural development is concerned with the varieties of human behavior across time and across cultural places.

### WHAT IS CULTURE?

Culture and ethnicity are often used interchangeably without distinction. Ethnicity is the label one uses to identify one's social identity, usually defined as race, national origin, or religion. Culture can be thought of as the set of beliefs, values, and practices of a particular group that are transmitted across

generations. Culture is dynamic, constantly shaped, and produced by members of its group.

Culture has qualities that are internal, external, and interactive. Internal qualities to the individual include knowledge, skills, and values. External qualities to the individual include tools or institutions. Culture has an interactive nature as well, such as shared social activities among people. The role of culture in behavior is pervasive and should be considered in any examination of human development across the life span.

### **WHAT IS HUMAN DEVELOPMENT AND WHY IS CULTURE AN IMPORTANT PART OF IT?**

Human development can be understood as the life-long interactional processes of perceiving and experiencing culture as triggered from the outside, shaped from the inside in one's mind, and cocreated with others in interaction. In other words, developmental and cultural processes are constantly intertwined. Groups of people share culture and negotiate cultural issues. At the same time, culture is subjectively experienced by the individual. Cultural experiences vary even among members of the same group.

Early studies of cross-cultural development were often ethnocentric, using the researchers' own values, beliefs, and practices as the standard for interpreting and evaluating the developmental processes and outcomes in other cultural groups. More recently, researchers have emphasized that every cultural group has its own standard and should be interpreted in its own right. This includes not only research that is conducted across cultures with national boundaries, but also for diverse cultural groups within a single society.

### **SYSTEMS IN THE STUDY OF CROSS-CULTURAL DEVELOPMENT**

The developmental niche is a useful theoretical framework proposed by Charles Super and Sara Harkness to integrate findings across cultures and disciplines. The developmental niche is composed of three interacting subsystems surrounding the child: the settings in which the child participates, the psychology of the caretakers, and the customs of the community regarding child care.

#### **Settings in Which the Child Participates**

Children develop by increasing their participation in cultural activities of multiple settings. This development

occurs as activities in one's daily experiences help to build the cultural beliefs and values under which the person operates. Culture becomes a kind of software built into the hardware of the biological system of the human body. The software is built through everyday interactions and practices that shape development, such as schooling, reading and writing, playing sports, carpentry, or weaving. The ways that children are engaged in these and other kinds of activities provide clues as to the rules for human behavior in a particular cultural place.

### **The Psychology of the Caretakers**

Parental goals vary across cultures, and they shape child care practices and outcomes. Robert LeVine proposed a universal hierarchy of parental goals. Once parents have ensured the survival and health of their children, they can focus on training children in skills needed for adult life, such as providing food, shelter, and clothing for themselves and a future potential family. Upon meeting these parental goals, they can then focus on ensuring that children are involved in activities to learn the cultural values of their group. In the case where child survival is low, parents may not reach the last goal because they will spend much of their efforts reaching the first goal of ensuring child survival.

### **Customs for Child Care**

Cultures differ widely in child-rearing practices. A predominant practice for many in the United States is to provide infants with active stimulation in cognitive and social areas. Cognitive stimulation is provided in the form of toys that teach or build skills of reading or counting; social stimulation is provided with a great deal of face-to-face contact and talk to babies and children.

In many of the world's cultures, however, there is a belief that children should not be actively stimulated, and child-centered conversations are minimal. For example, in the Gusii culture of Kenya, there is a predominant belief that infants can be easily overstimulated and that this can lead to illness. As such, low levels of cognitive and social stimulation are provided to infants; parents rarely speak directly to infants, they avoid eye contact, and they are careful not to excite infants' emotional responses. Although there are differences between the Gusii and Americans, children grow up with a sense of emotional well-being in either cultural context.

## DOMAINS OF STUDY IN CROSS-CULTURAL DEVELOPMENT

Cross-cultural researchers focus on understanding the cognitive and social domains of development. Research on cognitive development across cultures has included schooling, literacy, categorization, counting, and the use of tools. The use of tools can vary widely across cultures, and it can influence the ways that people think about the world. Familiarity with the cognitive goals of a cultural group helps researchers to avoid underestimating children's abilities. For example, among Maya children of Mexico, Ashley Maynard and Patricia Greenfield found that those children who knew how to weave performed better on a task of cognitive development that tapped weaving knowledge than they did on a task that tapped the same underlying knowledge, but in a different format.

Cross-cultural researchers also study social development. Areas of study include attachment, friendship, peers, and parent-child interactions. Attachment is a universal process by which infants and caregivers build close bonds with one another. The cross-cultural study of attachment has shown that the different patterns across cultures can be attributed to the dissimilarity of cultural goals across groups. In some cultures, such as the European-American middle class, the goal of the attachment relationship is to maximize children's independence, and the baby sleeps in a separate crib in a separate room. In other cultures, such as the Maya of Mexico, the goal of the attachment relationship is to encourage children's interdependence, so that the baby sleeps with the mother and is carried during much of the day on the caregiver's body.

## APPLICATION TO MINORITY IMMIGRANT CHILDREN

The study of cross-cultural development has implications for understanding the development of minority immigrant children. Historically, studies on the developmental processes of immigrant and minority children have followed a "deficit" model. This model takes mainstream cultural values as the standard for evaluating minority/immigrant children's behaviors. For example, immigrant students' lack of eye contact while interacting with teachers at school is sometimes interpreted as students' lack of self-confidence or unassertiveness. Yet, immigrant parents transmit to their children the cultural belief that looking directly at authority figures signals disrespect.

Ancestral values of minority groups in the United States and other multicultural societies shape the distinct patterns of socialization and development. For example, the values of ancestral homelands influence immigrant parents' participation in their children's schooling. Compared with the mainstream American value that places emphasis on parental participation to ensure children's school success, many recent Latino immigrant parents believe that teachers alone are responsible for children's schooling and that they should not micromanage it. Despite the fact that immigrant parents are likely to value education as highly as other parents, immigrant parents' lack of direct participation in children's schooling is often interpreted by teachers and administrators as lack of advocacy and support for their children's educational endeavors.

It is also important to recognize a power dynamic between ethnic groups, because the relationship between dominant and less dominant groups has an impact on development. For instance, social science curriculum in high schools is more likely to emphasize and to reflect the experiences of the majority rather than minority groups in the United States. To move away from this deficit model of educating minority children, it is important to incorporate the child's cultural values or language in school curriculum. Recent findings show, for example, that bilingual education that incorporates children's heritage language in instruction can actually improve their mastery of the English language. It was long believed, however, that "English-only" language instruction was critical for children's mastery of the English language.

## SUMMARY

The study of cross-cultural development generates knowledge about developmental processes and experiences in different cultures around the world. Cross-cultural researchers also generate findings about the minority and immigrant groups and about the interactions of different cultural groups when they come together. This knowledge is used to advance our study of development more generally.

In an age of increasing globalization, the study of cross-cultural development is central to our understanding of the variety of experiences available to people around the world, the varying pathways for development, and the increasing diversity of many multicultural societies. Understanding the cultural

variation in developmental processes furthers the understanding of the underlying construct itself.

## CROSS-SECTIONAL RESEARCH

---

The longitudinal method examines one group of people repeatedly over time, whereas the cross-sectional method examines several groups of people at one point in time. For example, if you investigated changes in social behavior in 20-, 30-, and 40-year-olds all measured at one point in time, you would be conducting a cross-sectional research study. In other words, cross-sectional studies examine age differences, while longitudinal studies measure age changes.

As with the longitudinal approach, the cross-sectional approach has its advantages and disadvantages. Advantages are that it is relatively inexpensive in that it usually does not take a long time to complete, it takes place over a relatively short span of time so it

is easier for participants to cooperate, it has a low dropout rate since it does take place over shorter period of time, and problems with staff retention are minimized since turnover is greatly reduced.

Cross-sectional research designs have their disadvantages as well. For example, it makes comparisons of groups difficult since all the data are collected at one point in time, it provides little idea as to the direction of change that a group might take (there are no previous data as in a longitudinal study), it examines people of the same chronological age who may be of different maturational levels, and reveals nothing about the continuity of development on an individual basis. The most serious disadvantage is the lack of comparability of groups, because the only thing they differ on is age.

Finally, cross-sectional research strategies suffer since cohort (the year in which participants are born) and age are confounded, meaning that the effects of the two cannot be separated. One does not know whether any age-related changes are in fact a function of changes in age versus a difference in the years in which the participants were born. Even with these shortcomings, along with longitudinal research designs, cross-sectional research designs are very popular.

## CRYING

---

Crying is not just the sound of a fussy baby or a bothersome noise. It is a direct and effective way that the young child communicates. For preverbal children, crying is definitely language.

Crying is an important part of the infant's earliest communication system that is used to convey various demands and needs, such as hunger or thirst, or pain from colic or teething. If they are well fed and warm, crying babies are most likely in pain, or at least uncomfortable, and it is unjust to grow suspicious of

their motives when they promptly stop crying on being picked up.

The infant's cry also seems to take on a special, distinctive quality, and there are a variety of factors affecting how well parents can discriminate cries, including the experience of the listener, the age of the baby, the type of cry (e.g., hungry or tired), how typical the cry is, and the length of the crying episode. With all these variables being important, it is easy to see why there can be differences in the way parents react to crying. In fact, many new parents learn their child's individual crying patterns very quickly and can even recognize them during the first month of life. They regularly report how they can easily tolerate the crying of other infants, but not their own.

Infant crying can also be a provocative and often unpleasant experience, probably because it is supposed to evoke caregiving behaviors from adults. In one study of 50 mother-infant pairs, the promptness with which mothers responded to their infant's crying was studied. The results showed that the average duration of crying was reduced by about one half over the 9-month length of the experiment, but that the number of crying instances remained about the same. So children cried for less time each time they cried, but continued to cry the same number of times. Most interesting is that delay of maternal responses reduced the number of crying bouts, contrary to the results of earlier experiments.

The pattern of cries and their significance become terribly important for the development of reciprocity between the parent and the child. First, the crying establishes a social link. More important, however, is that the very act of crying makes the infant more aware of the physical apparatus necessary to make sounds. When infants are about to talk, their spurts of crying take on the same duration as first words, so they develop a rhythm of communication that up to now has been much more unsystematic.

Ignoring prolonged crying entails the risk for missing a potentially important warning. A touch of hoarseness in the crying may mark the beginning of a croup attack with its characteristic barking cough. Some researchers suggest that the crying of babies who are ill may be unique among other cries to signal that special attention might be needed. For example, Zeskind and Lester found that certain high-risk children have distinctive features about their crying, and other researchers found that cries of Down syndrome children are more unpleasant than those of normal children.

Persistent crying has also been a focus of research. Persistent crying has been tied to family disruptions and child abuse. If you have ever had to face a baby who just will not quit (and you had no one to relieve you), you would understand how frustrating this situation can be.

Ignoring crying can have other consequences as well, both positive and negative. If the child is continuously ignored, he or she will learn not to place trust in others in an "unsafe" world. If the crying is responded to without any crimination, the child could end up not learning how to deal with frustration.

## CRYSTALLIZED INTELLIGENCE

---

The notion of crystallized intelligence was first proposed by the British psychologist Raymond B. Cattell in a 1943 article in which he outlined his perspective on the structure of intelligence, a perspective born of his efforts to develop a culture-free intelligence measure. Cattell's theory initially suggested that general intelligence could be conceptually subdivided into two related but distinct components, namely, fluid intelligence (Gf) and crystallized intelligence (Gc). In collaboration with J. L. Horn, Cattell expanded his theory by including additional cognitive abilities; this revised model came to be known as the Cattell-Horn theory. A further extension of the Gf-Gc theory—postulated by John B. Carroll on the basis of a survey of more than 60 years of factor analytic research on

human cognitive abilities and published in 1993—provides one of the most comprehensive and integrated treatments on the subject. Carroll's three-tiered taxonomy of cognitive abilities, known as the Cattell-Horn-Carroll model, is a fully hierarchical structure, with the general ability factor (g) at the top, Gf and Gc along with several other factors at an intermediate level, and many more specific factors at the lowest level of the hierarchy. Both the original version of Gf-Gc theory as well as its extensions have proved to be quite influential in the development of modern tests of cognitive abilities.

Cattell believed that psychometric intelligence, as reflected in mental ability tests, is a composite of two major factors. Fluid intelligence comes into play when individuals are confronted with unfamiliar tasks or tasks that require novel solutions. Crystallized intelligence, on the other hand, is displayed on tasks that require the recall of acquired knowledge or the application of well-learned skills. This differentiation is, by Cattell's own admission, reminiscent of D. O. Hebb's distinction between biologically determined capacity, or intelligence A, and the capacities that are acquired through experience and education, or intelligence B. It is also similar to the familiar continuum along which tests of ability can be placed—ranging from achievement-oriented to general ability or aptitude measures—depending on the degree of experiential specificity they assume in prospective test takers.

Although the fluid (Gf) and crystallized (Gc) components of intelligence are conceptualized as being interrelated, they tend to become increasingly more independent as development proceeds from infancy through adulthood. Crystallized abilities are derived from fluid abilities, but are developed through education, experience, and practice. As a general rule, fluid intelligence shows a steady decline in adulthood, whereas crystallized intelligence—which reflects the extent of acculturation—can slowly improve over one's life span.

Another important distinction between crystallized and fluid intelligence is in their susceptibility to brain injury. Performance on measures of fluid intelligence, such as series completion and analogies tests, tends to be more affected by damage to the brain, regardless of where the damage occurs. On the other hand, measures of crystallized intelligence—such as tests of verbal comprehension and content knowledge in specific fields—are more affected by damage to the brain areas associated with those abilities.

At present, the expanded model of Gf-Gc theory is very popular and is widely used in research studies on intelligence because of its ability to account for new empirical data. Variations of the Gf-Gc model have also been explicitly incorporated into the design of assessment instruments developed by Alan and Nadeen Kaufman, such as the Kaufman Adolescent and Adult Intelligence Test (KAIT) and the Kaufman Assessment Battery for Children-Second Edition (KABC-II), as well as other contemporary test batteries, such as the Woodcock-Johnson III. In addition, Flanagan and co-workers have applied their Gf-Gc cross-battery assessment approach to the interpretation of the Wechsler Intelligence Scales (WAIS, WISC, and WPPSI).

## CYSTIC FIBROSIS

---

Cystic fibrosis (CF) is a recessive hereditary disease that causes the mucous glands in the lungs and digestive tract to secrete unusually thick and sticky mucus. Instead of acting as a lubricant, these secretions clog the lungs and prohibit the pancreas from working efficiently, resulting in a number of secondary illness characteristics. CF affects approximately 30,000 people in the United States, and an additional 10 million are unaware that they are symptomless carriers of the disease. Because CF is an autosomal-recessive disorder, two recessive genes for the disease (one from each parent) are required for symptoms to develop.

Symptoms of CF include coughing and wheezing, poor digestive ability, salty-tasting skin, nose polyps, reduced growth, and infertility. There are thousands of mutations of the CF gene, which results in varied symptoms within the CF population. Adult CF patients also deal with health issues such as related diabetes and osteoporosis.

Treatment of CF varies with the range of symptoms and the stage of the disease. Mucus clearing of the lungs is a common, daily treatment for CF patients. Other treatments include antibiotics for lung infections, drugs that thin mucus for better lung functioning and fewer infections, and pancreatic enzyme supplements. Individuals with CF are also advised to be physically active and to adhere to a nutritious (often high-calorie) diet. People who have been diagnosed with CF have a mean survival age of 33.4 years. However, recent advances in available treatments have resulted in an increased life span for those suffering with CF.

CF patients may suffer from psychological issues related to the disease. For instance, patients of all ages can have difficulty coping with living with their disease. CF patients may have problems sleeping and may withdraw socially. Other psychological problems could be present because of anxiety-provoking medical visits and prolonged hospital stays related to the illness. Social issues that arise surround the problems or stigma that might shroud the CF patient because of coughing, wheezing, and medication noticed by peers.

There may be special psychological issues related to children diagnosed with CF. Children may have difficulty understanding their diagnosis. Many children with CF may also have problems with developmental tasks because of the nature of the illness and the treatment regimens. In addition, there are often problems in adherence to treatment regimens, which can possibly lead to decreased pulmonary functioning. Some children with CF also exhibit behavioral problems that may be related to their condition and management of their disease. Many children face problems with their education due to illness and hospitalization resulting in missed schoolwork and fewer social interactions with children. In adolescence, CF patients may face increased anxiety and apprehension as their responsibility for their

treatment increases. There are also possible issues with independence, feeling accepted by peer groups, and issues with planning realistically for the future. Infertility becomes an issue as individuals with CF age. Men with CF can become sterile, and women often find it difficult to carry a fetus full term because of limited lung capacity and other related problems. The CF patient may also battle with the decision of having children and possibly passing on the CF gene.

Early intervention is important so that CF patients can have the appropriate support during various times of need from the onset of their illness. It is crucial that early intervention is provided by individuals knowledgeable in the emotional and social aspects of living with CF.

There is currently no cure for CF, although medical advances have allowed those with CF to live longer and more comfortable lives. Quality of life for CF patients continues to improve, making the diagnosis of CF less inhibiting than in previous years. Although more research needs to be done from a medical and psychological aspect of CF, the outlook of the illness continues to look more and more positive.

## Death

*As a well-spent day brings happy sleep, so life well used brings happy death.*

—Leonardo da Vinci

---

### **DARWIN, CHARLES (1809–1882)**

---

Charles Darwin developed the theory of evolution by natural and sexual selection, which today unifies the life sciences. He was born in Shrewsbury, England. After graduating from Cambridge, Darwin embarked on the *H.M.S. Beagle* for a British scientific expedition to map the coastline of southern South America. As the resident naturalist, Darwin collected specimens and recorded observations of plants, animals, fossils, geological features, minerals, native peoples, and other items of interest.

Darwin's observations led him to speculate on a wide range of biological and other phenomena, including plate tectonics and the origins of coral reefs. The Galapagos Islands provided Darwin with a natural laboratory that was a particular influence in guiding his theory of natural selection, harboring many species of plants and animals that were similar to those on the mainland, but varied in remarkable ways. At the time, species of organisms were considered to be a primeval archetype, divinely created and unchanging. Variation was seen as noise imposed on the platonic ideal. It was also a common belief that one species was created to benefit others, for example, providing food.

Following Malthus, Darwin recognized the struggle among individuals for existence and limited resources. He also believed that the phenotypic variation of individuals, enabling some individuals to survive and reproduce more successfully than others, was partially heritable. He inferred that natural selection would over the course of time encourage the spread of traits that are more adaptive than others. Darwin published *On the Origin of the Species* in 1859, followed by *The Descent of Man, and Selection in Relation to Sex* in 1871, which outlined the principles of sexual selection. Sexual selection resolved phenomena puzzling to Darwin, describing how traits appearing to be detrimental to survival are beneficial in the competition for mates. Darwin went to great lengths to test the central predictions of his theory; he recognized how controversial his ideas might be, and tremendous amounts of evidence have since been amassed in support of his theories.

Darwin has made a tremendous impact in science, including psychological areas as diverse as the function and universality of emotions and the development of intelligence and imagination. In recent decades, increasing numbers of psychologists have been explicitly employing an evolutionary approach to understanding human thought and behavior. The recognition that proximate psychological mechanisms

serve ultimate adaptive functions holds the promise of uniting the disparate areas of psychology in a Darwinian framework.

## DATING

---

### CHANGING NATURE OF DATING ACROSS HISTORY

The definition and practice of dating continues to change across time and varies significantly among different cultures. For example, in 1977, according to *Webster's New Collegiate Dictionary*, dating in the United States was defined as a "social engagement between two people of the opposite sex."

Recently, however, this definition of dating in the United States has been modified in several ways. First, the construct of dating is no longer restricted to heterosexual interactions; instead, it can also transpire between two individuals of the same sex. At present, dating can also take place in groups rather than being restricted to a dyadic exchange. Furthermore, although dating is still considered a social engagement, this interaction no longer has to occur in person. In current culture, dating can, and often does, take place over the Internet or via some other type of technology. Today's dating can also occur in a variety of novel contexts such as part of a television reality show, as a result of joining a dating service, or as a consequence of placing a personal advertisement in a newspaper or another print medium.

Finally, while most empirical studies have focused on the dating behaviors of adolescents and never-married young adults, because of changing demographics in the United States, which include later marital age, increased frequency of divorce, and the aging of the

American population, dating is now an activity that includes people of all ages. In fact, even married couples have been admonished by the popular press to "keep dating" in order to keep the romance alive.

Dating among older Americans has some distinctly different features when compared with adolescent dating. For example, 50% of men 40 to 69 years of age date women 5 or more years younger than themselves, whereas less than 20% of women in this age group date men 5 or more years younger than themselves. Some gender differences in dating attitudes are also apparent among older daters. Men in this age group are 10 times more likely than women in this age group to think that sex on the first date is acceptable.

Therefore, to better encompass the current dimensions of dating, in the 2001 version of the *New Oxford American Dictionary*, the word *date* was redefined more broadly as "a special or romantic appointment or engagement," while *dating* was articulated as the process of "going out with someone in whom one is romantically or sexually interested," regardless of whether the individuals who are dating are heterosexual, homosexual, or bisexual, adolescent or older, in person or via the Internet, or single, divorced, or married.

To add complexity to the issue, debate exists about the extent to which both participants in the social engagement must agree that the shared event is a "date." According to adolescent self-report, being "in love" corresponded to being in a reciprocal love relationship only about half the time. In 1991, Sugarman and Hotaling theorized that dating can be said to occur in interactions that are characterized by commitment, expectation of future interactions, and physical intimacy. In practice, however, the two parties on the date may have quite different opinions about their commitment level, their expectations for future interactions, and/or the degree to which they want to share or have already shared physical intimacy. Data confirm that there is significant variation along these three dimensions, even among events that are clearly designated by both participants as dates. Thus, there does not currently seem to be a uniformly agreed upon indication that a particular social interaction is, in fact, a date.

Disagreement in designating an engagement as a date appears to be particularly common in the initial stages of adolescent relationships. Typically, romantic interest is assumed on the part of the individual who initiated the date; however, the degree of interest experienced by the invitee can often remain unclear throughout the first date. Moreover, uncertainty about

commitment levels can continue throughout the dating relationship.

The language used to describe different types of dates has also changed significantly over time and tends to reflect cultural notions of dating. These dating descriptors provide dating partners and observers important information about the nature of the dating relationship, including its exclusivity, seriousness, and/or its inclusion of sexuality (e.g., one-night stand, blind date, friend with benefits, fling, prom date or dance date, going out, getting together, boyfriend/girlfriend, significant other, fiancée, and life partner).

Historically, dating has been viewed as the typical way to find a marriage partner in many cultures. As such, the nature of dating has changed in keeping with norms regarding the function and timing of marriage and the degree to which sexual experience is considered taboo premaritally. For example, in the early to middle 1900s, the typical age of marriage was in the early twenties and virginity prior to marriage was the norm. Adherence to traditional gender roles was socially expected during courtship. Correspondingly, during this period, most dates began with the man initiating the date with the woman. Female-initiated dates were atypical. In general, the rules of dating etiquette were well established and formed the basis of books as well as newspaper columns. Men were expected to plan dates and pay for them. A “gentleman” arrived on time, interacted politely with the women’s parents, and displayed fine manners. Physical contact was expected to be either nonexistent or restricted to a light kiss goodnight after one of the early dates. The woman’s role on the date was to maintain decorum, halt amorous advances, listen to her date, and dress appropriately for the occasion.

Ideals for age of dating onset and the types of dating permitted for each age were also clearly specified. For example, in a national advice column published in the *Ladies Home Journal* in the 1950s, girls 12 to 14 years of age could attend chaperoned parties at one another’s homes; however, “solo” dates could not start until age 16 or later. Girls were also cautioned about dating boys who were more than 2 years older than themselves or who belonged to a different social group, religion, or race.

In the new millennium, dating continues to be a source of intimacy, support, and companionship for youth. Moreover, dating etiquette is still a prime subject of magazines, newspaper articles, and popular books. However, current literature describes today’s dating as more casual, spontaneous, cooperative, and

unrestricted than the dating that occurred 50 to 70 years ago. Dating one partner also occurs at an earlier age (often between the ages of 13 and 15), even though the current age of first marriage is later than it has been in previous decades. According to recent research, by age 16, 80% of adolescents have already experienced a significant romantic relationship within the preceding year.

These early adolescent dating relationships are generally short lived and less mature than later dating relationships. This has led theorists to view adolescent dating relationships as occurring along a continuum from close friendships, to casual dating, to exclusive dating. Similarly, Roche (1986) delineated a five-stage model of dating (dating with no particular affection; dating with affection but not love; dating and being in love; dating one person only and being in love; and, finally, engaged). Roche then demonstrated that men’s and women’s views of proper behavior also differed significantly by stage of dating.

The psychological nature of dating relationships also changes with increased age. Individuals describe their adolescent dating relationships as engulfing and meeting their needs for companionship, yet more problem-filled than adult relationships. In contrast, young adult dating relationships are described as more trustworthy, supportive, and stable than adolescent relationships. This suggests that there are both qualitative and quantitative differences in emotional involvement among different levels of dating relationships. However, across most time periods and throughout adolescence and young adulthood, dating has also consistently functioned as both a recreational event and as a means of learning about the opposite sex and how to behave with them. These latter definitions of dating highlight its important role in helping individuals develop social skills and mature into adults who are capable of both independence and interdependence.

## IMPORTANCE FOR SOCIALIZATION

On this basis, adolescent dating has been recognized by scholars as an important developmental event. Generally, according to Hansen, Christopher, and Nangle (1992), all adolescent social interactions function to provide an emotional support system for youth while offering a venue in which adolescents can explore their morals and values and establish their own personal identity. In addition to these functions, adolescent dating relationships are thought to be

particularly critical in promoting interpersonal competence and adult-like social behavior; recreation and entertainment; enhancement of status within the peer group; enhancement of independence, which facilitates separation from the family of origin; a context for experimentation with sexual activity and sex role behaviors; and increased skills with relation to courtship and mate selection.

Of note within these functions is that adolescent dating has been explicitly tied to the developmental task of separation and individuation from the nuclear family. Specifically, employing a developmental-contextual perspective, Brown (1999) theorized that adolescents experience a four-step sequence in their development of romantic relationships. The first step is the initiation phase. This phase coincides with puberty and is a time when youth become reoriented to members of the opposite sex while expanding self-concept. Dating during this phase typically occurs in groups and consists of unplanned meetings or casual interactions. The focus of the initiation phase is on the self.

The second stage is the status phase. During this phase, adolescents experience peer pressure related to whom they are dating and what kind of dating relationship they are involved in. By the end of this phase, it is expected that adolescents will have gained relationship skills and will be more willing and able to assert themselves within their peer group. The focus of the status phase is on the context in which the relationship is occurring.

The third phase is the affection phase. The focus in this phase is on the actual relationship, which is experienced as more involving, rewarding, and personal. The final stage is the bonding phase. The relationship is also central to this stage. As in the affection phase, feelings of involvement for the relationship dominate; however, other pragmatic concerns surface with regard to the degree to which the dating partner will remain a lifetime romantic partner. Identity concerns may resurface either as each partner's individual identity becomes merged with the other or as a couple identity is formed from which the individual identities are inseparable.

Other theories of the development of adolescent relationships include (a) considering attachment theory as it relates first from parent to child and then from child to romantic partner; (b) relating the increased intimacy in adolescent dating relationships to changes in the adolescent's relationship to parents, as occurring in the current context of prolonged dependency and delayed transition to adulthood; and (c) integrating developmental changes in peer relationships

with those occurring in dating relationships in a developmental sequence.

## **PARENTAL AND CULTURAL PROHIBITIONS ACROSS TIME**

A number of parent factors are related to adolescents' timing and experiencing of dating. For example, parents who raise their children with traditional sex role orientations are more likely to have sons who have a sexual orientation toward dating and daughters who have a romantic or affectional orientation toward dating. Mothers with higher educational attainment are less likely to have daughters who are sexually active in their early dating relationships; these daughters are also more likely to marry at an older age. Parental religious involvement may also impact adolescent dating behavior because individuals who are active in their church communities tend to be more sexually conservative in their dating. Adolescents raised in one-parent families are more likely to start dating at an early age and have a higher divorce rate when their dating relationships turn into marriage. Similarly, studies of adolescents who have formed close online relationships indicate that these youth are more likely to come from families characterized by high levels of conflict (adolescent girls) or low levels of communication (adolescent boys). Conversely, closeness in the parent-child relationship and in the parent-parent relationship is a predictor of romantic intimacy capacity for adolescents and young adults.

Parents (and peers) also engage in behaviors that can serve either to promote or deter the progression of particular dating relationships. Parental behaviors that signal relationship approval include relaying phone messages and communications from the dating partner, asking about the partner, being welcoming and pleasant to the partner, including the partner in family activities and events, and letting their child and the partner have time alone together. In contrast, disapproving behaviors include talking about other people that their child could date, making disparaging remarks about the dating partner, cautioning the offspring about their involvement in the dating relationship, and telling their child that it is better to wait before getting too serious in this dating relationship.

## **INTERRACIAL AND INTERCULTURAL DATING**

Although interracial and intercultural romantic relationships have been present throughout history, they

have rarely been culturally encouraged or even accepted. In fact, these relationships have often been prohibited. For example, in 1966, 17 of the 50 United States legally banned interracial relationships that transpired between individuals of White decent and “persons with one-eighth or more of Negro blood or those related within three generations to a member of a particular racial group” (as cited in Martin et al., 2003, p. 54).

On June 12, 1967, in the case *Loving v. Virginia*, the Supreme Court ruled these prohibitions illegal. However, it took 33 more years for all 50 states to concur. It was not until the year 2000 that Alabama finally modified its law against interracial marriages. Ultimately, however, an increase in racial and/or ethnic diversity within the United States should cause a corresponding increase in interracial and intercultural dating and marriage, eventually promoting greater acceptance of these relationships.

Researchers have studied why people choose to become involved in interracial romantic relationships, given their likelihood of social disapproval. According to research, demographics such as socioeconomic status, education, occupation, and residence influence the initiation, development, and maintenance of interracial dating relationships and marriages. The political and social contexts in which interracial and intercultural relations transpire also appear to influence whether friendships and/or romantic relationships develop between individuals of different races. Empirical research shows that individuals (a) who live in diverse neighborhoods, (b) who have interracially diverse friendships, and (c) who have family members who date people of other races and cultures are most likely to date interracially and interculturally. These findings have led to the general contact hypothesis, which states that “when people come into contact with others who are different from them under favorable conditions (neighborhood playgrounds, integrated classrooms, intercultural friends of the family), negative attitudes decrease, positive attitudes increase, and intercultural friendships and romantic relationships are likely to develop” (Martin et al., 2003, p. 67).

## SEXUALITY AND DATING

Much of the research on dating relationships has considered the degree to which these relationships include particular sexual behaviors. For example, several recent surveys of never-married men between the ages of 20 and 39 revealed that more than 85% of the men were nonvirgins. When asked about their sexual

behavior within the preceding year and a half, most of these single men had had a single coital partner; however, about 20% of the men had had four or more sexual partners during this time period.

Similar studies of single women between the ages of 20 and 29 indicated that about 80% of these women were nonvirgins. Again, the majority of these women had had only one sexual partner during the preceding 18 months, and less than 10% of these young single women reported having had five or more coital partners during this time period.

Dating and the initiation of sexual behavior seem to be sequentially related. By age 14, about 50% of girls have started dating. Three years later, about 50% of girls have had sexual intercourse. Thus, there typically appears to be a few years’ delay between first date and first experience of sexual intercourse.

Studies conducted in the late 1960s through the early 1980s demonstrated a growing permissiveness toward sexual behavior and attitudes within American culture. However, more recent research suggests that these permissive attitudes have been waning, perhaps because of the public concern regarding the spread of acquired immunodeficiency syndrome (AIDS) and other sexually transmitted diseases. Acceptance of sexual intimacy as part of dating relationships has also been shown to vary by culture. For example, North American men have been shown to be more accepting of premarital sex than Japanese men, for both men and women, whereas Russian men were more likely to endorse the traditional double standard, which grants more sexual freedom to men than women.

Greater acceptance of premarital sex has been shown to associate with an absence or reduction of religiosity, as well as with being young, politically liberal, Black, male, and single. A strong commitment to one’s dating partner also predicts greater support for engaging in premarital coitus. Four primary factors have been shown to influence one’s decision to engage in sexual intercourse with a dating partner for the first time: quality of relationship, sexual arousal, pressure, and circumstances related to the use of drugs and/or alcohol. Dating partners are also motivated to participate in sexually intimate acts in order to feel nurturing toward or show emotional commitment to their partner and/or to experience pleasure. Conversely, empirical research has found that men and women refrain from participating in initiated sexual activity for reasons including concern regarding pregnancy, sexually transmitted diseases, and AIDS; moral reasons; concern that their partner would view sex as commitment; and/or not liking their partner enough.

## DATING RELATIONSHIPS AT RISK FOR VIOLENCE OR RAPE

Thus, while dating relationships are clearly developmentally important, they are not risk free. Current research indicates that dating relationships can also include psychological, physical, and sexual violence. In fact, these events may be even more likely in dating relationships than in marital relationships. Efforts to predict which relationships are at risk or which dating partners are dangerous are ongoing. Data indicate that physical violence has occurred in approximately one third of all dating relationships, according to at least one partner's report. Male perpetrators are more likely to have low socioeconomic status, be undereducated, come from a family characterized by violence or in which sexual victimization occurred, have high levels of anger and hostility, have problems with depression, and be experiencing problems with alcohol and/or drugs. The rates of psychological abuse occurring in dating relationships are even higher than those for physical abuse. Perpetration of psychological abuse may be even harder to predict because it is ubiquitous.

Date rape is also a potential risk in relationships. This type of rape has been associated with family alienation, dating significantly older men, drug and alcohol use on the date, miscommunication about whether the woman was interested in sex, whether the man initiated the date and drove her to the date in his vehicle, and the degree to which he spent a lot of money on the women. Victim characteristics include earlier age of menarche, prior sexual activity, younger age at first intercourse, dating less familiar men, more sexually active with same-sex friends, poor peer relationships, and poorer emotional health. Perpetrator characteristics include attitudes condoning rape and violence against women, traditional sex role beliefs, personal irresponsibility, and lack of social conscience.

## DEADBEAT DADS

---

As the population of the United States shifted from rural, agrarian, or farming living arrangements to those of more urban and industrial conditions starting in the middle of the 19th century, men saw their role as parent transformed by employment demands that pulled them away from the home. Instead of holding a central role as instructor and instiller of core knowledge such as social norms and spiritual beliefs—tasks allowing great contact with one's children—a father's role has become more synonymous with the more distant role of absent provider for the family. Despite holding significant income advantages over mothers, fathers have lost much of the power to interact with—and therefore influence—their children on a daily basis.

Current American families reflect a much larger diversity in makeup or constellation compared with families of the past, as a result of higher rates of divorce and separation. Approximately half of all first marriages end in divorce, with rates exceeding 67% for second and third marriages. Many expectant parents decide not to marry. Indeed, 31.2% of today's custodial mothers have never been married. According to 2002 U.S. Census data, approximately 13.4 million custodial parents had custody of 21.5 million dependents under age 21 years in 2002. Approximately five of six (84.4%) of these

custodial parents are mothers, a proportion that has appeared stable for approximately one decade.

In many ways, a troubling characteristic of the contemporary family overall is that fathers are more likely to be rather absent from their children's lives than in previous times. Although every father likely struggles to enhance his presence in his child's life, some fathers actively choose to minimize or terminate their support of their dependent offspring. Studies suggest that many of these decisions by fathers to terminate relationships with their children occur as a collateral effect of conflict or disengagement with their children's mother. A "deadbeat dad" can be defined as a form of child abandonment in which an absentee or nonresident father worsens his child's living conditions by withholding his financial support, physical contact, and psychological, intellectual, and cultural tutelage. Earlier investigations of deadbeat dads in the literature focused predominantly on the financial support provided by noncustodial fathers, while later studies have explored the other facets of such an absent father.

## PREVALENCE

In the United States in 2002, approximately 7.1 million out of 11.3 million custodial mothers (63%) were court awarded child support, with awards averaging \$5,138 annually. Even more startling is that the amounts of child support actually received in 2002 averaged only \$3,192 annually—a mere 62% of the awards granted. Roughly 4.6 million mothers (74.7%) received some support, and less than half (2.8 million; 45.4%) received all of their awarded support. As evidence of the value of establishing and maintaining child support agreements, custodial parents who received all of the child support due to them in 2002 were less likely (14.6%) to have poverty-level annual income than were parents who received only some or none of their expected child support. Parental involvement of the father, as measured by father visitation, has been found to be positively associated with the provision of child support.

## CONSEQUENCES

Despite the emphasis of financial responsibility within the discussion of deadbeat dads, children appear to need far more than money from their fathers to promote and facilitate successful adjustment and development. Children who share healthy relationships with their fathers display a reduced likelihood of

parenting at an early age, abusing substances, or being declared a juvenile delinquent and have a greater probability of earning their high school diploma. Yet, this relationship is not explained merely by quantity of contact between father and child. A great body of literature suggests that a father's ability to be emotionally connected with his child, his provision of financial support, and his direct interaction with his child contribute to his child's cognitive competence, academic achievement, social competence, impulse control, and self-esteem. As a result of this foundation of developed characteristics, a child then is less likely to engage in delinquent behavior or to become involved with destructive peer groups.

## APPROACHES TO THE PROBLEM

The initial approach to the complex problems created through the absence of deadbeat dads was that of child support enforcement. The federal government created the Child Support Enforcement Program in 1975 after a correlation was established between claims for public assistance or welfare by custodial parents and the nonpayment of child support by the affiliated noncustodial parent. When this program failed to increase payment rates adequately, custodial parents and their children continued to rely on federal and state financial assistance. In 1984, federal legislation ordered state and local governments to enforce access and visitation rights for noncustodial fathers in a manner that complemented efforts to gather child support payments. In 1996, the Federal Welfare Reform Act included a mandate for states to pursue child support from nonpaying parents when a custodial parent seeks state financial assistance. The program allowed for the seizing of wages of nonpaying fathers. Individual states have developed creative ways to track the employment of fathers and to garner their future salaries for appropriate child support payments. Even deception has been used as a tool to arrest non-paying fathers who successfully avoid or disregard other legal attempts to recoup unpaid support. Examples of deception uses include contacting fathers about false winnings of a sweepstakes or sporting event tickets, then arresting them when they show to collect their "rewards."

Issues related to the collection of child support from deadbeat dads are the employability and job retention of those fathers. Recent studies find that fathers are often connected with their children at birth and report a desire to support and father their children. However, many fathers who fall into the "deadbeat"

category are “dead broke” young men with low literacy rates and poor work histories. Reviews focusing on teenage fathers report child support collection rates of only 13% nationally, significantly lower than overall rates. Low average wages amplify the limited ability of young fathers to financially support children. Successful child support enforcement or enhancement interventions, based on informative exploratory efforts such as the Parents’ Fair Share (1988–1996) and the Young Unwed Fathers Project (1992–1994), focus beyond mere child support payment collection and help fathers to develop basic employment skills, including job search techniques, résumé writing, communication skills, and vocational training.

Other intervention methods have focused on improving men’s ability to nurturantly provide for their children’s psychological needs. Peer support groups and psychoeducation sessions allow for the attainment of basic parenting skills, such as relationship building, child development concepts, anger management, and life skills training. Often it is helpful to include discussions about cooperative parenting to enable fathers to better interact with their child’s mother to allow the child an opportunity to experience both parents in a less combative environment. On a larger scale, media campaigns and public education efforts, such as those provided through the Fatherhood Project and the National Center for Fathering, have attempted to provide a broader redefinition of fatherhood that allows for greater nurturance and involvement with children.

As a preventive approach, many interventions that focus on reducing teenage pregnancies are broadening in scope from the emphasis on young women to focus on young men and include discussions of fathers’ financial and other obligations. Based on early projects such as the Teen Fathers Collaboration (1983–1985), these programs attempt to reduce underage parenting by moving from issues related to sexual behavior and contraception to the range of responsibilities carried by parents, especially young men. This enhanced message, whether received via such preventive efforts or by other means, appears to be making a difference among adolescents. Among male teenagers, approximately 50% reported no sexual intercourse in 2001, compared with 39% in 1990. Teenage pregnancies have decreased from 116.9 out of every 1,000 girls in 1990 to 83.6 per 1000 girls in 2000, with such a trend consistent across race and ethnicity groups in the United States. Although many factors may contribute

to these notable trends, discussions regarding parental responsibilities may continue to provide teenagers with the rationale necessary to make adaptive early decisions regarding sexual activity.

The promotion of healthy marriages is another avenue of prevention that has been applied to the topic of deadbeat dads. In an era of “no-fault” divorce, higher rates of dissolved marriages result in higher requests for government subsidies that typically fail to fully support a family. Many of these marriage-focused projects are church based and assume that responsible fathering is more likely to occur within the context of a marriage. Specific programs, including premarital counseling, prebirth parenting classes, and conflict resolution psychoeducation classes, appear to help decrease the likelihood of divorce among high-risk couples, and do result in higher annual incomes for families with children. Key factors affecting child outcomes include the qualities of the father-mother and father-child relationships within such sustained marriages. For men who have distanced from the mothers of their children, it may be more difficult to overcome unresolved issues between unwed fathers and mothers. The Institute for Responsible Fatherhood and Family Revitalization and similar projects assert that once a man’s heart is turned toward his children and their mother, even a successful marriage is possible.

## SUMMARY

The birth of one’s child is an event that every father should be allowed to celebrate. Helping more men to see the wisdom in waiting to parent until they are economically and emotionally ready adults, to view their potential influence of their children via fathering as irreplaceable, and to see themselves as equal partners with their children’s mothers in the rearing and support of their offspring will make the development of deadbeat dads less likely events.

## DEAFNESS

---

The word *deafness* encompasses the state of not hearing. Prevalence estimates indicate that roughly 34 million adults representing approximately 17% of the United States report having a hearing loss. Within this group, the number of adults with severe to profound hearing loss ranges from 464,000 to 738,000, with approximately 54% being older than 65 years of age. Roughly 83 out of every 1,000 children have hearing loss.

### DIAGNOSIS OF DEAFNESS

Deafness can be diagnosed very shortly after birth based on hearing screening in hospitals. Hearing loss can also occur suddenly, at any age, for a variety of medical reasons. Additionally, hearing loss can be progressive. In that situation, diagnosing deafness may take longer, depending on age. One factor that reinforces the delay in diagnosis is related to the difficulty in recognizing that a hearing loss may be present. For example, caregivers of toddlers may interpret the child's behavior as stubborn without realizing the child may not hear. If caregivers express their concern about the delay in spoken language, doctors may tell them to be patient instead of referring them for an audiological (hearing) evaluation. Currently, diagnosis of deafness tends to happen between 12 and 33 months of age. With universal newborn hearing screening now mandated in most

states, the use of electrophysiological methods that have been developed to screen infants for hearing loss is likely to significantly lower the age at which deafness is diagnosed.

Hearing loss levels are categorized as mild, moderate, severe, and profound. Severe and profound deafness means that the available hearing level is insufficient to permit the understanding of speech through the ear alone, with or without hearing aids. Hard-of-hearing persons tend to have mild or moderate hearing losses that make it difficult but not impossible to understand speech, with or without hearing aids. The audiological evaluation takes loudness and pitch into account in diagnosing hearing loss. Loudness is measured in decibels (dB) across a range of frequencies that goes from low to high. Pitch is the subjective term for frequency. Examples of low pitch include men's voices and vowels. Women's voices and consonants are examples of high pitch. Audiologists often use the average of the responses obtained at three frequencies across the speech range to determine the level of hearing loss.

### EARLY INTERVENTION PROGRAMS

After diagnosis, early intervention programs facilitate the family's ability to appropriately nurture and communicate with their deaf child from infancy onward. Families get basic information about deafness, auditory amplification devices, language development issues, communication approaches, techniques for providing stimulating and accessible environments, and educational options. Quality intervention programs are family centered in that they are sensitive to family variables and involve parent-child sessions during which caregivers have the opportunity to practice interaction strategies that will enhance the child's communication and social development.

Recent research confirms the effectiveness of early enrollment in family intervention programs after early identification of hearing loss in optimizing the deaf child's ability to communicate and meet developmentally appropriate social and educational milestones. Building on these findings, research is currently focusing on evaluation of the service delivery process by means of examining the interface of program components, the needs of the individual child, family variables including culture and parenting style, and service provider characteristics.

## LANGUAGE AND COMMUNICATION

Parents have to make decisions about language and communication issues. Language and communication are often incorrectly viewed as interchangeable. Language refers to conventionalized signs or sounds having understood meanings together with rules for manipulating expressions. In the case of deafness, language refers to spoken, read, or signed language (e.g., English, Spanish, American Sign Language [ASL], etc.). Communication refers to the process by which information is exchanged through a common system, whether spoken or signed. Deaf children can be exposed to spoken English, the spoken language of their home if different from English, signed English (signs matching English word order), cued speech (with handshapes on the face indicating the speech sounds of the language), and/or ASL. There has been a long history of conflict between supporters of spoken language for deaf persons and those who endorse the use of signed languages to facilitate optimal psychosocial development. Research with young children and their families indicates that the critical variable is not the communication modality but rather active family involvement. When service providers and families collaborate effectively in adjusting to the language and communication needs of the deaf child, this increases the chances of effective parent-child communication and in turn of achieving expected developmental milestones with minimal delay. It is important to recognize that deaf children rely most often on visual avenues for communication and language learning. Auditory training is essential if the focus is on spoken language and entails intensive time commitment. Family intervention programs as well as schools may emphasize spoken language, signed English, or ASL as a bridge to written English through bilingual approaches.

## AUDITORY AMPLIFICATION

Parents also have to make decisions about auditory amplification, most notably between hearing aids and cochlear implants, if they want to encourage spoken language development in their deaf child. Digital hearing aids provide sound-processing strategies that can be programmed to fit the individual user. Cochlear implants require surgery to insert an electrode array within the inner ear structures, the purpose being to provide access to sound. For young deaf children, the

process for learning to listen with any device tends to be lengthy because current technology does not match the cues offered by the optimally functioning ear. Current research on children with cochlear implants suggests increased potential for improvement in speech comprehension, although results are variable. However, emerging new technology continues to render earlier results obsolete, therefore requiring new research on the effectiveness of cochlear implants in facilitating the development of spoken language. In the case of individuals who become deaf after acquiring spoken language, research indicates that cochlear implants appear to be effective in facilitating speech comprehension.

## EDUCATING DEAF CHILDREN

Deaf children are educated in a variety of settings. Approximately 20% are in specialized schools for the deaf, with the rest (80%) in mainstreamed programs. Some of these children are in self-contained classes with deaf children only, some are fully mainstreamed with hearing peers, and others are partially mainstreamed and partially in a self-contained class. Placement decisions depend most often on what is available in the family's geographic location. Almost all of the children in mainstream education require support services such as assistive listening devices, sign language or oral interpreters, communication access real-time transcription (CART) using computers, and tutoring. Deaf persons graduating from both specialized and mainstream settings on average do not achieve educational parity with their hearing peers. Their nonverbal intellectual functioning is similar to that of their normal hearing group, but limited exposure to linguistic and environmental stimuli in addition to the possible presence of additional disabilities depending on etiology make it difficult to catch up educationally. However, many deaf students have gone on to higher education and are successful in achieving career goals, primarily because involved families provided necessary support in addition to what the schools provided.

## SOCIALIZATION ASPECTS

Research indicates that in the area of socialization, deaf children tend to socialize with deaf peers more often than they do with hearing peers, even in mainstream settings. The limited signing ability of hearing

peers and the variable speech intelligibility of deaf peers makes socialization between the two groups more difficult. School social skills intervention programs with proven effectiveness have the potential to increase interaction when implemented consistently.

## PERSPECTIVES ON DEAFNESS

To further understand deafness, it is necessary to note the presence of two basic perspectives of deafness. One is that of disability. The other perspective is sociolinguistic in nature and emphasizes deafness as part of the diversity spectrum.

The disability perspective is the one most individuals are familiar with. It focuses on deafness as a disability based on the biological function of the ear and the medical etiologies of hearing loss. Medical doctors are the ones who typically make initial recommendations when deafness is diagnosed, followed by audiologists. If medicine or surgery cannot eliminate the hearing loss, audiologists then recommend appropriate technology, including hearing aids, cochlear implants, and assistive listening devices, in order to enhance hearing ability. The goal is to overcome the isolating conditions of deafness by enabling the child or adult to hear and use spoken communication within the hearing family, school, and work environments.

The sociolinguistic perspective conceptualizes deafness as representing a linguistic and cultural minority. Specifically, the focus is not on the medical and disabling causes of deafness and auditory rehabilitation. Rather, the focus is on the use of ASL as a language that takes advantage of the deaf person's natural reliance on vision to communicate with other people. The use of ASL is seen as connecting individuals with the culture of deaf people and thereby mitigating their isolation within hearing communities. Deafness becomes a bond that brings deaf people together.

In conclusion, deafness is far more than just not hearing. There are complex ramifications that affect the lives of people who are deaf.

## DEATH

The subjects of “children” and “death” seem somehow contradictory and yet it is clear, based on children's drawings and writings, as well as a child's adulthood memories, that the two subjects are often related. Consider the history of certain chants and games:

1. “Peekaboo” is said to be derived from an old English word meaning “dead” and “alive.”
2. The children's rhyme, “Ring around a rosie, a pocket full of posies; Ashes, ashes, we all fall down,” began in the 1300s with children's awareness of the symptoms of the Black Plague that killed over 25 million people.
3. An old English children's prayer, “Now I lay me down to sleep, I pray the Lord my soul to keep; if I should die before I wake, I pray the Lord my soul to take.”
4. The history of the children's games of “hide and seek” and even “tag” are thought to be related historically to children's concerns with life and death.

Nevertheless, since the 1980s in the United States, we are experiencing the world's first death-free

generation, meaning that a child is likely to grow to adulthood and never experience a death in their immediate family. (Death is experienced once in approximately 20 years for primary family members.) Yet 60% of children younger than 18 years of age will live in a single-parent home, for many an emotional equivalent of death. (Twenty percent of teens now live in single-parent homes.)

## DEVELOPMENTAL ASPECTS OF DEATH

Just as children's understanding of their environment and their place in this environment change with time, so does their understanding of the concept of death. A child's understanding of death is often described in four developmental stages:

1. Birth to 3 years of age
2. Three to 6 years of age
3. Five or 6 to 9 or 10 years of age
4. Ten plus years of age

From birth to 3 years, a child has no cognitive awareness or mental image of death, yet a physical response to death does exist. Rene Spitz' classic work in the 1940s set the stage for the understanding of a very young child's awareness of death of a significant caretaker. Spitz observed children placed in institutional settings as a result of the death of a parent or parents and from this work coined the term *anaclitic depression*. The symptoms of anaclitic depression are weight loss, increased demandingness and weepiness, and the arrest of developmental progress, with some children by the 3rd month refusing contact with people and assuming a prone position in the crib with an averted face. This term described the physical characteristics listed above. Thirty-seven percent of these children studied by Spitz died from malnutrition and infection at the end of 2 years.

The sources of studies of children and death between the ages of 3 and 10 years usually rely on the observation of children's drawings and stories as told to various child development researchers. Two classic studies are those of Maria Nagy (1948) and Sylvia Anthony (1971). From 3 to 6 years of age, children see death as temporary and reversible. A child's understanding is that death is like taking a trip or sleeping. During this period, children think concretely, and destroying and reviving persons is commonplace in children's play. A young boy

of 4, several weeks after the burial of the family dog, suggested that the family go and retrieve "Peter" from the cemetery. His belief was that Peter was living in the cemetery and only required being "dug up," a reversal of the burying process that he had witnessed, to bring the pet back to life.

Another common thread in the belief set of 3- to 6-year-olds is the sense that death is not only temporary and reversible but also "living under changed circumstances."

One of Maria Nagy's interviews of a 6-year-old Hungarian boy is as follows:

"He stretched out his arms and lay down. He can't speak. Can't move or see. He lies for four days."

(Nagy) "Why for four days?"

"Because the angels don't know yet where he is. The angels dig him out and take him with them."

(Nagy) "What happens to him?"

"If it's a woman, she does the cleaning. If it's a man, then he'll be an angel. He brings Christmas trees."

(Nagy) "Well, what are you going to do when you get there?"

"I'm going to bake cakes the whole year. Each angel has his own stove."

This is wonderfully illustrative of the belief of the young child that death brings life under changed circumstances, and this particular 6-year-old believes he will be baking and delivering Christmas trees after his own death.

The next stage—5 or 6 until 9 or 10 years of age—is characterized by a more sophisticated but still concrete view of death. Hungarian children in Maria Nagy's study personified death, making death into a person or being that would capture or take little children. These children, from a different cultural background, discussed death as equivalent to the presence of skeletons, ghosts, or the boogiemán. They often described death as coming with a scythe. Children in the United States, even though equally fascinated by death as their Hungarian peers, describe their beliefs in different ways. Children in the United States are particularly fascinated with the subject of death and seem to be riveted by discussions, pictures, and the rituals of death and dying. Halloween is often the favorite holiday for children in this age group. Boys in this age group most often draw pictures of blood

and gore and emphasize the violence of death in their drawings and stories. Girls, on the other hand, emphasize the “romance” of death and put tombstones, flowers, angels, and other heavenly beings in their drawings.

Ten years and older marks the beginning of a more adult understanding of death. This is the first time that children begin to comprehend that death is final. It is around this age that children begin to comprehend abstractions and grasp the concepts of the universality, irreversibility, and nonfunctionality of death:

1. *Universality*: the knowledge that every living thing eventually dies
2. *Irreversibility*: the knowledge that once dead, living things do not return to life
3. *Nonfunctionality*: the knowledge that death means the cessation of all bodily functions

## EXPRESSIONS OF GRIEF

Children differ from adults in their expressions of the grieving process. Some of the more common expressions are as follows:

1. *Shock, denial, lack of feelings*: Children tend to grieve in “bits and spurts” rather than in a continuous fashion as do most adults; therefore, it is less obvious, when children are playing and seemingly not sad, that they are experiencing a grieving process.

2. *Physical changes*: Children are likely to express grief in physical rather than verbal ways. Children have little permission or opportunity to talk about death and are less capable of putting words to their feelings, and so they often express their sadness or loss by being tired, showing lack of energy, having difficulty with sleep or appetite, having headaches or stomach aches, and/or experiencing skin rashes or hair loss.

3. *Regression*: After the death of a caretaker, a child may become overly dependent on the remaining parent, often having an inability to separate from the still living parent.

4. *“Big man” or “big woman” syndromes*: Children experiencing a significant loss may take on the role of the missing adult, seemingly becoming more mature than their peers.

5. *Disorganization, panic, fear*: A child’s life after a significant death feels chaotic and out of control.

Many children express fear that their other caretakers may die as well.

6. *Explosive, “acting out” behavior*: Some children become increasingly angry at themselves or others, behaving uncharacteristically in an angry, out-of-control fashion.

7. *Loss, emptiness*: A child may become dependent on someone outside the family, avoiding the reminders in their home of the family loss.

8. *Relief*: Particularly after a long illness, a child will express relief that the difficult period has ended. This behavior is similarly felt among adults, but expressed more privately, in that this response is seen in society as an inappropriate one.

9. *Gender differences*: Girls and boys are socialized to express grief differently. Girls are likely to be reinforced for sharing grief openly; boys are expected to be strong and express their grief privately.

## SUMMARY

Death is a part of a child’s life. From birth onward, an understanding of death is expressed by children commensurate with their developmental age and gender. Children have characteristic ways of responding to death that differ from a typical adult response.

—Mary Ann Watson

## DEATH WITH DIGNITY

---

“Death with dignity” has long been a slogan of the “right to die” movement. Proponents of legalizing physician-assisted suicide and/or voluntary active euthanasia (in which mentally competent patients with terminal illnesses can request to end their lives and suffering) adopted this rallying cry as a means of speaking to the concern of the general public about the dehumanizing aspects of dying in increasingly technologically sophisticated health care settings. In contrast, opposition to “mercy killing” has arisen in some religious and ethnic communities who oppose the medical termination of life under any condition, either for moral reasons or because of historically conditioned distrust toward the health care system. Recently, proponents of palliative care as an alternative to assisted suicide and euthanasia have attempted to demonstrate that dignified deaths are possible when the dying person’s needs are attended to in sincere and caring ways. Thus, the concept of a “dignified death” is subject to varying interpretations, ranging from endorsement of the patient’s right to request physician assistance in dying, to the less ethically contested principles that a person can refuse futile treatment that only prolongs suffering and that systematic attention to pain management along with the patient’s (and family’s) psychological, social, and spiritual needs is essential to permit an appropriate death.

Interest in assisted suicide and euthanasia in the United States dates back to the early 20th century, with the first euthanasia bill drafted in Ohio in 1906 and the first euthanasia society in the United States being founded in New York in 1938. However, it was not until the 1970s that the movement gained significant traction, possibly as a result of the development and use of medical technology that could prolong life and, perhaps secondarily, increase perceived suffering. Although there had been widespread efforts to distribute “living wills” to permit patients to declare their end-of-life treatment preferences, the first state statute legalizing the use of living wills was not passed until 1976 in California, coinciding with the New Jersey Supreme Court’s decision to allow the parents

of Karen Ann Quinlan to disconnect the ventilator that was keeping her alive in an unconscious vegetative state.

The Hemlock Society (recently renamed “End-of-Life Choices”) was founded in 1980 with a charter principle to publish a book “about methods and strategies of planned death with dignity.” *Final Exit*, which provided explicit information, appeared in 1991, written by society founder Derek Humphry. “Death with dignity” was widely adopted as a catchphrase for the movement to indicate the desire to die in a way that did not sacrifice quality of life for quantity. Many subsequent legislative efforts were referred to as “death with dignity” acts or bills, such as an unsuccessful bill in Oregon in 1991, an unsuccessful act on the 1992 California ballot, and the successful 1994 Oregon Death with Dignity Act (which was passed again and implemented in late 1997).

This idea of “death with dignity” tapped into a core concern of the general public, because the possibility of losing one’s dignity near the end of life is one of the greatest fears of people in general and dying individuals in particular. Perhaps for this reason, numerous surveys of public and professional attitudes concerning end-of-life treatment decisions indicate widespread, but not universal, support for the principle of patient self-determination as a means of ensuring death without unnecessary suffering, at least in many Western countries. Partly as a result of this growing awareness of the problem, more attention is being given to the idea that a person can die with her or his dignity intact without having to resort to assisted suicide or euthanasia. Although this has been a core aspect of hospice care, it is likely that a diversity of efforts to enhance dignity near the end of life will be undertaken in medical settings and other long-term care institutions in the future.

## DEDUCTIVE REASONING

---

The study of reasoning is very important because it pertains to the heart of the question of whether people think logically and rationally. Do people follow the basic rules of logic when they make inferences? Some researchers highlight the flaws of human reasoning and its irrationality; others stress the enormous flexibility and rationality of human reasoning.

Reasoning can be distinguished in inductive reasoning and deductive reasoning. Inductive reasoning refers to moving from the specific to the general, for example, “You can find the whole of nature within one flower.” Studying the details of a flower can lead to general hypotheses and rules about nature. This is an inductive approach. On the other hand, deductive reasoning means taking a general rule or theory and making inferences about a specific example.

Deductive reasoning has been widely studied using propositions in the form of “If . . . then” statements and using deductive arguments, also called syllogisms. Let us take the following example for a proposition: “If A, and B, but not C at the same time of E, then F in order to avoid G.” This example is quite abstract. An example of this proposition is, “If you have a car (A) which runs on diesel (B), but not a car which runs on regular gasoline (C), when you want to start the car (E), then you have to wait a bit and let it glow before you start (F), otherwise you damage the motor (G).”

An example for a syllogism is the following: “All cats love sausages. Fluffy is a cat. Therefore, Fluffy loves sausages.” The syllogism consists of two arguments, also called premises, and one conclusion. According to rules of logic, if the premises are true, the conclusion is also true. In our example, the two premises are true; therefore, the conclusion is also true. The presented syllogism only consists of two premises. Syllogisms become difficult, however, when they consist of many premises, when they include the quantifier “some” instead of “all,” or when one premise is negated.

Several theoretical approaches have been developed that try to explain how people deal with syllogisms, that is, what cognitive processes occur when people solve syllogisms. A first approach, according to Sternberg, for example, distinguishes several components: encoding the information presented, mentally representing the meaning of the words in the premises, and controlling one’s own mental processes. A second approach, following Braine, for example, stresses the mental rules or inferences people use to draw conclusions. People might not be aware of these rules. These rules are often implicit like the rules of grammar we use to build sentences. A third approach, developed by Johnson-Laird, understands deductive reasoning as the building of mental models. Similar to understanding language by constructing mental models, people construct mental models when they read premises and draw conclusions. Recent neuropsychological studies of Goel and colleagues find initial support for the mental models approach. However, one might see these approaches not as mutually exclusive or contradictory, but as complementing one another.

In the context of cognitive development, the ability of deductive reasoning starts with the concrete operational stage (labeled by Jean Piaget) at around the age of 6 or 7 years. One prerequisite for deductive reasoning is the ability of the child to build groups and hierarchies of groups on different levels of abstraction, for example, the ability to know and differentiate dogs from cats and birds, and in greater complexity, differentiating German shepherds from poodles and bulldogs. This ability allows children to categorize objects correctly using necessary and sufficient criteria. Children at the preoperational stage of cognitive development, however, classify objects if they merely look similar (e.g., for them a carp and a whale are both fish). Although children in the preoperational stage can classify objects, children in the concrete operational stage are able to do this with more complexity and sophistication.

In the earlier years of childhood, some mistakes of deductive reasoning can be evident and observed. Many children, for example, overgeneralize and label every animal they see as “dog.” The implicit argument might be the following: “All objects that move, that have two eyes, two ears, a nose, and four legs are dogs. This concrete object that moves in the park has two eyes, two ears, a nose, and four legs. Therefore, it is a dog.” However, the object might not be a dog, but a sheep or a cat. In most cases, when the child then says “dog” and it is not a dog, other persons present

might correct the child and help the child to differentiate and further refine his or her schemata.

Another error in deductive reasoning is undergeneralization. A child might call only one specific brand of cereal, Cheerios, for instance, as “cereal” and not apply the category “cereal” to all other brands. The implicit argument might be the following: “This food which is round, small, and has a whole in the middle is cereal. This food is flat. Therefore, it is not cereal.” It is common knowledge to most adults that Cheerios and corn flakes are both cereal. However, the child only labels the Cheerios as cereal. In both examples regarding overgeneralization and undergeneralization, the mistake lies in the first premise, that is, that all objects that have two eyes, two ears, a nose, four legs, and move are dogs; and that only Cheerios are cereal. The child is not yet able to distinguish appropriately between groups and is not able to differentiate between levels of abstraction.

One way to help children improve their deductive reasoning is visualization, for example, using Venn-diagrams. Venn-diagrams are geometric figures (e.g., circles or rectangles) that show similarities by overlapping figures. When drawing a Venn diagram about dogs and German shepherds, it becomes visually quite obvious that the group of dogs is bigger and more encompassing than the group of German shepherds and that the group of German shepherds is all included and a part of the group of dogs.

The ability of deductive and inductive reasoning acquired during the concrete operational stage is further developed during the stage of formal operational thinking. The abstract quality of formal operational thinking helps adolescents step back from the concrete content and judge the validity of the inferences. Let us consider the following syllogism: “All scorpions are mammals. Mammals are warm blooded. Therefore, scorpions are warm blooded.” One might say this conclusion is true; another one might say this conclusion is not true. And both answers are right! The conclusion is logically correct and valid just following the abstract rules of logic and temporarily assuming the truth of the premises. However, the content of the first premise is untrue. In reality, scorpions are not mammals. Therefore, considering world knowledge about scorpions and mammals, people might think this is nonsense, and therefore might choose the answer “not true.” Similarly, one might abstract from the content of the two previous examples on dogs and cereals and only judge the logical validity of the conclusions.

Premises conflicting with world knowledge are one difficulty in working with syllogisms. We already mentioned that syllogisms with negated premises or abstract formulated syllogisms are more difficult than syllogisms that are not negated and concrete. There are still other factors that influence the accuracy of solving syllogisms. Researchers such as Luria, Scribner, and Cole presented syllogisms to people from different educational backgrounds in different cultures in Africa, America, and Asia. In all cultures, participants who have a formal education, attend school, or have gone to school were able to solve syllogisms better than participants who did not go to school. Participants without formal school education gave correct answers in about 50% of the cases, which is not better than chance. This result does not necessarily mean that people who go to school think more rationally than those who do not go to school. They might just be more familiar with such kinds of problems. Looking not just at right or wrong answers, but at the kinds of answers and justifications of participants without formal school education, shows their way of thinking. In one study, Scribner presented the following syllogism: “All children like candy. Mary is a child. Does Mary like candy?” Someone without formal education might answer: “How would I know if Mary likes candy. I don’t even know her!” or “Who is Mary?” These answers show that participants without formal school education interpret the syllogisms personally, using their world knowledge. They often refused to accept initial premises that contradicted their own experiences and they refused to treat general premises as truly general. It seems like they were not able or willing to stay within the problem boundaries. Interestingly, they could solve syllogisms easily that referred to familiar content.

To summarize, deductive reasoning is the ability to draw specific conclusions from general information. It is a key ability that children start acquiring in the concrete operational stage and that adolescents and adults further develop in the formal operational stage. Prerequisites for deductive reasoning are elaborated mental concepts on different levels of abstraction, as well as certain rules of inference. Research shows that in most cultures, formal schooling as well as familiarity with the material presented facilitate success on formal reasoning tasks.

## DEFERRED IMITATION

---

*Deferred imitation* refers to observing a model and replicating important aspects of the model's behavior after some significant period. Jean Piaget proposed that deferred imitation, along with language, imagery, and symbolic play, is an indication of the symbolic (or semiotic) function. Although Piaget stated that deferred imitation emerges at around 18 months of age, more recent research has indicated deferred imitation for simple behaviors at as early as 6 or 9 months of age, although the complexity of the actions imitated increases with age.

The length of delay over which behaviors can be imitated also increases with age. For example, Andrew Meltzoff (1985) reported that 45% of 14-month-olds and 70% of 24-month-olds were able to defer imitation over 24 hours. Patricia Bauer and her colleagues (2000) assessed imitation over delays ranging from 1 to 12 months. They showed infants a series of three-step sequences; for instance, the model placed a bar across two posts, hung a plate from the bar, and then struck the plate with a mallet. About half of 9-month-olds tested showed imitation of simpler two-sequence actions after a 1-month delay, although these infants required at least three exposures to the events before displaying imitation. Rate of deferred imitation increased substantially

for 13-, 16-, and 20-month-old infants, with older infants demonstrating higher levels of performance during each delay interval than younger infants did. In fact, by 20 months, children remembered individual actions for as long as 12 months.

Some have speculated that deferred imitation reflects a nonverbal form of explicit memory. Explicit, or declarative, memory refers to memory that is available to conscious awareness as reflected by tests of recall in verbal children and adults. This is contrasted with implicit, or nondeclarative, memory, which is memory without conscious awareness. Support for the position that deferred imitation reflects a type of explicit memory comes from research with adult amnesiacs. Adults with specific brain damage (usually to the hippocampus) are unable to form new explicit memories, although they are still able to form new implicit memories. For example, after practicing complicated motor tasks for several days, their performance improves substantially, although they have no conscious (i.e., explicit) recollection of ever having performed such tasks before. These brain-damaged patients perform similarly (and poorly) on explicit memory and deferred imitation tasks, suggesting that deferred imitation uses the same memory system as more conventional explicit memory tasks, implying that infants within their first year of life possess at least the rudiments of explicit cognition.

Evidence of deferred imitation as a nonverbal form of declarative memory may be especially important in comparative research with primates, investigating the possible phylogenetic origins of humans' unique cognitive abilities. Michael Tomasello (2000) has argued that true imitation requires that the observer not simply repeat the model's actions, but understand the model's goal, or intention. Evidence of deferred imitation of actions on objects has been observed in chimpanzees (*Pan troglodytes*), but only those that have been enculturated, or raised by humans, much as children are reared. Moreover, longitudinal research of deferred imitation in enculturated chimpanzees has shown that these abilities increase with age, with older chimpanzees being capable of more complex imitative behaviors, similar to the pattern observed for human infants. These findings suggest that chimpanzees, and possibly the common ancestor of both chimpanzees and humans, possess the rudimentary representational ability for explicit cognition.

Deferred imitation has been recognized as reflecting important cognitive abilities in children, beginning

with the work of Piaget. More recent research indicates that the representational skills underlying deferred imitation are found in infants much younger than proposed by Piaget and may be possessed, under certain circumstances, by humans' closest genetic relative, the chimpanzees.

## DELINQUENCY

---

### DEFINITIONS AND DESCRIPTIONS

Delinquency is a legal term, which is generally defined as antisocial or criminal acts that violate legal laws and cultural norms. Juvenile delinquents are almost always diagnosed with oppositional defiant disorder (ODD) or conduct disorder (CD). According to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*), the standard manual used by psychologists and psychiatrists, ODD is characterized by a recurrent pattern of defiant, disobedient, and hostile behavior toward authority figures that persists for at least 6 months. These negative behaviors include arguing with adults and authority figures, frequently

losing one's temper, actively disobeying the rules and requests of adults, continually blaming others for one's own mistakes or misconduct, being overly sensitive or becoming easily irritated by others, behaving in an angry or resentful manner, deliberately doing things that will annoy or anger others, or being actively spiteful or vindictive. Behavior exhibited by children diagnosed with CD involves violations of age-appropriate societal norms and the basic rights of others. These behaviors are often present in a variety of settings and can be placed into four main categories (i.e., threatening or aggressive behavior that causes physical harm to humans or animals, nonaggressive conduct that results in property damage or loss, deceitfulness and theft, and serious violations of rules and policies).

### ONSET, PREVALENCE, AND COURSE

CD and ODD are the most frequently diagnosed disorders in adolescents and children. Indeed, these disorders account for almost half of all mental health referrals in children. ODD has been reported to occur in up to 16% of all youth, and CD has been estimated to occur in up to 10% of the adolescent population. While onset of ODD is usually gradual, the disorder is usually evident before the child reaches 8 years of age. CD can occur as early as the preschool years. However, a significant proportion of symptoms are usually first evidenced during middle childhood and middle adolescence. Approximately one third of children diagnosed with ODD will subsequently be diagnosed with CD. It should also be noted that if a youth continues to exhibit the social violating behaviors characteristic of CD after the age of 18, then the diagnosis of antisocial personality disorder (ASPD) will be made instead of CD. Without intervention, the severity of criminal acts and related behavioral problems are often exacerbated with the passage of time.

### COMORBID DISORDERS AND CAUSES

There are many disorders that commonly occur in conjunction with delinquency, most often including attention deficit/hyperactivity disorder (ADHD), substance abuse disorders, and mood disorders, such as depression anxiety. Thus, it is not surprising that a child's risk for juvenile delinquency is often increased when a child's parent has been diagnosed with either

a substance misuse or abuse disorder, a mood disorder, schizophrenia, ADHD, antisocial personality disorder, or conduct disorder. Twin and adoption studies have indicated hereditary influences to delinquency, and parenting and familial risk factors have been shown to play an important role in the development and maintenance of conduct problems. For example, as compared with parents of nondelinquent youth, parents of children with conduct problems experience greater marital and interparental difficulties, stressful events, and chaotic environments. These parents are also more likely to make less positive and more negative statements, to perceive behavioral problems of their children as intentional, to have problem-solving deficits, and to abuse or neglect their children. Extrafamilial factors that have been associated with delinquency include low socioeconomic status, social isolation, and low parental social support. Children and youth with conduct problems often lack appropriate social skills, have poor peer relationships, and experience peer rejection more so than youth who do not evidence these problems.

### EMPIRICALLY SUPPORTED INTERVENTIONS

Treatment programs for delinquent youth are usually multidimensional. When the symptoms of delinquency are determined to be primarily biological, psychopharmacological (drug) medications are sometimes prescribed, including psychostimulants and neuroleptic medications. Very few studies have evaluated the effectiveness of psychostimulants for conduct disorders, because these medications are typically combined for use with other interventions. However, studies have been conducted to examine the effectiveness of psychostimulants in the treatment of ADHD (a comorbid disorder that encompasses problems of inattention, hyperactivity, impulsiveness). These studies have reported significant reductions in problems of conduct, aggression, verbal harassment, noncompliance, stealing, and property destruction. Neuroleptic (i.e., antipsychotic) medications have shown reductions in aggression, fighting, explosiveness, and hostility, probably due to their sedative effects. However, these medications have not been widely supported for the treatment of conduct disorders due to adverse side effects associated with these drugs (e.g., sleep disturbance, dry mouth, irritability), and outcome support is mixed.

One treatment approach known as “parent training” assumes that deficits in parenting skills have

been partly responsible for the development and/or maintenance of youth conduct problems. This treatment approach emphasizes prosocial goals and teaches parenting techniques, including training in positive reinforcement procedures, problem-solving techniques, role-playing practice, and structured homework exercises. Hanf and Forehand developed one of the first empirically supported parenting programs for younger youth (i.e., 3 to 8 years of age) who evidence ODD. The program focuses on child non-compliance and consists of two phases. In the first phase, the parent is taught to attend to the child’s desired behavior and later praise the child for performance of compliant behaviors. In the second phase, the parent is taught to use time out for noncompliant behaviors through various behavioral methods, including didactic instruction, modeling, and role-playing. Time out involves the child being excluded from opportunities to be reinforced. Treatment also includes observation of the parent in parenting situations through one-way mirrors, as well as “bug in the ear” devices, which allow the therapist to communicate with the parent during the parent-child interactions. In this treatment program, the parent learns to increase the frequency of social attention, reduce the frequency of competing verbal behavior, and use verbal and physical attention contingent on compliance and other appropriate behaviors. Finally, the parent learns to actively employ the newly acquired skills in the home setting. This program has shown to be effective in improving child behaviors (e.g., aggression, temper tantrums, destructiveness, inappropriate verbal behaviors) and parent behaviors (positive communication, reduction of corporal punishment), as well as parents’ perceptions of their children. Webster-Stratton and colleagues have developed an innovative parent training program that involves the use of videotapes. In this program (BASIC), a group of parents is shown videotapes that include examples of appropriate and inappropriate parent-child interactions. After each video clip, a therapist leads a group discussion in which the parents can discuss the video interactions that were modeled. Facilitators are also available to answer questions and provide guidance. The program has demonstrated clear support in controlled outcome studies with younger youth who evidence ODD. For instance, increases have been found in both mothers’ and children’s conduct, as well as in maternal satisfaction and perceptions of their children. Additional videotape components (i.e., ADVANCE, KIDVID) in

conjunction with the BASIC program have also resulted in improvements in child problem solving, conflict management skills, communication skills, and consumer satisfaction.

Family functional therapy (FFT) is a family-based intervention program that was designed to work with adolescent delinquents with both minor and major juvenile offenses. FFT concentrates on family members' expectations during treatment and serves to modify any inappropriate attributions or expectations. Various behavioral techniques are used, including role playing, communication skills training, and contingency management. Finally, the program serves to maintain therapeutic goals while also stressing the importance of the family's independence from the therapy context. FFT has shown improvements in communication variables and lower recidivism rates.

Multisystemic therapy (MST) focuses on multiple systems within an adolescent's world, including the role of family, school, and peer groups. Thus, the program incorporates school consultation, peer interventions, marital therapy, and individual therapy. The theoretical underpinnings of this program are family systems therapy and cognitive-behavioral therapy (e.g., joining family together, functional analysis, drug refusal skills training, stimulus control, and harm reduction). Recently, MST has incorporated a sophisticated contingency contracting procedure. The MST treatment approach has resulted in decreases in conduct problems, incarceration and arrest rates, peer aggression rates, substance-related arrests, and improved family relations. Unique to most programs, counselors usually visit youth in their home or school environment.

Problem-solving skills training (PSST) teaches youth with conduct problems how to solve problems in various situations and settings. Most PSST-based programs focus on teaching youth to learn four basic steps when confronted by a dilemma (i.e., state the problem clearly and succinctly, brainstorm options available and think of the advantages and disadvantages of each option, choose one or more options, implement one or more of the options). PSST has been shown to have positive effects in extremely aggressive children as well as in children with moderate to mild behavioral problems. Additionally, PSST has proven to be extremely effective when combined with parent training treatment programs.

Only one treatment outcome study has been conducted with youth formally diagnosed with both a conduct disorder and a substance abuse disorder (i.e.,

the two most prevalent mental health disorders among delinquent youth). In this study, Nathan Azrin and his colleagues found individualized cognitive problem-solving skills training programs and family behavior therapy to significantly improve problems associated with delinquency and drug abuse (e.g., decrease in depression, decrease in frequency of alcohol and illicit drug use, decrease in days institutionalized, increase in school and employment attendance, and decrease in misconduct). Additionally, youth and their parents reported greater satisfaction with one another.

When conduct is extreme, youth are often placed in institutional or group home settings where their conduct can be better monitored and controlled. In this regard, the Teaching-Family Model (TFM), developed by professors at the University of Kansas, is a model program. The more than 250 TFM group homes are managed by young married couples, known as "teaching parents," who have undergone extensive behavioral skills training and are certified by the Teaching-Family Association. These programs emphasize a strong positive relationship between youths and teaching parents. Treatment components include youth self-government procedures, social skills training, behavioral skills training, academic tutoring, and reinforcement systems designed to monitor school behavior (home-based token economy) and home conduct (level system). The TFM approach has proven more effective than comparison programs in school performance, offense and delinquency rates, and youth and school personnel satisfaction. However, similar to other programs, these differences dissipate when the adolescent leaves the group home.

## LATER CONSEQUENCES OF DELINQUENCY AS A CHILD

Delinquent youth will often "outgrow" their problems of conduct without intervention. However, they are at greater risk for continuing to engage in more serious behaviors throughout adolescence and into adulthood, particularly when the onset of conduct problems occurs at an early age (i.e., before adolescence). These individuals are also at high risk to be later diagnosed with ASPD and other psychiatric diagnoses. Indeed, as compared with their nondelinquent counterparts, delinquent youth experience severe negative life outcomes, including lower occupational adjustment and educational attainment, poorer physical health and relationships with others, and higher rates of divorce.

## CONCLUSIONS

There have been many encouraging findings and evaluations regarding the application of a variety of treatment approaches with conduct-disordered children and adolescents. Empirically supported treatments have predominately been family oriented and cognitive-behavioral or behaviorally based, and have also incorporated multiple interventions to address commonly encountered comorbid disorders (e.g., substance abuse and substance dependence).

It is important for all programs to take into account the progressive nature of conduct problems. For example, once conduct problems have been established and maintained, it becomes more difficult for changes and improvements to occur. Therefore, it is essential that treatment programs be implemented as soon as conduct problems first emerge or, ideally, prior to their onset through the implementation of prevention programming.

(deficits in learning new information or in recalling previously learned information) and at least one of the following: language (word retrieval difficulties, defects in understanding complex commands, loss of semantic knowledge), perception (problems in the identification of objects or in the recognition of familiar places), praxis (impairment in the ability to carry out complex movements), and executive functions (inability to plan and organize behavior). Calculation ability defects and conceptual difficulties are also commonly found. These deficits are usually progressive but in some cases are static. Dementia also comprises personality and emotional changes. Lack of awareness of the cognitive defects is frequently found. Psychiatric symptoms such as delusional ideation and hallucinations also might develop. As the disease progresses, these deficits impair the social and occupational functioning of the individual.

## DIFFERENTIAL DIAGNOSIS

The acquired component of dementia distinguishes it from congenital mental retardation. The diagnosis of dementia requires a decline from the previous level of functioning. Dementia should be distinguished from delirium, which is an acute impairment of cognitive and behavioral functioning with fluctuating disturbance of attention. Delirium lasts hours or days; in dementia, a relatively stable symptomatology is found. Dementia is more frequently seen in the elderly, and it needs to be differentiated from the age-related cognitive changes that are characteristic of normal aging. Normal elderly individuals frequently suffer from memory decline, but other cognitive areas are usually better preserved. Memory defects in normal aging are observed in the memory recall stage (poor retrieval of nouns and proper names, but improvement is seen with recognition or cueing) rather than in the storage of new information. Severe depression in elders may mimic a dementia (pseudodementia). Depression affects all measures that depend on speed, effort, and attention; memory retrieval difficulties are also frequent. Contrary to dementia patients, depressed patients are usually aware of their memory problems and complain about them. It is important to note that depression might coexist with dementia and that depression can be a major feature of many dementia types, particularly fronto-subcortical dementias.

---

## DEMENTIA

---

### DEFINITION

Dementia is characterized by the development of multiple cognitive deficits, including memory

## PREVALENCE

Dementia increases sharply with age. Most dementias are found in people older than 65. The prevalence for all dementias is over 2% by age 65 and over 30% for those 85 or older. Fifty percent to 70% of the cases of dementia correspond to an Alzheimer-type dementia; approximately 35% have pure Alzheimer's disease (AD); the remaining have AD associated with vascular disease or Lewy body pathology. The second most common type of dementia is vascular dementia, making up 10% to 30% of the dementia cases. The prevalence of frontotemporal dementia has been estimated at 5%. The prevalence of other types of dementia is less clear.

## SUBTYPES OF DEMENTIA

Several classifications of dementia have been proposed. They can be divided into cortical versus fronto-subcortical dementias based on clinical characteristics. Cortical dementias, such as AD, affect language, memory, praxis, perception, spatial skills, and executive functions; they involve the cerebral cortex. Most of the other dementias (i.e., Parkinson's, Huntington's, vascular, Lewy body, and human immunodeficiency virus [HIV] dementias) engage the fronto-subcortical structures (thalamus, caudate, and subcortical white matter), and the predominant features are lack of motivation, attentional difficulties, movement disorders, and slowing of cognition. Dementias can also be classified based on the etiology or cause of the dementia. There are degenerative dementias such as AD, Parkinson's disease dementia, and Huntington's disease dementia. Vascular dementias result from cerebrovascular insufficiency in different parts of the brain. Other types of dementias are infectious dementias produced by viruses, bacteria, fungi, and parasites. Examples are HIV-associated dementias, neurosyphilis, Lyme disease, herpes encephalitis, and cysticercosis. Prion dementias, such as Creutzfeldt-Jakob disease, are produced by small proteinaceous infectious particles that produce spongiform disease of the brain. Toxic-metabolic dementias are seen in cases of prolonged exposure to neurotoxins (alcoholic dementia, Wernicke-Korsakoff syndrome) or lengthened metabolic disruptions (hepatic encephalopathy, dialysis dementia, chronic hypoxia). Other types of dementia are traumatic, secondary to repeated blows to the head, and neoplastic, secondary to large brain tumors. Cognitive deficits are

frequently associated with some psychiatric conditions and can produce psychiatric-related dementias. Depression, for example, presents psychomotor retardation and cognitive impairment that in most cases are rather secondary to the mood impairment than to a real dementia. The term *pseudodementia* (*mimic dementia*) has been used to describe the cognitive changes observed in depression. When dementia and depression coexist, the cognitive deficits are more severe. There is also dementia associated with bipolar disorders and schizophrenia.

## CHARACTERISTICS OF THE MOST FREQUENT TYPES OF DEMENTIA

Alzheimer's disease is characterized by the presence of progressive cognitive decline in at least two cognitive domains. The decline in memory with deficits in episodic memory that progresses to amnesia is characteristic of AD. Word-finding difficulties that evolve into an anomia (poor naming) and impaired comprehension are usually observed. Visuospatial difficulties and inability to perform learned movements (apraxia) constitute another important characteristic of AD. In addition, AD is characterized by personality and social changes such as lack of initiative, decreased motivation, indifference, and apathy. AD has important hereditary components.

Vascular dementia includes a group of dementing disorders that results from cerebrovascular insufficiency such as thromboembolism or multiple cortical or subcortical strokes and hemorrhagic events. Risk factors for vascular dementia are advancing age, male gender, a history of hypertension, and previous strokes. The dementia characteristics of vascular dementia depend on the site of the lesions. Cortical lesions produce a cortical dementia type with symptoms of amnesia, agnosia, aphasia, and apraxia. Subcortical lesions, on the other hand, are characterized by psychomotor symptoms and attentional and behavioral difficulties.

Frontotemporal dementia is characterized by severe personality and behavioral disturbances that usually precede the cognitive decline.

## ASSESSMENT OF DEMENTIA

Dementia is a behavioral and cognitive syndrome, and its diagnosis is based on observable deficits that can be evaluated and measured through cognitive

assessment, clinical observation, and neuropsychological evaluation. The cognitive and behavioral assessments must be interpreted in the context of the neurologic examination. The presence of motor disturbances, for example, points toward a more fronto-subcortical dementia, while normal motor examination results plus cognitive deficits point to a cortical dementia. In addition, laboratory tests such as blood tests, urinalyses, and thyroid tests, as well as neuroimaging procedures (computed tomography or magnetic resonance imaging) help to establish the differential diagnosis among dementia syndromes.

## TREATMENT OF DEMENTIA

The treatment of dementia has two components. One is the pharmacological treatment directed to the patient who suffers from dementia. The other component is the dementia management directed toward the family and caregivers.

### Pharmacological Treatment

The pharmacological treatment of dementia varies depending on the etiology of the dementia. In the majority of cases, the conditions associated with dementia have no cure, but management of the symptoms or prevention can be undertaken. In the case of AD, researchers have identified some factors that can reduce the risks for developing AD; for example, preventing head injuries, exercising regularly, and using agents that reduce oxidative injury such as vitamin E. The fact that the brains of AD patients present a decrease in the levels of acetylcholine has led to the use of medications that increase the action of this neurotransmitter with very modest results. The treatment for vascular dementia includes the management of hypertension and the prevention of new strokes by using anticoagulants, cerebral vasodilators, and selective thrombin inhibitors. Dopaminergic therapy has been useful with motor and cognitive symptoms of Parkinson's dementia and Lewy body dementia. Infectious dementias are treated with antibiotics.

### Nonpharmacological Management

The patient usually loses insight, and in most cases the impact of dementia is greater for the family than for the patient. The family and caregivers need to learn how to manage the patient through the cognitive and

behavioral gradual decline. Caregivers slowly assume the patient's activities of instrumental living such as shopping, cooking, and driving. They also assist the patient in daily living activities such as dressing, eating, bathing, and toileting. Caregivers should promote functional independence by skills practice, positive reinforcement, and assistance of occupational and physical therapy. However, it is recommended to structure the patient's activities and to avoid changes in routine. Dementia patients should also be cognitively stimulated. Memory aids, notebooks, pegboards, and word association have been shown to be useful in cases of dementia. The family needs to learn how to maintain good communication and appropriate interaction with the patient. Behavioral disturbances, particularly irritability, aggression, and delusions, frequently require the patient's hospitalization. The family can learn to identify the precipitating factors of behavioral aggression, and family interventions can help to reduce the frequency of these events. Family education and counseling are essential to improve caregiver satisfaction and to delay nursing home placement. Family members also require legal counsel. After patients lose their decision-making capacity, the presence of a legal representative for health care decisions is important.

## DEPENDENT VARIABLE

---

In a scientific experiment, a researcher investigates whether changes in one or more independent variables have an effect on one or more dependent variables. A dependent variable is what is assessed as an outcome or effect of the study. It is a variable because the measure can take on some range of values. It is called dependent because it is hypothesized to be affected by

changes in the independent variable. The direction of the presumed effect is always the same: from the independent variable to the dependent variable.

For example, suppose that a researcher is interested in whether noise distracts children from efficient processing of information. A relevant experiment might involve testing children in three conditions: silence, mild noise, and moderately loud noise. The test might involve presenting a series of test trials in which each child is shown a set of digits (numbers), presented one at a time. After each set, the child is asked to say aloud as many as possible of the digits in that set, in the order presented. Some of the trials would occur with silence in the testing room, other trials would occur with some mild amount of background noise in the room, and other trials would occur with moderately loud background noise. In this experiment, the dependent variable is the outcome measure, namely, the number of digits correctly recalled. The researcher might hypothesize that the children would recall the most digits in the silent condition and the least digits in the moderate noise condition. If these results occurred, the researcher would conclude that the independent variable (noise condition) caused changes in the dependent variable (digit memory).

There are many kinds of measures that can function as dependent variables in psychological studies. A dependent variable can be a measure of behavior, such as performance on a test or reaction time to a stimulus. It can be a self-report measure, such as responses on a personality or attitude assessment. It can be a physiological measure, such as a change in brain waves or in levels of a hormone.

Dependent variables must be identified by examining the design of an experiment. That is, some variables could potentially function as independent or dependent variables, depending on the proposed pattern of cause and effect and on the way the variables are used in the experiment. For example, sugar consumption might be an independent variable in a study where you examine the effects of sugar on memory abilities by varying and controlling the amount of sugar eaten by groups of people over some time period and testing their memories. Sugar consumption might be a dependent variable in a study in which you compare a group of children who received specific nutritional classes to a control group of children who did not receive such classes, and you subsequently measure the amount of sugar consumed.

In selecting a dependent variable, researchers must consider the reliability and validity of the measure.

Reliability refers to whether the measure has stability. That is, if the study were repeated, would the measure be similar? If other responses that assessed the same task were used, would those measures show a similar response pattern to the initial measure used? Validity refers to whether the measure accurately reflects what was intended to be tested. For example, infant's attention may be operationally defined by the dependent variable of looking duration, as long as there is reason to argue that looking time accurately reflects infants' attention.

---

## DEPRESSION

---

The depressive disorders are characterized by a persistent sad or unhappy mood. Sometimes these disorders are referred to as the unipolar depressions. The current version of the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (*DSM-IV-TR*), published by the American Psychiatric Association (2000), identifies two primary depressive disorders: major depressive disorder (MDD) and dysthymic disorder (DD). MDD is an acute form of depression in which the individual is extremely sad, discouraged, or blue for at least 2 weeks. In contrast, DD involves a chronically depressed mood of at least 2 years in adults, and of at least 1 year in children. Thus, MDD is distinguished by its severity, whereas DD is notable for its chronicity. MDD and DD can have their

onset at any point in life, and there is a substantial overlap of symptomatology between the two disorders.

There are a number of key psychological symptoms observed in both MDD and DD. First and foremost, individuals with these disorders display depressed mood, in which the person is sad, hopeless, or down in the dumps. In younger children, depressed mood may emerge as irritability, crankiness, and destructive behaviors, rather than as the sad affect typically observed in adults. Also, depressed individuals may display anhedonia, or a loss of interest in normally pleasurable activities. For example, an adult may report losing interest in hobbies or decreased sex drive. Likewise, parents may describe a depressed child as socially withdrawn. Another psychological symptom often seen in depression is psychomotor agitation/retardation. In psychomotor agitation, the person may pace or wring his or her hands. In psychomotor retardation, the individual may have slowed speech or body movements. Additionally, feelings of worthlessness and guilt are commonly seen in depression. For example, depressed people may be overly self-critical, exaggerate their responsibility for negative events, or focus on their personal failings. Finally, thoughts of death and suicidal behavior are sometimes seen in individuals who are depressed. Indeed, depressed people may think about dying or about suicide, and in some instances may even have a plan for killing themselves.

In addition to these psychological indicators, there is also a range of biological symptoms associated with depression. For example, depressed individuals may experience appetite changes that produce substantial weight loss or weight gain. Also, sleep disturbances may be noted. The most common of these is terminal insomnia, in which the person wakes up a few hours too early each morning and is unable to fall back asleep. Energy disturbances such as chronic tiredness or fatigue upon mild physical exertion are a common biological symptom of depression. Finally, many individuals who are depressed often say that they have difficulty concentrating. For example, they may complain of being easily distracted or of problems remembering things.

Depression can begin at any point in life, although the most common age of onset is in the mid-twenties. The symptomatology of depression tends to vary across the life span. In children, certain symptoms are more common, such as irritability, social withdrawal, and somatic complaints (e.g., stomachaches). Sleep problems and psychomotor retardation are rarely observed in young people. In contrast, depressed adults are more

likely to evidence the classic symptom of depressed affect, along with the full range of symptomatology described earlier.

Depression is a very common disorder and approximately 20% of adults will experience at least one episode of depression in their lives. Depression is less common among young people, with prevalence rates ranging between only 1% and 8% of children. More females than males evidence depression, although this gender difference is not apparent until puberty.

## THEORIES OF ETIOLOGY

The predominant etiological models used to understand the causes of depression include the psychoanalytic, cognitive, behavioral, interpersonal, and biological perspectives. Each of these etiological models is briefly summarized here.

### Psychoanalytic Theory of Depression

According to Freud, depression has its origins in childhood. Freud hypothesized that when a child experiences loss through separation or withdrawal of affection, he or she begins to harbor negative feelings toward that person. Eventually, the child's anger toward the loved one is turned inward. Consequently, the classic psychoanalytic view of depression involves anger turned inward against the self. In contrast, modern psychoanalytically oriented attachment theorists believe that disruption of the infant-caretaker bond early in life (e.g., at 18 months) can produce a vulnerability to developing depression later in life.

### Beck's Cognitive Theory of Depression

In cognitive explanations of depression, thoughts and beliefs are considered to have a major role in causing or influencing the emotional state. According to Beck, depression results from faulty schemata or belief systems about the self and world. These negative schemata are evident in a pattern of thinking called the negative triad, which involves a negative view of the self, the world, and the future. Negative schemata produce characteristic distortions in thinking, such as the tendency to magnify the potential consequences of a negative event. Later in life, individuals filter events through these cognitive distortions, which can lead to depression.

## Helplessness and Hopelessness Theories

According to the learned helplessness theory, an individual's sense of being unable to act or control aversive events results in expectations of helplessness, in turn leading to depression. Eventually, this model evolved into the hopelessness theory of depression. Hopelessness, or a general expectation that negative events will occur and that nothing can be done about them, is said to be the cause of some types of depression. Hopelessness results from the different kinds of inferences that a person makes about negative life events. These inferences include the causes of the event, the consequences of the event, and the self.

## Interpersonal Theory of Depression

Depressed individuals tend to have few social networks and perceive them as providing little support. This reduced social support can lessen an individual's ability to cope with negative life events, making these people even more susceptible to depression. Furthermore, depressed individuals tend to elicit more negative reactions from others, thereby validating their negative self-concept.

## Biological Theories of Depression

Several biological causes have been implicated in the etiology of depression. It is well known that depression tends to run in families. Twin studies have shown higher concordances of depression in monozygotic than in dizygotic twins, suggesting a genetic component. Additionally, the effectiveness of drug therapies for depression suggests a biological component. Furthermore, levels of the stress hormone cortisol are higher in depressed persons than in those who are not depressed. These various sources of evidence suggest a strong biological underpinning to depression.

## TREATMENT OF DEPRESSION

### Psychodynamic Therapies

According to psychoanalytic theory, depression results from feelings of loss and anger that have been turned inward by the individual. Therefore, the goal of psychoanalytic therapy is to help the patient to uncover the unconscious sources of his or her depression. During therapy, the patient works to uncover

these feelings of loss and anger and is then able to achieve insight into his or her feelings and express the unconscious conflicts. Unfortunately, there have been few controlled studies evaluating the effectiveness of psychoanalysis for treating depression.

### Beck's Cognitive Therapy

According to Beck, errors in an individual's thinking are the cause of poor self-esteem and depression. The goal in cognitive therapy is to change the patients' maladaptive ways of thinking by teaching him or her new, more successful thought patterns. The patient is active in his or her own treatment by learning to monitor internal monologues and to identify distorted thought patterns that contribute to depression. Much research has been done evaluating the efficacy of Beck's cognitive therapy, and evidence suggests it is helpful in alleviating depression.

### Social Skills Training

This therapy focuses on enhancing the social skills of a depressed individual, thus helping the patient have more enjoyable social interactions and experiences with others. The patient learns new ways to interact with others, such as the ability to stand up for one's rights through assertiveness training.

### Biological Therapies

Antidepressant medication is the most commonly used biological treatment for depression. There are three major categories of drugs: (a) tricyclics, (b) selective serotonin reuptake inhibitors (SSRIs), and (c) monoamine oxidase inhibitors (MAOIs). The tricyclics and SSRIs work by blocking the reuptake of neurotransmitters such as serotonin, whereas the MAOIs work by blocking the action of an enzyme that breaks down the key neurotransmitters. Although the effectiveness of all three classes of drugs is similar, the SSRIs, which include Prozac and Zoloft, are associated with fewer side effects.

Electroconvulsive therapy (ECT) is sometimes used with patients who do not respond to medication or who are severely depressed. The procedure involves inducing a seizure in the patient by passing 70 to 130 volts of electricity through the right hemisphere of the brain. Unfortunately, the side effects of ECT include memory loss and confusion, but it may be the best treatment when all other therapies have failed.

## Nontraditional Therapies

Recently, individuals suffering from depression have sought new avenues of relief. Some of these therapies include exercise, which has been found to be successful in treating depression. Also, a B vitamin called folate, when administered with drug therapy, can enhance the effectiveness of antidepressants and reduced the side effects associated with the drugs. Additionally, the herbal supplement Saint Johns wort has been shown to be as effective as antidepressants in alleviating depression, although the mechanism of action is not clearly understood.

## DEVELOPMENT

---

Development is systematic change over time. In humans, development is the sequence of physical and psychological changes that occurs as people age. Scholars have studied human development with regard to physical growth and maturation, motor functioning, perceptual capacities, cognitive capacities and skills, emotional repertoire and functioning, social relationships, moral capacities and tendencies, and psychopathology, among other attributes. Specific examples of development include the development of the brain in both structure and function, improvements in vision in the first months of life, infants' advancement from crawling to walking, children's acquisition of memory strategies, toddlers' acquisition of social

emotions such as guilt, young children's progression from parallel play to social play, and changes in moral reasoning in adolescence and adulthood.

Changes considered to be developmental are typically progressions that result in enhanced, more complex, and more organized structures and functioning. Human prenatal development, from zygote to embryo to fetus, exemplifies such a progression. Toddlers' developing language abilities are similarly progressive, enabling children to better interact with their caretakers and more clearly express their needs. Adolescents' improved logical reasoning permits a more comprehensive and systematic consideration of hypothetical situations. However, regressive changes may also be considered developmental, such as the lessening of visual acuity in older individuals that results from aging eye structures. This example further illustrates that development can be viewed as lifelong. Although physical and psychological development is most obvious in infancy and childhood, changes occurring later in the life span have been characterized as development. Changes occurring in early, middle, and late adulthood in relationships, intimacy, memory, and perception, among other topics, have been the focus of developmental research. Developments in adulthood include both losses, such as those with regard to perception, and gains, such as the acquisition of wisdom.

Scientific efforts to understand physical and psychological development are directed at description and explanation. Characterizations of development vary with regard to whether development is viewed as continuous or discontinuous, that is, whether changes are gradual, quantitative, and incremental, or whether they are qualitative and stagelike. A child who becomes a baseball player might be described as gradually learning the required skills through practice. A child who, in time, judges that a ball of clay rolled into a snakelike form has not changed in amount might be described as having advanced to a qualitatively different stage of reasoning. Besides differing on the issue of continuity, developmental accounts differ as to whether development occurs in universal sequences or whether there are multiple courses of development, such as seems to be the case when children develop varying views of the relationship between individuals and society depending on the cultural context in which they are raised.

A third aspect of development that interests scholars is its determinants. Historically, theorists have disputed

whether nature or nurture is most responsible for developmental outcomes, but contemporary accounts concur that development results from interplay between endogenous forces, such as genetic constitution, and exogenous forces, such as environmental context. However, accounts continue to vary in their emphases on these influences and in their assumptions about how the factors interact, inspired in part by historical ideas from embryology and evolutionary theory as well as from early psychology. Jean Piaget's theory of cognitive development, for example, explains the increasing complexity and integrated organization of children's thinking in terms that are reminiscent of biological explanations.

Because change is the essence of development, developmental scholars often employ research methods that compare individuals of different ages (cross-sectional designs) or that permit repeated observations over time (longitudinal designs). Sometimes these research designs are combined to afford a comprehensive examination of development.

## DEVELOPMENTAL DIRECTION

---

The principle of developmental direction, one of Gesell's five principles of maturation, assumes that

development is not random but proceeds in an ordered and orderly fashion. The fact that development systematically proceeds from the head to the toes is a good example of how at any point a developmental trend will be more advanced in the head area than in the foot area. Thus, at birth, the newborn infant is relatively more mature in neuromotor organization in the head region than in the leg region, and coordination of the arms precedes coordination of the legs. This trend is described as the cephalocaudal (or head to tail) trend.

Another example is how development is more advanced at the center of the body compared to its periphery. The movements of the shoulders show considerably more organization early in life than the movement of the wrists and fingers. This proximodistal (or near to far) trend can also be seen in the child's grasping behavior, which at 20 weeks is quite crude and dominated by upper arm movements. By 28 weeks, however, with the increasingly sophisticated use of the thumb, the grasping is dominated by increasingly finer motor skills. Both the cephalocaudal and proximodistal trends illustrate Gesell's contention that development (and behavior) have direction and that this direction is basically a function of preprogrammed genetic mechanisms.

## DEVELOPMENTAL DISABILITIES

---

The 9 months that precedes the birth of every child involves an amazing process. From the moment an egg is fertilized to the birth of an infant, so many complicated steps have occurred. In each step, there are many chances for errors to happen. Yet the surprise is not the number of children born with birth defects, but the number of children who are born healthy.

A number of events that consequently affect a child's development can go wrong, including genetic abnormality, cell division, growth before birth, maternal nutrition, congenital malformation, infections, and teratogens (any agent that causes a defect in the fetus, such as radiation and drugs).

Developmental disabilities are a diverse group of physical, cognitive, psychological, sensory, and speech impairments that begin anytime during the development up to 18–22 years of age (depending on various state and federal definitions). In most instances, the cause of disability is not known.

## DEFINITION

The definition used by federal agencies of developmental disabilities is severe, chronic, or unending disabilities of a person that (1) are attributable to a mental or physical impairment or combination of mental and physical impairments; (2) are apparent before the person attains the age of 22; (3) are likely to continue indefinitely; (4) result in substantial functional limitations in three or more of the following areas of major life activity—(a) self-care, (b) receptive and expressive language, (c) mobility, (d) self-direction, (e) capacity of independent living, and (f) economic self-sufficiency—and (5) reflect the person's need for a combination and sequence of special, interdisciplinary, or generic care, treatment, or other services that are of lifelong or extended duration and are individually planned and coordinated.

## DEVELOPMENTAL DIAGNOSES

### Attention Deficit Disorder with or Without Hyperactivity

The core symptoms of attention deficit/hyperactivity disorder are developmentally inappropriate levels of inattention, hyperactivity, and impulsivity. These problems are persistent and usually cause difficulties in one or more major life areas: home, school, work, or social relationships.

### Autism, Pervasive Developmental Disorders

A diagnosis of autistic disorder is made when an individual displays 6 or more of 12 symptoms listed across three major areas: social interaction, communication,

and behavior. When children display similar behaviors but do not meet the criteria for autistic disorder, they may receive a diagnosis of pervasive developmental disorder, not otherwise specified.

### Cerebral Palsy

Cerebral palsy (CP) is a condition caused by injury to the parts of the brain that control our ability to use our muscles and bodies. *Cerebral* means having to do with the brain. *Palsy* means weakness or problems with using the muscles. Often the injury happens before birth, sometimes during delivery. CP can be mild, moderate, or severe. Mild CP may mean a child is clumsy. Moderate CP may mean the child walks with a limp. He or she may need a special leg brace or a cane. More severe CP can affect all parts of a child's physical abilities. Usually, the greater the injury to the brain, the more severe the CP. However, CP does not get worse over time, and most children with CP have a normal life span.

### Deafness/Hearing Impairments

Sound is measured by its loudness or intensity (measured in units called decibels, dB) and its frequency or pitch (measured in units called hertz, or Hz). Impairments in hearing can occur in either or both areas and may exist in only one ear or in both ears. Hearing loss is generally described as slight, mild, moderate, severe, or profound, depending on how well a person can hear the intensities or frequencies most greatly associated with speech.

### Down Syndrome

Down syndrome is the most common and readily identifiable chromosomal condition associated with mental retardation. It is caused by a chromosomal abnormality, an accident in cell development that results in 47 instead of the usual 46 chromosomes. This extra chromosome changes the orderly development of the body and brain.

### Emotional Disorders

Many terms are used to describe emotional, behavioral, or mental disorders. Children are said to have emotional disorders when their lives and education are significantly adversely affected by (a) an inability

to learn that cannot be explained by intellectual, sensory, or health factors; (b) an inability to build or maintain satisfactory interpersonal relationships with peers and teachers; (c) inappropriate types of behavior or feelings under normal circumstances; (d) a general pervasive mood of unhappiness or depression; or (e) a tendency to develop physical symptoms or fears associated with personal or school problems.

## **Epilepsy**

Epilepsy is a physical condition that occurs when there is a sudden, brief change in how the brain works. When brain cells are not working properly, a person's consciousness, movement, or actions may be altered for a short time. These physical changes are called epileptic seizures. Epilepsy is therefore sometimes called a seizure disorder. Epilepsy affects people in all nations and of all races. Some people can experience a seizure and not have epilepsy (e.g., febrile convulsion). A single seizure does not mean that the person has epilepsy.

## **Learning Disabilities**

*Learning disability* is a general term that describes specific kinds of learning problems. A learning disability can cause a person to have trouble learning and using certain skills. The skills most often affected are reading, writing, listening, speaking, reasoning, and doing math.

## **Mental Retardation**

*Mental retardation* is a term used when a person has certain limitations in mental functioning and in skills such as communicating, taking care of himself or herself, and social skills. These limitations will cause a child to learn and develop more slowly than a typical child. Mental retardation is diagnosed by looking at two main things: (a) the ability of a person's brain to learn, think, solve problems, and make sense of the world (called IQ or intellectual functioning); and (b) whether the person has the skills he or she needs to live independently (called adaptive behavior or adaptive functioning).

## **Speech/Language Impairments**

Speech and language disorders refer to problems in communication and related areas such as oral motor function. These delays and disorders range from

simple sound substitutions to the inability to understand or use language or use the oral-motor mechanism for functional speech and feeding. Some causes of speech and language disorders include hearing loss, neurological disorders, brain injury, mental retardation, drug abuse, physical impairments such as cleft lip or palate, and vocal abuse or misuse. Frequently, however, the cause is unknown.

## **Spina Bifida**

Spina bifida means "cleft spine," which is an incomplete closure in the spinal column. In general, the three types of spina bifida (from mild to severe) are (a) spina bifida occulta, (b) spina bifida meningocele, and (c) myelomeningocele. The effects of spina bifida may include muscle weakness or paralysis below the area of the spine where the incomplete closure (or cleft) occurs, loss of sensation below the cleft, and loss of bowel and bladder control. In addition, fluid may build up and cause an accumulation of fluid in the brain (a condition known as hydrocephalus).

## **Traumatic Brain Injury**

Traumatic brain injury (TBI) is an injury to the brain caused by the head being hit by something or by being shaken violently. This injury can change how the person acts, moves, and thinks. A traumatic brain injury can also change how a student learns and acts in school. The term *TBI* is not used for a person who is born with a brain injury. It also is not used for brain injuries that happen during birth.

## **Visual Impairments**

The terms *partially sighted*, *low vision*, *legally blind*, and *totally blind* are used in the educational context to describe students with visual impairments. Visual impairment is the consequence of a functional loss of vision, rather than the eye disorder itself. Eye disorders that can lead to visual impairments can include retinal degeneration, albinism, cataracts, glaucoma, muscular problems that result in visual disturbances, corneal disorders, diabetic retinopathy, congenital disorders, and infection.

## **SUMMARY**

Developmental disabilities affect the lives of nearly 4 million Americans. Developmental disabilities are

severe, chronic disabilities attributable to mental, physical, sensory, and speech impairment that begin before ages 18 to 22. Significant limitations in three or more areas result from developmental disabilities: self-care, receptive and expressive language, learning, mobility, self-direction, capacity for independent living, and economic self-sufficiency, as well as the continuous need for individually planned and coordinated services.

—Asiah Mason and Michelle Smith

## DEVELOPMENTAL PSYCHOPATHOLOGY

---

### WHAT IS DEVELOPMENTAL PSYCHOPATHOLOGY?

Pioneers of developmental psychopathology Sir Michael Rutter and Alan Sroufe offered that the field of developmental psychopathology is the study of the origins and course of individual behavioral adaptation, with special emphasis given to the *how* of developmental processes. Thus, the overarching questions asked by developmental psychopathologists include: How does psychopathology develop and how does this differ for individuals with different characteristics? How does a person's development affect psychopathology? How

does psychopathology affect a person's development? We will briefly consider what is meant by *psychopathology* and then consider why it is critical that *psychopathology* and *developmental* be linked.

### What Is Psychopathology?

Although a variety of conceptualizations are possible, what most scholars mean when they refer to psychopathology is abnormal behavior—what is variously called emotional/behavioral problems, psychiatric disorders, or psychological syndromes. While there remains debate regarding the intricacies of classification of psychopathology, there is much consensus and empirical support for what constitutes common syndromes of problems—depression, anxiety, autism, schizophrenia, and antisocial behavior are all generally accepted classes of behavior that are considered to be abnormal in and of themselves or when exhibited in excess. By abnormal we mean that these behaviors are maladaptive for either the individuals themselves or for society. By excess we mean a higher level of symptoms than exhibited by most individuals. Most people feel sad from time to time and many people occasionally break the law (i.e., drive too fast), but most people do not feel so sad and down that they cannot get out of bed for days on end, and most people do not repeatedly break the law and regularly violate the basic rights of others. It is the latter behavior, which violates societal norms, makes the person miserable, or renders one incapable of caring for oneself or others, that is defined as abnormal behavior, or psychopathology.

### Importance of Development

Why is it so critical that inquiry regarding psychopathology be developmental? Historically, the two concepts have not been linked, yet development is central to what we now know about how psychopathology works. Normal development presents individuals with frequent challenges in every domain of life (behavioral, cognitive, emotional, social, physical), that once mastered constitutes growth—this is how babies become children and children become adults. For example, toward the end of the first year of life, infants become aware that there is a large and fascinating world out there that other people move around in. More importantly, they come to understand that they are people—thus, if they could move around, they could partake in the fun. However, infants must learn how to crawl,

stand, and eventually walk in order to fully interface with this stimulating environment. This is a challenge for an infant, who does not just wake up one morning capable of walking. The infant must try and fail repeatedly before mastering this new skill. Virtually all infants eventually master it and become capable walkers. However, some infants are very large or have low muscle tone and the challenge is more difficult for them than for other children, and thus they walk later than other children. It is likely that for many of these late walkers, other gross motor tasks may be somewhat difficult for them as well, and thus the next developmental challenge that comes along involving gross motor skills or large muscle strength may also be a larger hurdle for them than for other children. Current research and theory suggest that this is how psychopathology operates as well. Some children have or develop emotion regulation problems that make developmental challenges involving or requiring emotion regulation difficult for them. While such a child may eventually make it through a particular emotion-related challenge with support, this area will likely remain an area of vulnerability for the child, and when the next emotion-related developmental challenge arises, the child may have difficulty again. Mindfulness of developmental challenges can help parents or teachers anticipate hurdles for vulnerable children and provide preemptive support to help the child through subsequent challenges and minimize disruptions. Thus, there is much to be gained by including development in the conceptualization and study of psychopathology.

### **History of Developmental Psychopathology**

While interest in description, classification, and treatment of psychological problems is not new, the field of developmental psychopathology is considered to have emerged primarily in the past three decades. This area of inquiry has its roots in several disciplines concerned with human behavior, including developmental psychology, clinical psychology, and psychiatry, and its links to these disciplines remain strong. However, it is now considered to be a unique field of science that has fundamentally changed child mental health research and policy.

To some degree, the field arose because of growing dissatisfaction with prevailing models of psychopathology that often left children out of the equation. The dominant diagnostic system (*Diagnostic and Statistical*

*Manual of Mental Disorders*) gave almost no consideration to development in the guidelines set forth for diagnosis of psychopathology. It was assumed that children either did not experience true psychopathology or that if they did, it would look very much the same as psychopathology in adults. Several landmark publications and meetings have elaborated on this concern and/or offered solutions for how to improve the study of psychopathology. Thomas Achenbach's 1974 textbook entitled *Developmental Psychopathology* introduced the idea that childhood psychopathology should be viewed as separate and distinct from adult psychopathology. Michael Rutter and Norman Garmezy are credited with charting the course of future inquiry for developmental psychopathology with their 1983 chapter on the topic in the *Handbook of Child Psychology*. Next, the 1989 Rochester Symposium on Developmental Psychopathology brought together and unified a diverse array of scholars whose work on psychopathology was explicitly developmental in scope and approach. Finally, the establishment of a journal in 1990 devoted exclusively to the topic, *Development and Psychopathology*, cemented the foundation of developmental psychopathology as a unique field unto itself. Developmental psychopathology has been an exciting and active area of research ever since.

### **KEY ISSUES IN DEVELOPMENTAL PSYCHOPATHOLOGY**

#### **Diagnosis and Classification**

The most basic question that developmental psychopathology is charged with answering is: What grouping of symptoms makes up a disorder? There are at least two approaches to answering this question: the top-down and bottom-up approaches. The top-down approach starts with the assumption that psychiatric diagnoses exist and, importantly, that we know what they are. Thus, the task at hand is to name the disorders and describe the set of symptoms that defines each one. The dominant nosology in American psychiatry was derived from a top-down approach: The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*), is a catalog of hundreds of psychiatric disorders used by clinicians to diagnose patients. The bottom-up approach to classification starts at an entirely different place: It starts with an observation of all of the different types of symptoms that people report and uses statistical analysis to see how symptoms tend to group

together to form syndromes. A major alternative to the *DSM-IV* can be found in these empirically based taxonomies, exemplified by the Achenbach system of empirically based assessment, where symptoms group into eight syndromes ranging from aggressive behavior to social withdrawal. Each of these approaches has strengths and weaknesses, and both are used currently. However, debate remains about which approach is most useful and accurate. Some developmental psychopathology researchers rely on the top-down *DSM-IV* approach and study psychological disorders such as autism or panic disorder, while many opt for the bottom-up approach and focus on syndromes or groupings of symptoms, such as anxiety or antisocial behavior. At one level, the differences between *disorder* and *syndrome* are semantic—we hope that in the end we are all studying the same underlying problematic processes. At another level, however, our definitions shape and constrain the questions we ask. Thus, for example, studying only disorders may preclude the possibility of finding that the underlying biological mechanism of all psychopathology is the same and it is various cultural, social, and environmental factors that determine what form of psychopathology emerges. Alternatively, studying only syndromes could preclude the possibility of attending to qualitatively different groups of individuals whose functioning is so far outside the typical range that they need special research attention, such as persons with schizophrenia. For the purposes of this chapter, we will go with the first assumption: Both types of inquiry will lead to roughly the same place in the end, an understanding of maladaptive behavior in its many forms.

### Risk, Resiliency, and Etiology

Much developmental psychopathology research is aimed at answering the question of etiology, or what causes psychopathology. Central to this line of inquiry are the concepts of risk and resiliency. What is risk? A developmental psychopathologist rarely asks the question “What causes disorder x?” expecting a simple answer. As with heart disease, there is no one cause. Some people appear to be vulnerable to developing heart disease because they are related to someone with heart disease—thus they are at genetic risk. However, being at genetic risk is not enough. It is a vulnerability that can be triggered by environmental stimuli, such as too much stress, being overweight, or having hypertension. The misconception that genes

are destiny is fundamentally wrong—genes are probabilistic, not deterministic, when it comes to psychopathology. Most forms of psychopathology appear to operate in a very similar fashion to heart disease. Risk for psychopathology comes in many forms: genetics is one form, but histories of trauma, growing up in poverty, parental psychopathology, and interparental conflict also make some individuals more likely to develop certain forms of psychopathology than those without such a history.

What is resiliency? Resiliency can be defined as thriving despite having serious risk factors. Emmy Werner and Ruth Smith conducted an extensive 40-year study of factors related to positive development in a cohort of almost 700 children born in 1955 on the Hawaiian island of Kauai. Eighty percent of the study children experienced multiple risk factors, including persistent poverty, parental alcoholism, parental psychopathology, and low parental education. Most of the children in this high-risk group experienced significant emotional, behavioral, academic, and/or occupational problems in childhood and beyond. However, 30% of this group showed none of these adverse life outcomes and in fact were thriving in childhood, adolescence, and adulthood. Werner and Smith documented the factors that made these children stand out from the rest—the factors that protected these children. They identified five personal protective factors and five environmental protective factors. Personal protective factors were autonomy/social maturity, school competence, easy/extroverted temperament, self-efficacy, and good physical health. Environmental protective factors included maternal competence; emotional support in childhood, adolescence, and adulthood; and fewer stressful life events. Thus, competence and emotional support appear to be strengths that vulnerable children can draw on to be successful and healthy despite significant adversity.

### *Diathesis-Stress Model*

A key theory espoused in much developmental psychopathology research and theory explicitly or implicitly is that of the diathesis-stress model. While this theory was originally developed as a theory specific to development of depression, it has broad applicability for a number of forms of psychopathology. Individuals develop diatheses (vulnerabilities) to psychopathology as a result of exposure to risk factors such as genetics, biological or environmental insults, child abuse/neglect,

or poverty. Vulnerabilities come in a variety of forms ranging from innate temperamental characteristics to problematic thinking styles, ineffective regulation of emotions/arousal, and poor problem solving. For some individuals, these vulnerabilities lie dormant for a lifetime and they never develop psychopathology. For many though, the vulnerability becomes activated under challenging or difficult circumstances. Take, for example, cognitive vulnerability to depression. A large number of studies have found that individuals with depression tend to make errors in how they think about themselves, the world, and the future. They tend to believe that they are the cause of negative things that happen to them and that they play little role in the good things that happen to them. Individuals who have this thinking style are more likely to develop depression following a negative life event than individuals without this negativistic, self-defeating thinking style. This thinking style is believed to result from previous experiences that teach an individual that they are powerless or helpless, but it does not lead directly to depression except under stressful or difficult circumstances. Thus, the negative thinking style is the diathesis that lies in wait for a stressor potent enough to activate it and create a cascade of negative thoughts and feelings.

### *Nature Versus Nurture No More*

For years a battle has waged between those who believed that the causes of psychopathology were primarily genetic or biological and those who asserted that the environment played the major role in the etiology of psychopathology. The past two decades have seen a major shift whereby most psychopathologists recognize that genetics play some sort of role in the development of most types of psychopathology, and at the same time recognize that the environment is often what determines whether a vulnerability or trait is expressed, what form it takes, and how severe it is. Behavior geneticists emphasize that genes are probabilistic, not deterministic. A study by Avshalom Caspi and his colleagues aptly demonstrates this idea. They showed that the dopamine transporter gene (5-HTT), thought to be implicated in the development of depression, only predicted future depressive episodes in the presence of a major stressful life event. The absence of a main effect for the 5-HTT gene shows that indeed genes are not destiny. Some genes need to be activated, as do other diatheses. If there is no trigger for the gene, there will be no depression. Similarly, a study by Eric

Turkheimer and colleagues at the University of Virginia showed that extreme poverty reduced the genetic influence on IQ to nonsignificance. In this case, the substantial and robust finding that approximately 70% of the variance in IQ scores can be explained by genetics received a noteworthy caveat: not in extreme environmental circumstances. Poverty has the power to suppress a child's genetic IQ potential to such an extent that aspects of the environment explain more variance in the IQ score than does heritability. These two studies illustrate the power of both the environment and genetics in determining psychological traits—in fact, these studies illustrate how woefully inadequate our explanations of psychopathology would be if we ignored either side of the equation.

### *Temperament*

Infants are born with different styles of reactivity and self-regulation. Some babies are easy to soothe; regular in their eating, sleeping, and elimination habits; and quick to smile. Other babies are irritable and easily upset, irregular in their habits, and hard to engage in smiling or cuddling. Alexander Thomas, Stella Chess, and Herbert Birch observed that these characteristics, which they called temperament, appear at birth, remain stable over time, and place some individuals at risk for psychopathology. They categorized infants on nine dimensions of temperament ranging from activity level to adaptability, and they identified several groups of children based on how they scored on the various temperamental dimensions. Children were categorized as having “easy” and “difficult” temperaments. Thomas and colleagues found that difficult temperament may predispose a child to negative interactions with peers, parents, and teachers, but this is not inevitable—thus, difficult temperament is only a vulnerability for psychopathology, not an eventuality. Thomas and colleagues introduced the concept of “goodness of fit” to describe the fact that parenting styles and children's temperaments may match well and promote optimal development or may clash and cause problems. Some parents are able to respond well to a “difficult” temperament and thus protect that child in the face of their temperamental vulnerability. Much of what is currently understood to be genetic risk may lie in these constitutionally based characteristic ways that individuals interact with the world beginning in infancy.

## Comorbidity

Another chief concern of developmental psychopathology surrounds what we call comorbidity. This is the co-occurrence of two or more different types of psychological problems in the same individual at the same time. Thus, for example, an adolescent who meets diagnostic criteria for both major depressive disorder and conduct disorder at the same time is said to have comorbid depression and conduct disorder. A national survey found that 14% of U.S. adults surveyed met diagnostic criteria for at least three disorders at once. There are multiple theories to explain comorbidity, and many of them are specific to the particular diagnostic pairings. For example, anxious and depressive disorders are highly comorbid, and one theory to explain this phenomenon is that anxiety and depression have a common underlying cause: a propensity to experience negative emotions (negative affectivity). Another theory is that the distinction between anxious and depressive disorders is largely artificial—that, for most individuals, anxiety and depression are simply facets of the same problem. Thus, prone individuals are likely to feel both nervous and sad at the same time. This is an important issue to sort out for anyone interested in the nature and course of psychopathology because, for example, there are different trajectories based on whether one has depression alone or in conjunction with another disorder. It also has treatment implications—comorbidity is related to more severe pathology and worse response to treatment. We know little about how best to treat depression in the face of another disorder—Which disorder takes precedence? Do you treat one before the other? Can you treat both at the same time? These questions remain largely unanswered.

## Epidemiology

Documenting how many people of what age and gender meet diagnostic criteria for what forms of psychopathology is the charge of psychiatric epidemiologists. For policy makers to estimate treatment funding needs, we need reliable data on the prevalence of psychopathology (i.e., the number of people with a psychiatric disorder at any given time). We now know, for example, that close to 50% of Americans can be expected to meet diagnostic criteria for a *DSM-IV* psychiatric disorder at some point in their lifetime. We also know that anxiety and depressive disorders are

more prevalent in females and that substance use disorders and antisocial personality disorders are more prevalent in males. In addition to basic questions about which disorders are most prevalent and for whom, developmental psychopathologists are particularly interested in determining the factors that influence prevalence rates. Thus, much research has attempted to address gender differences such as why women are prone to depression. The answer is multifaceted and as yet incomplete, but at this point stressful events appear to be a primary mechanism. Women are at heightened risk for experiencing a disproportionate number of stressful events/circumstances such as sexual abuse. Frequent stressful events repeatedly activate the brain's stress response system (hypothalamic-pituitary-adrenal axis; HPA), which can cause the system to become dysregulated. Dysregulation in the HPA makes people more sensitive to future stressful events and to resulting depression. There may also be genetic vulnerabilities to dysregulation of the HPA, which further complicates understanding of this gender-based risk. This is another example of the exquisite interplay of genetic and environmental influences on psychopathology.

## WHAT PROGRESS HAVE WE MADE?

Research has identified many factors that either place an individual at risk for or protect them against developing psychopathology. However, our remaining challenge is to begin finding the mechanisms of risk or the “hows” of risk. Mechanisms are often the factors that need to be targeted in intervention. For example, poverty is a substantial risk factor for the development of antisocial behavior, but not all individuals who experience poverty go on to develop psychopathology. Thus, the more we know about the factors that determine individual differences in response to poverty, the better able we are to target those most at risk with interventions. Here we review the research on antisocial behavior, one of the most common and persistent forms of psychopathology.

Antisocial behavior has received copious research attention, in part because of the social costs that result from delinquency and criminal activity. Longitudinal research has borne extremely useful information for understanding the development of antisocial behavior, from how the symptoms change with age, to the factors that place children at risk, to the different subgroups of antisocial children. The *DSM-IV* lists oppositional defiant disorder (ODD; a pattern of

negativistic, oppositional behavior), conduct disorder (CD; persistent rule breaking), and attention deficit/hyperactivity disorder (ADHD; inability to inhibit inappropriate responses) as three distinct entities with different symptom groupings. However, the preponderance of data clearly suggests that ODD and CD are the same thing—that aggression and oppositionality are the early manifestations of the disorder and that persistent rule breaking is the later manifestation of the disorder, both reflecting age-specific misbehavior. In addition, the data suggest that the impulsive inhibition problems of ADHD may also be a component of the same disorder, although this is less well established than the ODD-CD link.

Terrie Moffitt's studies following young children into adulthood were groundbreaking in showing that there are at least two distinct groups of antisocial youths. She found a relatively small group of antisocial children who were aggressive and antisocial at age 4 and remained so at every assessment until age 18 and beyond. This group of "life course persistent" antisocial children had multiple risk factors, including early aggression, impulsivity, poor peer relations, family adversity, and cognitive impairments. Their problems often progressed to adult criminality. The other major group in their study was a cadre of children who showed no antisocial behavior in childhood, but in adolescence began rule breaking at a level similar to the life course persistent group. This much larger group of "adolescence limited" antisocial children had none of the risk factors of life course persistent youths, but rather had poor parental monitoring and associated with antisocial peers. These teens tended to desist from delinquency in adulthood and rarely progressed to adult criminality. Individuals in this group did have some lingering mental health concerns in adulthood, however, such as impulsivity, substance abuse, financial problems, anxiety, and depression. There remain some important questions to be answered about delinquency in youths: Are there more than two groups of antisocial youths? Is ADHD part of a general disruptive syndrome? If so, how do we reconcile high genetic loadings for some forms of disruptive behavior (ADHD) and very low genetic loadings for other forms (adolescence limited antisocial behavior)?

## WHAT DON'T WE KNOW YET?

There are a few key areas in need of the attention of developmental psychopathology researchers in the

next decades. The first concerns measurement issues. Despite the recognition that it is a problem to rely only on parents or children to tell us about their symptoms, reconciling the reports of multiple informants has proven to be challenging. Parent and child reports of children's psychological symptoms tend to only be correlated at about 30%, indicating modest agreement. While a number of theories have been proposed to understand the poor cross-informant agreement on key psychological constructs, we no longer assume that any one person will be 100% accurate. The leading theory currently is that different informants are privy to different aspects of an individual's behavior; thus, each informant reports on the part that they are aware of. However, testing this theory has proven difficult and we still do not understand the mechanisms of informant disagreement—what predicts it, why it occurs, and what variations in disagreement mean vis-à-vis psychopathology.

The second area in need of future research attention involves gender differences in psychopathology. There are substantial gender differences in prevalence rates of some types of psychopathology. How much of this phenomenon is due to definitions that largely exclude one gender because they are unlikely to exhibit specific behaviors? Some researchers, for example, claim that the diagnostic criteria for conduct disorder are biased in favor of diagnosis for boys because of the overt aggressive nature of so many of the symptoms. These researchers assert that girls are antisocial as well, but that their aggression tends to be in the form of indirect or relational aggression. Thus, girls are less likely than boys to beat someone up, but they are likely to spread vicious rumors that serve to socially ostracize another girl. The current diagnostic criteria do not take such gender-based differences in behavior into account, which could account for gender-based differences in rates of conduct disorder, for example.

Finally, the brass ring of developmental psychopathology—etiology—remains out of grasp currently as we have much to learn about the causes of various forms of psychopathology. We do know that both genetics and the environment play a role in most forms of psychopathology and that these two things constantly interact, but we still do not understand the role of the mechanisms in the emergence of psychopathology. For example, if genetic vulnerability to depression operates indirectly through stress, then we need to search not for the depression gene, but rather the gene that makes individuals reactive to stress. Similarly,

we need to better understand the role of temperament and other inherited characteristics in how an individual responds to environmental challenges. We need to understand the mechanisms of environmental indicators (i.e., how do they trigger genetic or other types of diathesis?). Finally, we hope to one day fully understand the lasting biological and psychological changes created by environmental risk events.

## IMPLICATIONS OF DEVELOPMENTAL PSYCHOPATHOLOGY

George Albee has written extensively about the idea that individual treatment—in the form of medication or psychotherapy—can never change incidence rates of psychopathology. He asserts that the only way to stem the tide of psychopathology is through prevention. Even if there were adequate treatment services available for every individual with psychopathology (which there are not), the individualized treatment approach will always be a zero-sum game. The way to make things better is to take the public health approach and reduce incidence rates by reducing the pathogens (causes) of disease. Thus, for psychopathology, the known causes include poverty, trauma, and abuse, and the mechanisms of these risks include emotion regulation, problem solving, coping, academic preparedness, and the stress response system. Thus, prevention efforts have begun to target these risks and mechanisms in order to reduce incidence rates of psychopathology.

The contextual developmental psychopathology approach has also encouraged a communitarian perspective on treatment and prevention to emerge. Prevention scientists are calling for community-based interventions that reduce risk factors in an entire community. Thus, approaches to prevention that draw from Afro-centric community interventions and emancipatory education are exciting directions for community-oriented developmental psychopathologists. My colleagues and I, for example, have borrowed from the Afro-centric approach and are developing an empowerment prevention model that targets, builds, and channels resistance to race, class, gender, and sexuality oppression. With this contextual approach, we hope to use the best of developmental psychopathology research and theory to prevent delinquency in the most vulnerable, most treatment-resistant youths who currently see little hope for a future not marked by jail, failure, and a perpetual cycle of abuse and marginalization.

Thus, in addition to adding to our understanding of fundamental aspects of human behavior, developmental psychopathology has the promise of being transformative and making large-scale changes for the better mental health of all.

## DEVELOPMENTAL QUOTIENT

---

A development quotient (DQ), most frequently used with infants or preschool children, is a numerical indicator of a child's growth to maturity across a range of psychosocial competencies.

Typically, these include areas such as personal-social development, attention span, expressive and

receptive language, visuoperceptual skills, fine and gross motor skills, and initiative and independence, together with aspects of cognitive development, problem solving, and memory. A DQ should not be considered as a constant, but as a simplified index, reflecting changes in experience, patterns of interaction and learning over time, and summarizing the more detailed domain-specific information from which it is derived. Unlike the intelligence quotient (IQ), the DQ is a ratio statistic reflecting a child's overall development in relation to criteria logged in authentic social contexts. In contrast, the IQ is a deviation score based on statistical comparison of an individual's performance on contrived tasks under highly controlled test conditions with normative data for a given age group.

In clinical and educational work, it may be desirable to construct an accurate, fine-grained profile of a child's behavioral, communication, and intellectual development in order to inform an overall assessment of a child's learning needs, to make a diagnosis, plan an intervention program, or identify resources required. Using direct observation, play-based assessment or problem-solving tasks, a detailed developmental profile may be constructed using criteria and age reference points drawn from the research literature.

There is an extensive body of work—more detailed in early infancy—documenting the age at which most children achieve milestones in development, such as following an adult's line of gaze, crawling, reaching and grasping objects, and manipulating tools to perform tasks such as cutting or threading, as well as the appearance of speech sounds and word combinations in spoken language, moving on to more complex cognitive functions involving recall or reasoning. Age-equivalent scores for each domain may be converted to ratios or quotients, for example, to derive a social or language DQ. The simplest procedure to calculate an overall general DQ is to divide the subject's summated developmental age (DA) across domains by the chronological age (CA) and multiply by 100 ( $DQ = DA/CA \times 100$ ).

There are special situations where a developmental profile and DQ are very useful. For example, some children diagnosed with autistic spectrum disorder (ASD) or related communication and learning difficulties present uneven profiles, idiosyncratic response patterns to social and other stimuli, or noncompliance to formal testing. In fact, diagnosis of ASD is made from a consideration of such behavioral evidence. Materials such as the Psycho-Educational Profile-Revised

(PEP-R) (Schopler et al., 1990) provide a flexible, non-time constrained framework for an examiner to observe, evaluate, and record responses in order to depict a child's relative strengths in areas relevant to ASD, to plan intervention and monitor progress over time. A DQ derived from this or other informal assessment frameworks allows children's individual developmental trajectories to be plotted over time in order to probe the impact of intervention strategies and avoids some of the pitfalls of standardized intelligence testing for atypical groups. (See Webster et al., 2003, for an illustration of this research methodology.)

## **DIABETES**

---

Type I diabetes (insulin-dependent diabetes mellitus) is the most common endocrinology disorder, with onset typically occurring in adolescence. It is thought to be an autoimmune disorder that results in pancreatic beta cell destruction and the eventual loss of all insulin production. Insulin regulates blood levels of the sugar glucose and allows glucose to enter cells from the bloodstream, where it is absorbed and used as energy. Patients with type I diabetes must administer exogenous insulin daily in order to maintain normal blood glucose levels. In type II diabetes (non-insulin-dependent diabetes mellitus), insulin continues to be produced, but it is either produced in insufficient amounts to maintain normal blood glucose levels, or there is insulin resistance, and the body does not properly utilize insulin.

Approximately 5% to 10% of Americans with diabetes are diagnosed with type I diabetes, which occurs in approximately 1 in 500 to 600 children in the

United States and in the range of 0.6 to 2.5 in 1,000 children worldwide. The disease appears to occur equally in females and males, with peak onset of the disease typically around puberty, although it can be diagnosed through middle adulthood. Type I diabetes appears to occur in individuals with a genetic predisposition, accompanied by an environmental stressor. According to the American Diabetes Association (ADA), presenting symptoms at the time of diagnosis of type I diabetes include polyuria (increased urination), polydipsia (excessive or abnormal thirst), weight loss accompanied by dehydration as well as glucose levels of over 126 mg/dl (i.e., milligrams of glucose per 100 milliliters of blood) while fasting, or a random level of blood glucose over 200 mg/dl. The incidence of type II diabetes, previously considered a disorder of adulthood, has recently increased in younger children and appears related to increased rates of childhood obesity. In fact, type II diabetes currently accounts for approximately 10% to 20% of new diabetes cases in younger people. The incidence of type II diabetes is higher in African-American, Native American, and Latino populations.

In an effort to maintain near-normal blood glucose levels (between 80 and 120 mg/dl), daily blood glucose monitoring, administration of exogenous insulin, proper diet and meal planning, as well as exercise, are central to the treatment of type I diabetes. The goal of treatment is to maintain blood glucose levels close to the normal range in order to reduce the risk for complications. Blood glucose levels are measured several times daily (typically before meals and at bedtime) with a glucometer, which measures blood glucose from droplets of blood. In addition, a glycosylated hemoglobin (HbA<sub>1c</sub>) test provides patients with information about their average blood glucose level over the past 2 to 3 months and should be conducted quarterly at a doctor's office. Exogenous insulin is administered two to three times per day via injections or via an insulin pump with an indwelling needle/catheter under the skin in an effort to restore glucose metabolism. Insulin doses are calculated by individuals based on their blood glucose reading from a glucometer at the time of an injection/infusion as well as based on the content of an upcoming meal. As an alternative to daily injections, the insulin pump can help maintain better metabolic control by its administration of small amounts of insulin continuously throughout the day, with larger amounts/boluses at meal times. The diet recommended by the ADA typically includes 45% to

60% of total calories from carbohydrates, 30% from fat, and 10% to 20% of calories from protein. Exercise is an important aspect of the treatment of diabetes, as it also affects blood glucose levels. For some children with type II diabetes, the disease can be managed by appropriate diet and exercise in an effort to lose weight, sometimes in conjunction with oral medications. However, children with type II diabetes frequently also require daily insulin therapy.

When abnormal blood glucose levels are detected, they must be corrected to avoid episodes of hyperglycemia (blood glucose levels in excess of 180 mg/dl), as well as episodes of hypoglycemia (blood glucose levels below 70 mg/dl). Hyperglycemia can result from excessive carbohydrate intake or an insufficient dose of insulin, and is characterized by extreme thirst and hunger, frequent urination, unusual weight loss, extreme fatigue, irritability, nausea, and sweet-smelling breath. Prolonged hyperglycemia can result in the production of ketone bodies and in severe cases can lead to diabetic ketoacidosis, a serious condition where the body has dangerously high levels of acids (i.e., ketones) that accumulate in the bloodstream. This can lead to severe dehydration, coma, or even death and typically requires hospitalization. Hypoglycemic episodes can result from a missed meal, too much insulin, or exercise and includes symptoms such as dizziness, nausea, sweating, trembling, and confusion from insufficient levels of blood glucose to maintain normal brain functioning. Hypoglycemia can result in seizures, coma, and even death if not treated.

Potential long-term complications of diabetes include nephropathy (kidney disease), neuropathy (nerve damage), cardiovascular disease (heart disease), skin and foot complications, as well as retinopathy, which can lead to blindness. These complications have been associated with longer disease duration as well as with poorer metabolic control (i.e., chronic hyperglycemia). The maintenance of near-normal glucose levels can decrease and delay the development of these complications. Children with diabetes also are at an elevated risk for various psychiatric problems, including eating disorders, depression, and anxiety. Furthermore, from a psychological perspective, type I diabetes has been associated with an increased risk for learning disabilities, particularly with an earlier age of disease onset. However, maintenance of near-normal blood glucose through treatment, including administration of appropriate amounts of insulin, proper diet, and adequate exercise, can allow patients with type I diabetes

to lead a relatively normal life and avoid these potential consequences of the disease.

## DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS

---

The *Diagnostic and Statistical Manual of Mental Disorders (DSM)* is a compendium of all the known forms of psychopathology published by the American Psychiatric Association. Currently in its fourth edition, the *DSM* is utilized in both research and mental health settings for the purposes of reliably identifying psychological disorders and providing information to third-party payers.

### BACKGROUND

Beginning with the third edition, the *DSM* has been organized atheoretically. That is, each disorder has a set of objectively identified symptoms that would allow diagnostic identification by clinicians with diverse theoretical backgrounds. This stands in contrast to prior editions, which were based on a psychodynamic interpretation of each diagnosis. The change to an atheoretical approach to diagnosis has allowed for greater reliability between raters who use this guide for establishing the presence of psychopathology.

### USE AND APPLICATION

The DSM establishes diagnoses along five axes. These axes are as follows:

Axis I: Clinical disorders

Axis II: Personality disorders and mental retardation

Axis III: General medical conditions

Axis IV: Psychosocial environmental problems (rated with descriptive categories, such as economic problems associated with job loss)

Axis V: Global assessment of functioning (rated from 1 [persistent danger to self or others] to 100 [superior functioning in a wide range of activities])

The axis that has received the most attention has been axis I. This axis is composed of the following categories: schizophrenia and other psychotic disorders, mood disorders, anxiety disorders, somatoform disorders, disorders usually first diagnosed in childhood, eating disorders, delirium, dementia, amnestic and other cognitive disorders, factitious disorders, dissociative disorders, sleep disorders, impulse control disorders, and adjustment disorders. These categories of disorders have enjoyed high reliability.

Recently, researchers have turned their attention to axis II, particularly the personality disorders. The personality disorders are currently classified into three broad areas, or clusters, as follows: cluster A, odd and eccentric (paranoid, schizoid, and schizotypal); cluster B, expressive/labile (antisocial, borderline, histrionic, and narcissistic); and cluster C, anxious (avoidant, dependent, and obsessive-compulsive). Placing personality disorders on a separate axis from other axis I disorders serves two functions. Principally, it serves as a guide for diagnosticians to consider whether a personality disorder is present in addition to any axis I disorders. Second, it underscores the chronic and inflexible nature of this class of disorders.

Axis III accounts for medical conditions that may influence treatment outcome or for which psychological factors may play a role in their ongoing presence. For example, the absence of menstruation may have implications for the diagnosis and treatment of an eating disorder.

Axis IV accounts for environmental problems. This may represent areas that can limit the effectiveness of treatment for disorders on the previous three axes. For example, treatment of an anxiety disorder would be

complicated in an individual who has recently lost his or her job and suffers economic stress in addition to the presenting disorder.

Axis V presents a global numerical assessment intended to represent the overall functioning level of the client or patient. In typical use, this axis is rated for the functioning level at the time of diagnosis, as well as for the highest level estimated for the year prior to evaluative contact.

## IMPORTANCE

The DSM represents, in a single detailed document, a way for the diversity of mental health providers and researchers to communicate with one another regarding the nature of various psychological problems. Moreover, the atheoretical approach to diagnosis circumvents barriers to communication among mental health professionals who have varied theoretical backgrounds.

—Dean McKay and Steven D. Tsao

Throughout our lives, our views about how the world works change. New ideas can be learned through experiences with the world or through interpersonal interaction. As a person's views on a topic, behavior, or experiences begin to conflict with one another, that person may become motivated to resolve the conflict. Conflicts may be resolved by logically deciding in favor of one of the competing viewpoints—an analytic style of solution. However, they may also be resolved by seeking synthesis of the two competing viewpoints—a dialectical style of solution.

Consideration of dialectical thinking can be traced back to the philosophies of Georg Hegel and Karl Marx. In psychology, Klaus F. Riegel and Michael Basseches both proposed influential frameworks for understanding the development of dialectical thinking. Riegel, for example, proposed that development depended on conflicts that occur throughout life. In his view, development never ends. As people grow older, they tend to adopt a dialectical thinking style in which people seek to live with contradictions and accept that it is impossible to escape them.

Jean Piaget's influential theory of cognitive development proposed that children go through several unique stages, ultimately resulting in the formal operations stage. In the formal operations stage, a new kind of thought develops based on logic and consistency. However, there have been challenges to the belief that formal operations necessarily reflect the highest stage of thinking and that cognitive development plateaus prior to adulthood. Some recent challenges come from cultural psychologists, who have argued that analytic thinking (or formal operation-based thinking) is prototypical of Western thinking, while dialectical thinking is more prototypical of highly developed Eastern thinking. Both the analytic and dialectical styles of thinking are eventually learned in most cultures, but the emphasis on one or the other varies considerably. Which develops earlier depends on cultural values and parenting practices. Within a culture, development of reasoning styles is often thought to depend on interactions with peers.

The most relevant work in developmental psychology is on epistemic reasoning, a term used to describe peoples' beliefs about what constitutes a valid argument and their general approach to structuring arguments. Recent developments in this line of thinking have explored how people in American society gradually adopt more dialectical reasoning styles for dealing with problems that have no clear answer (called

---

## DIALECTICAL THOUGHT

---

Dialectical thought involves seeking a synthesis of two or more seemingly opposing viewpoints.

ill-structured problems), such as whether life or liberty is a more valuable ideal. Jan D. Sinnott, for example, believes that older adults tend to move toward a style that simultaneously embraces multiple thought systems while accepting that we are always limited in our knowing. Similarly, Patricia M. King and Karen S. Kitchener have outlined how young adults move from a reasoning style that involves conflicting ideas being judged quickly as either true or false to one in which people explore conflicting viewpoints and view ideas as relatively more likely or less likely based on the evidence. In each case, dialectical thinking emerges as people consider multiple possibilities and admit that there is no way to be absolutely certain in uncertain situations.

Currently, most mainstream cognitive psychologists find it difficult to accept the research on dialectical (or postformal) thinking because it often is not backed up by clear experimental results. Most of the frameworks are based on interviews or observation and cannot easily be confirmed using more traditional research techniques. However, recent developments tend to be based on experiments, so perhaps the field is moving toward broader acceptance of dialectical thinking.

## DIETING

---

Dieting is the purposeful restriction of food intake as a means of losing weight, experiencing health benefits, and/or avoiding medical complications

associated with excessive weight. Dieting is typically characterized by restrictive eating, where certain foods are limited or avoided entirely. Most diet plans are based on reducing any of the body's macronutrients, such as fats, carbohydrates, or proteins, which are vital sources of energy.

### WHAT IS DIETING?

Dieting refers to many diverse methods for inducing weight loss, such as controlled eating, fasting, and consuming diet aids. The prevalence of dieting has steadily increased over the past 40 years, since an increasing proportion of the population is overweight. The World Health Organization (WHO) has defined overweight as having a body mass index (BMI) of 25 to 29.9 kg/m<sup>2</sup>. Obesity is defined as having a BMI greater than 30 kg/m<sup>2</sup>. Reports estimate that 61% of adult Americans are either overweight or obese. Furthermore, the detrimental effects of being severely overweight are becoming increasingly clear. Overweight individuals have an increased risk for high blood pressure, cardiovascular disease, stroke, type II diabetes, cancer, and other complications (e.g., sleep apnea, gallbladder disease). Medical complications related to obesity are estimated to cost the United States approximately \$99 billion per year. In response to these health concerns and further cultural pressures, the percentage of men and women dieting has increased from 7% and 14% in 1950 to 24% and 40% in 1993, respectively. Not only has there been a marked increase in dieting among adults, but adolescent dieting is on the rise as well. Reports from the United Kingdom estimate that 35% to 60% of girls 11 to 18 years of age are currently dieting.

### THE NEED FOR DIETS

Many of the health risks associated with being overweight can be minimized by reducing 5% to 10% of overall weight. Successful diets can actually increase the body's metabolism through the consumption of smaller meals with greater frequency throughout the day. For example, instead of adhering to a traditional eating schedule of three meals a day, dieters that adhere to an eating schedule of five to six smaller meals stimulate the body's metabolism. The body's metabolism is spurred into action with each food source ingested, as the body must break down the necessary nutrients. Healthy, balanced diets can also increase energy levels

by omitting sugary and highly processed foods, which rapidly elevate and then drastically decrease blood glucose levels, affecting mood and energy levels. By consuming foods rich in fiber and proteins, blood glucose and energy levels can be maintained at a steadfast level, omitting drastic spikes in glucose levels. Healthy diet plans incorporate foods high in fiber and protein to help slow down digestion and keep glucose levels from rising or falling too rapidly.

The psychological benefits of a successful diet plan can be just as empowering as the physical benefits. As dieters lose weight and improve their health, well-being, and physique, they gain confidence in themselves and experience heightened self-esteem and body satisfaction. Successful dieters report increased life satisfaction and emotional well-being as a result of their weight loss and improved health.

## THE IMPORTANCE OF PROPER NUTRITION

Obtaining proper nutrients is essential for growth, reproduction, and maintenance of good health. Nutrients supplied through food sources provide support for all life activities in the cells of all organisms. Nutrients are labeled as carbohydrates, proteins, fats, vitamins, minerals, and water. Our bodies rely on these nutrients for building and repairing tissue, maintaining heart rate and pulse, and providing sufficient body heat. Without adequate nutrition, the body becomes frail and less apt to fight infection. The brain exhibits delayed reactions, the heart ceases to function properly, and in cases of extreme deprivation, death is possible.

## THE DIETING DILEMMA

The dieter must distinguish between the nutrients essential for proper bodily functioning and excessive calories that are counterproductive to weight loss.

Successful dieters must learn to correctly identify the body's needs and the satisfaction of these needs. The boundary between hunger and satiation is referred to as the diet boundary. This distinction, the diet boundary, is complicated by the fact that people frequently eat for other reasons than the body's need for nutrients. For example, people may eat to escape boredom, to cope with stress, or as a means of social interaction. Hence, dieters face a dilemma of maintaining an adequate diet boundary as they are immersed in a social world, surrounded by an array of circumstances and food choices. In the midst of these

situations, dieters must determine when to eat, how much to eat, and what types of food are appropriate.

## HOW DIETS WORK

It is ultimately the amount of calories consumed per day that determines the amount of weight lost or gained. The body burns calories as fuel for basic bodily functions. Weight loss occurs when fewer calories are consumed (e.g., dieting) or when more calories are burned (e.g., physical activity). Creating a caloric deficit of 500 calories per day (e.g., via dieting or physical activity) results in weight loss of approximately 1 pound per week. The optimal amount of weight loss per week is 1 to 2 pounds. Amounts exceeding the optimal amount can cause muscle to be burned rather than fat.

## RESTRAINT AND DISINHIBITION

One of the hallmarks of dieting is restrictive food intake. As dieters attempt to lose weight, they limit the types and amounts of foods consumed. These rigid periods of restraint can be physically and psychologically draining, as dieters must change the way they eat. This change often results in dieters neglecting the foods they enjoy for the foods on the diet. As a result of these intense periods of restrictive eating, dieters often exhibit the opposite extreme of restraint: disinhibition or overindulgence. These bouts of overeating, also referred to as disinhibited or binge eating, usually occur when dieters exceed their diet boundary.

There are both physiological and psychological factors that perpetuate this restraint-disinhibition connection. Successful diets yield weight loss, which can cause a state of chronic hunger. When body weight drops below a certain set point, the body attempts to physiologically defend the appropriate weight. Intense hunger pains and chronic hunger ensue to cue the individual that more food is required. Binge eating succeeding restrictive eating can also occur as a result of the reduced amounts of fat in most diets. Because fat causes feelings of satiation and fullness, reduced fat intake may increase hunger.

These physiological responses to dieting are amplified by psychological responses to restrictive food intake. As dieters alter their current eating patterns, feelings of perceived deprivation and preoccupation with food frequently occur. Perceived deprivation is caused by dieters eating less than usual, less than

desired, or less of the foods they enjoy, rather than by an actual calorie deficiency. Preoccupation with food is defined as the amount of time spent thinking about food. As food, eating, and weight begin to dominate the dieter's thoughts, the dieter becomes more likely to consume larger portions of his or her favorite foods. This preoccupation with food often leads to the dichotomous thinking of foods in terms of "good" and "bad." Dichotomous thinking is frequently seen in anorexic patients. As their disease progresses, more foods are labeled "bad" and are restricted.

### **TYPES OF DIETS**

There are currently many diverse types of diet plans available. Diets vary extensively in calorie intake, type of food restriction, flexibility, duration, and manageability. The key to diet selection is making an educated, well-informed decision. Some diets are simply not physiologically sound and may impose health threats that supersede weight loss. For example, many people either restrict calories or stop eating altogether to lose weight. When the body receives cues that food is scarce (i.e., limited food intake), the body attempts to prepare for periods of limited food. The body's metabolism slows down to avoid demanding more food when none is available. The effect of this slowed metabolism on the modern dieter is the opposite of the intended purpose. That is, the dieter experiences rapid weight gain once normal eating patterns ensue.

Some diets substitute one or more meals with a meal replacement shake or bar. The aim of meal replacement or formula diets is to provide the dieter with necessary nutrients while minimizing excessive calories. There are two central advantages to formula diets: they are easy to follow and they reduce the decision-making process. There are also several disadvantages to formula diets: they are monotonous and the dieter does not learn to make healthy food choices. Furthermore, formula diets that are extremely restrictive (e.g., 300 calories per day) can be detrimental to health.

Different diets emphasize varying aspects of nutrition. For example, high-protein diets stress the importance of the amino acids contained in protein and avoid carbohydrates. High-protein diets usually cause rapid initial weight loss because of the reduction in carbohydrates, which causes water loss. High-protein diets generally do not count calories and are often high in saturated fat. These diets may produce

dangerous effects on the body because of the fat content and the excessive amounts of uric acid released.

On the other end of the dieting spectrum are high-carbohydrate, high-fiber diets. High-carbohydrate diets stress the importance of nutrients contained in vegetables, fruits, nuts, and whole grains. High-carbohydrate diets may assist the dieter's feeling of satiation due to the high-fiber content. High-carbohydrate diets exhibit slower weight loss over an extended period of time. These diets can be dangerous if the calories are too low or if the protein or fat intake is insufficient to fulfill nutritional needs.

Yet other diets advocate food combinations to promote weight loss. These diets generally do not count calories and are structured around combining different food sources. Food combination diets vary in terms of the nutrients obtained and the well-roundedness of the food selections. Some of these diets (e.g., the Beverly Hills Diet, Jane Fonda, *Bloomington's Eat to Succeed*) can cause vitamin and mineral deficiencies. Dieters should search for well-balanced diets containing adequate protein, vitamin, and mineral sources.

In opposition to the food combination diets are the food segregation diets that separate different types of food sources. For example, Suzanne Somer's *Get Skinnier on Fabulous Food* advocates separating protein and carbohydrate sources. This diet is based on the assumption that when protein and carbohydrates are consumed at the same time, their enzymes cancel each other out, creating a halt in digestion and causing weight gain. However, there is no scientific research to support this claim. Furthermore, the high-fat content may put dieters at risk for heart disease or high cholesterol.

The most successful diets promote lifestyle changes involving both eating and exercise behaviors. A healthy diet should consist of moderate-sized portions of a wide variety of foods to ensure that proper nutrients are obtained. Dieters should avoid diets promising a "quick fix" to weight problems or other solutions that seem too good to be true. Dieters should instead seek out well-rounded diet plans that promote gradual, long-term weight loss and advocate lifestyle changes.

## DISASTERS

---

Natural and technological disasters are exceedingly stressful events that disrupt communities and families and traumatize individuals. Natural disasters are events beyond the control of human technology such as earthquakes, hurricanes, and tornadoes. Technological disasters include events such as explosions, floods due to dams breaking, industrial accidents, and nuclear power plant failures. Both natural and technological disasters can create health and psychological problems due to death, injury, property loss, economic changes, and loss of shelter, food, and water supplies. Although the immediate safety of people is paramount, government and public health authorities give insufficient attention to the later psychological effects. Both types of disasters are associated with increased psychological morbidity, especially in those

with preexisting conditions or susceptibility. Alcohol and other drug abuse often rises after a disaster, especially in men. Children sometimes show regression in their developmental skills such as toileting, dressing, and speech. Older children and adolescents usually experience longer-lasting effects of disasters than younger children.

Technological disasters pose slightly different problems than natural disasters. Community cohesion can increase as a result of a natural disaster, but technological disasters often divide communities due to uncertainties in blame, community connections to the source of the disaster, the injustices of the event, the stress of seeking government or corporate remedy, loss of trust in the government and public agencies, and the uncertain extent of long-term harm due to exposure to toxic substances. Examples of technological disasters are the toxic wastes at Love Canal, New York; nuclear reactor accidents at Three Mile Island, Pennsylvania, and Chernobyl, Ukraine; and the explosions of chemical plants in Seveso, Italy, and Bhopal, India.

Leaking toxic wastes at Love Canal created a crisis in 1978 that involved an elevated rate of miscarriages, lower child growth rates, and high stress due to failure of government and corporate officials to cope with waste. Many residents demanded relocation and compensation for health and property. Lawsuits were resolved only after approximately 15 years. As a result of Love Canal, the U.S. Congress passed the “Superfund” law that taxed companies in order to create a fund for cleaning up landfills.

The first proper epidemiological studies of the psychological effects of a technological disaster were conducted after the 1979 Three Mile Island nuclear reactor accident. Follow-up studies 5 years or longer after the accident found that Three Mile Island residents who evacuated had higher levels of blood pressure, stress hormones, disturbed sleep, depression, and intrusive thoughts compared with samples from other areas matched for socioeconomic status. Mothers who had preschool children at the time of the accident were especially susceptible to adverse psychological effects. Risk perceptions of the damaged plant were positively related to negative psychological effects. As of 2005, there are still scientific debates about the physical health effects of the radiation released during the accident. However, there is agreement that the accident created long-lasting negative psychological effects. The same is true of the accident at Chernobyl, Ukraine. The

psychological effects of the chemical plant disasters in Seveso and Bhopal were not studied.

## DISCIPLINE

---

The term *discipline* is used variously in the literature. The more restrictive view of discipline is to define it as consequences for child misbehavior (e.g., using time out, spanking, removing privileges). The more comprehensive view of discipline, the view elaborated here, defines it as behaviors aimed at helping children learn how to behave. In this vein, discipline includes providing positive motivators for desired behavior as well as punishing child misbehavior.

### TYPES OF DISCIPLINE

Positive forms of discipline, those forms aimed at increasing the frequency of desired behaviors, include attention, praise, privileges, and concrete rewards (e.g., stickers, tokens, money). Punishment, which is aimed at decreasing the frequency of unwanted child behaviors, is frequently divided into categories of physical punishment and nonphysical punishment. Physical punishment involves inflicting physical pain or discomfort. The most common form of physical punishment used by parents is spanking, but other forms of hitting (e.g., slap on the wrist) are also considered physical punishment. Nonphysical punishment includes behaviors such as removing attention, privileges, or child possessions; isolating a child for a period of time as in time out; scolding; shaming; or asking a child to perform a task that he or she regards as difficult or undesirable such as chores.

In the late 1960s, Diana Baumrind proposed three major approaches to child discipline in Western

culture. She proposed the term *authoritative* to describe discipline that combines high levels of emotional support with limit setting, requests for child cooperation, reasoning, and monitoring of child behavior. The term *authoritarian* refers to discipline that is low in emotional support and high in control and punishment. A *permissive* approach to discipline includes high levels of emotional support but relatively few limits set on the child's behavior.

### EFFECTIVE HOME DISCIPLINE

Since the late 1960s, research has demonstrated the relative effectiveness of particular parental discipline strategies and the relative ineffectiveness of other strategies.

Effective parental discipline strategies include the use of clear rules and commands, time out, brief withdrawal of privileges, consistency in implementation of discipline behaviors, and immediate reinforcement (e.g., praise, reward) of appropriate child behavior. Parents should be sure that the child is capable of performing behaviors that he or she is asked to do. When one delivers punishment, he or she should remain as unemotional as possible so as to not give additional attention to the child's misbehavior.

Parental discipline behaviors that have been found to be relatively ineffective include use of unclear rules and commands, attention for inappropriate behavior, laxness (i.e., failure to follow through on planned consequences for child misbehavior), and use of harsh physical punishment. Discipline is also less effective when there is a long delay between child misbehavior and parental discipline and when the parent gives many warnings to the child before giving the child a consequence for misbehavior.

Studies have found that the effectiveness of specific discipline strategies varies to some extent depending on the child's age. For example, time out is most effective from ages 2 to 9 years. Removal of privileges is more effective for children 4 to 17 years of age than for children younger than 4 years. Reasoning (i.e., negotiation regarding rules and consequences for child misbehavior) is more effective with adolescents than younger children.

### EFFECTIVE SCHOOL DISCIPLINE

The literature regarding effective discipline for children in school settings parallels that of effective home discipline. It is recommended that teachers post

rules clearly in the classroom to remind children of appropriate and inappropriate behavior. Effective discipline strategies for the classroom include structured reward programs aimed at increasing children's appropriate behavior (e.g., remaining seated, completing seat work, raising a hand when one wishes to speak), time out, and loss of privilege. Response-cost programs, which combine reward for appropriate behavior and punishment for inappropriate behavior, have also been found to be effective. In a response-cost program, a child is given points for appropriate behaviors and loses points for inappropriate behaviors; accrued points can be exchanged for desired rewards such as computer time or attractive school supplies. When one is considering the implementation of a discipline program in the classroom, one must consider issues of teacher acceptability of various discipline strategies. Research has found that teachers most often favor discipline programs that reward appropriate child behavior rather than punish inappropriate behavior. Additionally, teachers may prefer discipline programs that include every child in the classroom over programs that focus attention solely on one child's behavior.

### CROSS-CULTURAL ISSUES IN DISCIPLINE

Studies have attempted to determine possible variability in the effectiveness of discipline behaviors as a function of family cultural background. Some studies suggest, for example, that an authoritarian discipline style may be more effective in African-American, Latino, and Asian-American families than in European-American families. As another example, extensive verbalization while disciplining children may be a more effective discipline strategy for Chinese-American parents than for European-American families because extensive verbalization during discipline is congruent with a more general Chinese philosophy regarding the importance of educating children why particular behaviors are appropriate or inappropriate. At this time, the cross-cultural literature regarding discipline is limited.

### LEGAL ISSUES REGARDING USE OF PHYSICAL PUNISHMENT

The use of physical punishment, or corporal punishment, is controversial in the United States. The U.S. Supreme Court ruled in 1977 that physical punishment in schools violated neither children's due

process rights nor their rights to protection from cruel and unusual punishment (*Ingraham v. Wright*, 430 US 651). Although there is no federal law banning the use of physical punishment in public schools, 28 states have passed such laws.

A panel convened by the American Academy of Pediatrics in 1996 recommended against the use of physical punishment for children under age 2 years and also stated that there is more evidence of long-term negative effects from physical punishment than evidence of short- or long-term positive effects. Arguments discussed in the literature against the use of physical punishment in disciplining children include the following: (1) there is a lack of evidence that physical punishment is as effective as nonphysical forms of punishment; (2) the use of physical discipline is associated with increased rates of behavioral and emotional difficulties in childhood and adulthood; (3) the use of physical punishment teaches that violence and force are acceptable means of interpersonal communication; and (4) physical child abuse may result from unintended escalation of use of physical force while administering physical punishment for child misbehavior.

There is a small body of literature that suggests, however, that use of physical punishment may not always lead to negative child outcomes. For example, studies suggest that mild spanking, delivered calmly, may lead to a decrease in preschool children's misbehavior, particularly when the spanking is combined with other methods of child discipline such as time out.

In the United States, the use of physical punishment in the context of parental discipline is legal in every state. Approximately 60% of American families with children under the age of 18 use physical punishment as a means of discipline. Within this group, there is considerable variability in the frequency and severity of physical punishment used. Moreover, there is substantial evidence that some parents use physical punishment in combination with many other types of discipline, whereas other parents rely predominantly on physical punishment to attempt to control their child's behavior.

A substantial body of literature has attempted to identify parents who are most likely to use physical punishment as a means of child behavior management. Robust predictors of use of physical punishment include parental frustration, parental depressive symptoms, stress, negative perceptions of the parenting role, negative perceptions of the child, hostile attributions regarding child misbehavior, younger parent age,

single parenthood, and child aggressive behavior. Studies regarding the relationships between parental use of physical punishment and race, ethnicity, socioeconomic status, education, child gender, parent gender, and religious beliefs show mixed findings.

## OUTCOMES OF INEFFECTIVE DISCIPLINE

The research and theoretical literature regarding discipline have identified broadly two problematic parental discipline styles: harshness and laxness. Harshness is defined as the parent responding to child misbehavior with yelling, belittling, or use of physical punishment delivered in the context of high levels of emotionality. As defined above, laxness is the failure of the adult to follow through on planned consequences for child misbehavior (e.g., threatening a consequence for child misbehavior without following through on the consequence).

Harshness has been found to be associated with anxiety symptoms, oppositional behavior, defiant behavior, juvenile delinquency, and aggression in children and adolescents. Harsh discipline experienced in childhood has also been found to be associated with depression and substance abuse in adulthood. Punishment that is given noncontingent on the child's behavior (i.e., the parent "disciplines" the child although the child has not engaged in any misbehavior) may lead to feelings of helplessness. Children may also become insensitive to punishment if punishment is increasingly coercive over time.

Lax discipline has been found to be associated with child noncompliance and antisocial behaviors.

## CLINICAL IMPLICATIONS

Studies that identify parents who are most likely to use frequently excessive physical punishment and other forms of harsh discipline may be helpful in developing early intervention and prevention programs. Helping parents to cope with stress, frustration regarding child behavior, and depression may decrease the chance of parents using harsh discipline. Promotion of self-monitoring of negative thoughts and feelings may help parents to choose less punitive methods of discipline when faced with child misbehavior. Studies suggest that interventions aimed at changing parents' attitudes regarding the effectiveness of physical punishment may also be helpful. It is important to note that only half of parents indicate that they have enough

information about effective discipline strategies; thus, many parents may benefit from information about effective, nonharmful methods of child behavior management.

## DISGUST

---

Disgust has been described as an evolutionarily important emotion. According to Darwin, the function of disgust is to prevent orally ingesting contaminants or other biologically harmful substances. There are characteristic reactions associated with disgust, including physical (such as nausea), psychophysiological (muscle tension around the nose and mouth, reduction of vascular tension), and behavioral (typically avoidance). Overall, the description offered by Darwin, and the associated reactions described here, are straightforward and unidimensional.

While Darwin's conceptualization may have been unidimensional, recent research has shown that disgust is multifaceted. According to contemporary disgust theory, there are eight broad areas of disgust elicitors, or stimuli, that provoke disgust reactions:

1. *Food*: Culturally unacceptable foods, or unacceptable combinations, provoke disgust. An example would be ice cream on chicken.
2. *Animals*: Contact with food by an animal, particularly one associated with unclean places. For example, a spider walking across a cookie.
3. *Death*: Stimuli associated with death, such as cemeteries, cremation urns, or coffins.
4. *Sex*: Any culturally unacceptable sexual practices can lead to disgust reactions.
5. *Body Products*: Feces, urine, or mucus are examples of body products that can lead to disgust reactions.
6. *Body Envelope Violations*: Images of or actual exposure to internal organs or viscera.
7. *Sympathetic Magic*: This occurs when an otherwise neutral object comes in contact with an item associated with an item for consumption. For example, a label that says “saliva” placed on a cup that is known to contain spring water.
8. *Moral*: Any contact with items associated with immorality or individuals deemed immoral.

## DEVELOPMENT OF DISGUST

According to recent conceptualizations, disgust develops largely through a process called evaluative conditioning. This is promoted through two major routes. One is via instructional learning such as through caregivers, who identify items as disgusting (i.e., “yucky”) while making characteristic facial expressions for disgust when teaching young children about the environment. This is typically in reference to items that should not be eaten or put in the mouth.

Broadly speaking, disgust reactions to different stimuli may develop after childhood, often for items associated with previously established disgust-provoking stimuli or by labeling those items as such. For example, there is nothing about a sweater that is disgusting. However, if one were informed that it was cleaned but previously was covered with maggots, there would be a reluctance to wear that sweater because of the label and associated image bestowed on it.

## ASSESSING DISGUST

Currently, there are a few ways of evaluating disgust reactions. One way is via a self-report measure. A few major instruments exist for evaluating disgust, with sound psychometric properties. Another effective

approach involves assessment of muscle tension around the nostrils or upper lip. Each of these areas typically grows tighter when exposed to items that evoke disgust reactions. Blood pressure is an assessment that is being validated in some laboratories for evaluating disgust reactions. Items that provoke disgust should lead to lower blood pressure.

## CONTEMPORARY APPLICATIONS OF DISGUST RESEARCH

A great deal of recent work has concentrated on the role of disgust in different forms of psychopathology. Most notably, there is increased evidence that disgust is implicated in many specific phobias, particularly blood-injury-injection, spider, snake, and other small animal phobias. Some data also suggest that disgust plays a role in contamination fear associated with obsessive-compulsive disorder. This is an active area of new developments in psychology.

## DISTANCE LEARNING

Distance learning occurs when instructors and learners are separated by space and possibly time. Distance learning is part of a system of learning, teaching, communication, design, and management. The learning is interactive and may happen synchronously with instruction or asynchronously. The interaction among instructors, learners, and information is mediated by one or more technologies.

Synonyms and similar terms for distance learning include cyberschooling, distance education, distributed learning, e-learning, m-learning, online learning, open schooling, remote education, telelearning, and virtual schooling. The growth in interest in distance learning stems from the benefits it affords, such as convenience in location of learning, flexibility in scheduling learning, effectiveness for learning given the proper conditions, a multisensory interactive approach, and efficiency in use of time and resources. Distance learning applications for adult learners include professional development, continuing formal education, needs-based instruction, mentoring, and personal enrichment.

Most distance learning students learn effectively, and online courses and programs can be just as effective as face-to-face experiences. Successful distance learning requires that both students and instructors use different skills than they would use in a traditional teaching and learning environment because of the unique characteristics of the distance learning situation.

### TRANSACTIONAL DISTANCE

The distance between learner and teacher as stated by Michael Moore “is not merely geographic, but educational and psychological as well. It is a distance in the relationship of the two partners in the educational enterprise.” In general, novice students need more structure, and as they acquire skill, knowledge, and expertise, their need for dialogue increases and the distance between educators and students decreases no matter their physical distance.

The communication transaction between educators and students varies depending on the background of

**Table 1** Types of Interactive Distance Learning

students, their prior knowledge of a subject, and their motivation and readiness to engage in learning, as well as the nature of the subject matter, the complexity of the discipline, and the breadth and depth of the curriculum. Transactional distance changes not only during the course of a term, but in each session.

### EFFECTIVE DISTANCE EDUCATION

Distance education and its technologies require extensive planning and preparation. Teachers must be proficient in the use of communication technology and in the techniques proven effective in the distance education environment. Media must be appropriate to the technology and to the needs and abilities of the students. The distance educator has the role of a guide or moderator more than that of a presenter or performer. Skills in communication are considered to be more important than content knowledge, because interaction of students is the factor that contributes most to learner success in distance education.

Distant students bring basic characteristics to their learning experiences, which influence their success in learning. Success as a distance learner depends on factors such as having the necessary skills for learning and communication, adapting to the technology-mediated social setting, engaging the learner in relevant activities, and having the appropriate technical skills and resources, according to Greg Kearsley.

The quality of distance learning courses or modules depends on content, pedagogy, motivation, feedback, organization, usability, assistance, assessment, and flexibility. The process of developing and implementing effective distance education happens in an iterative cycle proposed by Cathy Cavanaugh involving

resources–practices–results. Broadly considered, the three stages in the cycle are:

1. Procurement and preparation of the resources necessary to meet the distance education goals
2. Delivery of instruction using the best practices from education, business, and research
3. Analysis of the results of distance education to gauge achievement of the goals

—Cathy Cavanaugh

## DIVORCE

---

Divorce, or the legal dissolution of marriage, is a common occurrence that affects millions of individuals and families throughout the world. The divorce rate in the United States and in much of the Western world is higher than it has ever been. Current estimates in the United States suggest that 50% to 67% of first marriages will end in divorce within 40 years, and the figure is even higher for second marriages. The United States leads the world in the incidence of divorce and in the proportion of children affected by it. In each year since 1970, more than 1 million children are affected by divorce. As of 1994, 4.7 million children lived with a never-married parent, 5.9 million lived

with a divorced parent, and 4.8 million lived with a separated or widowed parent. By the year 2000, 25% of people between the ages of 18 and 44 had divorced parents.

It is worth noting, however, that accurate divorce statistics are difficult to determine. Several states (California, Colorado, Indiana, and Louisiana) do not even keep track of the number of divorces granted each year, so statistics are always estimates based on available data. Furthermore, statistics are always based only on legal marriages and do not include dissolution rates of unions in which couples do not legally marry in the first place.

### HISTORY

Until the late 19th century, divorce was relatively uncommon in the United States. Most marital disruptions occurred as a result of informal separation or desertion, and the majority of marriages lasted until the death of one partner, an event that typically occurred much earlier than it does today. Divorce rates in this country began to rise shortly after the Civil War and continued on a steadily upward course for over 100 years. In 1867, roughly 5% of marriages ended in divorce. By 1964 the divorce rate for first marriages was 36%. There was a sharp increase in the incidence of divorce from the mid-1960s to the late 1970s, a period sometimes referred to as “the divorce revolution.” In 1965, there were 2.5 divorces per 1,000 population. That rate had increased to 3.5 per 1,000 by 1970 and 4.8 per 1,000 by 1975.

Blaine Fowers, in a recent book examining attitudes and expectations of marriage, suggests that the dramatic increase in the divorce rate in the past 150 years has coincided with changes in our society’s views of marriage. He points out that prior to 1850, “expectations for what we call *emotional fulfillment* had little to do with whether couples entered into marriage or terminated the union. . . . Contrary to our modern assumption that marriages are made and maintained by love, spouses at this time did not necessarily expect their marriages to be emotionally gratifying so much as to enable them to have an orderly, virtuous life” (pp. 64–65). He further posits that as expectations that marriage should be based on love and should provide emotional fulfillment have risen, the chances that one will feel disappointed in a relationship have also risen. The rising divorce rate in the past century reflects this shift in values.

The women's movement and other sociopolitical changes of the past 35 years have also contributed to changes in our culture's views of marriage, parenting, divorce, and custody. Prior to 1970, most state laws defined marriage in a hierarchical manner favoring the husband. Basically, a married woman's legal identity was submerged in her husband's. Women were typically required to assume the husband's name, domicile (permanent state residence), and credit rating. Matters such as obtaining a credit card, taking title to a marital home, or registering to vote could not be accomplished unless husband and wife shared the same last name. Until the mid-19th century and the passage of the Married Woman's Property Acts, all of a woman's assets and property became her husband's upon marriage. Even laws regarding sexual assault reflected the view that the woman herself was the property of her husband, and in most states a married woman could not be raped by her husband because her body belonged to him.

Changes began to occur in the 1960s, including the first "no-fault" divorce laws. Up until the introduction of these laws, divorce was based on an adversarial model in which divorce could not legally be consensual. One party had to show that he or she was not at fault and had not contributed to the "wrong" and that the other party had done something so heinous (typically cruelty or adultery) that it destroyed the marriage. If the grounds were not proven, divorce was not granted. Because of the strict requirements for cruelty or adultery, grounds were often difficult to prove unless there was de facto cooperation from the defendant. Until 1967, the only legal ground for divorce in New York State, for example, was adultery.

Fault-based divorce influenced not only the means by which one could obtain a divorce, but the assignment of property and decisions about the care and custody of children. It was hard to separate evidence for proving grounds for divorce from litigation over custody, alimony, and child support. For example, a Florida statute used to deny alimony to a woman who was proven to have committed adultery.

In 1969, California became the first state to implement a divorce law without any fault-based grounds for divorce. While only a few states have entirely eliminated fault as a basis for divorce, all 50 states have enacted some mechanism for couples to go through an uncontested divorce without assigning blame to one or the other spouse. There is some disagreement in the field about the effects that no-fault

divorce have had both on the divorce rate and on the economics of divorce for families and children. Although the divorce rate was rising during the years that no-fault divorce laws were first enacted (1970 to 1976), they have not continued to rise since that time. Many researchers conclude that fault laws were ineffectual and were not fully enforced for many years before the advent of no-fault laws so that the change in law has been a minor factor in the fluctuation of divorce rates themselves. There is less agreement as to the economic effects of no-fault laws. Many researchers believe that divorce has a negative economic effect on women and children. This is due to the fact that women still earn, on average, only 70% of what men earn, and that most divorces still result in mothers caring for minor children. Other researchers point out that divorce negatively affects both men's and women's economic status since maintaining two homes is more expensive than managing one.

## TYPICAL DIVORCE CHRONOLOGY

There are two major methods for obtaining a divorce: doing it yourselves, usually with the help of a manual or divorce kit, and hiring attorneys to help you litigate your divorce. For couples with no children, few assets, and who are basically in agreement about wanting the divorce, the divorce itself is mainly a matter of completing the appropriate paperwork for their state. These couples may choose to negotiate their settlement and file their own papers. Most people use a manual or divorce kit to help them through this process. Since divorce laws vary by state, you must obtain a book or kit with the forms and procedures that will be required for the state in which you reside at the time of the divorce. Of course, having children and assets does not bar you from handling your own divorce, but it does make the process more difficult and complicated. It requires a great deal more negotiation than a simpler situation, but it is also less costly than a contested divorce would be.

Most couples who can do so choose to hire attorneys to handle the divorce proceedings for them. This better ensures that both parties fully understand their rights and obligations during the divorce process.

Although the precise manner in which a divorce proceeds varies from one location to another, most contested divorces follow the following course: One spouse gets a lawyer, who writes up a petition or complaint. The complaint is a legal document that outlines

the reasons for the divorce and how the complainant wants to settle financial and custody issues. The petition is then filed with the court. The court ensures that the petition or complaint is served on the other spouse and also serves a summons that requires a response.

The spouse who has not initiated the process must answer the complaint, usually with the assistance of his or her own attorney. The answer outlines the manner in which this partner wants to settle financial and other legal issues. If the served spouse does not answer the petition, the court usually assumes that he or she agrees to its terms. The couple then exchanges information about property and income in order to decide how to divide up property and how to manage child support, custody, and alimony. Sometimes the couple can voluntarily resolve all these issues through mediation.

Mediation is the use of a neutral third party who has been specifically trained to help adversaries work out a compromise on issues of disagreement. Mediators often have backgrounds in counseling, law, or financial planning, but they typically receive additional training in doing divorce mediation. The work of a mediator, unlike that of the divorce attorney, is to work on the side of compromise and/or for the best interests of any children involved rather than in the interests of one or the other divorcing partner.

Once a settlement is reached, the agreement is shown to a judge at an informal hearing. The judge will determine whether both parties understand the agreement and voluntarily signed it. If this is the case, and the judge approves the agreement, the couple will be granted a divorce decree that documents the issues to which they agreed. If the judge does not approve it, or if the couple cannot reach an agreement, the case will go to trial.

At trial, the attorneys present evidence and arguments for each side, and the judge decides the unresolved issues, including child custody, visitation, child and spousal support, and property division. Once these issues are decided, the judge grants the divorce. Either or both parties may appeal the judge's decision to a higher court, but it is unusual for appeals courts to overturn a judge's decision.

## CUSTODY

There are a number of considerations that divorcing couples and the courts must make regarding the future care of children (and in some instances, animals

or pets) after a marital dissolution. Legal custody of a child is the right and obligation to make decisions about children's upbringing such as where they will live, what school they will attend, medical decisions, and the like. Physical custody is the right of a parent to have the children live with him or her. Joint custody or shared custody refers to a situation in which both parents share legal and/or physical custody of their children. If parents share physical custody, it means that the child spends a significant portion of time with each parent. Parents who share physical custody almost always share legal custody, but not necessarily the other way around. Sole custody means that only one parent, who is referred to as the custodial parent, has the right to make major decisions regarding the child's upbringing and also that the child lives with him or her. Usually the noncustodial parent has visitation rights, meaning that he or she is permitted to spend time with the child, but not to have the child living in his or her home. In most states, courts are moving away from awarding sole custody to one parent and are increasingly enlarging the role that the father plays in children's lives. Much less common is bird's nest custody, a shared custody arrangement in which the children remain in one home and the parents take turns moving in and out.

The demographic shift away from sole custody arrangements to shared ones are based in findings from the past 25 years that indicate that children do better, both economically and emotionally, when both parents remain closely involved in their lives. Judith Wallerstein and Sandra Blakeslee (2000) cite research indicating that children who have close relationships with their fathers in childhood surge ahead of peers without such relationships in cognitive and social development. As adults, they experience greater empathy and happiness as parents. In contrast, children whose noncustodial parent distances himself or herself from them and who fails to maintain close contact develop much more anxiety, loneliness, and difficulties in adult relationships than do children who maintain a relationship with both parents.

Although shared custody arrangements seem to be preferable in most cases to sole custody in terms of children's adjustment to divorce, they can be extremely difficult to navigate. To work well, joint physical custody requires that parents continue to live near each other, preferably in the same school district, but minimally within easy commuting distance of each other. This requirement continues until all

children are at least out of high school, which may limit career or remarriage options for one or both parents if they are committed to the shared custody arrangement. In working out a schedule for sharing custody, parents have to remain flexible and find ways to communicate cooperatively with each other, a task that may seem daunting at times, especially in the early stages of the divorce. It is important to consider the children's social, athletic, and academic schedules as well as the parents'.

Some couples are unable to navigate these challenges. Carla Garrity and Mitchell Baris (1994), in a book that provides guidance for handling high-conflict divorce, describe five levels of conflict, with escalating levels exacting more emotional damage to children. Minimal conflict couples are able to cooperate on shared custody issues, exercise self-control, and find ways to resolve conflict. Mild conflict is characterized by occasional quarrels or temporary efforts to form a coalition with the children against the other parent, but these efforts are quickly discontinued. Moderate conflict is characterized by increased intensity and duration of fighting and/or attempts to discredit or berate the other parent. At this level, children begin to be seriously affected in a negative way. Moderately severe conflict is characterized by almost constant or daily fights, physical violence, continued litigation, and parental alienation syndrome, in which one parent actively attempts to exclude the other from the children's lives. Children are almost inevitably scarred by parental conflict at this level. Finally, severe conflict is characterized by all of the problems of moderately severe situations, with the addition of direct threats to the children's physical safety such as physical or sexual abuse, parental alcoholism or drug abuse, or serious psychopathology. In situations of moderate to severe conflict, these researchers recommend the creation of a parenting plan with the help of a trained mediator or therapist. The parenting plan is designed to contain or reduce parental conflict, ensure compliance with the visitation or custody arrangements in the divorce decree, and ensure that both parents maintain ongoing, but safe, relationships with the children. A parenting coordinator may be required to help the couple implement the plan.

## EMOTIONAL STAGES OF DIVORCE

Every divorce is unique, and no two people will experience it exactly the same way. Nevertheless,

there are clearly definable stages in the decision and recovery process that are similar to stages of grieving other losses. Divorce, even when it is wanted and planned, represents a loss of previously held hopes, dreams, and wishes for the future, as well as concrete losses such as financial stability and a familiar living situation. At first, as people are deciding whether or not to divorce, they typically experience intense ambivalence and uncertainty. The pain of a troubled marriage is weighed against the pain of ending it. People question their own ability to cope and wonder what impact a divorce will have on their future and that of their children.

Once one or both partners make a final decision to leave, emotional reactions often include a combination of shock, numbness, or denial. It is not uncommon to experience some relief as well. Symptoms of shock or denial may include sleeping more than usual, drinking or using drugs, working more than usual, or refusing to believe that the divorce is actually happening. Symptoms of numbness may include an inability to feel or to express emotions. It may be difficult to cry, and difficult even to get through the day's activities. Physical symptoms such as aches and pains or loss of appetite are also common.

The next stage of recovery is often one of extreme and alternating emotions. This phase is usually at its most intense during the first year after a decision to divorce is made. It is not uncommon to burst into tears or explode in a rage somewhat unexpectedly or with minimal provocation. Anxiety is very common, especially about what to expect, how to handle being single again, and how one will cope financially. Difficulty eating or sleeping, or eating or sleeping too much, are common symptoms. Most people experience guilt about mistakes they made during the marriage, as well as guilt about things they are doing or feeling during the divorce itself. Review work is another common part of the grieving process and involves looking back on your marriage and on your life before marriage to see what you or your partner could have done differently or how the divorce might have been avoided. Feelings of anger, failure, and loss; a sense of being unloved; loneliness; and occasional unexpected feelings of euphoria are all part of this stage.

It is extremely important to find ways to manage these stressful and unpredictable emotions. Many decisions will have to be made during the divorce process that will have an effect on your life for years to come. If you have children, it will be difficult if not

impossible to attend to their emotional needs if you have not taken care of your own. It is vitally important during times of extreme change and emotional distress that you exercise, eat healthfully, sleep, and maintain supportive social and spiritual contacts with others. It may be helpful at this time to consult a counselor or therapist as well.

The third phase of recovery is characterized by an increased focus on the self and a marked decrease in emotional pain and volatility. During this stage you may experiment with new interests and activities, find that you are interested in dating again, or realize that you are reconsidering career choices. The final phase is one of integration and a renewed sense of stability. It is a time to integrate what has happened into a new sense of identity. For people with children, a sense of being a new family, either as a single parent or as a parent and stepparent, emerges. Divorce may be experienced now as an opportunity rather than a burden. Regret may be less fraught with intense anger and blame. Relations with the ex-spouse are more likely to be cooperative and friendly.

Children go through emotional phases that are similar to those their parents experience, but for children the emotional upheaval and effects on functioning are often much longer lasting than they are for adults. In fact, there is evidence from several long-term longitudinal studies of children from divorced families that suggest that the emotional impact of divorce on children lasts well into adulthood. The best known and most widely cited of these studies has been done by Judith Wallerstein and her colleagues, who began to study 131 children and adolescents from 60 divorcing families in Marin County, California, in 1971. The children were studied intensively for 6 weeks near the time of the marital separation, and a subset of these children were interviewed again at 18 months, 5 years, 10 years, and 25 years postseparation. Wallerstein asserts that "children in postdivorce families do not . . . look happier, healthier or more well adjusted even if one or both parents are happier" (2000, p. xxiii). In fact, children who experience parental divorce, compared with children in continuously intact two-parent families, exhibit more conduct problems, lower academic achievement, more social difficulties, and poorer self-concepts. Adults who experienced divorce as children may have great difficulty navigating romantic relationships and establishing a secure sense of trust and connection to a romantic partner. Some of the factors that may contribute to these phenomena include exposure to financial and residential

instability, the absence of one parent and/or parts of the extended family, the inability of the custodial parent to respond adequately to the child's emotional needs, and continued parental conflict.

## HELPING CHILDREN COPE

A parental divorce is, for most children who experience it, one of the most stressful events they will ever experience. Even when children have been exposed to serious parental conflict, most would prefer that their parents stay together and that the family as they know it remain intact. Although painful to accept, it does help children if their parents realize that their divorce will, at least temporarily, cause great upheaval in their children's emotional and psychic lives and to take steps to ameliorate it. Accurate information about what is happening and what to expect can help children maintain at least some sense of control and predictability during a time of great change. Parents may think that shielding children from information will protect them from emotional pain, but this is rarely the case. For example, a child who is told that a parent is going on a vacation instead of being told that the parent is leaving the home permanently can later become fearful of any vacation or any temporary separation from a parent. For very young children, using and explaining the word "divorce" is a good idea. For children under 4 years of age, just explaining that divorce means that mom and dad will live in separate homes and that the child will spend time with each of them can give him or her an idea of what to expect. For older children, some explanation and validation of the things they have observed can be helpful. For example, it might be appropriate to explain that the parents have tried hard to resolve their differences but have not been able to do so and so have mutually decided that it would be better to divorce and create two homes. It is important to listen carefully to children's questions and concerns and make an effort to answer them accurately and empathically. It is particularly important to let children know what to expect in terms of where each parent will live, what the visitation arrangements are likely to be, and whether or not he or she will have to move. It is not necessary or advisable to give children younger than 5 or 6 details about finances, infidelities, or other private matters; however, some explanation of the reasons for the divorce decision can help allay fears that the decision was unfounded or capricious. For older children,

especially teenagers and adults, it may be appropriate to share this kind of information, and it will probably not be a surprise to them.

While it is understandable that parents wish to tell children anything that will help them feel safer and more secure, it is important not to give children false reassurance. If children are told that “nothing will change” or that they will see a nonresidential parent as often as before, they not only know it is untrue, but will face continued disappointment as they experience the inevitable changes that do occur. Reassurances that are more likely to be true might be assurances that both parents will continue to love and care about the children or that they will make every effort to protect them from harm.

Children often feel that they are to blame for their parents’ marital difficulties, and even for the divorce itself. Paradoxically, younger children may feel especially guilty, despite the fact that they have less autonomy and control than teenagers and young adults. The younger a child is, the less capacity he or she has to imagine how an adult might feel or think, or to recognize that parents make choices that are not always directly about him or her. Although it might seem obvious to parents, it is important to assure children that the divorce is not their fault.

One of the most destructive elements of divorce for children’s long-term adjustment is ongoing parental hostility and efforts to make a child choose one parent over the other. Children strongly identify with both parents, so making a child feel that to love one parent is to betray the other can be destructive to the child’s self-esteem and feeling of security. No matter how angry one parent may be with the other, it is extremely helpful to allow the children to maintain warm and loving feelings toward both parents. Parents should never complain about the other parent to the children and should avoid having angry or hostile discussions in their presence. Each parent should encourage visitation with the other parent and should never limit phone or e-mail contact except in the rare instances in which a parent may be abusive to the child.

Parents should never put children in the position of keeping secrets from the other parent, having to spy on the other parent, or having to act as a go-between in matters of finances or legal conflicts. This creates a tremendous loyalty conflict for the child, who is connected emotionally to both parents. Remember that just because you may have ceased to love your spouse, your children have not. These situations create enormous emotional stress for children.

The effects of divorce continue over time, throughout childhood and adolescence and into adulthood. Therefore, parents may find that they have to help their children with the same issues and concerns repeatedly at different developmental stages. For example, a 6-year-old child may be satisfied with one answer to questions about why a divorce occurred, but have renewed questions and concerns about it when he or she is 12 and more questions and concerns at 19.

At any age, children’s emotional and financial stability is enhanced if both parents remain actively involved in their lives. In order to do this, it is essential for them to find ways to interact in a cooperative manner. It may help to keep in mind that it is in your children’s best interest to cooperate with your ex-spouse even if you feel hurt, angry, or betrayed. Each parent should make an effort to spend time with the children during the week as well as on holidays and weekends. This often means arranging custody or visitation in such a way that holidays or weekdays are alternately spent with one parent or the other. If possible, both parents should know who their children’s friends are, who their teachers are, and what they are most interested in doing. Parents may alternate in attendance at school events, sports activities, and the like, or they may both choose to attend these events, but it is helpful for children to feel that both parents are interested in sharing the significant milestones of their lives.

One should try to minimize the number of changes the children experience as a result of the divorce. If it is possible to keep them in the same school and to maintain the home in which they were living before the divorce, that will help. If possible, they should continue with their customary activities and friendships. Parents should encourage children to talk about their feelings, wishes, and fears about the situation. This is not always easy to accomplish. It can sometimes help to read a book together or to discuss the divorce experience that children in a movie or TV show are having.

Most children whose parents are divorcing will have a range of emotional reactions, including fear, sadness, anger, and confusion. Many parents assume that their children are adjusting well to a divorce because they do not express these feelings directly. However, children may exhibit other signs or symptoms of emotional distress, such as poor school performance, withdrawal from social activities, physical illnesses, sleep difficulties, eating problems (overeating or excessive dieting, especially among teens), or delinquent activities. Some children become

“hyper-responsible” and take on a role of caring for the distressed parents both emotionally and in terms of practical matters such as preparing meals or handling bills. Many parents find that helping a child handle angry feelings, especially anger at the parent, is a particularly daunting task. Parents should help children understand that feelings are signals. Anger can be a signal that something is wrong or unfair. When one’s parents divorce, children typically feel a sense of helplessness and powerlessness since they had no say in the decision. Helping children find ways to express their anger and frustration in a safe and acceptable manner can help. For example, talking about angry feelings, drawing pictures, or playing hard in sports or athletics may be ways of letting go of angry feelings. Allowing children to participate in decisions such as visitation arrangements or decorating their new home or room may help them achieve some sense of mastery or control of an uncontrollable situation.

## DIVORCE MEDIATION

---

Divorce mediation is the use of a third-party neutral mediator who assists parties in developing their own financial and parental agreements at the time of a divorce. The mediator, unlike a judge, has no authority to impose a decision on the parties. Mediation encourages the parties to communicate directly and fashion an agreement that suits their particular needs. Mediation is often used in situations where emotions run high and parties will continue to have a relationship after the resolution of the present conflict. In most divorce cases, both of these characteristics are present since most marriages ending in divorce involve children.

Although mediation is an ancient practice in many cultures, its widespread use in divorce cases in the United States is of relatively recent origin. California established court-connected conciliation services in 1939, the aim of which was to promote reconciliation in marriages. The focus later shifted to divorce counseling and child custody mediation. During the 1970s, attitudes toward divorce began to change in the United States. As a result, many states abandoned the system whereby a judge was called upon to decide whether one of the parties was guilty of a marital “fault” such as adultery, abandonment, or abuse. Instead most states moved to a system of “no-fault” divorce, allowing the spouses themselves to determine whether to continue the marriage. Issues related to property division began to resemble business partnership dissolution proceedings and became more predictable as well. It followed then that parties took the opportunity to privately order their divorce and began to look for ways to do so with the assistance of a nonjudicial third party.

In 1978, O. J. Coogler, an attorney and marriage counselor, established one of the first family mediation centers in Atlanta. In his book entitled *Structured Mediation in Divorce Settlement*, he outlined a process for resolving the issues attendant upon divorce using a facilitator.

While mediation is often used to resolve issues relating to the economic aspects of divorce, its most common application is in the area of decision making regarding children. Psychological research in the 1970s and 1980s concluded that children would benefit after divorce from a continuing relationship with both parents. This research, in addition to other political and social trends, led to the enactment of joint or shared custody statutes in many states. These arrangements required more planning and cooperation on the part of parents. Mediation is seen as a process that allows parents to create agreements that best suit their families and at the same time help to build a relationship that will encourage ongoing cooperation. A majority of states now require mediation for child custody disputes before parents can ask for a court to make a decision about the care of their children.

Mediation of property issues related to divorce is usually conducted by a lawyer who acts as the mediator. The lawyer does not represent either of the parties in the divorce but rather assists them in creating a settlement agreement that is then reviewed by their own attorneys. Mediation of child custody disputes is generally performed by lawyers, mental health professionals, and employees of the court who are specially trained for this function. The courts are still involved in divorce cases because divorce agreements must be approved by the judge who will grant the divorce.

Divorce mediation is not without its critics. Some worry that without lawyers to negotiate on behalf of clients, a spouse might be taken advantage of in mediation. Proponents of the practice respond by noting that mediators are trained to identify and address such power imbalances and that most parties will have lawyers who, while not present at the mediation, will nevertheless review the agreement before it is finalized.

There are no standard requirements for becoming a mediator. Many programs and states set their own qualifications, which generally include some educational credentials as well as specialized training.

## DOMESTIC VIOLENCE

---

Every family has conflict, but families differ in the ways they resolve arguments, disputes, and disagreements. For some families and couples, attempts to settle differences can escalate into domestic violence, typically perpetrated by one family member. Domestic violence is either the occurrence or a pattern of abusive and coercive behaviors, including physical, sexual, and psychological abuse, as well as economic coercion, between partners or family members. Domestic violence negatively influences child development and family life in numerous ways.

### HOW COMMON IS DOMESTIC VIOLENCE?

Approximately 9 million incidents of physical violence occur every year according to the U.S. Department of Justice. The majority of victims are women and children. In fact, 1 out of every 5 women reports having been assaulted by an intimate partner during her lifetime, versus 1 out of every 14 men. Women are also much more likely to be injured than men. Most victims of violence live in families, and the majority of incidents occur in victims' homes. Violence against women often co-occurs with child abuse, which is the leading cause of death in children under the age of 1 year. In fact, 3 to 10 million children are thought to be exposed to violence each year. Because many incidents of violence are not reported to authorities, it is believed that domestic violence is far more prevalent than rates reported by official studies.

### COSTS AND CONSEQUENCES OF DOMESTIC VIOLENCE

Each year it is estimated that domestic violence costs the United States \$67 billion. These costs to

victims, their families, and society include lost school and workdays, medical and mental health costs, property damages, and legal costs in the victim's services and criminal justice systems. In addition, there are costs when the offender is incarcerated, such as lost family wages and incalculable psychological damages to family relationships. Society also accrues significant losses in second-generation costs for future victims and offenders of violent crimes. There is increasing evidence that street criminal violence may be exacerbated by domestic violence as well.

### **DOMESTIC VIOLENCE AND ITS IMPACT ON FAMILIES**

Children are victims of violence even when they do not experience the abuse firsthand. For example, trauma symptoms appear to be more common in children who are exposed to violence, as are emotional and behavioral problems. Children who witness violence between family members frequently are victimized themselves, and child abuse can increase the likelihood that later in life a victim will abuse substances or have psychological difficulties. Although the majority of children who are abused or who have witnessed violence do not grow up to become abusive, children who are exposed to violence in the home are more likely to be abusive to their partners as adults and to be more aggressive than children not exposed to violence.

### **RISK FACTORS FOR DOMESTIC VIOLENCE**

Although there is no one particular cause to explain domestic violence, there are several important risk factors known to be associated with domestic violence. Men who witnessed parental violence are more violent in comparison with men who were not exposed to parental violence. Alcohol use is thought to be involved in one out of four incidents of violence against women, and when alcohol is present, injuries tend to be more severe. Violence between partners occurs most commonly between ages 18 and 30 and among families who are of low socioeconomic status. Although women are reported to initiate violence as often as men, they are not as severely violent, often engage in violence out of self-defense, and commit a much smaller proportion of intimate homicides than men. Social attitudes condoning violence against partners may also be related to domestic violence. Men who think they have the right to control and punish

their women partners tend to be more violent than men who do not share these beliefs. Violence is more common in households in which women have little work experience, depend on their male partners for financial resources, and have young children at home. Impulsivity, the inability to regulate emotions and behaviors, including aggression, is also a risk factor for the perpetration of domestic violence.

### **PREVENTION OF FAMILY VIOLENCE**

It is important for responses to domestic violence not only to include reporting and investigation efforts but also to engage in prevention and treatment. There is a variety of models for prevention that has been utilized, tending to focus on advocacy and education. Advocacy groups speak out about the costs of domestic violence and work to improve education as well as treatment, deterrence, and policy efforts. These groups include the National Coalition Against Domestic Violence and the National Organization for Victims Assistance. Many cities have local domestic violence projects or councils that can direct people to community research, legal aid, and resources (e.g., <http://www.growing.com/nonviolent/index.htm>). Public education campaigns on the dangers of abuse appear to be having an impact as more people consider the physical punishment of children to be harmful.

Educational efforts to teach elementary school children about domestic violence have suggested that these programs do appear to increase children's knowledge and protection skills. These programs are being mandated in school settings at increasing rates. High school and college programs to combat dating violence and sexual assault have been shown to alter beliefs and attitudes toward violent behavior. Training programs to educate legal and health care professionals about signs, warnings, and effects of domestic violence have been increasing as well, with some regulatory bodies requiring that their members complete courses as part of their licensure requirements.

### **TREATMENT OF FAMILY VIOLENCE**

There are a number of different treatments for domestic violence offenders, victims, and families. More comprehensive treatment approaches for batterers tend to include an intake process, typically at the first contact with the criminal justice system; a psychological assessment to assess future dangerousness and

develop treatment plans for mental illness, substance abuse, illiteracy or other needs; an orientation to the services planned and preparation for treatment; group therapy, often including anger management training, feminist education, and relationship skill building; and development of a follow-up plan that might include self-help groups or the staggering of group meetings. Mandatory court reviews in which offenders are scheduled to appear in court at a specified time to report their progress in treatment appear to improve compliance. There is growing evidence that treatments for batterers are effective in reducing future violence, but little evidence exists to suggest that any one mode of treatment is best across all types of batterers.

Treatment plans for survivors of abuse often begin with safety planning in which victims identify ways to get out of their homes quickly and safely with documents and items of importance already prepared, set up independent bank accounts and funds, and get to shelters. There are programs that provide cell phones programmed to call 911 in case of emergencies that can be helpful in securing protection rapidly. Shelters can provide protection for victims, assist with obtaining orders of protection and temporary welfare benefits, and help victims prepare for employment. Support groups can continue to provide ongoing support for abuse survivors as they make these transitions. Resources for victims can be obtained from the National Domestic Violence Hotline, 1-800-799-SAFE.

Children who have been exposed to domestic violence either as witnesses or victims can benefit from treatment as well. Most often treatment occurs in groups, either in shelters, safe homes, family court clinics, or community mental health facilities. The main focus of these groups is to help children label their feelings about the domestic violence, manage their anger, develop safety skills, secure social support, positively expand their self-concept, relinquish any responsibility they may feel for the domestic violence, increase their understanding of violence, and increase their skills in family communication. Studies suggest that the groups are most helpful in changing children's attitudes and reactions to anger and aiding them to let go of any responsibility for the domestic violence. The National Coalition Against Domestic Violence has a list of local resources to access for treatment for children.

Domestic violence is known to occur among the elderly and within gay, lesbian, or bisexual families. Resources are emerging to address intervention and

treatment issues relevant for these specific populations. Further information on abuse within gay, lesbian, or bisexual relationships can be found at the National Coalition of Anti-Violence Programs (<http://www.avp.org/ncavp.htm>), and information on elder abuse can be found at the National Center on Elder Abuse.

---

## DONOR INSEMINATION

---

Although an inadequate number of sperm contributes to approximately a third of all infertility, there had been little, if any, effective treatment for low sperm counts until the introduction of intracytoplasmic sperm injection in the late 1990s. As a result, the insemination of women with the sperm of anonymous donors, known as donor insemination (DI), has been widely practiced in this and other countries for almost half a century and has resulted in the births of hundreds of thousands of children. Although DI is not illegal anywhere in the United States, only a minority of states have laws guaranteeing the legality and legitimacy of DI. Often these laws are cursory or limited to specifying financial support obligations.

Sperm for DI is purchased from commercial sperm banks that screen and test prospective donors to minimize the risk of a sperm-transmitted infection and to reduce the chances of birth defects and genetic diseases. Because of concerns about human immunodeficiency virus (HIV) transmission, the tested sperm is frozen and quarantined for 6 months. Available information about the donor may range from the rudimentary physical characteristics of height, weight, eye color, hair color, and ethnicity to more detailed personal information such as education, occupation, interests, and hobbies. Although most sperm donors remain anonymous, the relative candor about infertility and the social and ethical questions raised by the introduction of advanced reproductive technologies, including egg donation, may well lead to changes in how DI is practiced in the future.

Although the majority of DI parents in the United States have not planned to tell their offspring how they were conceived, this issue remains highly controversial. Indeed, the disclosure decision is a serious and ongoing issue for DI parents that in many cases remains incompletely resolved or even undecided for many years. Psychologists, ethicists, and social workers have generally concluded that the use of donor sperm is ethically suspect and psychologically burdensome (or even harmful) if practiced in an atmosphere of secrecy, frequently referring to an adoption model that holds that children raised without knowledge of their genetic heritage have an incomplete sense of identity. Yet as very few studies have actually looked at the psychological and social functioning of families created through the use of a donor, current opinions concerning the well-being of the couple and their children cannot be reliably verified or refuted.

Parents who disclose to their children usually cite honesty or the principle that it is the child's right to know his or her biologic origins, while parents who do not plan to tell their children usually refer to a broad concept of privacy and confidentiality that suggests that they are wary of subjecting themselves and their children to public scrutiny and judgment. Regardless of their disclosure decision, most DI parents emphasize the importance of a spiritual and emotional connection with their children and often state a belief in the preeminence of the social parenting role, asserting that parental responsiveness, rather than biological relatedness, is responsible for fostering healthy social and emotional development. Although most DI parents come to a united disclosure decision that reflects and supports their beliefs in what is best for the child and the family unit, they continue to grapple with a broad range of issues and concerns that interacts in complex and subtle ways. Because the disclosure decision-making process involves an interaction between the psychological states of the parents and the social, cultural, and familial context within which this decision must be negotiated, DI parents will likely experience some degree of ongoing tension until cultural attitudes concerning the relative values and meanings of biological versus social fatherhood have further evolved.

## DOWN SYNDROME

---

Down syndrome is a chromosomal disorder that affects more than 350,000 U.S. citizens. Down syndrome ranks second to fragile X syndrome as the most frequent genetic cause of mental retardation. Although recognized by Edouard Seguin, a French physician and educator, as early as 1846, the first written description of the disorder was published in 1866 by John Langdon Down, a British physician from whom the syndrome derives its name. Jerome LeJeune, a French geneticist, and his colleagues established the genetic basis of Down syndrome in 1959.

Down syndrome is estimated to occur in 1 in 1,000 live births. The syndrome can be diagnosed prenatally through chromosomal analysis derived from either chorionic villus sampling or amniocentesis. Boys outnumber girls 1.3 to 1.0, and the disorder occurs in all racial and ethnic groups. Down syndrome is predominantly (95% of cases) due to trisomy of chromosome 21, involving a nondisjunction or failure of the two chromosomes of pair 21 to separate during meiosis prior to ovulation. Five percent of Down syndrome cases result from translocation in which part of chromosome 21 attaches to another chromosome or from mosaicism due to an error in cell division soon after conception. Increased maternal age is related to both nondisjunction and mosaicism. Down syndrome is incurable. The only current preventive strategy is termination of pregnancy, an option that appears to be increasingly utilized.

### PHYSICAL AND MEDICAL ASPECTS

Affected individuals share to varying degrees a set of physical characteristics. The most common features

of Down syndrome include a flattened face with a recessed bridge of the nose; upward slanting eyes with epicanthal folds; small ears and mouth; large tongue; short, broad hands and feet; stubby fingers; broad neck; stocky appearance; and loose skin folds at the nape of the neck. Down syndrome has a large number of associated medical problems including congenital gastrointestinal and cardiac abnormalities, eye problems, low muscle tone, and mild to moderate conductive hearing loss secondary to chronic middle ear infections. Infants and young children with Down syndrome are also at greater risk for acute leukemia than the general population.

High rates of hypothyroidism have also been linked to Down syndrome, using normative values from the general population. Lower thyroid functioning values for people with Down syndrome may reflect the susceptibility of adults with Down syndrome to experience “premature aging” and not thyroid disorder. Despite increased truncal obesity among people with Down syndrome, traditional risk factors for type II diabetes and cardiac disease, including hypertension, elevated lipids, and elevated glucose, are less than those reported by the general U.S. population.

### DEVELOPMENTAL ASPECTS

Children with Down syndrome are delayed in reaching early developmental milestones compared with typically developing children. In particular, gross motor development is attained at later ages in children with Down syndrome. Independent sitting is usually attained at 1 year of age, while independent walking is not achieved until 2 years of age. Early language development, especially language production, is also slow to progress.

People with Down syndrome typically function within the mild to moderate range of mental retardation on standardized intelligence tests, although some function in the borderline range and a few have severe mental retardation. The intellectual impairments of people with Down syndrome are generally attributed to a reduction in the size of the cortex and cerebellum relative to matched controls and an immaturity of brain development evident in neurons and their synaptic connections. People with Down syndrome show greater deficits in verbal linguistic skills relative to visuospatial skills. Delayed language acquisition may be related to the overall slowed intellectual development revealed in longitudinal studies of infants and

young children with Down syndrome. People with Down syndrome mosaicism typically have IQs that are 12 to 15 points higher than people with trisomy 21. Adaptive behavior is generally commensurate with intellectual ability.

Children with Down syndrome show more maladaptive behaviors than typically developing children, but have a lower risk for psychopathology than other children with intellectual disabilities. Commonly occurring problems include oppositional behavior, stubbornness, and inattention. Research suggests that maladaptive behaviors are most prevalent during adolescence. Adults with Down syndrome show fewer externalizing problems but may have increased internalizing problems such as depression. However, stubbornness often remains characteristic of people with Down syndrome across ages. Interestingly, 7% to 8% of people with Down syndrome may meet criteria for autism.

Children with Down syndrome express fewer positive social signals, show delayed responsiveness, and generate less predictable responses in mother-child interactions than typically developing children. Without clear and frequent signals from their children, mothers of children with Down syndrome may be more likely than mothers of typically developing children to adopt a controlling and directive interactive style during naturalistic play.

Parents of children with Down syndrome report experiencing less stress and feeling more rewarded by their children than do parents of children with other intellectual disabilities. Similarly, siblings of children with Down syndrome experience fewer adjustment problems than siblings of children with other intellectual disabilities. Reasons offered for this Down syndrome advantage include mothers being "older and wiser," parents having a better understanding of their child's condition than parents of children with less researched syndromes, greater sociability and cheerfulness of children with Down syndrome compared to children with other learning difficulties, greater public knowledge and recognition of Down syndrome, and the perceived youthfulness of people with Down syndrome due to their immature-appearing physical features and "babyfaceness."

## AGING

People with Down syndrome have a greater early mortality rate as compared to people of similar ages from the general population and to people with comparable

levels of mental retardation due to other causes. Congenital heart disease contributes greatly to the increased early mortality rate, but so do respiratory tract infections, leukemia, and congenital gastrointestinal tract anomalies. Although improved medical management of respiratory infection and congenital heart disease in young children with Down syndrome has significantly increased the life expectancy, people with Down syndrome have lower life expectancies than the general population. The average life expectancy for people with Down syndrome is approximately 55 years.

Interestingly, genes linked to the development of dementia of the Alzheimer type are also located on chromosome 21. The triplication of chromosome 21 may result in an increased risk for developing Alzheimer's dementia. Seventy-five percent of adults with Down syndrome over 60 years of age show neurological abnormalities and behavioral signs of Alzheimer's disease. These symptoms frequently include seizures, personality change, focal neurological signs, apathy, and loss of conversational skills. The allele for the gene apolipoprotein E (ApoE) may affect the risk for Alzheimer's dementia. Down syndrome people with the ApoE e4 allele have been found to have a heightened risk for developing Alzheimer's type dementia, whereas the ApoE e2 allele may serve as a preventive factor. Recent studies suggest that Aricept (donepezil hydrochloride), a drug targeting deficiencies in cholinergic neurotransmission, may improve cognitive functioning, and specifically language performance, in nondemented people with Down syndrome and slow deterioration in cognitive functioning and adaptive behavior among people with Down syndrome and Alzheimer's type dementia.

High rates of epilepsy (8% to 13%) have been noted among people with Down syndrome. It is estimated that 40% of cases begin before 1 year of age and another 40% appear in the second to third decades of life. Early-onset epilepsy often involves infantile spasms and tonic-clonic seizures with myoclonus, whereas epilepsy in adults typically involves partial simple or complex seizures and may be associated with Alzheimer's disease. Prevalence of epilepsy is thought to increase with age and is estimated to be as high as 46% among adults with Down syndrome who are over 50 years old.

## INTERVENTIONS AND COMMUNITY LIVING

Infants and young children with Down syndrome typically receive early intervention designed to help

them reach their fullest developmental potential. Although it remains unclear whether early interventions lead to increased intelligence, improvements in independence, community functioning, quality of life, language, and motor skills have been shown. Reading, writing, and arithmetic are commonly combined with daily living and social skill training for school-aged children and adolescents with Down syndrome. Successful transitions from school to work and family to community living hinge on obtaining the necessary skills for self-care, maintaining strong interpersonal relationships, and developing appropriate work habits and skills.

Lifelong programs aimed at monitoring nutrition, preventing obesity, and maintaining bone density are associated with improved health outcomes. These programs commonly include food selection, behavioral interventions, physical activities, and social activities. Programs targeting exercise and health education have been found to increase positive attitudes toward exercise, increase life satisfaction, and slightly reduce risk for depression. Cognitive and affective (e.g., too boring and too difficult) and pragmatic obstacles (e.g., lack of transportation and high costs) often hinder people with Down syndrome from engaging in fitness programs.

Adults with Down syndrome typically live in family homes, community group homes, or in independent or semi-independent living situations. Many adults with Down syndrome maintain paid employment, often with some support (e.g., supervision, training, or transportation). Increased longevity requires parents to adopt a long-term perspective in planning for their child with Down syndrome.

---

## DRUG ABUSE

---

The majority of people *use* drugs. Caffeinated soft drinks, aspirin, or prescription medications are legal, and they are consumed widely by children and adults. In addition, many people drink alcohol or smoke cigarettes despite the fact that these products are legal only for adults. Finally, some people use drugs that are illegal for everyone, such as cocaine or methamphetamine. Unfortunately, many people who use drugs also abuse them.

### DRUG ABUSE DEFINED

In drug abuse, the social and health-related costs are greater than the benefits. By this definition, much drug use is abusive.

Social costs of drug abuse include the deterioration of relations with other persons such as failure to carry out responsibilities, arguments, abuse, lost income, and time spent in jail or drug treatment.

Health-related costs of drug use include addiction, a physiological or psychological need for the drug. Other health-related costs include diminished physiological capacity, illness, and death. In 1998, 19,277 deaths were caused by the use of illegal drugs.

Social benefits of drug use include enhanced capacity in relations with others, as with psychotropic drugs that reduce symptoms of mental illness. Health benefits of drugs include regulation of bodily functions, as with thyroid hormone that controls metabolism. Health benefits of drugs also include management of disease agents such as fungi, bacteria, or viruses. Studies show

that for every passing year, life expectancy increases 3 months. Most of this increase is due to the effectiveness of drugs in treating disease.

## THE DRUG INDUSTRY

Worldwide, the pharmaceutical industry produces more than 400,000 products. Together with the alcohol and tobacco industries, the worldwide drug business is worth perhaps a trillion dollars per year. Currently, world organizations are complaining that health is being degraded by widespread marketing of cigarettes to children, and the cost of prescription medicines is too high for poor nations to treat pandemics such as acquired immunodeficiency syndrome (AIDS).

## REGULATION OF DRUG USE

Until the 20th century, laws did not regulate production, distribution, or consumption of alcohol, tobacco, or other drugs, except for a few laws against public drunkenness. Today, production, marketing, distribution, and use of most drugs are regulated. Alcohol and tobacco products are taxed, and heavy criminal penalties are imposed on illegal drugs.

## RATES OF DRUG USE AND ABUSE

Most drug abuse has its roots in adolescent experimentation with alcohol, tobacco, and other drugs. In the United States, the rates of use of alcohol, tobacco, and other drugs have been tracked by the Monitoring the Future project. In 2003, 48% of seniors in high school reported that they drank alcohol in the preceding month. In 1975, the rate was 68%. The rate for marijuana use was 21% in 2003, and in 1975 it was 27%. In 2003, the rate for smoking cigarettes by adolescents was 24%, and in 1975 it was 37%.

In 1998, there were 3.3 million hard-core users of heroin and cocaine in the United States, and as many as 7 million persons may need drug treatment. Among adults, 25% smoke cigarettes, and the rates for men and women are about equal. Smoking peaked in the 1940s, when well over half of the adult male population smoked. Currently, approximately half of persons 12 years of age or older drink alcohol. The rate for men is 57%, and the rate for women is 45%. Almost 7% of the population 12 or older are heavy drinkers who have five or more drinks 5 or more days per month.

From 1992 to 1998, deaths from the abuse of illegal drugs decreased from 24,000 to 19,000. In 2000,

more than 2,500 deaths occurred from alcohol abuse and more than 13,000 persons were killed in alcohol-related traffic crashes. By far the largest killer is tobacco. In 1999, tobacco smoking killed more than 440,000 persons.

## MONETARY COSTS OF DRUG ABUSE

In the United States from 1988 to 2000, the cost of buying illegal drugs decreased from \$116 billion to \$63 billion. However, the indirect costs of drug abuse are much higher. In 2000, they were \$167 billion per year. The indirect costs include health care (drug treatment, violent crime due to drug abuse, treatment of related illnesses including drug-exposed infants, human immunodeficiency virus [HIV]/AIDS, and tuberculosis), lost productivity (premature death, illness, hospitalization, and incarceration), and other costs (police protection, spending to reduce supply, and legal fees). The indirect costs of alcohol abuse are one and one-half times higher than those for illegal drug abuse, and the costs of tobacco abuse are as high as those for alcohol abuse. Including the costs of buying these drugs, costs total perhaps a trillion dollars per year, more than \$3,500 per citizen, or about half of the federal budget.

## ABUSE OF PRESCRIPTION DRUGS

Abuse of prescription drugs has tripled in the past 2 years, and currently this form of abuse has outstripped the use of all illegal drugs except marijuana. In abuse of prescription drugs, orders are placed through a Web site outside of the United States where regulations are less stringent, or the drugs are obtained via “doctor shopping,” a process in which one who is not ill finds a physician who will write a prescription for a drug that is not indicated by the person’s medical condition.

## MORAL AND ATTITUDINAL ISSUES

Surveys show that drug use patterns are segmented into two polar opposite groups: abstainers/occasional users and heavy/problem users. This pattern has been part of the creation of a moral climate of indignation and lack of sympathy for drug abusers. Following this split, laws and other drug abuse policies have emphasized punishment for drug abuse, and they have deemphasized treatment.

This process can be seen readily in reaction to tobacco smoking. Smoking has been banned in public

places because of the health risks of second-hand smoke (and because of the socially unacceptable odor associated with it). Increasingly, tobacco smokers are treated as outcasts. In addition, due to successful lawsuits against tobacco companies for marketing an unsafe product, state governments in the United States have received large monetary settlements. These settlements are intended to mitigate the costs created by smoking, but the states have put the funds to a variety of uses, including the balancing of state budgets. The greatest growth of tobacco sales has been in poor countries where the laws are not as strict.

### **POLICIES ON ILLEGAL DRUGS**

In an effort to address the problem of drug abuse, the War on Drugs was begun in the 1980s. It represented an attempt to limit the supply of illegal drugs in the United States that were imported or produced domestically. It involved the hiring of more police officers and stricter penalties for drug offenses. In 2000, the cost of these programs was \$5.5 billion. In addition, the War on Drugs attempted to curtail the demand for drugs through drug education and by sending many drug users to jail. Current estimates show that about 30% of inmates are serving time for drug violations. The War on Drugs appears to have decreased use and abuse slightly and to have shifted the substances of choice from imported drugs such as cocaine to domestically produced drugs such as methamphetamine.

### **DRUG EDUCATION**

Since the 1980s, drug education has focused on youth. Beginning in elementary school, programs such as the 17-week Drug Abuse Resistance Education (D.A.R.E.) have sought to delay the onset of experimentation with alcohol, tobacco, and other drugs. The tenet is that the later youth begin to experiment with drugs, the less abuse will occur. D.A.R.E. uses uniformed police officers in the classroom to deliver a message that use of alcohol, tobacco, and other drugs has negative consequences. Officers also teach youth how to resist peer pressure to use these substances. Evaluations of D.A.R.E. has shown it to have some short-term benefits in raising social skills, making attitudes toward drug use more negative, and building positive attitudes toward police. No long-term effects have been shown.

### **DRUG TREATMENT STRATEGIES**

Seven million people in the United States need drug treatment, and 1 million people receive it each year at a cost of over \$6,000 dollars per case. Some individuals participate in one program after another. Alcoholics Anonymous (AA) is the most famous program for the treatment of alcohol abuse. AA uses peer pressure and support as the main mechanisms of treatment. Treatment strategies for other types of drug addiction have borrowed principles from AA. Often, treatment takes place in a residential facility, and counselors use the mechanism of resocialization. Typically, treatment lasts several months, and the self-concept of the abuser is isolated and torn down so that it can be reconstructed as a responsible adult self.

Another method of drug treatment is for an agency to administer a less addictive drug to the abuser, such as methadone treatment for heroin users. The goal of this type of treatment is to gradually decrease the dose until the person no longer is addicted. Unfortunately, this process of weaning may not be effective, and some of the drugs used in the treatment of drug abuse are themselves addictive. Thus, programs of drug treatment can become maintenance programs for drug addiction rather than cures. Advantages of maintenance programs are that they remove addicts from the illegal drug market, and they may have indirect health benefits such as addicts no longer sharing contaminated needles.

### **SUCCESS OF TREATMENT**

Results from Florida may be typical of treatment success rates. A study of nine medium-intensity drug treatment programs at 26 facilities was begun in 1991 for drug abusers who had failed in an outpatient setting. From then until 1999, almost 19,000 persons had been admitted. Fifty-three percent completed the 6-month programs. Of these persons, 54% were not recommitted to prison or supervision after 2 or more years. A parallel study that analyzed data from almost 4,000 offenders in six treatment programs of 9 to 18 months in length for extreme substance abusers who had several previous treatment failures showed that 30% of participants completed the program, and of these, 56% were not recommitted to prison or supervision after 2 or more years.

Since surveys show that 70% of smokers would like to quit, smoking cessation for the 48 million tobacco

smokers in the United States has become big business. Drug companies (including ones that also sell tobacco products) market products that deliver nicotine in chewing gum or through patches worn on the skin. One company even sells a pill that aims to decrease nicotine withdrawal, the intense cravings that follow a decrease in the dose of the drug. Research from over 50 studies using nicotine replacement or the pill shows that about one fourth of the research subjects receiving the drug were able to quit for 6 months or more.

## THE FUTURE

A problem in trying to control the supply of illegal drugs is that poor farmers who produce the raw materials can make more money by producing illegal crops than they can by raising and selling legal crops. In response, government programs have subsidized legal crops and corporations have encouraged farming families to sew clothing or to make high-end buttons from locally produced nut shells.

Complicating the problem of illegal drug production of opium poppies in Afghanistan and coca in Colombia is the fact that the processors and exporters of the illegal drugs have armed themselves and taken over political control of drug-producing regions.

In the United States, domestic production of illegal drugs has presented additional problems. Marijuana can be grown almost anywhere, including indoors. In addition, methamphetamine can be made from commonly available chemicals in small, inexpensive, mobile laboratories. Instructions on the cultivation of marijuana and the manufacture of methamphetamine can be found easily on the Internet. In addition, many people can make more money by selling illegal drugs than they can by doing legitimate work.

A movement toward the legalization of marijuana has been underway in the United States for decades. Current laws in most states in the United States have reduced penalties for possessing small amounts of marijuana. Recently, several court decisions have made the use of marijuana legal for medical reasons such as appetite regeneration for chemotherapy patients. While the Prohibition Laws of the 1930s showed that the government could not curtail illegal behavior that was popular among adults, it is not known how legalizing a previously illegal drug, like marijuana, could affect abuse.

## DRUNK DRIVING

---

Drunken driving motor vehicle crashes remain a leading cause of death and injury to people in the United States. In fact, motor vehicle crashes are the leading cause of death among people 16 to 24 years of age, and a substantial percentage are alcohol-related

crashes. There were 17,419 alcohol-related automobile deaths in 2002, representing one alcohol-related motor vehicle death every 30 minutes. Part of the reason for these statistics is that arrests have been made in only 1% of the 120 million self-reported episodes of driving under the influence of alcohol or drugs (DUI). Younger people are more likely than older people to be involved in alcohol-related crashes. In fact, one fourth of the motor vehicle deaths among 15- to 20-year-olds were alcohol related. Furthermore, approximately 66% of children under 15 who died in alcohol-related motor vehicle deaths between 1985 and 1996 were passengers of an impaired driver. In addition to the costs of drunken driving measured in human lives, the National Highway Traffic Safety Administration reported that alcohol-related crashes in 2000 were associated with more than \$51 billion in total costs.

A major determinant of alcohol-related motor vehicle crashes is the age at which a person started drinking. Researchers have shown that people who began drinking alcohol at an earlier age were more likely to report driving after drinking too much and being in a motor vehicle crash because of their drinking even after adjusting for current/ever diagnosis of alcohol dependence and number of years the person had been drinking. Education and interventions geared toward delaying alcohol use among young people may be an effective means of reducing drunken driving crashes and deaths. There are additional effective measures to reduce drunken driving in the United States. Among these preventative measures are license suspension of drivers arrested for DUI, lowering the legal blood alcohol content (BAC) limit to 0.08% in all states, zero tolerance for drivers less than 21 years of age, and sobriety checkpoints. There are also policy level interventions, including increasing federal and state alcohol excise taxes and treatment approaches such as multifaceted community alcohol control and DUI prevention programs. Research has also shown that people who participate in a driver intervention program after a DUI arrest were less likely to be charged again with an alcohol-related driving offense or to be the driver in an alcohol-related crash than a similar group who were jailed.

Consistent law enforcement of DUI laws, national reduction of the permissible BAC to 0.08%, and zero tolerance for underage drinkers appear to be the most effective means. For long-term, effective behavioral change, it is also necessary to change social norms of

drunken driving so that there is zero social tolerance of drunken driving.

## DUAL-EARNER HOUSEHOLDS

---

One of the most significant transformations over the past 50 years has been the growing proportion of women earning an income from paid employment after marriage and childbirth. In the 1950s, more than 70% of American families maintained a “traditional” employment structure comprising a male breadwinner and an economically inactive wife. By the 1990s, this arrangement gave way to the norm in couple families of both

parents pursuing employment outside the home, often for long hours. Notwithstanding a general decline in the proportion of “nuclear” families, and increased household diversity associated with delayed family formation and single parenthood, the majority of children in Western countries grow up today with two working parents.

Dual-earner household proliferation stems from both cultural change and economic restructuring. Cultural influences include the women’s liberation movement, advances in contraception (contributing to smaller families and control over the timing and spacing of maternity leave), rising consumer expectations, and a common perception that paid work confers higher status and a stronger source of identity than homemaking and motherhood. Economic restructuring charts the decline of heavy industry and manufacturing and with it a permanent loss of skilled blue-collar jobs previously paying large numbers of men a family wage. New jobs that have opened up in the service sector generally call for skills that are socially constructed as “feminine,” paying low wages for nonstandard working hours. The combined effect of women’s increased employment opportunities, reduced male earnings, and widespread job instability is that most couples believe they need both partners to work if living standards are to be maintained. This is especially true where the cost of living (notably house prices relative to incomes) is rising.

The normalization of a dual-earner structure is remarkably consistent throughout the Western world. In a survey of Australia, Canada, Great Britain, and the United States, for instance, O’Connor and colleagues found 60% to 65% of women in couples with children in dual-earner structures. Yet this population of dual-earner households is not homogeneous. The dual-earner strategy has a far longer history in African-American than in White middle-class families, for example. Similarly, cross-national variation exists in the working hours, occupational status, and child care arrangements of dual-earning parents. Used too broadly, the term can obscure important differences between partners who both work full time and those who combine full-time (male) with part-time (female) employment. Moreover, it is usual in the literature to differentiate between couples working for an hourly wage and those where partners are equally committed to a rewarding career. The former are sometimes referred to as two-job households and the latter as dual-career households. Labor force survey data for the United States and United Kingdom

indicate that only a minority (10% to 20%) of dual-earner households represent the dual-career type most likely to feature gender role equality. A similar-sized minority represents two-job households with both parents working full time, but in less skilled, sometimes poorly paid jobs.

It is important not to assume that the dual-earner household is synonymous with a dual-career arrangement. Indeed, with the possible exception of the Nordic countries, notably Sweden, where state policy supports an egalitarian model of work life balance, it is questionable whether a truly symmetrical structure of shared earning and coparenting exists anywhere in practice. Rosemary Crompton positions the idealized dual-earner/dual-career arrangement at the extreme end of a continuum that begins with the traditional male breadwinner/female career model. She argues that in situations where dual-earner households constitute one and one-half income couples, as is typical in the United Kingdom, this represents a “modified breadwinner” arrangement perpetuating traditional gender roles. Further along the continuum are dual-earner structures based on more equal earning arrangements, where care is provided for dependents either by the state (as in ex-state-socialist countries) or the market (as is typical in the United States and Canada) and parenting is still generally asymmetric. Notwithstanding emphasis on market provision, child care falls extensively to mothers and grandmothers in modified breadwinner arrangements.

Academic interest in the dual-earner household takes three forms. The first concerns the relative importance of the state, the market, and the family in stimulating proliferation of this household type. On the one hand, the reason why women in the United States tend to work full time after maternity leave might be explained by a welfare regime emphasizing self-reliance through private market provision. Scott and Dunscombe point out that health care insurance in the United States is costly and generally only available to full-time workers. On the other hand, the local transmission of gender roles and parenting standards might be said to exert a powerful cultural influence on a mother’s decision to reduce her hours or drop out of paid employment. U.K. mothers who take up full time employment can experience castigation for not “being there” for their children. Whether household earning behavior is influenced by fiscal, economic, or socio-cultural factors, there exists distinct variation in child care practices by race, class, occupation, and region.

A second strand asks whether a shift away from gender role specialization to that of shared earning and multiple, often conflicting, roles fundamentally alters the balance of power in household decision making. Within this strand, particular attention has been paid to financial arrangements. Dual earning is shown to improve household income at all levels of earnings distribution. Data from the U.K. Equal Opportunities Commission indicate that 40% of women earn the same or more than their partner, and in the U.S., Levy and Michel observe that by the early 1990s one third of all the income of families with working wives came from their earnings. This leads to the question whether women who contribute an income from paid employment have greater bargaining power in key household decisions. Are they better able to resist being the “trailing spouse” in situations of migration for male spouse promotion? The research suggests that women who work full time in relatively high-status careers are better able to resist migration that is damaging to their employment, but the relationship between earnings and influence is not axiomatic. One alternative to the wholly moving household is dual-location living. This is used as a temporary or permanent strategy so that couples can live together some of the time while maintaining careers in different locations.

A third strand of research focuses on the effects that the rise of dual-earner households has on children, marital relations, and family life. While dual-earner households are “work rich,” they are also “time poor.” Families have gained the income women earn from paid employment but lost the time that they are available for unpaid caring and domestic services in the home. At the same time, very-low-income families are unable to improve their situation by becoming dual earners because of the cost (in cash and support terms) of child care. Understandably, there is concern in dual-earner households that less time is given over to the care of children and elderly relatives. Some researchers argue that maternal employment is damaging to children’s emotional and behavioral development and consequently view the rise of dual-earner households as potentially harmful. Nevertheless, the popular image of “latch-key kids” and the erosion of family obligations can be exaggerated. Undermining notions of a growing care deficit are studies suggesting that parents spend more quality time with their children today, largely as a result of labor-saving technologies in the home.

Much is made of the need for dual-earner families to buy time through the purchase of goods and services. Yet census data show that private child care was purchased by just 55% of U.S. and 35% of British working families in 2000/2001. A significant proportion of dual-earner households manage child care informally, either by off-shifting spouse employment or relying on an army of unpaid “granny nannies.” The continuing importance of family care in dual-earner families reflects not only the influence of parenting norms but also financial constraint. Affluent dual-earner households are in a position to purchase support services such as high-quality child care and domestic help. Yet their solutions to coordination problems rely on low-wage child care providers and cleaners for whom private child care is prohibitively expensive, even where they themselves form part of a dual earner or multijob household.

In fact, there is remarkably little difference in overall rates of market provisioning between single-earner and dual-earner families. This is because much social reproduction is performed as a “labor of love.” Women no longer choose between work *or* family but instead manage the conflicting responsibilities of work *and* family. Mothers are consequently hardest hit by the time squeeze, widely observed to experience role strain carrying a dual burden of paid employment and unpaid domestic and caring work. Symptoms of physical, emotional, and marital stress are widely reported. Consequently, much dual-earner household scholarship is about attaining greater balance to life through greater recognition of the value of women’s social reproduction work.

## DYING

---

Although all people die, everyone's dying process is unique. Many people think of dying as merely a physical process, but dying is an experience of the whole person and is influenced by a combination of physical, psychological, social, cultural, and spiritual factors. There are as many ways to die as there are to live, so in order to better understand how people who are dying experience the process, researchers and clinicians have developed different models or theories that attempt to account for how people cope with dying.

### THEORIES/MODELS OF DYING

#### Elisabeth Kübler-Ross's Stage Theory of Dying

The general public is most likely to be familiar with Kübler-Ross's theory of dying. In 1969, she published a book titled *On Death and Dying*, which was based on interviews collected from 200 dying patients. In the book, Kübler-Ross discerned five stages that dying people experience. The five stages, which reflect different reactions to dying, are denial, anger, bargaining, depression, and acceptance.

Denial is the "No, not me!" stage where the person is in shock or denial and cannot believe that they are going to die. Denial is self-protective and gives the person time to adjust psychologically to the news that he or she is going to die. Anger is the "Why me?" stage and may involve, in addition to anger, resentment, rage, and envy at God, doctors, nurses, family members, or anyone who is not dying. Bargaining is the "Yes me, but. . ." stage and often involves bargaining with God and attempts to postpone the inevitable ("Yes, I am going to die, but if only I could live long enough to see my child graduate," etc.). Depression involves mourning for current and past losses (reactive depression) and anticipated losses (preparatory depression and grief). Finally, acceptance emerges. Acceptance is not a happy stage, but rather is characterized by an absence of feeling, a giving up or resignation, or even a sense of peace

that occurs as the person realizes that death is imminent and cannot be avoided. Although not a stage of dying, hope is an important aspect of all five stages and can persist throughout all of them.

In spite of its general popularity, Kübler-Ross's theory has been criticized on several points. Two of those criticisms are that there is really no evidence that stages are present in coping with death, and there is also no clear evidence that people who are dying actually move through the five stages that Kübler-Ross identified. Many people have also taken the stages as a prescription that dying persons must experience, rather than acknowledging that dying persons react and cope in different ways and may not want to or need to go through the five stages of dying.

Regardless of these criticisms and others, Kübler-Ross taught us important lessons about the dying process. First, she shed light on the much avoided topic of dying and was the catalyst for continued discussion and research on the issue. She also brought to light the challenges of dying and taught that dying people are still living and have needs and desires that need to be understood and supported throughout their dying process.

#### Task-Based Models of Dying

Task-based models of dying differ from Kübler-Ross's stage theory in several ways. First, they focus less exclusively on the ways that people cope emotionally with dying and instead take a more holistic approach by considering the ways that dying persons actively cope with a variety of potential challenges across numerous dimensions of life. They also do not explicitly or implicitly imply an order or sequence, which offers a more flexible, less prescriptive perspective from which to view the challenges of both dying patients and their loved ones.

#### Charles A. Corr's Task-Based Model of Dying

Charles Corr has presented one popular task-based model of dying that describes four areas of task work (physical, psychological, social, and spiritual) and basic types of tasks related to coping with dying in each of those areas. Corr identified two primary types of physical task work of dying persons: satisfying bodily needs and minimizing physical symptoms of distress in a manner personally acceptable to and consistent

with the dying person's values. Psychological task work includes striving to maximize psychological security, autonomy, and richness in living one's life until death. Social task work includes sustaining and enhancing both significant personal attachments and select societal interactions. Finally, spiritual task work involves the identification, development, and reaffirmation of one's meaning in life, connection to the source of spiritual energy, and ultimately, one's hope.

Corr's model is consistent with the premise presented at the beginning of this entry—that how a person experiences dying depends on a combination of physical, psychological, social, spiritual, and cultural factors.

### PHYSICAL FACTORS IN DYING

The specific physical challenges associated with one's dying process depend on the characteristics of the disease from which one is dying. For example, presence and amount of pain, effects of medical treatment, medications used to treat the illness, rate of physical deterioration, and amount of loss of control all relate to the rate and ways in which one will experience the dying process.

Dying trajectory, a term coined by Barney G. Glaser and Anselm L. Strauss, describes the overall pattern of an individual's dying process with respect to shape and duration. Shape refers to the general course of the dying process (i.e., predictable/unpredictable and expected/unexpected), and duration refers to the length of time between onset of dying and the actual time of death. Four dying trajectories have been described and are presented below:

*Downward slant:* represented by a rapid decline toward death with little or no chronic phase of an illness

*Gradual slant:* represented by a long slow decline, perhaps lasting for years

*Peaks and valleys:* represented by alternating periods of decline/relapse and remission

*Descending plateaus:* represented by long, slow periods of decline followed by remission or restabilization

These general courses of physical decline influence the social and emotional response of the dying person and their loved ones. For example, although many people say their ideal death would be to die from a sudden heart attack, that type of death is shocking

for the survivors and gives no time to prepare or say goodbye. On the other hand, prolonged dying processes can be financially and emotionally exhausting for everyone involved.

When a person is dying from a terminal illness and death is very near, within hours or days, the phase of active dying occurs. Physical changes that signal the phase of active dying include changes in breathing, incontinence (loss of bowel and bladder control), sweating, nausea and/or vomiting, decrease in appetite and thirst, loss of ability to swallow, change in skin color, increased periods of sleep, decreased consciousness, disorientation or confusion, restlessness or agitation, social withdrawal, and decreased ability to communicate.

### PSYCHOLOGICAL/EMOTIONAL FACTORS IN DYING

Dying threatens one's emotional equilibrium, and intense, grief-related emotions can feel overwhelming. Fear, anxiety, sadness, depression, anger, hostility, helplessness, powerlessness, depression, guilt, and shame are some of the most common emotional reactions experienced by people who are dying. All of these emotions are normal, serve a purpose, and need to be allowed expression.

Denial is a common coping strategy that helps people to find internal strength and external support before confronting the implications of their diagnosis, prognosis, and impending death. Denial should not be judged as good or bad, but rather should be evaluated in terms of its helpfulness or interference in facilitating coping.

Anger and hostility are natural responses to having everything in one's life threatened and ultimately taken away. Common sources of anger are a sense of failure, poor communication, abandonment, pain, and the turn of events that will result in one's death. Anger can also be a "cover" for more vulnerable emotions such as fear, anxiety, hurt, helplessness, and disappointment.

Fear and anxiety can feel incapacitating to people who are dying. Some of the most common fears associated with the dying process include pain, abandonment/loneliness, indignity, the unknown, loss of control, separation from loved ones, meaninglessness, being a burden to others, the process of dying, and the afterlife. All of these fears can lead to both physical (e.g., tension and restlessness) and psychological (e.g., worry, apprehension) symptoms of anxiety.

Depression is a natural response to the perception of imminent loss among the dying, and while mild

depression is natural and adaptive, severe depression, which is rarer among the dying, can rob them of their remaining quality of life. Depression is often difficult to distinguish from preparatory grief, the normal dying process, and reaction to poorly controlled physical symptoms.

Helplessness and powerlessness are related to perceived loss of control. Although the natural dying process results in increased dependency, dying persons need to be offered control to the extent to which it is both desirable and possible. There are always possibilities for control of at least some facets of life.

Finally, many consequences of illness and dying can produce guilt and shame. People who are dying may experience patient responsibility guilt, for the deterioration of their health, moral guilt for having done something wrong to have caused their impending death, guilt for not responding to treatment, or guilt for causing their loved ones to suffer.

## SOCIAL FACTORS IN DYING

People do not live or die in a social vacuum, but rather, in the context of family, friends, and community. Dying people want to maintain relationships with special people in their lives for as long as their physical and emotional energy allows. Additionally, they often need to complete unfinished business with loved ones, which may include saying goodbye, reconciling differences, gaining closure in relationships, or expressing regrets, forgiveness, and appreciation.

Communication facilitates the accomplishment of those tasks as well as the continuation of bonds with loved ones during the dying process. Yet, one of the greatest challenges facing many dying persons and their loved ones is finding a way to talk about important issues, including the dying person's diagnosis and prognosis, as well as feelings, thoughts, and questions related to life plans, dying, and death.

## Awareness Contexts and Communication

Glaser and Strauss studied family interactions that occurred when a member was diagnosed with a life-threatening illness. They discerned four levels of awareness of dying that shape the communication styles within families and that can shift any time during the course of a life-threatening illness as the course of the disease progresses and medical interventions change.

The closed awareness context is characterized by the dying person not being aware that he or she is dying, but others being privy to that knowledge. Accordingly, there is little if any communication about the person's illness or impending death.

The suspected awareness context occurs when the dying person suspects that he or she is dying, but no one confirms those suspicions. However, the dying person senses a shared secrecy and experiences the emotions and strained communications of others, and so the suspicions are confirmed indirectly. Because others are not willing or able to communicate with the dying person, he or she is left to cope with the emotional process of dying alone, in social isolation.

In the mutual pretense context, both the dying person and others know that death is imminent, but none speak directly of the issue. Everyone knows that the person is dying, but they may all act as if everything is normal and the person will recover up until the moment of death because they cannot face the situation directly. Again, the dying person is left to cope with dying alone, without the benefit of a shared experience and social support.

Finally, in an open awareness context, both the dying person and others acknowledge and discuss the impending death. Shared social support is maximized when this awareness context dominates. An open awareness context does not necessarily assure an easier acceptance of the inevitability of death, but may provide for optimal support.

Many people value an open context of awareness and communication early in the dying person's disease process because they feel it may facilitate optimal completion of relational tasks. This is important, because as a dying person's life energy wanes, a gradual process of withdrawal typically occurs. There is a lack of interest in surroundings, current events, and, finally, a withdrawal from even close loved ones. The dying person becomes more inner directed and silence becomes more meaningful. However, social withdrawal and a turning inward should not be mistaken for a cessation of the need for love and connection. For most dying persons, valued relationships are vital until the time of death.

## RELIGIOUS AND SPIRITUAL FACTORS IN DYING

For most dying persons, spirituality and/or religion provide support in coping with dying. Spirituality

involves a sense of connection to the universe and a higher power and the way that one makes sense out of life and death. Religion is an organized system of worship that gives structure to one's spiritual beliefs and relationship with a higher power. One or both may serve people while they cope with their dying process.

In addition to finding meaning in life, suffering, loss, and death, and feeling connected to a universal source of energy, a dying person's spirituality and religion also provide support in learning to give and receive selfless love and in finding hope. There is potential for significant growth and development at this time of a person's life, but there is also the possibility for despondency if the person who is dying feels that they have not lived a meaningful life and will not leave behind a positive legacy.

Maintaining hope is a universal challenge supported through one's spirituality and religion. Long after the hope for a cure is relinquished, people who are dying can remain hopeful. They can hope for peace, comfort, dignity, a good day, minimized loss of control, that loved ones will be able to manage without them, and living long enough to experience a cherished life event such as a family birth, marriage, or graduation.

Making the transition from living to dying is another task supported by a dying person's spirituality and/or religion. Religion provides an answer to the question of what happens after death, and having an acceptable answer can make the challenges of dying more tolerable.

The means by which dying people embrace their spirituality and/or religion and seek solace during the dying process vary across individuals, cultures, and religions. Some common forms of spiritual and religious connection include praying, attending religious services, reading spiritual or religious texts, connecting to nature, meditating, listening to spiritual music, focusing on spiritual objects (e.g., rosary, cross, altar), burning candles or incense, and being purified or anointed.

## HOSPICE

The care that dying patients receive at the end of life should support them in completing the multifaceted tasks of dying. Traditional medicine is based on the Western medical model and focuses almost exclusively on curing diseases and providing medical treatments for one's physical body. It provides little or no support for the psychological, social, and spiritual dimensions of people who are dying. Hospice, on the

other hand, offers holistic end-of-life care to dying persons and their families. The goal of hospice is to offer comfort, state-of-the-art pain control, symptom management, and loving care in an effort to reduce suffering so that dying persons can continue to live as fully as possible until their death.

Hospice is not institutionalized care but, rather, a community-based, comprehensive concept of care that is designed to address the physical, psychological, social, and spiritual needs of dying persons and their families. Care and support are provided during the dying process and may continue during the family's period of bereavement. Hospice care is provided 24 hours a day, 7 days a week, by an interdisciplinary team of professionals consisting of physicians, pharmacists, nurses, social workers, home health aides, physical and occupational therapists, and chaplains, as well as hospice volunteers, family, and friends.

Although most hospice care in the United States is provided in the dying person's home, the hospice philosophy and program of care can be provided for dying persons in any setting (e.g., hospital, nursing home, hospice residential facility) and in any part of the world. Although hospice care exists in some form on every continent of the world and in more than 100 countries, it is still greatly underutilized in many developing nations, as well as among minorities in the United States, who currently account for only about 5% to 8% of hospice patients. American minorities, who are more likely to have experienced neglect and inequities in health care than their White counterparts, are more likely to view hospice as medical abandonment versus compassionate care for the dying.

## CULTURAL FACTORS IN DYING

In general, people from Western cultures are more death denying and death avoiding than either people from Eastern cultures or ethnic groups within the United States. However, although White Americans are generally death avoidant, they place a high value on patient autonomy, open communication between physician and patient, and the dying individual as primary decision maker during the dying process. These values are consistent with Western medicine and White culture, but there are many people in the United States and abroad for whom these values do not pertain. Ethnic and religious minorities are considered to be more death affirming, but patient autonomy and open communication may not be highly valued.

Cultural and ethnic differences in dying must be considered because dying is a sociocultural event and one's identity as a member of a culture influences the dying process and its impact on the individual and the family. Even when people have not maintained close connections to their culture's traditions, they often identify very strongly with their cultural backgrounds during a life crisis such as dying.

### Native Americans

Although each tribe, clan, and nation is unique, in general, Native Americans view life and death holistically and the mind, body, heart, and spirit are interconnected with each other and all other things. This philosophy is consistent with their strong desire to meet death with dignity, since dying and death are believed to be part of a natural cycle. Additionally, most Native Americans are deeply connected to the Creator and believe that the spirit continues to live on after death. This belief influences one's response to dying and is consistent with the saying that "today is a good day to die."

When a person is dying, the extended family provides care with the support of the entire community. It has been noted that although formal hospice services are not often utilized by Native Americans, they have been using a hospice approach for hundreds of years in their communities. Many elders prefer traditional tribal medicine to that of Western medicine, and it is not uncommon for Native Americans of all ages to refuse medical procedures or treatments without having first seen the tribal medicine man/woman. They may also visit sweat lodges for purification and use sage, cedar, or grasses in healing rituals meant to return strength and balance to the heart, soul, mind, and body.

Although there are some similarities in worldview across nations or tribes, some specific beliefs, attitudes, and behaviors related to illness, dying, and death also vary. For example, while most Native American tribes believe in a continuation of life in another world following death, the Navajo do not. The Apache consider the body to be an empty shell, whereas the Lakota regard the body as sacred. The Lakota also prefer to have loved ones die at home rather than in a hospital, whereas the Navajo bring their dying to the hospital to protect the home from pollution.

### Hispanic Americans

The terms *Hispanic* and *Latino* apply to diverse groups of people from more than 17 Spanish-speaking

countries, including Mexico, Puerto Rico, Argentina, Cuba, and Peru, among others. Because Mexican Americans represent the largest Hispanic group living in the United States, they will be the focus of this discussion.

"Family-first" characterizes Mexican-American life. Accordingly, dying is a family affair and both nuclear and extended family members provide a strong supportive network for the dying person. A family-centered style of medical decision making is common, and the eldest male often has final authority over medical decisions. Families generally want to be told medical information about the dying person's condition first and will then decide if and by whom the news will be conveyed. Some Mexican Americans believe an open discussion of death will cause a loss of hope and disease acceleration, in which case medical information may be withheld from the family member who is dying.

Mexican Americans utilize hospice services less than any other group in the United States and rely on family to provide care for the dying person at home as long as possible. Some traditional Mexican-American families rely on *curanderismo* (folk healing), although this is not a universal practice. If hospitalization becomes necessary, family members maintain a bedside vigil so that the person is comforted and does not die in isolation.

The role that religion and spirituality plays in the life of Mexican Americans is deeply embedded in centuries of cultural rituals and practices. Mexican Americans adhere to fatalism and view death as inevitable, the result of fate or the will of God; and pain and suffering are seen as a test of one's faith. One's spirit must be considered in all health care situations, including the dying process. Many Mexican Americans are Catholic, and religious symbols (such as rosaries, holy water, candles with pictures of Saints, medals, and prayer cards) and practices (such as prayer, Novenas, and anointing the dying person with holy water for the last rites or sacrament of the sick) provide support throughout the dying process.

### Black Americans

Like Hispanics, Black Americans comprise a diverse population, including immigrants from the Caribbean Islands and countries in Africa. In spite of such diversity, religion and church are generally integral sources of support for Blacks, who are primarily Christians, but also Muslims and members of other

faiths. Regardless of the specific religion or denomination, Blacks are generally death accepting, and religion and spirituality form the foundation of efforts to cope with illness and dying.

Church attendance, prayer, spirituality, and assistance from pastors, ministers, other religious leaders, church members, and extended family and kinship networks provide support to families during the dying process. Formal caregiver services are infrequently utilized during the dying process because of a strong sense of family responsibility, a desire for kin to provide home-based care for loved ones, and a well-documented, heightened mistrust of the medical community based on years of medical care disparities across race and ethnicity. Hospice care is often not utilized for the reasons above and because of a lack of knowledge about their services, the inability to identify with providers who are predominantly White, and the perception that to enlist hospice support is to go against God's will by giving up hope. More than any other group, Blacks also want more aggressive, life-extending treatment during terminal illness.

### Asian Americans

Among Asian Americans, illness and death are viewed as fate, and medical intervention may be resisted for fear that it may interfere with one's spirit. However, use of acupuncture, acupressure, coin-rubbing (to draw out the illness from the body), and herbal remedies are common practices. Many Asian Americans believe in reincarnation; therefore, death is viewed as a transition into some other life, rather than the end of life, and consequently is not feared.

Many families of Korean, Chinese, and Japanese descent prefer that terminally ill and dying family members receive care in the hospital, and traditional Chinese-American and Japanese-American families maintain bedside vigils and minister to the dying person's needs, while medical personnel provide technical medical care. In Korean and Japanese families, the family, rather than the dying person, is told the news of the terminal nature of the illness, and the eldest son makes medical decisions regarding the dying person's treatment and care. Chinese Americans are more likely to prefer that the ill or dying person be given the diagnosis first, and then that person, rather than the physician, tells others. Vietnamese-American families prefer their loved ones to die at home, and the person who should be told about the terminal medical

condition depends on who is believed to be the strongest. In traditional Chinese family structure, if a parent is sick or dying, the sons will provide care at the bedside, rather than daughters.

### Religion, Culture, and Dying

Although one's culture influences one's response to dying and death, religion is the mainstay of many cultural groups. Thus, any particular response to dying may vary within a culture, depending on a particular person's religious beliefs and customs. India provides a good example to illustrate this point, because in India people are Hindus, Buddhists, Muslims, and Christians, and each religion and every region has its own traditions and beliefs related to death and dying. Although a comprehensive account of those traditions is beyond the scope of this entry, several examples of the characteristics of the non-Christian religions will be highlighted.

Even though the Hindu culture is death affirming, it is customary to purify the home and those who have contact with the dead body before engaging in any other activities. In South India, among Hindus, when death is anticipated, the family members move the person who is dying to the patio or to the front yard so that the soul does not become entrapped in the house when death occurs. During this period, loved ones usually stay with the dying person until their last breath. Holy water from the river Ganga is placed in the person's mouth to purify the body and the soul as the person takes the last breath.

The concept of "good death" is very prevalent in Hindu cultures. It is believed that if one lives life to the fullest and does good while alive, the person usually has a good death. Karma, or a person's deeds in life, determines what the end is going to be, and this belief becomes a guiding principle to live life accordingly. Hindus also believe in reincarnation or rebirth depending on what a person did in his or her life. If a person has lived a righteous life, the person is reborn as a higher being. Conversely, if the person has not lived a good life, the person is reborn as a menial creature. For Buddhists and for Hindus, life on earth becomes a transitional phase between reincarnations. Death, in fact, challenges people to live their lives better.

Muslims consider illness, especially of a terminal nature, as atonement for one's sins or wrong doings. Although death is believed to be a part of the journey to meet the creator, Muslims emphasize the sacredness of

life and need to prolong life. In Islam, when a person is dying, the head of the person is turned towards Mecca (i.e., east-south-east). The immediate family usually stays by the bedside of the person who is dying and makes sure that the person is comfortable.

## SUMMARY

Dying is a natural life passage, as much a part of our life cycle as being born, entering puberty, or becoming an adult. If a dying person's whole self is supported within a cultural context, there is significant opportunity for continued growth and development during the last stage of life.

—Brenda Moretta Guerrero and  
Lavina M. Noronha

## DYNAMICAL SYSTEMS

Dynamical systems theory is a relatively new framework within which virtually any area of inquiry can be conceptualized. In what follows, this framework is applied first to ecosystems and then to human development. The examination of ecosystems will illustrate some important properties of dynamical systems, properties that apply as well to human development. Human development will be examined across two scales of time: a large scale embracing evolution of the human species over millennia, and a short scale embracing the life span of individual humans.

## DYNAMICAL SYSTEMS THEORY

### General Properties of Dynamical Systems

Much of Western science attempts to understand systems by analyzing them into their parts. By contrast, the dynamical systems approach looks at the whole system. The approach is holistic rather than reductionistic. The idea behind this approach is that the essence of a system may be an emergent phenomenon that cannot be found in the parts. Because of emergent phenomena, the whole is often greater than the sum of the parts. Liquidity and the life-sustaining properties of water cannot be found in the hydrogen and oxygen molecules of which it is composed. Human consciousness, personality, wit, and charm are evident in a whole person but cannot be found in any of her or his parts. A living, breathing person is an emergent phenomenon of a vast sea of interacting internal and external webs of relationships.

Dynamical systems theory views reality, including the entire universe, as composed of coevolving webs or patterns of relationships rather than of static, discrete entities or things. A system is what it is only in relation to other systems. For example, the human body is made up of hierarchically organized and interacting networks of cells, tissues, organs, and physiological systems, none of which can function independently of the others. Furthermore, any given person is embedded in much larger sets of relationships, including families, communities, ecosystems, and the entire planet Earth. A distinction may be drawn between two arrows of time: the positive and negative arrows. The positive arrow reflects the buildup or development of systems, and the

negative arrow reflects their eventual breakdown or death in accord with the second law of thermodynamics. A nascent system may grow and complexify away from thermodynamic equilibrium, but it will inevitably succumb to the second law and disintegrate. Thus, the life trajectory of a system tends to describe an inverted U. For example, the human body starts off as a single cell very near equilibrium, grows into a complex person composed of billions of interacting webs of cells (e.g., tissues and organs) with various emergent properties, and eventually deteriorates and dies. The development of a system across the positive arrow of time is self-organizing because it is not designed or guided by an external agent or blueprint. This self-organizing development is usually characterized by a series of phase transitions from one basin of attraction, or attractor, to another.

Systems in attractors are self-perpetuating; they behave as though they want to come to rest and conserve energy. When a system is in an attractor, it is relatively stable and predictable. However, systems are in constant, though sometimes imperceptible, change; they are perturbed from time to time by effects that reverberate across the multiple webs of which they are composed and in which they are embedded. When these perturbations are sufficiently strong, systems are forced to change, or undergo phase transitions, into new attractors. Thus, across a normal life span, a person develops across such attractors as infancy, childhood, puberty, young adulthood, various phases of formal education and training, career changes, marriage, divorce, and retirement.

The stability of systems in attractors is more apparent than real because systems are constantly renewing or reconstructing themselves. Living cells are never the same from one moment to the next because there is a constant turnover in the molecules of which they are composed. A human face is recognizable year after year even though it is always being reconstituted by different cells and tissues. Thus, the overall pattern of relationships defining a system can appear stable even though it is constantly being reconstructed or regenerated. The continual renewal of the patterns of relationships defining a system serves to keep it alive (e.g., away from thermodynamic equilibrium). Still, given enough time, the pattern itself is bound to change.

Natural systems tend to participate in coevolving relationships in which changes in any one can effect changes in the others with which it is connected. Thus, environmental changes can lead to evolutionary

changes in organisms, and those changes can, in turn, lead to environmental changes in an ongoing spiral of coevolution. This coevolutionary relationship between organisms and their habitats, or niches, has been referred to as niche construction. In addition, most natural systems are likely to exemplify deterministic chaos. Because of the constant reverberations across the webs of which any given system is composed and in which it is embedded, its life trajectory is usually inherently unpredictable. A defining feature of a chaotic system is its extreme sensitivity to initial conditions. The tiniest of changes in start-up conditions of a nascent system can send its life trajectory off into vastly different directions. Indeed, the tiniest of changes in the conditions the system encounters anywhere along its life trajectory can divert it off into drastically different fates. A simple virus can invade a human body and cause its demise. These tiny effects are referred to as butterfly effects.

### **The Edge of Chaos, Fitness Landscapes, and System Diversity**
