Toward the end of the second year, as the capacity for forming mental representations emerges, toddlers develop a sense of an independent self. Signs of this budding sense of self can be found in the toddler's self-references ("Me do it!"), the ability to recognize his/her own image in the mirror, and the increasing likelihood to meet parental requests with an emphatic "NO!" Erik Erickson (1902–1994), a developmental psychologist who proposed a life span theory of psychosocial development, considered achieving a sense of autonomy to be a key task of the toddler period. Toddlers who have the opportunity to engage in self-help skills (e.g., feeding and dressing themselves) and make simple decisions tend to develop an autonomous sense of self. When caregivers do not permit toddlers to make simple choices or do things for themselves, or consistently reject bids for autonomy, the toddler's sense of personal agency may become riddled by feelings of shame and doubt. Importantly, the toddler may swing sharply between striving for autonomy and clinging to caregivers, especially when tired, ill, or afraid. This mixed desire for independence, on one hand, and the security of the caregiver's lap, on the other, is a central tension of toddlerhood. In this sense, the toddler period has been referred to as the "first adolescence."

In conjunction with an emerging sense of self, toddlers demonstrate a growing awareness of and interest in others, especially other children. Toddlers in the second year of life will typically play side by side with little or no interaction. Throughout the third year, though, toddlers will show increasing ability to interact with peers and these interactions often stem from toddlers' propensity to imitate others. Two-year-olds are also able to distinguish among playmates and may develop playmate preferences. Thus, peer interactions in the toddler years pave the way for the advent of friendships in the preschool years.

Finally, as the toddler develops a sense of self as separate from others, new emotions emerge that were not present during infancy. For instance, toddlers are

openly affectionate and show signs of empathy and concern toward others' injuries or distress. Toddlers also show positive self-evaluations (a precursor to pride) when accomplishing a goal and shame when behaving in a socially unacceptable or prohibited manner. These emotions are often labeled "social" or "self-conscious" emotions because they reflect feelings about the self in relation to others. As a result of increasing awareness of the social rules for appropriate behavior and the emotions that may accompany such awareness, toddlers may begin to develop a sense of a "moral self."

Given the toddler's frequent demands to "have it all" and the "clash of wills" that may result when the goals of the parent oppose those of the toddler, it is no wonder that the toddler years are challenging for parents and children alike. Older toddlers, in particular, are famous for their increased negativity, thus the label the "terrible twos." Yet, such negativism reflects the child's increasing wish for autonomy and is a normal part of toddler development, especially in Western cultures. Caregivers can promote a positive sense of self by respecting the toddler's need for autonomy. At the same time, when the toddler seeks the caregiver's comfort or protection, it is important to provide reassurance that support is available. By the end of this period, children who have learned that caregivers are available and responsive when needed will be more secure and independent than children who have been "pushed" toward independence. In light of the increasing physical and cognitive capacities of the growing toddler, caregivers tend to first establish rules for behavior during this period. Caregivers should strive to consistently hold to a clear set of rules that serve the safety and well-being of toddlers and others around them. Providing simple reasons for rules may also foster toddlers' understanding of others' feelings and perspectives. Remarkable physical, social-emotional, and cognitive-linguistic growth mark the toddler years, and it is likely that children will benefit when caregivers are responsive to the toddlers' need to "do it myself," provide safe and simple choices, and keep an open mind and sense of humor during these busy times!

—Nancy L. McElwain

## TOILET TRAINING

---

Toilet training is an important developmental milestone in every child's life. Although toilet training is universal, variation exists in everything from the timing to the method of the training. Cultural and societal norms have a significant influence on the practice of toilet training. In the United States, the suggested age of initiating toilet training has ranged from 1 month to 24 months of age. In other industrialized societies, recommendations for the timing of training vary widely, as well. Children have been thought to be "ready" at approximately 5 months in London, 8 months in Paris, and just over 1 year in Stockholm.

The variation in beliefs about readiness may be related to the methods used and attitudes toward toilet training. In some cultures, the responsibility for toilet training falls primarily on the child's caregiver. For example, in the Digo tribe in East Africa, caregivers are trained to recognize and tend to a child's need to urinate or defecate. Children are expected to attain complete dryness by 1 year of age. In contrast, in the United States and other Western societies, the responsibility is placed largely on the child to be independent and therefore dryness is achieved at a much later age.

Despite all the disparity in beliefs and practices related to the timing of toilet training, research indicates that most children are successfully trained by 24 to 36 months of age, with nearly all children being trained by the age of 4. One factor contributing to successful training is the child's level of physical and intellectual maturity. Physical readiness includes a fairly regular pattern of wetting during the day that occurs less frequently (e.g., 4 times per day). Also it is helpful if the child has developed the level of physical dexterity needed to raise and lower his or her pants quickly. Thirdly, the child needs to both understand and be able to convey concepts such as *wet*, *dry*, and *potty*. Finally, for toilet training to be successful and

efficient, a child must be able to comply with simple requests given by the parent. All of these “prerequisites” signal that a child is likely to be effectively trained. Given the readiness criteria, it is not surprising that the later training is initiated, the faster dryness is accomplished. For example, children who begin toilet training at 26 months or later tend to be successfully trained twice as fast as those whose training begins before 24 months.

As the differences are great regarding the age of initiating toilet training, opinions about the method of toilet training are equally wide-ranging. Over the years, the prevalent thinking regarding toilet training in the United States has varied between gentle child-centered approaches and intense prescribed methods designed for rapid training in as little as 4 hours. Many diverse techniques and strategies are included in training methods such as the use of scheduled toilet sits, charts, rewards, books, and dolls to assist the child’s learning. Despite their differences, varying methods appear to have similar rates of success, given that approximately 90% of children are successfully trained by age 4.

Although toilet training is typically achieved by the age of 4, it is not uncommon for accidents to occasionally occur in children of 3 to 6 years of age. Typical accidents occur when children are intently involved in play activities. Professional guidance is rarely needed in these cases. However, up to 25% of boys and 15% of girls have persistent problems with wetting the bed or their pants. Additionally, from 1.5 to 5% of children have difficulty with soiling or defecating in their pants. These persistent concerns can be effectively treated, but may warrant professional assistance from a physician and/or psychologist.

## TOUCH

---

Touch typically refers to sensations that occur when skin receptors are triggered by external stimuli. Touch has been described as one of the most fundamental means of contact with the world and the simplest and most straightforward of all sensory systems. It is the first sense to develop in utero and by 14 weeks after gestation, the surface of the fetus is almost entirely sensitive to tactile stimulation. By adulthood, the skin constitutes the largest organ of the body, covering 1.8 square meters of the average person.

The importance of touch has been implicated in several domains of life across the life span, particularly in early life. Touch helps us learn about the world around us and plays an integral role in biological, cognitive, and social development. Below, each of these domains is described along with the physiological underpinnings and physical dimensions of touch that help make it such a rich and important modality in life.

### THE PHYSIOLOGICAL UNDERPINNINGS AND PHYSICAL DIMENSIONS OF TOUCH

As mentioned, the skin is the largest organ of the human body and weighs between six and ten pounds. The skin is a multilayered structure containing several receptors, each of which sends unique signals to the brain via neurons via the spinal cord. Information from the spinal cord enters the thalamus—the “relay station” of the brain—and input from there is sent to a strip of the brain called the somatosensory cortex located on the parietal cortex. The more area on the somatosensory cortex that is dedicated to a given area of skin on the body, the more sensitive that area of skin is to tactile stimulation. Thus, areas of the body such as the fingers and lips—two of the most sensitive areas of the body to tactile stimulation—are well represented on the somatosensory cortex compared to less sensitive areas of the skin such as the back.

When considering the impact of touch, one must consider not only the physiological underpinnings of the modality but the physical dimensions of tactile stimulation on the skin. The dimensions of touch can be divided by the *qualities* of touch (the actual tactile stimulus that is administered) and the *parameters* of touch (where and how much touch is administered). The following constitute the qualities and parameters of touch:

### Qualities

- Action: the specific movements on the skin (e.g., stroking, squeezing)
- Intensity: the degree of pressure on the skin
- Velocity: the rate at which something is impressed upon or across the skin
- Abruptness: the acceleration or deceleration that the skin is touched
- Temperature: the temperature of the tactile stimulus on the skin

### Parameters

- Location: where the tactile stimulus is on the skin
- Frequency: the number of times that the skin is touched
- Duration: the elapsed time that the skin is touched
- Extent of surface area touched: the amount of surface area that is covered

Together, these dimensions of touch comprise the richness of the tactile modality.

## LEARNING ABOUT THE WORLD VIA TOUCH

Throughout life we actively explore the world with our hands to learn about objects in the world—a process known as haptic perception. Haptic perception, in conjunction with vision, is particularly important for infants to learn about the world. Research indicates that by 3 months of age infants can distinguish objects by size and shape (e.g., a cube from a hollow square), by 6 months of age they can distinguish objects by hardness and texture, by 9 months of age they can distinguish objects by weight, and by 15 months of age they can distinguish between shapes that are similar in features but differ in spatial arrangement.

## EFFECTS OF TOUCH ON BIOLOGY

Touch plays an instrumental role in brain development and growth, especially in early life. Without

adequate tactile stimulation early in life, the brain does not grow to a normal size and the synapses between neurons do not develop properly. In addition, adequate tactile stimulation early in life can buffer the effects of tactile deprivation later in life. Thus, exposure to adequate amounts of touch early in life seems to form a foundation for later nervous system development.

The importance of touch does not wane later in life. Research indicates that when nonhuman animals are provided extra tactile stimulation later in life, their brains increase in size and the synapses between neurons increase. Moreover, tactile stimulation can help stimulate neuronal growth due to brain lesions and infarcts in the brain later in life.

In addition to studying the effects of touch on the brain, researchers have investigated the effects of touch on premature infants' growth. In one study a group of premature infants received a 10-day protocol of massage therapy comprised of tactile/kinesthetic stimulation while a control group did not receive the massage therapy protocol. Compared to the control group, the treatment group gained 47% more weight, was more active and alert, and spent 6 fewer days in the hospital. If all of the premature infants in the country received massage therapy, an estimated total of \$4.7 million would be saved in medical costs annually.

Massage therapy improves a host of other biological and health related phenomena. Children and adults receiving massage therapy experience less anxiety, lower levels of stress hormones (cortisol, norepinephrine, and epinephrine), enhanced immune system functioning, and heightened alertness as indexed by EEG. Massage therapy can also play a role in the treatment of several medical conditions including juvenile rheumatoid arthritis, fibromyalgia, chronic lower back pain, migraine headaches, depression, autism, attention deficit hyperactivity disorder, post-traumatic stress disorder, and some eating disorders.

## EFFECTS OF TOUCH ON COGNITION

Touch has a significant impact on cognitive development. A wide body of literature suggests that cognitive development is intimately tied to brain development in the childhood years and, as mentioned, touch plays a pivotal role in neuronal development in the early years of life. Parental aversions to touch as well as harsh touch have been implicated as factors in the development of language and learning disorders. In addition, research suggests that parents who use touch to stimulate the central nervous system

regularly and appropriately have children that are more likely to develop an accurate and sophisticated body image. These parents provide a variety of forms of tactile stimulation to a number of areas on the body.

### EFFECTS OF TOUCH ON EMOTION AND SOCIAL INTERACTION

Touch plays an integral role in the caregiver-child relationship from the beginning of life. In one U.S. sample, infants were touched for 33% to 61% of the time during brief interactions with their mothers. The frequency of contact is much higher in some cultures such as the !Kung and the Efe tribe of Zaire where mothers spend approximately 75% of the time in contact with their infants.

In infancy, caregivers' touch is thought to serve a variety of communicative functions while they are in contact with their infants. Two of the most important are the communication of emotions, as well as the communication of security. A number of studies indicates that touch is capable of communicating and eliciting positive and negative emotions. One powerful demonstration of the power of touch to elicit positive emotions has been shown when researchers use the "still-face paradigm" to study infant emotionality. The still-face paradigm is comprised of a period of interaction when the caregiver assumes a still-face, thereby not responding to the infant's actions. During this period, infants typically react negatively because this is an unusual event in most infants' lives. Several studies indicate that if caregivers touch their infants during the still-face period, their infants' emotional displays are significantly less negative and more positive compared to infants who are not touched during the still-face period.

The quality of caregiver-infant touch is a central feature of the responsive and available caregiving environment that is necessary to foster an infant's sense of security. Several studies suggest that touch between the caregiver and infant is the "ultimate signal" of security of the infant. In one experimental study, researchers compared how infants were attached to their caregivers when they carried their infants ventrally in soft infant carriers versus those who were carried in harder infant seats. The researchers found that infants carried in the soft infant carriers were significantly more likely to be securely attached to their caregivers than infants who were carried in the infant seats. This study and others strongly suggest that touch plays a key role in the communication of security to children.

Touch continues to play an integral role in social communication in adulthood. For example, touch communicates power and emotions to others, as well as aids in persuading others to comply with our requests. In addition, touch increases verbal interaction among people, gains attention from others, and communicates our attraction toward others.

In sum, touch not only helps us learn about the world in which we live but plays an integral role in several other domains of life including biological, cognitive, and social development. Although touch may be one of the most powerful and most important sensory modalities across the life span, the study of touch has remained minimal. Future work on touch will continue to unravel the mysteries of touch.

## TOURETTE'S SYNDROME

---

Tourette's syndrome (TS) is a neurobehavioral disorder named after the French neurologist Georges Gilles de la Tourette who in 1885 described nine patients with TS symptoms including verbal and motor childhood-onset tics and other behavioral problems including poor impulse control and obsessive-compulsive behaviors. The disease, once believed to be extremely rare, is now considered to be quite

common, affecting approximately 2% percent of the population. The disease afflicts males 5 times more often than females. The onset of TS, as characterized by the emergence of motor and vocal tics, typically emerges between the ages of 3 and 8 with a reduction in these symptoms occurring by age 20.

## SYMPTOMS

The hallmarks of TS are the motor and verbal tics. These tics vary in complexity, duration (ranging from 1 year to lifelong), intensity (from mild to severe), and frequency (from rare to constant). Tics are brief movements or sounds that appear unpredictably. They emerge individually or in choreographed clusters and can be expressed either intermittently or continuously for hours. These tics fall into one of several categories: (1) motor tics which can include intense eye blinking, throat clearing, and neck and arm twitching; (2) phonic tics such as repeated utterance of a particular word, shouting (obscurities), or grunting; (3) aggressive phenomenon such as self-injury, hitting, kicking, or biting self or others; and (4) compulsive behaviors that may include hand-washing, door locking, checking and organizing objects, and touching or tapping others and objects.

The motor and phonic symptoms typically wax and wane. This waxing and waning is most likely influenced by ongoing brain developmental changes and environmental influences such as stress. Additionally, medications for TS can also cause changes in the brain that result in corresponding behavioral changes. The repertoire and severity of symptoms of TS patients, therefore, require constant monitoring by the patient and family, as well as by the physician who will adjust the dose and type of medication accordingly. Studies have reported that the highest incidence and severity of tics occur with anticipation or resolution of emotional changes. Consistent with this, stress, anxiety, and fatigue exacerbate tics, and ironically, the very urge and attempt to control the tic can itself lead to additional stress and anxiety. Altogether, the disease and its consequences can often lead to problems in school performance and self-esteem, and also in a variety of social and behavioral problems at school, at home, and in society in general.

## GENETICS

Tourette's syndrome has a significant genetic component. Several genes have been identified through

family studies, segregation analyses, candidate gene studies, and linkage studies. TS inheritance may involve several mechanisms including autosomal dominant, bilinear, or polygenic mechanisms. Candidate genes for TS pose a genetic susceptibility with such factors as pre- or postnatal stress, and other environmental factors such as viral infections or stress, increasing their likelihood of expression. It is critical therefore to continue studies designed to identify specific gene-environmental interactions. The candidate genes identified thus far appear to be involved in the regulation of brain development and neurochemical signaling. For example, several dopamine (DA) receptor (D1, D2, D4, D5) and noradrenergic receptor (ADRA2a, ADRA2c and DBH) genes and a few serotonin genes have been identified. In conclusion, many candidate genes that pose a susceptibility to developing TS have been identified. The heterogeneity of identified TS genes together with their varying etiologies and environmental interactions make it impossible to provide a single or simple explanation for the etiology of TS. Research progress in this area will lead to a better understanding and predictability of the etiology of TS and improved treatments for these patients.

## NEUROBIOLOGY

Numerous neuroanatomical and brain imaging (fMRI, PET, SPECT) studies have identified the prefrontal cortex (PFC)-basal ganglia (BG) circuit as the major system involved in Tourette's syndrome. This circuit is involved primarily in regulating a variety of motor, limbic, and cognitive functions. The dorsal striatum (consisting of the caudate and putamen) of the BG is implicated primarily in motor control and habit formation, whereas the ventral striatum is implicated in compulsivity and addiction. The prefrontal cortex is involved in such higher-order executive decisions as impulse control. Other related areas such as the brain stem, which has been implicated in eye blink reflex, have also been implicated as well as other areas that interact with the PFC-BG circuit including motor, cingulate, temporal, and parietal cortical areas, Broca's area, thalamus, and cerebellum.

The overriding problem in TS appears to be the overactivity of motor and motivational/reinforcement systems with an inability of the prefrontal cortex to override or inhibit those related behaviors. TS patients, like patients with prefrontal damage, reveal poor performance on impulsivity control tasks. A functional neuroimaging study revealed an increase

in neural activity in the prefrontal and caudate nucleus and a decrease in the motor-related putamen and globus pallidus in a tick suppression task. Performance on tasks requiring other higher-order functions such as learning and memory, however, remained normal in TS patients.

Examination of the specific neuroanatomical abnormality of the prefrontal-BG circuit has revealed a decrease in the volume of these brain areas in TS patients. It remains unclear, however, as to whether these brain differences are necessarily due to damage or due to compensatory mechanisms. The compensatory nature of the brain further suggests that these individuals may develop alternative cognitive and behavioral strengths that are not dependent on the damaged brain areas. Special efforts should be made by the family, educators, and physicians to help the patient identify such strengths and talents.

Detailed synaptic and receptor microcircuitry abnormalities within the PFC-BG circuits, however, have not been fully explored. The identification of specific cellular and biochemical circuits will help to improve site-specific targeted treatments for this disorder. For example, striatal cholinergic neurons of the striatum are known to signal reward and in turn influence motor signaling as well as incoming prefrontal cortical signals. Dr. Alcantara's work has implicated these neurons and their corresponding dopamine D2 receptors to play a key role in the development of drug abuse and possibly in the treatments designed to treat addiction. Further investigations should examine whether these cholinergic neurons are also critical for motor and impulse control in TS patients.

TS patients express comorbidity with two other PFC-BG related disorders: obsessive-compulsive disorder (OCD) and attention-deficit-hyperactivity disorder (ADHD; which involves increased inattention, hyperactivity, and impulsivity). TS patients also have a high incidence of depression, anxiety, and aggression. Additionally, family members of TS patients show a higher than normal incidence for OCD, ADHD, drug or alcohol dependency, depression, anxiety, eating disorders, and panic disorders, all of which share a common neuroanatomical and biochemical basis with TS.

## NEUROTRANSMITTER SYSTEMS

Two neurotransmitter systems most likely affected by TS are the dopaminergic and norepinephrine systems. The dopamine system, central to the PFC-BG circuit, is suggested to be hypofunctional, further

implicating the supersensitivity of dopamine D2 receptors and therefore requiring drugs that block these receptors. The norepinephrine (NE) system originating in the brain stem influences motivation, attention, and arousal in the PFC-BG circuit and is also suggested to be hypofunctional, requiring the use of adrenergic (NE) receptor agonists.

## TREATMENTS

### Pharmacological Treatments

Two classes of antipsychotic drugs that target the DA and NE systems are most widely used. These include the neuroleptics, including fluphenazine, haloperidol, pimozide, sulpiride, and tiapride, which are effective in reducing the symptoms of TS (side effects include sedation or dysphoria). Additionally the alpha2 adrenergic agonists such as clonidine, desipramine, guanfacine, and risperidone often show benefit (side effects include sedation and irritability).

### Behavioral Treatments

Behavioral treatment or combined behavioral treatment with drugs is the most effective in treating the symptoms of TS. Cognitive behavior therapy (CBT) is the main behavioral treatment of choice. CBT includes habit reversal, which is the most promising treatment consisting of awareness training, self-monitoring, relaxation training, competing response training, and contingency management. Also hypnotherapy, biofeedback, conductual therapies, acupuncture, electroconvulsive therapy, meditation, and surgery have been employed. Surgery, however, is the most invasive and can lead to subsequent brain circuit deterioration. Both drug and behavioral treatments can target and modify the affected brain areas and related receptor and synaptic microcircuits. These treatments thereby show much promise for the successful long-term treatment of TS. Continued research in the areas of TS and improved animal models should continue to shed light on our understanding of the etiology of TS and the development of improved site-specific targeted behavioral and pharmacological treatments for Tourette's syndrome.

—Adriana A. Alcantara

## TOXOPLASMOSIS

---

Toxoplasmosis (toxo) is a common parasitic infection that, often completely asymptomatic when acquired by adults, may have serious adverse consequences when transmitted by a pregnant woman to her embryo/fetus. The responsible parasite, *toxoplasma gondii* occurs worldwide, but infections are more common in warmer climates. Infection generally occurs through eating undercooked meat or unwashed fruit/vegetables or contact with infected cat feces or soil.

### ADULT INFECTION

Testing reveals evidence of toxo in many adults. In a minority of normal adults with primary adult infections, symptoms do occur and may include fever, general malaise, and enlargement of lymph nodes. Subsequently, the parasite forms cysts throughout the body which may remain latent for years. Reactivation of the cysts in the eyes of a small percent of affected individuals may cause recurrent vision problems. In adults with severely impaired immune systems, primary toxo infection may have serious consequences, including death. Primary infection generally leads to development of antibodies that protect against reinfection.

### PRENATAL/CONGENITAL INFECTION

Major concern with toxo is its potential congenital effects. Toxo is one of several infections that may have serious adverse effects on offspring if primary infection of a pregnant woman is transmitted pre- or perinatally to her embryo/fetus. Such infections are variously called prenatal/perinatal, congenital, or maternal infections. Since newborns affected by these

infections share characteristics, identification of the particular agent is often only through laboratory analysis.

Overall probability across pregnancy of congenital infection of the embryo/fetus is about 30%. However, probability of infection is inversely related to duration of gestation: Risk is very low early in pregnancy and only about 6% at 13 weeks, but thereafter rises virtually exponentially to about 80% just before birth.

Congenital toxo can lead to intrauterine growth retardation (IUGR) and, rarely, stillbirth. Many children with congenital toxo are asymptomatic. In those who do show symptoms, the most common is retinochoroiditis. Hydrocephalus, intracranial calcification, mental retardation, and other neurological deficits may also occur. Hearing impairment may develop in childhood. Incidence and severity of adverse effects are inversely related to time in gestation at which infection occurs: Adverse impact is greatest with infection early in pregnancy and diminishes thereafter. Ocular lesions can occur and reoccur at any age, but again, risk appears to diminish with gestation age at time of primary maternal infection. When a toxo infection is identified, which may not be until 12 months of age, antiparasitic agents may be administered.

### IDENTIFICATION AND PREVENTION

Since primary *T. gondii* infection leads to subsequent production of antibodies that protect the embryo/fetus from infection, concern is with women who have no antibodies at the beginning of pregnancy. Serological testing can identify women who do not have *T. gondii* antibodies at the outset of pregnancy and retesting can identify development of antibodies, indicating a primary infection. Ultrasound detection of signs such as enlarged cerebral ventricles and intracranial calcification are suggestive of prenatal toxo. Diagnosis can be confirmed through detection of the parasite in amniotic fluid. In cases of maternal or embryonic infection, pregnant women may be treated with antiparasitic agents in an attempt to prevent adverse effects. However, although such identification programs and treatments are common in Europe, their use involves risks to the embryo/fetus, and their effectiveness is controversial. In cases of confirmed diagnosis, the pregnancy may be terminated. See Gilbert (2000) for a detailed discussion.

The best prevention of congenital toxo is for pregnant women to avoid primary infection. Given

that the most severe adverse consequences occur with early prenatal infection, much damage to the embryo may occur if a woman suffers primary *T. gondii* infection before learning she is pregnant. The best prevention is for women who may become pregnant to avoid primary infection by not eating undercooked meat, washing hands and work surfaces after preparing raw meat, washing fruits and vegetables, and avoiding contact with used cat litter or soil that may contain animal feces.

—Robert T. Brown

## TWIN STUDIES

---

Twin studies represent one of the oldest scientific methods of evaluating the influence of heredity on human development and behavior. During the course of the 20th century, twin studies became more versatile and have encompassed a wider range of behavioral constructs. As the field advanced, debates about whether nurture or nature is more influential have been replaced with the notion of nature *via* nurture. This ideological shift has been driven by an increasing number of twin studies demonstrating that certain environments in combination with genetic influences produce a particular developmental outcome. What follows is a brief overview of the twin study method and applications of the method that have led to discoveries in human development.

### BEHAVIORAL GENETICS AND THE TWIN STUDY METHOD

Behavioral genetics is the study of the influence of genes and environment on variation in human behavior. In traditional non-twin family study designs,

genetic and environmental influences are confounded with each other, making it difficult to determine the relative degree to which familial resemblance reflects contributions from genes and environment. The basic twin study method treats twinning as a natural experiment that makes use of monozygotic (MZ) twins, who share 100% of their genetic material, and dizygotic (DZ) twins, who on average share only 50% of their genetic material (like ordinary siblings). The environment is assumed to affect members of both types of twin pairs equally, so observed differences in similarity between MZ and DZ pairs are interpreted as reflecting genetic effects. Genetic influences are inferred by the degree to which MZ twins are more similar than their DZ counterparts. Possible limitations to the twin design include the representativeness of twins to the general population and difficulties recruiting the large-scale samples of twins necessary to estimate adequately genetic effects. Nevertheless, twin studies, when combined with traditional family and adoption designs (where parents and their children are not genetically related) have provided many insights into genetic influences on human behavior.

Three types of influences on behavior can be estimated from the basic twin method: genetic factors, shared environmental factors, and nonshared environmental factors. An estimate of genetic influence gleaned from the twin method is referred to as *heritability* or the proportion of variation in a given behavior that is due to genetic factors. Heritability estimates range from 0.0 to 1.0, with a value of 1.0 indicating that 100% of the variability in the trait can be accounted for by genetic factors. *Shared environmental factors* refer to environmental experiences that members of a twin pair share in common, and act to make individuals similar to each other. Examples of shared environment include growing up in the same neighborhood and being reared by the same parents. Shared environmental effects are inferred when the similarity of DZ twins approaches that of MZ twins. *Nonshared environmental factors* refer to those unique factors that members of a twin pair do not share, and thus act to make individuals different from each other. An example of nonshared environmental influence is distinct peer group influence for each member of the pair. Such nonshared environmental effects are inferred from the degree to which MZ twins are dissimilar for a trait of interest. At this most basic level, behavioral geneticists estimate degree of genetic, shared and nonshared environmental influences,

but such an analysis cannot identify specific environments or genes influencing behavior.

A variation of the basic twin design is the *twins reared-apart method*. This method identifies rare sets of MZ twins separated early in development and reared in different families. Any similarity in behavioral traits observed in such twins can be attributed to genetic effects because they did not share common rearing environments. Thomas Bouchard, a leading scientist in the twins reared-apart method, collected extensive behavioral data on a relatively large sample of such twins. His data showed striking behavioral similarities between reared-apart identical twins, many of whom met for the first time in his laboratory. Similarities were found for diverse attributes, including personality, vocational choices, attitudes, and religious beliefs, providing compelling evidence for the influence of genes on the development of numerous facets of behavior and psychological functioning.

The twin design can also be used to evaluate the effects of specific environments on a behavior. In the *discordant twin method*, researchers focus on MZ twins who are discordant (or lack similarity) on a given behavior or trait. Sets of twins who are discordant for the behavior are then examined on the basis of measured environmental variables. For example, studies of twins discordant for schizophrenia have shown that the structure of the affected twin's brain differs from that of the healthy co-twin, indicating that some environmental factor has led to the development of anomalous brain anatomy in the MZ twin with schizophrenia.

Key environmental variables have also been integrated into the basic twin method to elucidate the effects of particular environments on behavior. For example, a researcher seeking to test whether the environmental effects on the initiation of substance use are attributable to peer influence may examine the association between these two factors within MZ and DZ twin pairs to determine if peer influence accounts for a substantial proportion of the individual differences in substance use initiation attributable to environmental influence. In this type of twin investigation, specific environmental effects are evaluated in the presence of genetic influences.

### Longitudinal Twin Studies

Twin studies using a *longitudinal design*, or repeated measurements on individuals at several intervals over time, provide a unique opportunity to examine the

complex nature of genes and environments over the life span. Waddington put forth the concept of *canalization*, or the idea that as individuals mature, their range of possible developmental outcomes narrows. Similarly, evidence from longitudinal twin studies have generally suggested that genetic influence on behavior increases as individuals grow older. Large-scale twin studies spanning infancy, adolescence, adulthood, and late adulthood have been undertaken in several countries. Results of these studies have offered insights into the nature of environmental influence on alcohol and drug use behaviors ranging from initiation of alcohol use to severe forms of alcoholism. Studies of Danish twins during the course of very late adulthood have offered insights into the effects of genes on normal aging.

### Gene-Environment Correlation and Interaction

Sandra Scarr, a developmental behavior geneticist, has emphasized how heredity and environment work synergistically rather than independently. Genes and environments are *correlated* when individuals with certain inherited propensities develop associations with environments partial to their genetic inclinations. For example, a child with genes favoring the development of musical talent may seek out friends who enjoy music and join a band. Rather than environmental exposure simply encouraging the development of musical talent, genetic proclivities encourage the selection of musically relevant environments. A *gene-environment interaction* results when an inherited tendency is more likely to be expressed in one environment than another. For instance, heritability estimates of alcohol use may differ in urban and rural environments. In urban settings, where there is less community monitoring and accountability and more avenues to access alcohol, more opportunities exist for increased expression of genetic dispositions to drink alcohol.

### THE APPLICATION OF TWIN STUDIES TO UNDERSTAND DEVELOPMENTAL PHENOMENA

The study of human development has benefited from the use of twin studies, and psychologists have used the method to evaluate several psychological domains. In his 1929 pioneering study, Gesell used twins to demonstrate the influence of genes on learning. A pair of infant twins was compared on

stair-climbing behavior. One twin was trained in the behavior and one twin was not. The untrained twin soon independently learned the behavior, thus demonstrating that without explicit training (or environmental intervention), a natural developmental phenomena can take place.

Twin studies have also offered insights into the development of temperament and emotion regulation. Goldsmith and colleagues examined infant twins on measures of temperament, behavioral inhibition, and responses to strangers. His studies demonstrated that a significant proportion of variation in early temperament can be attributed to genetic factors. Thus, genes may influence an infant's shyness or soothability. These scientific developments provided convincing evidence that infants were not born *tabula rasa* (or "blank slates"); rather, some significant amount of emotion and behavior can be accounted for by genes.

One of the most significant advances in understanding the causes of schizophrenia originated from the findings of twin studies. In the early 20th century, a predominant etiological theory of schizophrenia placed the blame for the development of this psychosis on poor parenting. Twin studies by Irving Gottesman demonstrated that, contrary to the importance assigned to family environment, schizophrenia is strongly influenced by heredity. The information gleaned from such twin research has led to shifts in how schizophrenia is treated and studied, including providing the rationale behind the push to identify candidate genes influencing schizophrenia's development.

### The Future of Twin Studies

Twin research remains a viable natural experiment that helps to elucidate the effects of genes and environments. The application of state-of-the-art scientific methods to the area of twin studies (including brain neuroimaging techniques and molecular genetics) will offer exciting new opportunities to understand how genes and environments combine to influence behavioral attributes.

### SUMMARY

Twin studies provide a useful natural experiment to evaluate the degree to which genetic and environmental influences determine variability in a given trait. Life-span studies of twins have offered specific

insights into normal and abnormal developmental processes, ranging from the development of stair-climbing to the emergence of alcohol misuse and schizophrenia. Results of twin studies are used to guide research into the development of a broad array of psychological attributes.

## TWINS

---

Twins are a biological fact. As such, they occur in at least two different ways. One pattern involves one egg, fertilized by one sperm, which splits sometime during the first fourteen days after fertilization, thus producing *monozygotic* (uniovular) or "identical" twins. These twins have the same genetic make-up as each other and are always the same sex, being both boys or both girls.

The other twin pattern involves two eggs, each egg fertilized by a separate sperm. Eventually they produce *dizygotic* (binovular) or "fraternal" or "nonidentical" twins. Nonidentical twins may either be of the same sex, that is, two boys or two girls, or unlike sex pairs, that is, a boy and a girl. Genetically, either type of nonidentical twin, same sex or unlike sex pairs, are genetically as similar as any other two siblings. This genetic relationship can range from 25% to 75% of genetic similarity.

There are also some rarer types of twins. These categories include: mirror-image twins, who are identical twins; polar body twins, called half-identical twins; or conjoined (Siamese) twins, who are identical twins.

With the increasing use of ultrasound scans, twins have been detected early in a pregnancy but have

“vanished” according to subsequent ultrasounds. This phenomenon has been termed the vanishing twin syndrome.

The incidence of identical twins has remained more or less constant; this constancy applies to most cultures over any given time period. Roughly about one third of all twins are identical and two thirds of all twins are fraternal.

In both the United States and the United Kingdom, the probability of having twins as of 1999/2000 is roughly 1 in 35 pregnancies. The chances of having twins in these two countries has risen recently mainly due to older mothers having babies and the increasing use of fertility treatments.

Rates of fraternal twins vary in different countries, with African countries producing the highest rates and Asian countries the lowest rates of twinning.

## MYTHS ABOUT TWINS

Myths about twins picture twins as being both positive and negative, harmonious and rivalrous, happy and unhappy, divine and human. Throughout the world’s cultures, myths identify twins as gods who are deified men or women (such as in North and South American cultures). Other twin myths are foundation myths such as in the Biblical story of Jacob and Esau, indicating that two nations are to be born, or the most famous myth about the founding of Rome by twins Romulus and Remus.

Still other myths treat the issue of double paternity; that is, one twin is depicted as the child of a human father while the other twin has a different and divine father. One version of the *Dioscuri*, Castor and Pollux, otherwise known to us as the Heavenly Twins constellation, Gemini, falls into this group. Some myths attempt to provide answers to the culturally unanswerable. Some North American indigenous peoples, such as the Mohave, believe twins function as rain-makers; others believe that human twins are sent from heaven to bring both rain and fertility.

Thus the very many mythologies and cultures of the world contain quite a considerable number and diversity of myths about twins.

## EXPLAINING TWIN BIRTH

The birth of twins occurs in all cultures of the world. In most, the appearance of twins itself is a matter of surprise, even shock, both for the parents and the community at large.

In more traditional, nonindustrial societies, the birth of twins often disrupted the structure of the family and the position of individuals within the family. Twins caused a disturbance to the normal order of things. Sometimes this even involved a potential threat to the social order, so that in some extreme cases one or both twins were faced with infanticide; occasionally, the mother also faced death or, at the very least, ostracism. In these societies, concern about the question of who actually fathered the twins and the ensuing anxiety about the real (or even the imagined) disruptions to the established social system were expressed.

In more industrialized societies, due to the intervention of hospital equipment such as scanners and the increasing use of fertility drugs, which are one of the main reasons for the recent increase in twins and higher multiples, dealing with twinship begins at a much earlier stage, although some parallels with non-industrial societies can be made.

Attitudes toward twins in different societies are mixed: Whether positive, negative or even ambivalent, these attitudes have been and are currently complex and intense. These qualities of complexity and intensity may include feelings of disturbance, anxiety, and unease about identity, especially individual identity.

## TWINS IN THE MEDIA

Twins have provided an endless source of fascination for writers over the centuries. Initially, the overwhelming focus of attention was on the comic potential of mistaken identity, especially for monozygotic or “identical” twins. Subsequently, however, writers began to explore stereotypical—opposite—characteristics of twins, such as moral opposites of good versus evil, or opposites of identity, like versus unlike, twins as same versus twins as fundamentally different. Fiction writers also used the double (or the *doppelganger*) in their writing.

Alongside questions of identity, twins have been used by writers to illustrate a range of human behavior associated with twinship. One ever-present theme of this type would be the closeness of twins, such as is found in Bruce Chatwin’s famous novel *On the Black Hill*. Another example of the very strong bond thought to exist between twins is found in Thornton Wilder’s *The Bridge of San Luis Rey*. In children’s literature, we find *Sweet Valley Twins*, where identical twin girls look so much alike it is virtually impossible to tell

them apart, but yet they are described as having very different personalities.

In films, twins have been used in general to illustrate and explore themes of personal, psychological, and social identity. Several look at mistaken identity and its consequences, such as in *The Parent Trap*; others explore the indelible effects of twinship, such as Jodie Foster's twin portrayal in *Nell*. But the very refreshing and recent expression of the dichotomy of twins is Ivan Reitman's *Twins* where Danny DeVito and Arnold Schwarzenegger play twin brothers, causing the audience to think that they can't be twins because they do not look anything alike, let alone look identical!

Twins in the press fare somewhat differently. Articles often appear about famous twins and famous parents of twins, such as agony aunts Ann Landers and Abigail van Buren or parents of twins Mia Farrow or James Stewart. Other articles focus on the unusual nature of being a twin, exploring the possible psychic affinity between twins, especially looking at those twins who were separated for one reason or another early in their lives. The actual birth of twins and the subsequent parenting of twins forms another category, followed by articles explaining or exploring what it is actually like to be a twin. Finally there are articles revolving around science and nature, often using twins to measure intelligence.

## UNIQUE RELATIONSHIPS AND CHARACTERISTICS

The bottom line for analyzing the unique relationship between twins must be the fact that unlike singletons, twins are two babies who are born more or less at the same time. This biological fact has consequences for the twins from the first prenatal stages of their lives, through the birth itself, and quite obviously for their subsequent development as children, as young people, and eventually as adults.

Scientists studying twins are currently debating about the role that genetics plays in relation to environment, also known as the nature versus nurture debate. Twins have been used to prove the greater influence of either nature or nurture on behavior, although more and more studies accept the interplay between the two (influences). This is vital for actually understanding the determinants of behavior of different sets of twins.

Knowing whether a twin is identical or fraternal is also vitally important for those scientists hoping to

explain behavior and development by twin type. The most popular current method of *zygosity* determination (determining whether twins are fraternal or identical) is by DNA testing; a swab of cheek cells from each twin will determine whether they are identical or not.

Much twin research has focused on the different types of twins, hoping to establish relationships concerning the role that genetics plays. Other social scientists are concentrating on the role that environment plays, but they are now not assuming that twins necessarily share the same environment, any more than any other sibling in a family shares the same environment. In other words, each twin has another person (his or her twin) directly or immediately in their environment, virtually from the moment of conception. And this other person, the twin, modifies and determines the environment in which they both live. They are defined and often treated as twins, although like other siblings they also face varying environments due to gender differences, positions in the family, relation to parents, and so on. Nonetheless, they share the "twin factor."

## SUMMARY

Twins are different, distinct, special, and fascinating. They have been studied, analyzed, and written about for a long time in all cultures, yet there is still a great deal to learn both about twins and from twins.

—Elizabeth A. Stewart

## ULTRASOUND

---

The use of ultrasound in medical diagnosis had its beginnings as *sonar* (sound and navigation ranging) used in the First World War by submarines for underwater navigation. Ultrasound generation and detection was based on the use of a piezoelectric crystal such as quartz or PZT (lead zirconate titanate) whose inherent composition allowed it to convert electric to mechanical energy, as well as the reverse. An electrical impulse was used to excite the crystal, which generated a wave of high-frequency sound (above 1 million cycles per second, or 1 megahertz) that traveled through any solid or fluid medium but not through air. When this pulse wave encountered a material of differing density, some of the energy would pass into it and some would be reflected back to the emitting crystal. If the crystal was kept inactive, it would detect the returning pulse wave and would convert this mechanical vibration into an electrical impulse that would be displayed on a monitor or oscilloscope.

In the early 1940s, the piezoelectric effect was used to detect flaws in metal. Using one of these early systems, Karl Theodore Dussik, a neurologist at the University of Vienna, detected some brain tumors. In Denver, Joseph Holmes, a kidney specialist and

acting director of Medical Research, had his engineers build the first two-dimensional ultrasound scanner in 1951. The patient was placed in a water bath while the ultrasound probe moved around the abdomen. This unit was called the Somascope and was featured in the Medicine section of *Life* magazine in 1954.

Ian Donald, a professor of Obstetrics and Gynecology in Glasgow, saw the potential of this technique and first reported on its use in women to detect masses and to differentiate solid from fluid-filled or cystic masses. With the help of some engineers, he built an ultrasound scanner that did not require placing the patient in a water bath, thereby making the technique much more accessible. The case that changed his life was that of a woman who had been diagnosed with a large abdominal mass thought to be an inoperable tumor. Using ultrasound, he saw that the mass was a simple fluid-filled ovarian cyst, promptly removed it, and “saved” her life. Ian Donald was a remarkable individual with whom I had the privilege of studying in the early 1970s. He was not only a leading obstetrician and researcher but also an accomplished painter, pianist, scientific writer, and sailor, all the while suffering heart failure from a leaking mitral valve.

Ultrasound has been used during pregnancy routinely since the late 1970s. It can visualize the pregnancy

Completing a sonogram

from 5 to 40 weeks of gestation; determine the correct fetal age by measuring the fetus' length, head, abdomen, and legs; and monitor fetal growth. The fetus can be examined using ultrasound, and most abnormalities in all of its vital organs can be detected. It can detect multiple pregnancies and ectopic pregnancies. The position of the placenta is also routinely examined by ultrasound during pregnancy.

Ultrasound is used in more than 75% of pregnant women to accurately establish the age of the fetus and to detect abnormalities in the fetus, amniotic fluid, and placenta. Ultrasound scanners are found in most hospitals around the world and in many obstetricians' offices.

An ultrasound scanner today is basically a computer, and as computers get smaller and faster, so too does the scanner. It is now capable of producing stunning three-dimensional images. Finally, even though the technology is sophisticated, it requires a trained operator, technologist, and physician to accurately interpret the information collected.

—Edward A. Lyons

## UNIVERSAL GRAMMAR

---

The definition of universal grammar has evolved considerably since first it was postulated and, moreover, since the 1940s, when it became a specific object of modern linguistic research. It is associated with work in generative grammar and it is based on the idea that certain aspects of syntactic structure are universal. Universal grammar consists of a set of atomic grammatical categories and relations that are the building blocks of the particular grammars of all human languages, over which syntactic structures and constraints on those structures are defined. A universal

grammar would suggest that all languages possess the same set of categories and relations and that in order to communicate through language, speakers make infinite use of finite means, an idea that Wilhelm von Humboldt suggested in the 1830s. From this perspective, a grammar must contain a finite system of rules that generates infinitely many deep and surface structures, appropriately related. It must also contain rules that relate these abstract structures to certain representations of sound and meaning—representations that, presumably, are constituted of elements that belong to universal phonetics and universal semantics, respectively.

This concept of grammatical structure is an elaboration of Humboldt's ideas but harkens back to earlier efforts. In *Cartesian Linguistics*, Noam Chomsky traces precursory work related to UG in the writings of Panini, Plato, and both rationalist and romantic philosophers, such as René Descartes (1647), Claude Faure Vaugelas (1647), Cesar Chesneau DuMarsais (1729), Denis Diderot (1751), James Beattie (1788), and Wilhelm von Humboldt (1836). Chomsky focuses in particular on early efforts by the 17th-century Port Royal grammarians, whose rationalist approach to language and language universals was based on the idea that humans in the "civilized world" share a common thought structure. Moreover, he traces the conception of linguistic structure that marked the origins of modern syntactic theory to Lancelot and Arnaud's 1660 Port Royal work, *Grammaire generale et raisonnee*, which postulated a link between the natural order of thought and the ordering of words. Much of what came to be known as modern linguistics in the 20th century belied philosophy in favor of behaviorist currents and various structuralist approaches that on the one hand narrowed this domain of inquiry, while on the other hand providing an expanded database that came to be critical for those willing to use it in a return to traditional concerns. The rejection of historical approaches occurred in part because of the newfound optimism, inspired by contemporary scientific methods and by the "new methods" in linguistics, about the possibilities for making real advances in our understanding of how language functions. In the background of this optimism lie the great discoveries in mathematics and physics, the promise of a new computer and telecommunications industry, the political requirements for enhanced language research, and the concomitant funding offered for such endeavors by the American government, particularly after 1939.

Consistent with earlier work on universals, Universal Grammar came to refer to aspects of the grammatical structure that form the makeup of grammars of all "natural languages." According to Chomsky's early work, there are two keys to the understanding of human language, universal grammar and deep structure, the former described as a sort of metatheory, the latter a technical term pertaining to the particular grammar and designating a precise stage in the derivation of a sentence. To advance our understanding of both, his early goals were threefold: first, to determine what is the nature of the intuitive, unconscious knowledge that permits the speaker to use his or her language; second, to construct an explanatory theory; and third, to consider the general principles of language as the properties of a biologically given system that underlies the acquisition of language.

Chomsky enters the scene in the 1940s, at the height of the optimism, and in a project that both furthered and challenged this work, he wrote an undergraduate thesis called "Morphophonemics of Modern Hebrew," later expanded to a master's thesis with the same title in 1951. That work was a "generative grammar" in the contemporary sense because it contained a rudimentary generative syntax. Chomsky claims it as the first example thereof, but also recalls classical precedents, including Panini's grammar of Sanskrit and, at the level of morphology and phonology, Leonard Bloomfield's *Menomini Morphophonemics*, published only a few years earlier. The goal of this work was an attempt to demonstrate that the generative grammar presented was the simplest possible grammar in a well-defined technical sense: namely, given a certain framework for the formulation of rules and a precise definition of "simplicity," the grammar was "locally optimal" in the sense that any interchange of order of rules would lead to a less simple grammar. This work was undertaken for Zellig Harris, who at that time was involved in a related, but differently focused, problem of transformations in a structuralist paradigm. Chomsky's early sense was that the discovery procedures and the methods employed by structural linguists such as Zellig Harris were in principle correct, and that only some refinements were necessary to make them work, in the sense of being able to produce a correct grammar with infinite descriptive scope from a finite corpus of the language.

What irked Chomsky early on, however, was Harris's deferring to behaviorist and empiricist models, which he resisted, on the basis of his "Cartesian" belief that one should assume that the general form of the

resulting system of knowledge should be given in advance. For Chomsky, the system required to produce human language could not be constructed gradually, step by step, by induction, segmentation and classification, generalization and abstraction, and so on. This was different for Zellig Harris, for whom the goal was to use certain “transformations” to “normalize” the discourse, to transform complex sentences into uniform simple structures to which the methods of structural linguistics might apply: segmentation of sequences, substitution of elements, classification, and so on, all of which suggested that transformations were simply systematic relations between sentences and surface structures. If Harris’s assumptions were right, then obviously machines could play a role in such a project, and indeed he believed, along with many others, that computers were going to permit the automation of discovery procedures in linguistics. The idea would be to present a corpus of material to the computer so that it would work out the grammar of the text, on the assumption that the taxonomic procedures of analysis that had been developed were in essence sufficient and adequate to determine grammatical structure. It was quite generally supposed within such circles that B. F. Skinner’s theory of behavior approached adequacy, and that the notions developed within the theory of communication furnished a general framework for the study of language within this structuralist paradigm. Chomsky rejected the empiricism of this model, so that even in his earliest work, a transformation is not a relation between two sets of sentences, or between two surface structures; it is a rule within a system of rules that assigns structural descriptions to an infinite class of sentences. In the derivation of a particular sentence, a transformational rule applies to an abstract representation of this sentence and transforms it into another abstract representation. The initial representation is the so-called *deep structure*, which is transformed step by step into terminal (or surface) structure through transformational rules. These surface structures take on a particular phonological form and emerge as the sentences one actually hears.

With Chomsky, therefore, a shift in scientific paradigms in the work of linguistics occurs that works on universal grammar away from the ambitions of mathematics, structuralism, empiricism, and behaviorism and toward biology and a branch of cognitive psychology wherein the basic problem is posed by the human capacity to acquire a natural language, something that he insisted we should see as remarkable, with regard

both to what the child experiences and to what he or she acquires. What the child acquires is an indefinitely extensive creative capacity to produce and to understand an open-ended set of sentences that he or she has never heard before. To explain the gross disproportion between what is acquired (in the form of competence) and what is experienced (in the form of speech), Chomsky posited a strongly constrained, internal, innate mechanism that, when triggered by the experience of speech, builds a cognitive structure, a grammar of the language, within limits set by very specialized schemas. Because any child can learn naturally any human language, these schemas had to be universal; thus, when Chomsky referred to the properties of the innate mechanism, he indicated that each of us possesses, indeed knows, the principles of a universal grammar. What exactly is involved in the innate component, what principles the language-acquisition device is armed with, are the technical matters that make reading Chomsky’s work so complex; however, in terms of overall objectives, the more general question is to describe their presence, which he did through the terminology of unconscious, innate *knowledge* that, once again, is his way of connecting his theories with those rationalist thinkers of the 17th century.

Therefore, from the early 1960s, the universal grammar objective was to abstract general principles from the complex rule systems devised for particular languages, leaving rules that are simple, constrained in their operations by underlying principles. By the mid-1970s, many particular aspects of the theory had changed, notably on the matter of the relations between syntax and semantics, leading Chomsky to abandon the “standard” theory of *Aspects of the Theory of Syntax* (1965), by which semantic interpretation was applied to deep structure, and instead to apply semantic interpretation to surface structure. He also abandoned his use of the term *deep structure* for those initial abstract base sentences to which the transformations are applied because not only these base sentences, but also processes applied at the level of surface structure, were deemed “deep” in the sense that they express important and hidden human powers. This is the shift that is familiar to those who have read more recent work by Chomsky because it insists on the power of linguistic theory to reveal the depth of the human mind. It implies an uncovering of lower, but continuously related, levels of human thought, further questioning the shallower and more mechanical view of the empiricist outlook, which incidentally can

be easily associated with a denial that there is a human nature, an idea that perhaps had currency for its ability to be employed for manipulative and authoritarian conceptions of purposes, one of the few links between language and politics in Chomsky's work.

As far as methodology was concerned, in Chomsky's early universal grammar work, much effort was exerted to extract and describe a great number of rules, and no distinction between rules and conditions of rules was made at this stage; by the 1970s, Chomsky was trying to do the opposite, to limit the expressive power of the rules. Thus, there is considerable evolution in the theory of universal grammar, even while there is consistency, as he himself notes in the Minimalist Program. Chomsky maintains some underlying factual assumptions that date back to his work in the 1950s, notably that there is a component of the human mind or brain dedicated to language and the language faculty, which interacts with other systems. He also maintains that performance systems are in part language specific (and hence are components of the language faculty) and that the cognitive system interacts with the performance systems by means of levels of linguistics representation. Thus, for the model, the cognitive system is deemed to interact with the articulatory-perceptual system and with the conceptual-intentional system through two interface levels—phonetic form at the articulatory-perceptual interface and logical form at the conceptual-intentional system—which links his work to earlier ideas about the relation of sound to meaning. What is new, and what has led to recent works such as Baker's *The Atoms of Language*, is the emphasis on principles and parameters, which holds that languages have no rules in anything like the familiar sense and no theoretically significant grammatical constructions except as taxonomic artifacts. There are universal principles and a finite array of options for how they apply (parameters), but no language-particular rules and no grammatical constructions of the traditional sort within or across languages. The resulting project aims to show that the apparent richness and diversity of linguistic phenomena is illusory and epiphenomenal, the result of interaction of fixed principles under slightly varying conditions. As Chomsky put it, these are the "new horizons in the study of languages and the mind"—new in emphasis, ancient in ambition.

—Robert F. Barsky

---

## U.S. BUREAU OF THE CENSUS

---

The U.S. Census Bureau, also known as the U.S. Bureau of the Census, has existed as a separate agency

since 1903. The primary task emanates from the constitutional mandate for the taking of a census every 10 years for purposes of apportioning political representation among the states according to the distribution of the population. Just as dramatic changes occurred over time in implementing this count, as technologies evolved from hand calculations and early tabulating machines to efficient, high-capacity computers and the population grew and diversified, according to the Census Bureau, the mission has become “to be the preeminent collector and provider of timely, relevant and quality data about the people and economy of the United States. We will succeed by valuing our employees, innovating in our work, and responding to our customers.” The crucial topics are people, housing, business, and governments, and the major resource is the decennial census of population and housing, although this leading statistical agency is increasingly central for other sources (surveys, administrative statistics, and other information).

The U.S. Census has been taken 22 times. Early census information appears not only in yellowed volumes but also online for 1790 to 1870, as does 1990 and 2000 census information. These statistics are the population’s historical record and appear in compilations (e.g., Statistical Abstracts) and comprehensive reviews, other publications, and the integrated public-use microdata sets from the University of Minnesota. As a federal agency pioneering electronic dissemination of reports in the past decade, the Census Bureau releases data promptly, and this empowers data users with easy access and capabilities. The decennial censuses account for core activities to gather data on the demographic, social, and economic characteristics of the U.S. population that are reported in government publications, scholarly articles, and census monographs supported by the Russell Sage Foundation, which help explain changes during the decade. The Census Bureau staff implements other federal surveys that examine labor force trends, health status, and program participation, and one of these, the Current Population Survey, provides the basis for annual poverty and income measures.

The first census in the new millennium has been noted as the best census ever, and the 2000 census may also have been the last census that involved collection of detailed characteristics. The usual positive correlation of economic development with statistical infrastructure simply may not be applicable for the United States confronted with considerable capabilities for

gathering statistics on a complex population given the escalating costs of that effort. The 2010 census is to be the reengineered census, with the American Community Survey regarded as the way to collect detailed characteristics nationally on a continuous basis.

Censuses have historically compensated for serious gaps in statistical systems, and regular counts are especially valuable, with 10s of millions of migrants in a world on the move. From about 2 million in 1950, the U.S. Hispanic population has grown quickly to 35 million in 2000, particularly affecting states and metropolitan areas of high immigration of the West and South. Demographers are intrigued not only by the classical questions of changing composition and changing propensity but also by quantifying population change. After the 2000 U.S. Census count of 281.4 million was higher than expected, several studies concluded recent unauthorized immigration in the 1990s was higher than officially allowed. Thus, census demographers have been able to benchmark the population estimates with more “correct” components of population change.

The overall population growth as a consequence of fertility and immigration of Asians, Latinos, and others means the United States is the only developed nation projected in the top 20 countries by 2050. Amnesty programs for unauthorized residents and agricultural workers in the late 1990s transformed the U.S. Mexican population as to lawful presence, unauthorized migration continued despite intensified enforcement at the southern border, and authorized immigration continued, especially of family members, enhancing integration within American places and institutions. Scholars are building a collection of new immigrant and new ethnicity studies on the basis of statistical portraits from census and surveys in conjunction with rich, qualitative studies.

## UTOPIANISM

---

Utopian dreaming is not unique to one historical period but represents a theme that runs throughout human history. Although Thomas More coined the term *utopia* in 1516, utopian thought is evident in ancient texts and stories, including Greek and Roman mythology, Plato's *Republic*, the Hebrew account of the Garden of Eden, and Christian conceptions of "a transcendent heaven of splendor" (Pitzer, 1997, p. 4). Utopian scholars are loath to say that utopianism is part of "human nature," but it is probably accurate to say that all people dream of a better life, if not for themselves, at least for those who are wanting. As Sargent (1994) puts it, "At its root, then, utopianism is the result of the human propensity to dream while both asleep and awake" (p. 4).

Utopianism is evident not simply in literature but also in experimentation. Today, numerous utopian communities can be found around the world, some of them relatively well known and established. Although these communities share the goal of working toward a better world, their differences in religion, politics, economics, governmental structure, and lifestyle often outweigh their similarities. Examples of contemporary utopian communities, as described in 2000 in the Fellowship for Intentional Community's *Communities Directory*, include the following:

- Auroville, a community of more than 1,000 people in India, whose purpose is "to realize human unity"
- The Federation of Damanhur, founded in 1977 in Italy, with a current population of more than 400 people. "Since the very first day of its foundation, Damanhur has been engaged in creating a sustainable way of life."
- Findhorn Community, founded in 1962 in Scotland, which works toward "a joyful, loving and sustainable future on Earth"

- The Kibbutz movement in Israel, which traces its beginnings to 1910 and currently includes about 123,000 people in more than 250 kibbutzim. One group, Kibbutz Lotan, works to create a community based on Reform Zionist Jewish values "including equality, economic cooperation, living in harmony with the environment, mutual respect and the betterment of ourselves, our people and the world."

- The Farm community in the United States, formed in 1971, which is "a place where we can relate to each other and the natural environment in a sustainable way, draw upon the collective strength of the community, and contribute to the positive transformation of the world."

- The Twelve Tribes Network, founded in 1972, which is an international network of communities with a focus to serve God and "to love each other as our Master Yashua loved us, to love our Creator with all our heart, soul, mind and strength and to love our neighbors who live around us as we love ourselves."

- The Emissaries of Divine Light, founded in the 1940s, which is "a worldwide spiritual organization dedicated to the spiritual regeneration of humankind."

- Comunidad Los Horcones, in Mexico, which is a community inspired by B. F. Skinner's novel, *Walden Two*, and whose "basic objectives are to design a society where people cooperate for a common good, share property and reinforce egalitarian, pro-ecological and pacifist behaviors."

As Levitas wrote in 1990, "utopia expresses and explores what is desired; under certain conditions it also contains the hope that these desires may be met in reality, rather than merely in fantasy. The essential element in utopia is not hope but desire—the desire for a better way of being."

—Deborah E. Altus

## VACCINATION

---

Vaccination is a process that artificially confers immunity to an individual against a specific type of disease caused by infectious microorganisms (viruses, bacteria, fungi, or parasites). Vaccines work by using the body's ability to remember previous infections. When an individual becomes infected by an infectious organism for the first time, the immune system recognizes and then destroys it by mounting an immune response specific for that organism. Upon an individual's second exposure to the same microorganism, the immune system recognizes and eliminates it by mounting immune responses that occur more rapidly and are greater in magnitude than those induced on the first encounter. Thus, the infection will not develop to a severe level or to the disease stage. This ability to remember infections, called *immune memory*, allows people to become immune to a disease after they have caught it once. A vaccine simulates that first infection by exposing an individual to a particular microorganism or portions of that microorganism without causing infection and illness. There are several disease-causing microbes for which vaccines

exist. Thus, these diseases can be prevented. Some of the most common vaccine-preventable diseases are diphtheria, tetanus, pertussis, some forms of bacterial meningitis, pneumococcal pneumonia, measles, mumps, rubella, chickenpox, influenza, hepatitis A, hepatitis B, poliomyelitis, and rabies. However, there are still many diseases for which effective vaccines are not available. Some of these diseases are the acquired immunodeficiency syndrome (AIDS), malaria, and schistosomiasis.

Vaccines are made from either all or portions of the microorganism against which the vaccine protects. These portions of the microorganisms are called *antigens* and, in most cases, are proteins, glycoproteins, or polysaccharides. There are three traditional types of vaccines. *Inactivated vaccines* are made from organisms that have been killed in such a way that they still retain most of their original structure. Examples are the inactivated polio vaccine and the influenza vaccine. *Live-attenuated vaccines* are made of live organisms that have been weakened so that they replicate poorly in the human host and therefore do not cause disease. Examples are measles, rubella, and chickenpox vaccines. *Subunit vaccines* are made from only some portions of the organism. These often

contain toxins that have been altered so that they are no longer dangerous, and are called *toxoids*, as, for example, the tetanus and the diphtheria vaccines. Other subunit vaccines contain recombinant protein antigens, as, for example, the hepatitis B vaccine. A particular class of subunit vaccines is represented by conjugate vaccines, which consist of bacterial polysaccharides linked to protein carriers. An example is the *Haemophilus influenzae* type B vaccine.

Several types of vaccines are still in the experimental stages and will be part of a new generation of vaccines in the future. These include *DNA vaccines*, which use the gene encoding a particular protein from an organism, and *recombinant vector vaccines*, which use an attenuated virus or bacterium to introduce a gene from another microorganism into the host, thus eliciting an immune response against the antigen encoded by that gene. A third type of experimental vaccine is one that does not target microorganisms, but rather is designed to aid in the elimination of cancer cells. This type of vaccine, termed *dendritic cell vaccine*, relies on the host's own dendritic cells, a category of white blood cells responsible for the activation of T lymphocytes, to recognize cancer cells and therefore contribute to the mechanisms necessary for their elimination.

Vaccine efficacy is usually improved through the use of adjuvants. These include natural or synthetic compounds used in vaccine formulations that aid in enhancing the immune response to vaccines. Although there are hundreds of compounds being evaluated as vaccine adjuvants, the alum (aluminum hydroxide) adjuvant, first described in 1926, remains the only one used in human vaccines licensed in the United States. Vaccine efficacy is also improved by giving recurrent doses of a vaccine. This practice, called *boosting*, is done to allow the immune system to remember previous vaccinations by exposing it to the vaccine more than once, and therefore to produce stronger memory immune responses that are effective for an extended period of time.

The U.S. Food and Drug Administration (FDA) requires extensive research and testing to ensure vaccine safety and efficacy. Before a vaccine can be licensed for general use, preclinical studies must take place, usually in the form of laboratory and animal testing. Researchers test candidate vaccines using cell cultures and animals such as mice, rabbits, guinea pigs, or monkeys. If the vaccine is successful in these

preclinical studies, it can go on to be tested in humans. Human studies involve a series of clinical trials consisting of four phases. Phase I studies enroll up to 20 people and primarily test for safety. Phase II studies involve 50 to several hundred people. These studies continue to test for safety and try to determine the best dosage and gather preliminary data on a vaccine's effectiveness. Phase III studies involve thousands of people and are designed for thorough testing of vaccine efficacy. Finally, phase IV studies are conducted to test for rare or delayed adverse reactions that might not have been detected in the smaller studies leading to licensure.

An important goal in vaccine efficacy is to protect an entire community against disease. Individuals who are vaccinated have antibodies and immune cells against a disease-causing organism, so they are much less likely to become infected and transmit that organism to others. This allows individuals who have not been vaccinated or whose vaccines are not fully effective to be protected. This concept is known as *herd immunity*. As the percentage of vaccinated individuals increases, the rate of herd immunity increases.

Since the conception of vaccines, their use has been strongly debated. Several literature reports claim that vaccines have failed and have sometimes caused adverse reactions. In 1998, the American Medical Association reported that measles, a typical childhood disease, is becoming more prevalent among adults as the immune response to the vaccine eventually wears off. The inefficacy of the whole-cell pertussis vaccine was demonstrated when the Centers for Disease Control and Prevention (CDC) released reports that, in 1993, pertussis was at the highest levels since 1976. The failure of manufacturers to sometimes do sufficient research before releasing a product became evident when in 1999 the FDA cancelled use of the rotavirus vaccine almost 1 year from the day it was released. This vaccine protected children against the leading cause of childhood diarrhea but resulted in a dangerous bowel obstruction in infants. Incidents such as seizures, brain damage, ataxia, aseptic meningitis, paralysis, learning difficulties, and deaths have been documented within days or weeks following certain vaccinations. In 1986, the federal government established the National Vaccine Injury Compensation Program (NVICP) to compensate those who suffer from adverse effects of vaccines. Since that time, more than \$1 billion has been paid in injury awards to these individuals.

Another concern regarding vaccines relates to the chemicals that are used in the manufacturing process. Chemicals such as formalin and thimerosal are often used as preservatives and bactericidals in vaccines, whereas aluminum salts are commonly used as adjuvants. There is concern about the exposure to these chemicals, which may be toxic. Although studies indicate that the levels of chemicals used as preservatives in manufacturing vaccines are within a safe range, the CDC, FDA, Academy of Pediatrics, and Public Health Service have recognized this as a legitimate concern. As a result, the FDA has encouraged pharmaceutical companies to manufacture single-dose vials of the vaccines without thimerosal, formalin, or other chemicals.

Despite reports of adverse reactions linked to vaccines and the chemicals used in the manufacturing process, statistics show that the numbers of such reports are extremely low compared to the number of children vaccinated each year. Very few reports have shown definitive evidence linking vaccines to all adverse effects. Illness occurring after a vaccination is regarded as an adverse effect of that vaccine, although the exact cause may be unknown. Further studies are needed to document evidence of vaccines causing adverse reactions.

In the early 20th century, infectious diseases were widely prevalent and had an enormous toll on the population because few effective treatment and preventive measures existed. Since then, substantial achievements have been made in the control of many vaccine-preventable diseases in many countries. Smallpox, which once caused rampant epidemics, was officially eradicated in 1980 as a result of the World Health Organization (WHO) mass vaccination campaign. Poliomyelitis and measles are other infectious diseases targeted for eradication. The rate of occurrence of vaccine-preventable diseases has dramatically decreased in the past decades. The use of vaccines is one of the few approaches that can prevent a disease from occurring, rather than attempting to cure it after it has developed. In general, the risks for adverse effects to vaccines are considered insignificant compared with the benefits of vaccination. According to the CDC, vaccination rates are at an all-time high, and occurrences of childhood diseases are at an all-time low. Thus, although few concerns exist, it is clear that vaccine benefits outweigh the risks.

## VALIDITY

---

Validity refers to the extent to which a test measures the construct it purports to measure. Essentially, validity has to do with the meaningfulness and usefulness of the specific inferences made from test scores. For example, regarding a measure of assertiveness, the question of its validity would be whether it actually measures assertive behaviors. A truism is that a test can be reliable (i.e., stable and consistent) but not valid, but a test cannot be valid without first being reliable. The different types of validity include *face*, *content*, *criterion*, and *construct validity*.

*Face validity* is the simplest type of validity and refers to how well items on a test reveal the purpose or meaning of the test. For example, the test item "I feel sad all the time" has obvious face validity as an item measuring depression. The downside of test items with clear face validity is that they may be easily manipulated by respondents, either to minimize or exaggerate problems. Some psychometricians appreciate tests that lack face validity but still possess general validity. Test items that still measure what they purport to measure but lack face validity are harder for respondents to manipulate.

*Content validity* of a test refers to the adequacy of sampling of content across the construct being

measured. Given the published literature on a particular construct, are all aspects of that concept represented by items on the test? Consider a psychological theory of depression that holds that depression is caused by negative thoughts about oneself, the world, and the future. A test of depression according to this model should include items that measure these three aspects. A strategy testmakers follow to achieve content validity is to summarize what experts claim to be the nature of a particular construct and then create test items to reflect the consensus. Items measuring a construct should appear in equal proportion to what the literature search reveals or what the experts claim about that particular construct.

*Criterion validity* (also called *predictive* or *concurrent validity*) refers to the comparison of scores on a test with some other external measure of performance that is theoretically related to the first measure. The relationship can be assessed by a simple correlation coefficient. Some psychometricians further divide criterion validity into predictive or concurrent validity. With predictive validity, the new test is given to a group of participants who are followed over time to see how well the original assessment predicts some important variable at a later point in time. In concurrent validity, a new test is given to a group of participants who complete other theoretically related measures concurrently (at the same time). How can a testmaker demonstrate concurrent validity if he or she is the first to create such a test? Unfortunately, this is not easy. The testmaker must use forms of validity other than concurrent validity if there are no other known measures of that construct. This problem is particularly troublesome for diagnostic measures in psychology. Because there are no definitive biological markers used for the diagnosis of any mental disorder, there are no objective gold standards for diagnostic accuracy. This fact makes it difficult to assess the criterion-related validity of any diagnostic test in psychology.

*Construct validity* refers to the extent to which a test captures a specific theoretical construct or trait. This requires a test to be anchored in a theory that delineates clearly the meaning of the construct, its uniqueness, and its relationship to other variables measuring similar domains. Psychometricians typically assess construct validity by giving other measures of a trait along with the new proposed measure of a trait and then testing prior hypothesized relationships among the measures. Such hypothesized relationships typically include a mixture of

meaningful positive relationships and meaningful negative relationships.

## VERY LOW BIRTH WEIGHT (VLBW)

---

The birth of a newborn infant is a joyous event, but for many families, the reality of an extremely premature baby can be sudden and unexpected. Recent changes in prenatal care practices have enabled the survival of many infants that would have otherwise died after birth. Very low birth weight (VLBW) is part of a larger category of low birth weight. In 1950, the World Health Organization adopted the figure of less than 2,500 grams (5 lb., 8 oz.) as a universal cutoff to determine low-birth-weight status. Within this definition, very-low-birth-weight cutoffs were determined at weights less than 1,500 grams (3 lb., 4 oz.), and extremely low-birth-weight was defined as less than 750 grams (less than 2 lb.). VLBW infants are all born preterm (less than 37 weeks' gestational age) and are likely to experience varying degrees of intrauterine growth failure. Today, VLBW children constitute 1.5% of all births in the United States and less than 15% of low-birth-weight births. Racial differences are apparent within this range: 1.2% of white infants and 3.1% of black infants are born at VLBW.

## SURVIVAL AND TREATMENT

VLBW is a natural result of preterm delivery, describing babies born chronologically too soon, and is defined as a live-born infant born before the end of the 37th week of gestation (compared with full-term gestation of 40–42 weeks). Gestational age is a predictor of survival, and even a few days may make the difference between survival and death. For example, very few 22-week-old babies have survived. About 50% of 23-week-old babies and 75% of 24-week-old babies given intensive care survive. At 25 weeks' gestation and beyond, although much risk still remains, the chances that a baby will survive and be healthy in the long run are better.

Table 1 shows outcomes based on information obtained from babies less than 29 weeks' gestation born in 1996 in 50 neonatal intensive care units. This table contains information on the survival rate, short-term complications, and treatments, highlighting the importance of gestational age to health outcomes.

An individual baby's chances of surviving depend on four factors: (1) the time into that week (a baby barely 23 weeks' gestation is less likely to do well than a baby almost 24 weeks); (2) the baby's gender (girls tend to do better than boys); (3) multiple pregnancy (singletons tend to do better than individual babies from multiple pregnancies); and (4) whether there was time before birth to give steroid shots to the mother, which helps the baby's chance of surviving and avoiding severe brain bleeding. Depending on these factors, estimates for an individual baby's chances for survival can be anywhere from 25% to 75%.

For babies as small as 500 and 600 grams born at about 24 weeks' gestation, newborn intensive care can currently improve survival. Typically, intensive care may be reconsidered after the first 3 days, when breathing and blood pressure problems are usually resolving and the first brain ultrasound has been reviewed. Most extremely premature babies who survive have at least some degree of handicap. The problems related to the brain are by far the most important because brain injuries often affect uniquely human traits and characteristics, and because brain injuries cannot heal themselves. There is much medical uncertainty of decisions about instituting intensive care in very preterm infants, thus causing difficult ethical decisions for anxious parents.

## COMPLICATIONS AND RISKS

Health outcomes are often more favorable when a baby has minimal difficulty with immature lungs, blood pressure, infections, and other problems that can result from an extremely premature birth. Unfortunately, an additional complication is the problem of severe bleeding into the brain, which happens to some extremely premature babies. Small amounts of bleeding in the brain can have little or no effect on a baby, whereas severe bleeding in the brain often cause significant permanent handicaps. When severe bleeding occurs, it almost always happens in the first 3 days after birth. If no severe bleeding is seen, a major hurdle has been successfully cleared. If severe bleeding is seen, the possibility of surgeries for hydrocephalus (excessive fluid accumulation within the brain) and cerebral palsy increases. There is also a greater likelihood that the child will develop serious disorders, including developmental delays, seizures, and learning disabilities.

Several additional health complications are possible, such as retinopathy of prematurity (ROP), an abnormal growth of blood vessels in the retina. ROP occurs because the vascular system in the baby's eye hasn't fully developed. Many cases of ROP disappear on their own, but sometimes the condition leads to scarring. Some premature infants are also at risk for a potentially severe intestinal problem known as necrotizing enterocolitis (NEC). In the most serious cases, this condition can be life threatening. Premature babies are also at increased risk for sudden infant death syndrome (SIDS), a condition in which babies die in their sleep, which claims the lives of about 2,500 infants each year.

Not all preemies have medical or developmental problems. By 28 to 30 weeks' gestation, the risk for these complications is much lower. For babies born between 32 and 35 weeks, most medical problems are short term. Finally, infections in VLBW infants are also common and can cause a baby to become much sicker or die. Unfortunately, the ventilators that help babies breathe and keep them alive also damage the lungs. This can lead to problems with pneumonia through the early childhood years, requiring more time in the hospital.

## DEVELOPMENTAL IMPLICATIONS

Of the possible handicaps, perhaps the most important is cerebral palsy, found to be 25 times more

**Table 1** Outcomes From Babies Less Than 29 Weeks' Gestation Born in 1996

	<i>Gestation in Weeks</i>			
	23	24	25–26	27–28
Estimates for survivors	23	24	25–26	27–28
Total no. of babies admitted to NICU in 1996 (% of babies who survive)	209 (18)	291 (52)	455 (81)	761 (91)
% with breathing problems needing asst ventilation	100	98	98	90
Average no. of days in hospital before going home	130	97	91	69
Significant abnormal brain scans %	23	20	19	10

common in children who had been VLBW infants. VLBW children experience combinations of various neurosensory, developmental, and health problems, which can worsen clinical and educational outcomes. For example, VLBW infants perform more poorly on extensive batteries of neuropsychological tests than do infants born either at higher weights or at term. As they age, there is an increased risk for behavioral problems, especially among boys, including conduct disorder, hyperactivity, and attentional weaknesses. Patterns of shyness, unassertiveness, and withdrawn behavior have also been documented.

### School Age

Generally, predictions of future outcomes for VLBW infants depend on waiting until these children are at least 8 years old. Some cognitive skills may be more compromised than others in low-birth-weight children, and this may eventually be reflected in school performance and academic achievement. Levels of achievement in reading, spelling, and math are lower for VLBW children than for children born at full term. These problems are reflected in much higher proportions of low-birth-weight children than normal-birth-weight children who are enrolled in special education programs or repeat grades. About 50% of all low-birth-weight children are enrolled in special education programs.

Within the VLBW group, different classifications of handicap are evident and show different outcomes

for the conditions stated previously. VLBW children who are classified in the *moderate* handicap group have borderline intelligence that falls between low-normal and mildly mentally retarded and also often have mild cerebral palsy. With the cerebral palsy, children have permanent difficulties with muscle control, need physical therapy, and usually begin to walk much later than most children. Vision may be impaired even when using glasses. Most children in this group need special education in school. Many children in this group are not able to live independently as adults.

Children in the *severe* handicap group are mentally retarded or have severe cerebral palsy, usually to a degree that keeps them from ever walking without

assistance. Children in this group also tend to have the most serious problems with their vision. Although blindness is quite rare, vision is often impaired enough to be a significant problem, even with the best possible glasses. Virtually all children in this group need special education in school, and most are not able to live independently as adults.

### Family Considerations

Family issues can become part of the larger picture from the start, particularly when the birth is well-ahead of expectations. Poor parental understanding in the hospital can result from many interactions: poor communication techniques and lack of time in consultations, contradictory messages, parent denial, inexperience in terminology, unwillingness to ask questions, and the lack of opportunity to review the information given. Family-centered neonatal care has been created to empower parents with support, respect, and encouragement, thus enhancing parental strength and competence.

There is always grief when a baby is born extremely prematurely because, no matter how well things go thereafter, the dream of a full-term pregnancy and a healthy baby has been lost. When children grow up to have serious handicaps, it is hard to predict how the family will be affected. A seriously handicapped child can be a cherished member of one family, whereas another family may be torn apart by the experience. Other children in the family

may feel neglected because of the greater attention a seriously handicapped child requires, but they may also learn important lessons in compassion. Having a child with many medical problems can also be a heavy strain on family finances. Even when the infant eventually develops normally, families can be affected greatly by the experience of having an extremely premature baby. Some marriages fall apart under the stress, and varying degrees of depression may occur. Parenting an extremely premature baby can be a difficult, frustrating experience, but with the proper medical and parental education and social supports in place, parents can help their children to flourish.

## VERY OLD AGE

---

Because of the growing population of older adults in technologically advanced countries, researchers in a number of disciplines are becoming increasingly more interested in examining differences between older adults and *very old* adults as well as the transition to very late adulthood. Very old adults (also referred to as *the oldest old*) are typically defined in the literature as those adults who are 85 years old or older; however, some researchers set the criterion at 75 years old. In general, this population has a higher percentage of women compared with other age groups and is characterized by a high degree of comorbidity (i.e., multiple illnesses or conditions), a lower level of education in relation to other age groups, and high rates of institutionalization. The focus of this entry will be on the physical, psychological, emotional, and social characteristics of this group as well as changes that occur in these domains when older adults

transition into being part of the oldest old population. It is important to note that this population is characterized by a high degree of heterogeneity, making generalizations very difficult.

### PHYSICAL CHARACTERISTICS

As people age, the functioning of bodily systems tends to decline. In addition, the likelihood of adults older than 65 years having one chronic illness is extremely high (80%), with 50% having two or more conditions. These percentages are even higher in adults older than 85 years. The most prevalent of these diseases are cardiovascular disorders, arthritis, and diabetes, with many attributable to health risk behaviors (e.g., smoking, poor diet). In addition, the percentage of very old adults living with Alzheimer's disease increases from 3% in those who are 65 to 74 years old, to 18.7% of those 75 to 84 years old, to 47% of those living past 85 years old. Alzheimer's disease is also the most common reason for institutionalization. Another factor related to institutionalization is functional ability, or the ability to perform activities of daily living (ADLs). Functional ability is generally at a lower level in the oldest old compared with the young old. Research suggests that about one fifth of young-old adults require assistance with at least one ADL, whereas about one third of the very old require assistance with at least one ADL.

Sensory functioning also tends to be at a lower level in the oldest old compared with young-old adults. Longitudinal studies have also found that most (70%) older adults tested for visual and hearing acuity at age 70 had no visual or hearing impairment, and there was no coexistence of visual and hearing impairment. When tested again at age 81, about 10% demonstrated normal visual or hearing, and about 5% demonstrated a coexistence of hearing and visual impairment. At age 88, none of the men and fewer than 10% of the women had normal hearing and vision, and 8% to 13% demonstrated coexistence. In addition, mild impairment was evident in only 0.5% of the sample when tested at age 70, but increased to 23% and 9% for visual and hearing acuity, respectively, at age 88.

### PSYCHOLOGICAL CHANGES

The psychological functioning of the oldest old has also received increased attention recently. The most

commonly studied aspects of psychological functioning are cognitive abilities. Research suggests that cognitive decline in the oldest old differs from that in young-old adults in that it is more broad, more marked, less amenable to interventions, and more constrained by biological factors compared with cultural factors. For example, longitudinal research has found that the loss trajectory becomes markedly more negative after the age of 80 in terms of perceptual speed, memory, and fluency. Knowledge (e.g., vocabulary), on the other hand, tends to remain stable until about 90 years of age. Much of the variance in cognitive loss can be accounted for by sensory decline. This has been suggested by some researchers to represent an age-related slowing of the central nervous system (also referred to as the *common cause hypothesis*). Factors such as education, socioeconomic status, ethnicity, sex, and the presence of certain chronic conditions (e.g., diabetes, cardiovascular disease, Alzheimer's disease) also contribute to the heterogeneity of cognitive abilities in late adulthood. However, in general, old-old adults are more likely to be assessed as having lower psychological functioning than young-old adults.

Another research question is whether personality and self-identity remain stable into and throughout this stage. For example, it has been found that very old adults have a relatively stable sense of self, despite believing that some of their characteristics have changed. This suggests that there is a continuity of self into very late adulthood. Research has also found that self-esteem begins to decline in late adulthood. However, rather than being negative, this may represent an increased comfortableness and acceptance with one's self and personal faults. Finally, cross-sectional research examining stability of personality traits as measured by the revised NEO Personality Index (NEO-PI-R), found that the oldest old scored lower on extraversion and on the facet traits of impulsiveness, warmth, and positive emotions in relation to the young-old group, but were similar in terms of neuroticism, openness to experience, conscientiousness, and agreeableness, thus suggesting an overall stability of personality.

## SOCIAL RELATIONSHIPS

It is widely recognized that as people enter later adulthood, their social networks tend to decrease in size. Activity theory suggests that this decrease is a

result of factors such as decreased mobility, death of people in the social network, and other obstacles to social contact. In contrast, disengagement theory suggests that there is a mutual disengagement between society and old adults in preparation for impending death. However, recent research suggests that older adults are proactive in selecting their social partners in later life. Laura Carstensen's socioemotional selectivity theory posits that as people age, the importance of emotional support and regulation increases, while the salience of acquiring information decreases. Thus, older adults actively select relationships on which to focus their potentially decreasing resources in order to maximize the likelihood of positive experiences. Often this results in a decrease in the number of less close social contacts and stability in the relatively small, but very close and meaningful, social partners.

Another factor affecting social relationships in this age group is the high likelihood of being widowed. Because men have a shorter life expectancy, women are much more likely to be widowed and men are more likely to be married, thus providing men with a more salient source of social support.

## EMOTIONAL CHANGES

Research has found conflicting results concerning changes in the experience and expression of emotion in very late adulthood. Some researchers suggest that because of increasing disability and role loss, the amount of negative affect experienced increases, whereas the amount of positive affect decreases. It has also been suggested that the experience of both negative and positive affect decreases because of less exposure to affect-inducing events or because of increased emotional regulation, and that positive affect increases and negative affect decreases as a result of older adults actively selecting situations that optimize the likelihood of experiencing positive affect. In a meta-analysis of the literature, it was found that negative affect does tend to increase and positive affect tends to decrease in the oldest old, and that the frequency and intensity of experiencing high-arousal emotions also decreases.

Research on depression in older adults generally suggests that age is not predictive of clinical depression, but depressive *symptoms* do tend to increase when transitioning into later life. Many researchers suggest that this increase is due to increased scores on negative symptoms and not decreased scores on items

assessing well-being. Also of interest is that the relationship of functional ability, cognitive impairment, and depression is often mediated by psychological resources (e.g., mastery). This suggests that it may not merely be the presence of disabilities that lead to depression, but the ways in which they are interpreted.

## CONCLUSION

Because the population of people older than 85 years is the fastest growing population in terms of age groups, research examining this age period is becoming more important. Although researchers have identified trends, the heterogeneity of this age group cannot be underemphasized, thus increasing the need for longitudinal studies examining intraindividual change. Caution should also be taken when interpreting the results from studies examining the oldest old because participants typically represent a very positive selection of the population and of their cohort. Finally, because of the relationships between the aspects of aging discussed (e.g., sensory ability and cognition, social relationships and emotion), there is a need for multidisciplinary research to further explicate when and how these interactions occur.

## VIDEO GAMES

### ORIGIN AND GROWTH OF THE VIDEO GAME INDUSTRY

The first interactive computer game, *Spacewar*, was written in 1961 by an MIT student named Steve Russell on a Digital Equipment PDP-1 computer. The first consumer video game, *Pong*, was released a decade later in 1972. Throughout the 1970s and into the 1980s, most video games were played in arcades (in this chapter, we define video games to include arcade games, computer games, and home console games such as PlayStation). Several recurring themes began to emerge at this time: multiple companies vied for market dominance, displacing older systems with each new technological advance; the popularity and cultural impact consistently grew over time; and concerns arose regarding the effects games might have. Concerns about video game violence first became highly salient in 1976 with the game *Death Race*, in which the goal was to drive a car over stick figures called “gremlins.”

Currently, video game images are created out of many polygons; therefore, the number of polygons processed per second (pg/s) is a common measure of graphics quality. The Sony PlayStation, released

in 1995, processed 350,000 pg/s. Sega's Dreamcast, released in 1999, leaped ahead to more than 3 million. A year later, Sony's PlayStation 2 jumped to 66 million pg/s. One year after that, Microsoft's Xbox boasted 125 million pg/s. The stated goal for Sony's PlayStation 3 is 1 billion. At the same time, this increased speed and graphic capacity allowed for games to become more realistic, including far more realistic and graphic violence. Returning to an old theme, the top-selling video games from 2001 to 2003 were the *Grand Theft Auto* series, which included running down pedestrians with cars, and killing police, prostitutes, and others with a variety of weapons. The video game industry is now bigger than Hollywood, raking in more than \$10 billion annually in the United States in 2002 and 2003. As games have taken up more of children's time and become more realistic and engaging, researchers have begun to study children's uses of video games and the varied effects they may have.

#### CHILDREN'S USE OF VIDEO GAMES AND SEX-CORRELATED DIFFERENCES

The amount of time children spend playing video games has increased over the past three decades. Considering both home and arcade playing in the mid-1980s, children averaged about 4 hours per week. By the early 1990s, home playing had increased and arcade playing had decreased, and sex-correlated differences had begun to emerge. Girls played an average of about 2 hours per week, with boys playing an average of 4 hours per week. In the mid-1990s, home play had increased for fourth-grade girls to 4.5 hours per week and 7.1 hours per week for boys. In 1999, school-age children (boys and girls combined) averaged 7 hours per week. Most recently in elementary and middle-school populations, girls are playing about 5.5 hours per week and boys average 13 hours per week. Perhaps surprisingly, the average amount of television watched has not dropped as video game playing time has increased.

It is still unclear at what age video game playing begins, but it is likely to be younger with each passing year. In a nationally representative survey, parents reported that children aged 2 to 7 play an average of 43 minutes per day. In studies of preschool children, even preschoolers aged 2 to 5 play an average of 28 minutes per day. It is also unclear when play peaks, if it does, and when it declines, if it does. Regardless of when children start playing, and whether there is a normative

peak time, it is clear that gamers do not stop playing once they turn 18. The average age of a video game player has risen steadily, and is currently 29. It is important not to let this average mask the fact that video games have become ubiquitous in youth culture, with 92% of 2- to 17-year-olds playing.

Three sex-correlated differences have been found consistently across studies. First, males are more likely to play video games than females. Second, males are more likely to spend more time playing video games. Third, males prefer more violence in their video games. Most researchers define violence in games as when the player can intentionally harm other characters in the game. Content analyses show that most games contain some violent content, and about half of those include violence that would result in serious injuries or death. When asked, a majority of fourth- to eighth-grade children prefer violent games.

#### VIDEO GAME EFFECTS

Video games are natural teachers. Children find them highly motivating; by virtue of their interactive nature, children are actively engaged with them; they provide repeated practice; and they include rewards for skillful play. These facts make it likely that video games could have large effects, some of which are intended by game designers, and some of which may not be intended. We review several of these intended and unintended effects below, grouped into what could be considered "positive" and "negative" effects.

#### Positive Effects

The educational value of educational software and video games (known as *discrete educational software*) has been so widely accepted that such software is second only to word processing software in its availability and use in school classrooms. Although the quality of research in this domain varies widely, meta-analyses of recent high-quality studies of the efficacy of discrete educational software show an effect size of 0.38. That is, the average correlation between student use of educational software and student achievement is 0.38. The average correlation is 0.35 for educational games teaching reading skills and 0.45 for games teaching math skills. The efficacy for teaching prereading skills may be even greater than for teaching reading skills. The average correlation between educational software/games and reading skills is

0.44 for prekindergarten and kindergarten children.

Video games with other specific types of content have also shown positive effects. Video games have been used to teach children healthy skills for the self-care of asthma and diabetes and have been successful in imparting the attitudes, skills, and behaviors that they were designed to teach. In a study of college students, playing a golf video game improved students' actual control of force when putting, even though the video game gave no proprioceptive feedback on actual putting movement or force.

Some researchers have argued that video games are the "training wheels" for computer literacy. Computer literacy includes skills beyond traditional literacy skills, specifically iconic skills (image representation and manipulation). Research suggests that people can learn iconic, spatial, and visual attention skills from video games. For example, a study with college students to determine relative ability to keep track of several different things on a computer screen at the same time (a skill similar to those needed by flight controllers) concluded that expert video game players were better at maintaining divided visual attention than novices. In a second study, 5 hours of playing a video game led to increased response speed in the visual attention task, regardless of previous video game experience. Other studies have documented relations between video game play and visual selective attention, spatial visualization, mental rotation, and reaction times. Video games can also provide opportunities for practice in following directions and in the use of fine motor skills. There have even been studies with adults showing that experience with video games is related to better surgical skills.

### Negative Effects of Violent Video Games

Of several negative effects that have been studied, the one that has received the most attention is aggressive behavior. Dozens of studies have been conducted on the relation between playing violent video games

**Figure 1** Effects of Violent Video Games on Aggressive Behavior, Aggressive Cognition, Aggressive Affect, Helping Behavior, and Physiological Arousal, All Samples

SOURCE: Anderson, C. A. (2004). An update on the effects of violent video games. *Journal of Adolescence*, 27, 133–122. Copyright by Craig A. Anderson and Academic Press. Reprinted by permission.

NOTES: K = number of independent samples. N = total number of participants. Vertical capped bars are the upper and lower 95% confidence intervals.

and aggression-related variables. When analyzed using modern meta-analytic techniques, these studies show remarkably consistent results that are in line with theoretical predictions and with the much larger research literature on violent television and film effects. As can be seen in Figure 1, there are five major effects of playing violent video games.

1. *Violent video games increase physiological arousal.* Experimental studies show short-term increases in physiological arousal, such as heart rate and blood pressure.

2. *Violent video games increase aggressive cognitions.* Experimental and correlational studies show short-term and long-term increases in aggressive cognitions. Measures have included reaction times to

aggression-related and unrelated words, aggressive content of story completions, hostile attributions to ambiguous provocations, and aggressive completions of word fragments, among others.

3. *Violent video games increase aggressive feelings.* Experimental and correlational studies show short-term and long-term increases in aggressive affect, sometimes labeled *anger* or *state hostility*.

4. *Violent video games increase aggressive behaviors.* Experimental and correlational studies show short-term and long-term increases in aggressive affect. Aggressive behaviors have been measured in several ways, ranging from highly ecologically valid approaches such as physical fights at school to highly controlled (and internally valid) laboratory approaches such as attempts to deliver highly noxious noise blasts to a game opponent. These effects have been found in children and adults, and in males and females, in nonaggressive and highly aggressive individuals. In a recent longitudinal study of third to fifth graders, violent video game play was related to increases in verbally and physically aggressive behaviors even after controlling for sex, hostile attribution bias, amount of screen time, parental involvement, and prior aggression levels.

5. *Violent video games decrease prosocial behaviors.* Experimental and correlational studies show short-term and long-term decreases in positive or prosocial behaviors.

As may be seen from this meta-analysis, violent video games appear to be every bit as good at teaching aggressive skills as educational video games are at teaching reading skills.

### Incidental Negative Effects

Several studies have documented relations between video game play and a wide array of other negative effects, most notably academic performance. This appears to be related to the amount of play more than the content of the games, in that students who spend a lot of time playing video games tend to get poorer grades.

There are also a number of concerns about the potential effects of heavy video game play on children's physical health, including obesity, video-induced seizures, and postural, muscular, and skeletal disorders such as tendinitis, nerve compression, and carpal tunnel syndrome. The causes for these types of disorders vary from posture at the computer to the repetitive nature of movements used with input devices (e.g., keyboards,

mice, and joysticks). Most of the information on these types of disorders has been collected on adults. However, some have been documented in pediatric populations. In March 2000, Nintendo of America, a major video game manufacturer, acknowledged the problem by agreeing to provide protective gloves to about 1.2 million children because of numerous reports of hand injuries caused by the control stick of a particular game. Excessive video game playing has also led to documented cases of a form of tendinitis dubbed "Nintendinitis," caused by repeatedly pressing buttons with the thumb during game play.

Finally, some studies are beginning to document the existence of what appears to be video game "addiction." Studies suggest that perhaps as many as 15% to 20% of video game players could be considered "addicted" by criteria similar to the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (*DSM-IV*) criteria for gambling addiction. Although the correlates of video game addiction are only recently being investigated, it appears that this may be a growing problem.

### SUMMARY

Children are becoming more engaged with video games as the technology advances and brings more realistic and exciting games into millions of homes. Partly because so many children play games for increasing amounts of time, researchers have begun to ask what the consequences of play may be. In short, video games appear to be excellent teachers. Many of the things they teach are intended (e.g., reading or math skills), but many are not (e.g., aggressive attitudes and behaviors, visual attention skills). Furthermore, the amount of time spent with video games may also have a negative impact on school performance and physical health for many children.

The question of whether video games are "good" or "bad" for children is oversimplified. Playing a first-person shooter game for hours every day could have a negative effect on school performance, a negative effect on aggressive behaviors, and a positive effect on visual attention skills. We prefer to recognize that video games can have powerful effects on children, for good or ill.

—Douglas A. Gentile and  
Craig A. Anderson

---

## VIOLENCE

---

Violence is an act of physical force or threat of force that causes damage or is intended to produce harm. The damage inflicted by violence may be physical, psychological, or both. Violence may be distinguished from aggression, a more general type of hostile behavior that may be physical, verbal, or passive in nature.

### TYPES OF VIOLENCE

Violence can be categorized in a number of ways. Violent crimes are typically divided into four main categories, based on the nature of the behavior: homicide (intentionally ending the life of another person), assault (attacking another person with the intent to cause harm), robbery (forcibly taking something from another person), and rape (forcing someone to engage in sexual activity). Other forms of violence overlap with these categories, such as child sexual abuse (engaging in sexual acts with a child) and domestic

violence (violent behavior between relatives, usually spouses).

Violence can also be categorized according to the motivation for it. Reactive, or emotional, violence typically involves the expression of “hot-blooded” anger—a hostile desire to hurt someone—that arises in response to perceived provocation. Proactive, or instrumental, violence is more “cold blooded” and calculated, done in anticipation of a reward. Psychologist Kenneth Dodge found that these two types of violence involve distinct physiological states: a person engaging in reactive violence experiences increased autonomic nervous system arousal (i.e., increased heart rate and breathing, sweating), whereas a person committing an act of proactive aggression experiences low autonomic arousal.

Another method of categorizing violent behavior involves distinguishing between predatory and affective violence. Predatory violence involves planned acts of hostile force. Affective violence is more impulsive and unplanned. Other types of violence have been suggested, including irritable (motivated by frustration), territorial (motivated by intrusion into one’s perceived territory or space), fear-induced (motivated by fear), and maternal (motivated by a threat to one’s child) violence.

### FREQUENCY OF VIOLENT BEHAVIORS

Since the time of early civilizations, violence has occurred throughout the world, in forms ranging from war between countries to individuals behaving violently toward other individuals. In recent decades, rates of violent crimes committed by individuals have been documented by the United Nations. Although every country experiences violence, rates of violence (calculated as the number of crimes per 100,000 people) vary considerably across countries. For example, in 2000, the reported homicide rate was relatively low in countries such as Greece (0.76), Japan (0.50), Pakistan (0.05), and Switzerland (0.96). Much higher homicide rates were reported that year in Colombia (62.74), Jamaica (33.69), Russia (19.80), and South Africa (51.39). In 2000, the homicide rate in the United States was 5.5 per 100,000 people. In the United States, 1,426,325 violent crimes were reported to the police in 2002; the violent crime rate that year was 494.6 per 100,000. Assaults accounted for the largest proportion (62.7%) of reported violent crimes in the United States, followed by robbery (29.5%), rape (6.7%), and homicide (1.1%). These rates do not account for all violence that occurs in the United

States, however. The Department of Justice's National Criminal Victimization Survey indicates that a large number of violent crimes are not reported to the police. Assault seems to be the most frequently under-reported act of violence, with 79% of assaults not reported to police in 2002. Sixty-two percent of rapes were unreported that year, whereas only 8% of robberies were not reported to police.

The frequency of violent behavior changes across the life span. Very young children (i.e., younger than 8 years) are least likely to engage in serious violence. Older children show some violence, but less than adolescents. Older adolescents and young adults (i.e., 16 to 25 years of age) are more violent than any other age group. Beyond the 20s, the frequency of violence decreases steadily with age. To see changes in violence over the life span, consider homicide as an example. A few very young (i.e., under 8 years) murderers exist, with rates increasing slightly with age until a noticeable increase occurs in the 13- to 16-year-old age group. The homicide rate peaks in the 20- to 24-year-old age group, and then declines steadily with age.

Gender differences exist in the rates of violent crime in the United States. Males are much more likely than females to behave violently. The victims of violent crimes such as homicide and assault are also more likely to be males. Rape victims are most likely to be females, though, as are the victims of domestic violence.

## CAUSES OF VIOLENCE

With so much violence occurring all over the globe, it is natural to wonder what causes people to behave violently. Researchers have been attempting to answer this question by examining a variety of possible causal factors. The one point that all researchers seem to agree on is that violence is multicausal, meaning that no single factor is responsible for violent behavior. Instead, violence results from a combination of variables within a person, factors in the social or cultural environment, and immediate situational forces. Researchers have examined multiple factors within a person that may contribute to violence, including genetic predisposition, neurochemical abnormalities (e.g., high testosterone levels), personality characteristics (e.g., lack of empathy for others), information-processing deficits (e.g., tendency to view others' actions as hostile), and experiencing abuse or neglect as a child.

## EFFECTS OF VIOLENCE

Regardless of its cause, violence has a negative impact on those who witness or experience it. Violence can cause physical damage as well as psychological harm. Several psychological disorders, including posttraumatic stress disorder, dissociative identity disorder, and borderline personality disorder, are associated with experiencing or witnessing violence. Other psychological symptoms, such as depression, anxiety, and mood swings, are common in victims of violence.

Children seem to be particularly susceptible to the negative effects of violence. Children who experience or witness violence may develop a variety of problems, including anxiety, depression, insecurity, anger, poor anger management, poor social skills, pathological lying, manipulative behavior, impulsiveness, and lack of empathy. As these examples show, some children may respond to violence in "internalizing" ways, such as feelings of insecurity, anxiety, and depression, whereas others may react in "externalizing" ways, such as feeling angry and behaving in an antisocial manner. Although some of the effects of violence may manifest during childhood, others may not appear until adulthood. For example, abused girls are more likely than nonabused girls to have substance abuse problems as adults.

Exposure to violence can also increase violent behavior in children. Psychologist Albert Bandura showed that children often imitate violent behaviors, especially if those acts are committed by trusted adults (e.g., parents). Children also imitate violence shown on television and in other forms of media. Children exposed to greater amounts of media violence are more likely than other kids to become violent adults. This is particularly true if the child identifies with the violent characters and if the child believes that media violence represents reality.

## PREVENTION OF VIOLENCE

Once a person engages in violent behavior, the likelihood of future violence is quite high. Of those individuals convicted of a violent crime, a large proportion of them reoffend if released from prison. Research also suggests that many arrestees commit several violent crimes before being arrested for the first time; for example, the average rapist rapes seven women before being caught. As a result of these high rates of reoccurrence of violence, mental health

professionals have recognized the need to develop effective violence prevention programs.

Because the tendency to behave violently develops during childhood, most prevention programs target young people. Many of these programs are school based, although some involve the family or the community. The most successful violence prevention programs are those that target all children, not just those who are considered to be at risk for violence. In addition, the most success has been found in school-based programs with committed and involved teachers and programs that include parent training.

An example of an effective school-based violence prevention program is the Resolving Conflict Creatively Program, developed in the New York City public schools. This program includes the training of teachers and students in conflict resolution, problem-solving lessons for students aimed at promoting nonaggressive choices, and peer mediation to facilitate conflict resolution. Effective community-based programs include those that provide children with positive after-school activities and nonviolent role models. Family-based prevention is most successful if the parents are taught to be firm, clear, and understanding and to use nonviolent methods of discipline.

A variety of programs have been developed to reduce or prevent violence in individuals who have already shown a tendency toward violence. For example, a number of prison-based programs attempt to reduce the likelihood of reoffending among violent and nonviolent criminals. These programs often involve a variety of components. Violent offenders may receive training to improve parenting and other relationship skills. A mental health component may be included, such as substance abuse treatment. Job training is another common component of prison-based prevention programs. Occasionally, drugs such as antidepressants, beta-blockers, and benzodiazepines may be used in addition to other methods. Overall, the most successful programs for preventing future violence are those that teach behavioral changes.

## SUMMARY

Violence is a relatively common type of human behavior that occurs throughout the world. People of all ages may be violent, although older adolescents and young adults are most likely to engage in violent behavior. Violence has a number of negative effects on those who witness or experience it; children are

especially susceptible to its harm. Fortunately, various programs have been successful at preventing and reducing violence.

## VISUAL CLIFF

---

The visual cliff, designed by Richard D. Walk and Eleanor J. Gibson, is an apparatus used for testing depth perception of human infants and animals. Visual cliffs are constructed by placing patterned surfaces (e.g., checkerboard) on each side of a central platform. Both surfaces are covered by a sheet of glass. One surface is directly beneath the sheet of glass, however, whereas the other surface is dropped several feet below the glass. This creates shallow and deep “visual cliffs” on the opposing sides. Organisms are placed on the platform of the apparatus and allowed to locomote or are coaxed toward the deep cliff.

Early research using the visual cliff found that a variety of species, including rats, cats, goats, and human infants, avoided the deep cliff as soon as they could locomote independently. This avoidance was interpreted as evidence that the organism could perceive the depth or height of the cliffs. The findings that avoidance occurred early in development for most species, when the animals had little motor or perceptual experience, was also interpreted as supporting that this avoidance or wariness was innate or independent of experience.

Subsequent research has offered alternative interpretations for the avoidance response of human infants. Nancy Rader and John E. Richards presented a maturational interpretation of the avoidance response, arguing that the initial avoidance seen in early infancy is not based on fear, but on a response-specific visual-motor program. Their research provided evidence that avoidance behavior is predicted by crawling onset age. Additionally, infants avoided the deep side of the cliff when crawling but not when placed in a walker, suggesting that avoidance does not reflect a generalized fear response to heights.

An experiential interpretation of infant avoidance reactions, presented by Joseph J. Campos, Bennett I. Bertenthal, and colleagues, argued that infants' avoidance does reflect their wariness of heights and that this wariness is related to self-produced locomotion. This research revealed that wariness and avoidance of depth are related to amount of independent locomotion and that wariness is accelerated in infants who are not yet crawling but who have experienced "artificial" locomotion through use of walkers. This research measured infants' behavioral avoidance responses and their heart rate responsiveness when placed over the deep and shallow cliffs. Accelerative heart rate responsiveness, which indicates fear or wariness, was related to locomotor experience. Decelerative heart rate responses, indicating attentional responses but not fear, were recorded in prelocomotor infants. These decelerative responses indicated that precrawling infants could detect differences in depth, but were not yet responding to depth with wariness. According to Campos and colleagues, several processes may underlie the development of wariness. As infants begin coordinating crawling with goal-directed behaviors, the infants may fall, resulting in negative affect becoming associated with these situations. Infants also experience negative emotional reactions of their parents in situations in which they are likely to fall.

These experiences contribute to their wariness of situations involving depth or height. Additionally, as infants acquire crawling experience, they coordinate normally co-occurring visual and vestibular inputs. Wariness is experienced when visual and vestibular cues do not match, such as being lowered over the edge of a surface (e.g., the deep cliff). This experiential interpretation of human infants' depth perception and avoidance reactions is consistent with accumulating data from studies of nonhuman species (e.g., cats, rats, chicks) that depth perception and avoidance of depths is dependent on specific types of visual and locomotor experiences.

---

## VITAMIN DEFICIENCY

---

Vitamins are organic *substances* needed for their catalytic activities and cannot be synthesized by humans. They are essential to body metabolism and bioactivities.

### FAT-SOLUBLE VITAMINS

#### Vitamin A

There are three forms of vitamin A: retinols, which are found in animal sources of food; beta-carotene, which is the plant source of retinol from which mammals make two thirds of their vitamin A; and carotenoids. Vitamin A is the third most common

nutritional deficiency worldwide and is also seen in patients with disorders associated with fat malabsorption.

Vitamin A deficiency can affect the eyes, causing night blindness, complete blindness, and xerophthalmia; less common are Bitot's spots, corneal perforation, keratomalacia, and punctate keratopathy. For the skin, hyperkeratosis, phrynoderma, and destruction of hair follicles can result from vitamin A deficiency. Immunity-related effects include impairment of the humoral and cell-mediated immune system through effects on the phagocytes and T cells.

### Vitamin D

Vitamin D is found in fortified milk, fatty fish, cod-liver oil, and eggs. When there's deficiency in vitamin D, reduced intestinal absorption of calcium and phosphorus and demineralization of bones leads to osteoporosis in adults and rickets in children. Hypocalcemia causes a secondary hyperparathyroidism that leads to bone resorption and osteomalacia.

### Vitamin E

Vitamin E is an antioxidant that protects cell membranes from destruction. Vitamin E deficiency occurs in patients with disorders associated with fat malabsorption. Neuromuscular disorders associated with vitamin E deficiency include skeletal myopathy, spinocerebellar ataxia, and pigmented retinopathy. Some studies suggest an association between development of Alzheimer's disease and vitamin E deficiency. In premature infants, hemolytic anemia is encountered in the presence of vitamin E deficiency. Congenital hemolytic disorders may be associated with low vitamin E plasma levels.

### Vitamin K

The name *vitamin K* comes from the German/Danish word koagulationsvitamin (clotting vitamin). Dietary vitamin K<sub>1</sub> (phylloquinones) is found in green vegetables such as spinach and broccoli. Gut microflora synthesize vitamin K<sub>2</sub> (menaquinone). Vitamin K deficiency leads to impaired coagulation manifested by easy bruisability, mucosal bleeding, and melena. Hemorrhagic disease of the newborn is due to an immature liver, low vitamin K content of breast milk, a sterile gut, and poor placental transfer of vitamin K.

## WATER-SOLUBLE VITAMINS

### Vitamin B<sub>1</sub> (Thiamine)

Thiamine serves as a catalyst in the conversion of pyruvate to acetyl coenzyme A. Deficiency of thiamine is associated with beriberi. Infantile beriberi is clinically apparent between the ages of 2 and 3 months, manifested as fulminant cardiac syndrome with cardiomegaly, tachycardia, a loud piercing cry, cyanosis, dyspnea, and vomiting. For adults, dry beriberi is a symmetrical sensory and motor peripheral neuropathy. Wet beriberi includes a neuropathy and cardiac involvement with cardiomegaly, cardiomyopathy, and congestive heart failure.

Wernicke-Korsakoff syndrome is largely described in chronic alcoholics. Wernicke's disease is a triad of nystagmus, ophthalmoplegia, ataxia, and confusion. Korsakoff's psychosis is impaired short-term memory and confabulation with otherwise grossly normal cognition.

Leigh's syndrome is a subacute necrotizing encephalomyopathy, leading to symmetrical foci of spongy necrosis and demyelinating changes in the thalami, brain stem, pons, and even peripheral nerves. It is manifested with ataxia, dysarthria, movement disorders, areflexia, muscle atrophy, and weakness.

### Vitamin B<sub>2</sub> (Riboflavin)

Riboflavin is an essential component of coenzymes involved in multiple cellular metabolic pathways. Riboflavin deficiency is often accompanied by other water-soluble vitamin deficiencies in patients with anorexia nervosa, malabsorptive syndromes, rare inborn errors of metabolism, and long-term use of barbiturates. It is characterized by sore throat, cheilitis, stomatitis, glossitis, normocytic-normochromic anemia, and seborrheic dermatitis.

### Vitamin B<sub>3</sub> (Niacin)

Nicotinic acid and nicotinamide are the two common forms of the vitamin most often referred to as niacin. Niacin occurs in alcoholics and in poorer countries where diet intake is inadequate. It is associated with carcinoid syndrome, prolonged use of isoniazid, and Hartnup's disease. It manifests as a symmetric hyperpigmented rash on exposed areas of skin, a red tongue, diarrhea and vomiting, insomnia, disorientation, delusions, dementia, and encephalopathy.

### Vitamin B<sub>5</sub> (Pantothenic Acid)

Vitamin B<sub>5</sub> is an essential cofactor in many acetylation reactions. It is found mainly in egg yolk, liver, broccoli, and milk. Deficiency of vitamin B<sub>5</sub> is mainly seen in severely malnourished individuals. It is manifested by paresthesias and dysesthesias, referred to as *burning feet syndrome*.

### Vitamin B<sub>6</sub> (Pyridoxine)

Meats, whole grains, vegetables, and nuts are the best sources of vitamin B<sub>6</sub>. Deficiency is usually manifested as nonspecific stomatitis, glossitis, cheilosis, irritability, confusion, and depression. It can lead to elevations in plasma homocysteine concentrations, a risk factor for the development of atherosclerosis and venous thromboembolism.

### Vitamin B<sub>12</sub> (Cobalamin) and Folic Acid

Cobalamin and folate deficiency share many similarities. Animal products provide the only dietary source of cobalamin for humans. Folate comes from animal products and leafy vegetables. Cobalamin deficiency is usually a result of inadequate absorption associated with pernicious anemia or gastric disease and also occurs in elderly people.

#### Hematologic

Megaloblastic anemia presents with symptoms of anemia, atrophic glossitis, and mental sluggishness.

#### Neurologic

Subacute combined degeneration of the dorsal and lateral spinal columns is characteristic. Neuropathy, paresthesias and ataxia, and loss of vibration and position sense can progress to severe weakness, spasticity, clonus, or paraplegia.

Folate deficiency is due to poor diet, alcoholism, elderly age, and drug-induced (e.g., trimethoprim, methotrexate, and phenytoin) interference with folate metabolism. There is an increased requirement in pregnancy and lactations and in patients with hemolytic anemias and exfoliative skin disease. The hematologic manifestations are similar to those of cobalamin deficiency, without neurologic abnormalities.

### Hyperhomocysteinemia

Deficiencies in these vitamins can lead to elevations in plasma homocysteine levels, which is a risk factor for the development of atherosclerosis and venous thromboembolism.

### Biotin

Biotin is found in yeast and liver. Biotin functions as a cofactor to the carboxylase enzyme. In the setting of biotin deficiency, pyruvate levels rise and are converted to lactic acid. Nonspecific symptoms may include changes in mental status, myalgia, anorexia, and nausea. Chronic deficiency can lead to maculosquamous dermatitis of the extremities, seborrheic dermatitis, and alopecia.

Multiple carboxylase deficiency is manifested by a slow but progressive loss of biotin in the urine, leading to the typical organic aciduria of multiple carboxylase deficiency. The neonatal type is seen in the first week of life, and the late onset type is generally seen before 1 year of age.

### Vitamin C

Vitamin C functions as a cofactor, enzyme complement, cosubstrate, or a strong antioxidant in a variety of metabolic processes. Vitamin C deficiency is related to scurvy. Scurvy is a clinical syndrome, largely due to impaired collagen synthesis. It occurs mostly in severely malnourished individuals, drug and alcohol abusers, or with inadequate oral intake. Symptoms include ecchymoses, bleeding gums, petechiae, hyperkeratosis, and impaired wound healing.

---

## VOLUNTEERING

---

*Volunteering* is a term used to describe a broad range of helping behaviors intended to benefit a variety of recipients, including large organizations, smaller groups of disadvantaged individuals, and even family members, neighbors, and friends. There are many ways to help others, such as by donating money or time (instrumental help) or by being willing to listen if another person needs to talk (emotional support). Emerging life-span perspectives on volunteerism and service emphasize the importance of providing help to others for feeling useful, especially in older age.

Recent evidence within behavioral medicine, epidemiology, and health psychology suggests that volunteerism and helping others may be an important part of why social relationships are beneficial to the health of older adults. Volunteerism has been shown to improve physical and mental health, and the act of helping others has been shown to reduce distress and improve satisfaction within interpersonal relationships. Among elderly populations, providing support to others improves physical functioning and promotes

longevity. For example, a prospective study of bereavement and mortality demonstrated that older adults who provided tangible forms of assistance (e.g., help with child care, transportation, errands) to friends, relatives, and neighbors were between 40% and 60% less likely to die during a 5-year period, compared with individuals who did not provide this type of assistance to others. Furthermore, providing emotional support to a spouse (e.g., making a spouse feel loved and cared for) was also protective, leading to a 30% lower chance of mortality risk during the same period. Individuals who reported receiving support from others (e.g., feeling loved and cared for by a spouse or other family members) did not have a similar decrease in their mortality risk.

Added to the direct health benefits shown to be associated with volunteering and helping others, indirect evidence links perceptions that may be associated with volunteering, such as a sense of meaning, purpose, belonging, mattering, self-efficacy, and self-esteem, to happiness and reduced depression. These benefits of volunteering and related feelings may reflect the fact that there are adaptive, evolutionary benefits of helping others. For example, kin selection and reciprocal altruism theory suggest that helping others is necessary to ensure inclusive fitness—our own reproductive success plus the reproductive success of individuals who share our genes. Helping others would have maximized inclusive fitness either by enhancing the welfare of relatives who would survive and pass on common genes or by enhancing the welfare of reciprocal altruists who would survive and direct future acts of altruism toward the helper or toward individuals who share the helper's genes.

Both kin selection and reciprocal altruism theory specify the circumstances that altruism could have evolved; however, they do not address the motivational mechanisms that would have impelled individuals to give away their own valuable resources to help others. Selective investment theory was advanced to address the motivational basis for allocating valuable resources to others on a long-term basis, and even in the absence of reciprocity. According to selective investment theory, giving, and not receiving, is the evolutionary function of interpersonal relationships that are characterized by a social bond. Other evolutionary theories of relationship processes have made similar arguments, suggesting that emotional commitments between individuals may have evolved, in part, to promote altruism.

These evolutionary theories of altruism and close relationships have important implications for volunteering. Most notably, they suggest that individuals will be more motivated to volunteer, and may provide the most help to another person, when there exists the potential to develop a personal relationship with the recipient. The possibility that interpersonal relationship processes play an important role in stimulating and maintaining volunteerism is a new area of research that awaits further study.

## VYGOTSKY, LEV (1896–1934)

---

Born in 1896 in Orsha, Byelorussia, Lev Semenovich Vygotsky is best known for his sociocultural approach to human development, a very influential set of ideas about how the child's social world and culture affect development. His ideas about how children develop within sociocultural context, now required reading for contemporary scholars of psychology and education, were themselves a reflection of the cultural-historical context of his time—namely Marxist socialism of early 20th-century revolutionary Russia.

Vygotsky's early life experiences were constrained by the limited opportunities afforded to Jewish families at that time. He grew up in the city of Gomel and went to a combination of public and private schools for his education. Vygotsky studied law at Moscow University and also enrolled in the “unofficial” Shaniavsky People's University. After graduation, Vygotsky returned to Gomel, where he taught at Gomel's Teacher's College. Following his marriage to Roza Smekhova and the birth of his daughter Gita,

Vygotsky moved to Moscow, where he began his career as a researcher and psychologist and where he started his fruitful collaboration with students A. R. Luria and A. N. Leont'ev.

Vygotsky maintains that what is unique about human development is that it occurs through the internalization of language and cultural tools and symbols. All higher-order cognitive abilities first appear socially in interactions between people and then become part of children's individual mental lives. Language is seen as the primary cultural tool that children internalize as private speech (self-talk) to guide their own thinking and behavior. Because different cultures have different languages, customs, and primary activities, children's cognitive and behavioral development can be very different across cultures.

Vygotsky's contributions to educational and psychological practice include the notions that (a) instruction should take place in the zone of proximal development (ZPD), a hypothetical region defined by the distance between what a child can accomplish alone and what the child can do with the help of someone else; (b) child assessment should be dynamic (done over time, examining cognitive changes due to teaching) rather than static (standardized individual tests); and (c) that children with special needs should be exposed to as normal social interactions and environments as possible.

The fundamentals of Vygotsky's theory appear in *Thought and Language* and in *Mind in Society*. Vygotsky frantically wrote as much as possible before his untimely death from tuberculosis in 1934. His 180 works had not begun to be translated into English until the 1960s, and his complete works in English were not available until 1999.

## Work

*Far and away the best prize that life offers is the chance to work hard at work worth doing.*

—Theodore Roosevelt

---

### WATSON, JOHN B. (1876–1958)

---

John Broadus Watson was born a poor rural boy from Traveler's Rest, South Carolina, raised by his mother in urban Greenville, at a time when American Progressivism was making a university education and graduate specialization a means for individual, social, and cultural advancement. He received a master's degree in philosophy from Furman University (1899) and achieved the University of Chicago's first PhD in psychology (1903). He was then an instructor at Chicago (1903–1908) and a professor at Johns Hopkins University (1908–1920), but a scandal forced him to leave academe. Undeterred, he became the first "pop" psychologist and a successful advertising executive in New York City (1921–1945).

Watson began as an animal and comparative psychologist, where some of his research was the earliest and best work in ethology. For this, experimental psychology had to be the study and science of behavior, not the then-standard introspection of conscious contents ("Psychology as the Behaviorist Views It," 1913). The former became Watson's classic behaviorism, which was taken seriously because of the high regard in which his research was held. Indeed, his

stature was such that he became the editor and founder of prestigious journals (e.g., *Psychological Review*, *Journal of Experimental Psychology*) and president of the American Psychological Association.

As a systematist, Watson held that psychology's goal was to formulate the laws and principles of human behavior through systematic observation and experimentation (*Psychology from the Standpoint of a Behaviorist*, 1919, 1929). For this, he advanced prediction and control as a means for understanding behavior, promoting behaviorism, and advancing cultural change. He adopted the conditioned reflex as a basic principle of behavior. He analyzed thinking, feeling, and imagining as implicit responses, not as independent mental processes. And, he viewed anatomy and physiology, not instincts, as the biological basis of human behavior (*Behaviorism*, 1924, 1930).

In extending his science to human development, Watson focused on infancy and early childhood. He made groundbreaking observations of normative emotional development. He pioneered in studying conditioned emotional reactions and their elimination. Watson published articles in the popular press on childrearing (e.g., *Cosmopolitan*), culminating in *Psychological Care of Infant and Child* (1928). Here, he was an early opponent of corporal punishment and

an advocate for sex education, but advised unwisely about emotional attachment. His advice, though, was not based on classic behaviorism, but was more personal. Empirically validated child-rearing advice would await the emergence of human development as a science.

## WECHSLER ADULT INTELLIGENCE SCALE (WAIS)

---

The Wechsler Adult Intelligence Scale (WAIS) measures intellectual ability in 16- to 89-year-olds. The first version of the WAIS was released in 1955. The WAIS-III, released in 1997, is the most recent version. The WAIS is currently the most widely used, individually administered adult intelligence test in the world.

The WAIS is one of three Wechsler intelligence scales. The others are the Wechsler Preschool and Primary Scale of Intelligence, for 2.6- to 7.3-year-olds, and the Wechsler Intelligence Scale for Children, for 6- to 16-year-olds.

The WAIS is divided into two major subscales: Verbal and Performance. The Verbal scale measures verbal knowledge, verbal reasoning, and attention to verbal materials. It includes seven subtests: Arithmetic, which measures the ability to perform arithmetic operations; Comprehension, which measures the understanding of practical and social issues; Digit Span, which measures memory for digits; Information, which measures knowledge of factual information; Letter-Number Sequencing, which measures sequential memory for digits and letters; Similarities, which measure the ability to infer relationships between concepts; and Vocabulary, which measures the ability to define words.

The Performance scale measures fluid reasoning, spatial processing, attention to detail, and visual-motor coordination. It includes seven subtests: Block Design, which measures the ability to build a model with blocks; Digit Symbol-Coding, which measures the ability to learn a code of digits and symbols; Matrix Reasoning, which measures the ability to infer a rule in a sequence of geometric shapes; Object Assembly, which measures the ability to assemble a puzzle; Picture Arrangement, which measures the ability to sequence pictures to tell a story; Picture Completion, which measures the ability to identify a missing element in a picture; and Symbol Search, which measures the ability to identify a target symbol within a group.

The WAIS provides normative, age-corrected intelligence quotient (IQ) scores for the Verbal and Performance scales. It also provides a full-scale intelligence quotient (FSIQ) score, which measures general mental ability. By convention, the average FSIQ within an age group is set at 100 and the standard deviation is set at 15.

In addition to the IQ scores, the WAIS provides four index scores of specific cognitive processes. The Verbal Comprehension index measures verbal knowledge and reasoning. The Perceptual Organization Index measures fluid reasoning, attention to detail, and visual-motor coordination. The Working Memory Index measures the ability to hold and manipulate information in memory. The Processing Speed Index measures the ability to process information quickly.

The psychometric properties of the WAIS are excellent. The test–retest stability of WAIS FSIQ (retest interval: 2–12 weeks) is extremely high for 16- to 89-year-olds ( $r = 0.95$ , corrected for the variability of the standardization sample). The internal consistency reliability of test items used to compute WAIS FSIQ is also extremely high for 16- to 89-year-olds ( $r \geq .97$ ).

Intercorrelations among the WAIS subtests are almost always positive. This indicates that all the WAIS subtests measure the same latent construct, which has been labeled  $g$ . The  $g$  loading of a WAIS subtest (i.e., the correlation between the subtest and  $g$ ) can be determined using factor analysis. Factor analysis shows that some WAIS subtests have relatively high  $g$  loadings (Vocabulary and Block Design), whereas others have relatively low  $g$  loadings (Digit Span and Digit Symbol-Coding).

The pattern of WAIS subtest and index scores is related to a number of psychological disorders,

including mental retardation, attention deficit hyperactivity disorder, reading and math learning disabilities, Parkinson's disease, traumatic brain injury, and schizophrenia. The WAIS scores are also related to cognitive tests of academic achievement (Wechsler Individual Achievement Test), attention and concentration (Trail-Making Test), memory (California Verbal Learning Test), fine motor dexterity (Grooved Pegboard), and executive functioning (Wisconsin Card Sorting Test).

## WECHSLER INTELLIGENCE SCALE FOR CHILDREN (WISC)

---

The Wechsler Intelligence Scale for Children (WISC) was developed in 1949 by David Wechsler to be an individually administered assessment of the cognitive abilities of children aged 5 through 15. The WISC was initially a downward extension of Wechsler's adult intelligence test, the Wechsler-Bellevue Intelligence Scale (WBIS, 1939). The WBIS provided a measure of verbal, performance, and overall intelligence by using 12 subtests. Wechsler retained 11 of these subtests for the WISC and added an additional subtest (mazes) as a means of assessing a child's planning and perceptual abilities. The other 11 subtests are Information, Arithmetic, Similarities, Vocabulary, Digit Span, Comprehension, Picture Completion, Picture Arrangement, Block Design, Object Assembly, and Coding.

Since its initial publication, there have been three revisions of the test in order to meet changing testing needs and to reflect current research. In 1974, the WISC-R was published with some updated test items while retaining the original 12 subtests. The age range was increased to cover ages 6 through 16. The WISC-III, released in 1991, retained the original 12 subtests with a few updated test items and also added a new subtest, Symbol Search, as a means of assessing perceptual discrimination, processing speed, and freedom from distraction. Some additional changes to

the test makeup were performed with the newest revision, the WISC-IV, released in 2003. The addition of three new subtests, Matrix Reasoning, Cancellation, and Picture Concepts, and the elimination of the Mazes subtest brought the total number of subtests to 15. Yet, throughout the changes and editions of the test, the basic goals have remained the same: to be able to assess the child's general intellectual ability (full-scale intelligence quotient [FSIQ]) as well as other more specific cognitive domains (Index Scores).

In previous editions of the test, the individual's performance was divided into verbal and performance (nonverbal) measures of intelligence. This separation did not reflect a belief in different forms of intelligence, but rather reflected different means of measuring the one underlying general level of intelligence (Spearman's *g*). However, the WISC-IV focuses on measuring more specific cognitive domains represented by the four indices—Verbal Comprehension, Working Memory, Perceptual Reasoning, and Processing Speed—in addition to the overall FSIQ score. Each index is composed of subtests that collectively measure a specific cognitive domain. The Verbal Comprehension Index is composed of Similarities, Vocabulary, and Comprehension. The Perceptual Reasoning Index is composed of Block Design, Picture Concepts, and Matrix Reasoning. The Working Memory Index includes Digit Span and Letter-Number Sequencing, whereas the Perceptual Speed Index has Coding and Symbol Search.

Upon completion of the WISC-IV, an FSIQ score can be derived. Historically, an IQ score was the ratio (or quotient) of an individual's mental age (MA) to her or his chronological age (CA), as shown below.

$$IQ = \frac{MA}{CA} \times 100$$

Today, instead of using the quotient method, standard scores are derived by comparing an individual's score with a set of normative scores within the individual's age range. Thus, the FSIQ represents the child's ability in relation to her or his peers. The average FSIQ score is 100, with 68% of scores falling between 85 and 115; 95% of scores range from 70 to 130. Standard scores are often represented as percentile rankings. Someone with a standard score of 100 would have a percentile ranking of 50%, meaning that the child scored greater than or equal to 50% of her or his peers.

The WISC-IV is used in clinical, counseling, and school settings to assess the cognitive abilities and deficits of children. Many institutions use this instrument to assess for admittance into “gifted” programs and to assist in the diagnosis of learning disabilities or mental retardation.

## WEIGHT

---

Weight refers to the amount or quantity of heaviness or body mass, that is, the force that gravity exerts on an individual or thing. A person’s body weight includes the heaviness of the skeleton, muscles, bodily fluids (e.g., blood, water), internal organs, and adipose (i.e., fat) tissue that surrounds and protects the bone and organs. Adipose tissue (also known as *body fat*) also stores energy for later use. Without fat cells, people could not afford to skip a meal; thus, famine or illnesses that interfere with appetite would lead to certain death.

Height and weight are correlated. As human bodies grow and develop, they generally increase in both stature and mass. Failure to thrive, malnutrition, and metabolic disorders are among the reasons infants might not gain weight, and all are obvious reasons for concern. The rate at which infants gain weight varies. It depends not only on the infants’ general health and the amount of food they are offered but also on genetic differences in metabolic rate and the initial size and number of their fat cells. As children grow, their activity levels also affect their body weight, as some use more of their energy stores than others.

There are certain times in human development when people are more or less prone to add fat cells or for existing cells to increase in size. For example, boys’ percentage of body fat tends to increase during prepubertal phases of development and to decrease during the adolescent growth spurt (i.e., they become

leaner following puberty). In contrast, girls’ percentage of body fat is relatively stable in childhood, but increases during the adolescent growth spurt. Between ages 10 and 15, on average, the percentage of body fat in boys decreases from 17.8% to 11.2%, and the percentage in girls increases from 16.6% to 23.5%. Girls’ pubertal increase in body fat is a necessary prerequisite for menarche, the initiation of the menstrual cycle. Other reproductive milestones (e.g., pregnancy, menopause) also result in weight gain for women. Epidemiologic studies indicate that between the ages of 20 and 50, men’s percentage of body fat doubles and women’s percentage increases by about 50%. Furthermore, metabolic rate slows as people age. Therefore, if older people do not cut their caloric intake below levels that were typical for them at midlife, they are likely to gain weight. Chronic illness or disability may result in decreased activity level, which also increases the likelihood of weight gain.

There is considerable evidence to support what scientists call the *set-point hypothesis*, that is, the idea that all animals (including humans) are designed to maintain their weight within a certain genetically programmed range, the middle of which is known as the set-point. The system works much like the thermostat connected to a furnace. If people increase their activity levels, the brain increases their appetites and slows down their metabolism so that their body weight will remain about the same. Similarly, if people increase their eating or decrease their activity levels, the brain increases the metabolic rate and decreases appetite in an attempt to maintain the “preferred” weight range. The set-point moves during growth and development to accommodate the changes described earlier. It may also move or become inefficient if the system is dysregulated by, for example, binge-purge behavior, yo-yo dieting, medication side effects, or metabolic disorders.

### CONSEQUENCES OF SIGNIFICANT WEIGHT LOSS OR GAIN

Failure to thrive and undiagnosed metabolic disorders (e.g., diabetes mellitus) can result in death. Severe protein malnutrition (rarely seen in developed countries) results in kwashiorkor, a disorder in which a child’s stomach, face, and legs swell with water even though their arms are as thin as sticks and their skeletal growth has ceased. More common results of

malnutrition are vitamin and mineral deficiencies (e.g., beriberi, pellagra, anemia), cognitive deficiencies (e.g., memory difficulty, slowness of thought, depression), weak bones, and digestive problems (e.g., constipation, heartburn). Malnutrition during adolescence and adulthood can result in the cessation of menstrual cycles (i.e., amenorrhea), and malnutrition during pregnancy can result in miscarriage, low birth weight, or premature birth.

Anorexia nervosa is an eating disorder that is characterized by excessive dieting, distorted body image, an intense fear of gaining weight, and, in women and girls, amenorrhea. Although it is classified as a psychiatric disorder, anorexia nervosa is a form of self-starvation, which results in malnutrition and other physical signs and symptoms, such as brittle bones, bone marrow failure, reduced thyroid function, dry and yellowed skin, slowed breathing and cardiac rhythm, intolerance of cold temperatures, swollen joints, reduced muscle mass, brittle hair and nails, anemia, feeling faint, dehydration, and kidney abnormalities. As many as 5% to 10% of anorexics die from either starvation or suicide. The disorder can occur in either sex, but it is more common in girls and women.

Excessive weight gain can also have serious consequences for individuals. Excessive weight, especially in the form of adipose tissue that collects around the waist, is a risk factor for a number of chronic illnesses, including diabetes, hypertension, heart disease, arthritis, gallbladder disease, and some forms of cancer. Extra weight means extra stress on the joints and cardiovascular system, which can result in decreased stamina and flexibility and make it difficult to maintain physical fitness. Furthermore, heavy people who live in societies that value thinness (and believe that only thin people can be attractive) are often subject to discrimination (e.g., in hiring, promotion, college admissions) and social prejudice (e.g., teasing, bullying).

Lifestyle changes during the decades of the 20th century in industrialized societies have made it increasingly likely that people will gain excess weight. As economies have shifted from agricultural and heavy manufacturing to light manufacturing and service industries, people have used less energy to perform their jobs. The ubiquity of automobiles has resulted in less time spent walking or bicycling, and entertainment and leisure activities have also changed in a more sedentary direction. People are now more likely to watch sports than to participate in them, and television, computers, and electronic games have become

the favorite pastimes of many children and adolescents. In addition, high-calorie foods (e.g., those high in fat and sugar) are increasingly available and heavily advertised. Sociocultural pressures to eat more and exercise less can lead to dysregulation of the set-point system because the body can only do so much to compensate for the energy imbalance that people create. Furthermore, fad diets and diet products can also dysregulate the set-point system. If people suddenly and significantly restrict their caloric consumption, the brain reacts the same way it does when a natural famine occurs. The metabolic rate will slow as much as possible, which makes it much harder to lose weight while on the diet and much easier to gain it back once the diet is over.

### HOW MUCH WEIGHT IS TOO MUCH? HOW LITTLE IS TOO LITTLE?

Individuals' "ideal" weight may be determined genetically, the set-point described previously. However, the set-point is theoretical and cannot be measured. Physicians who worked for the Metropolitan Life Insurance Company reviewed thousands of files of their customers in an attempt to determine the average weights of the healthiest and unhealthiest. Their research led to the construction of tables of ideal weight ranges based on small, medium, and large body frames, and these tables were used as guidelines for many years. Unfortunately, the data in the tables came primarily from white, midlife, middle-class men, the people who were most likely to buy life insurance. There is no way to be sure that the weight ranges are actually ideal for any given person, and the determination of body frame size is, in many cases, arbitrary.

The calculation of body mass index (BMI) avoids the frame size controversy by dividing weight (in kilograms) by the square of height (in meters). However, the cutoff points that divide healthy from unhealthy BMIs remain arbitrary, may not be culturally appropriate, and do not allow us to distinguish between the weight of constituent parts of the body. Percentage and location of body fat seem to be more important to health than is body weight. Methods of calculating the percentage of body fat (bioelectrical impedance analysis, hydrostatic weighing, caliper tests) have been developed; however, their accuracy is debatable, and the amount of fat that is considered ideal remains an arbitrary cultural construction. Perhaps the only

way ever to know how much weight is too much and how little is too little is when symptoms of malnutrition or chronic illness appear. No one wants to test that hypothesis; thus, the best advice we can follow is to take steps to prevent weight-related illnesses.

### FOCUS ON HEALTH, NOT WEIGHT

Once people lose or gain a great deal of body weight, the set-point makes it difficult to return to a healthy weight range. Therefore, people should eat a variety of healthy foods and avoid eating large amounts of high-calorie snacks and desserts. Foods high in fat and sugar content should be considered “treats” and eaten occasionally, as opposed to daily. The amount of dietary fat people need varies with developmental stage; infants and young children need greater amounts than midlife and older people do, and consumption should change with age. Don’t forget the other side of the energy equation: Most people in industrialized societies should increase their activity levels. At every developmental stage, people need to get regular exercise by engaging in sports or walking or jogging regularly. Work activities (e.g., vacuuming) and hobbies (e.g., gardening) help us to maintain physical fitness and keep our energy intake and expenditure in balance, as do small lifestyle changes, such as parking farther away from our destination and taking stairs instead of elevators.

People have much less control over their body weight and shape than most Americans believe, but there are steps we can take to increase our chances of being healthy and physically fit. A focus on health rather than weight is very important. Our body is our friend, not our enemy, and we should treat it with respect rather than with loathing. Respect includes proper feeding and exercising, so that we work with our body, not against it.

## WELL-BABY CHECKUP

Physicians typically use well-baby checkups to monitor a child’s growth and development, conduct necessary medical tests and interventions, and provide parents with anticipatory guidance. Thus, well-baby checkups are an invaluable means of promoting the health and development of infants and young children, although the events of each appointment may vary according to the child’s age and issues unique to the child or family. Typically, physicians check a child’s growth by measuring head circumference, height, and weight and then calculating a body mass index (BMI). Thus, health care providers are able to track a child’s growth over time and ensure that growth is following a healthy trajectory.

Physicians also use regular baby checkups to observe and ask parents questions about their child’s development. All aspects of development can be evaluated, including gross motor, fine motor, speech, and social-emotional development, as well as hearing and sight. For newborns, physicians likely would inquire about an infant’s ability to move all four extremities, sucking reflex and visual tracking, and response to the parent’s face and voice. For older infants, physicians’ questions likely would include whether the infant is able to sit and crawl, whether the baby is grasping and mouthing objects, and whether the baby is babbling, smiling, and laughing.

Conducting recommended medical tests and interventions allows the physician to check for signs of illness. Each infant’s temperature, heart rate, and respiratory rate are measured, and a thorough physical examination is conducted, including the infant’s skin, eyes, ears, mouth, abdomen, and joints. A hearing screening is often conducted at some point. Tests are run for metabolic and blood disorders. If risk factors are present, children may also be tested for lead exposure. In the well-child appointment, mandatory immunizations are conducted according to a schedule set by the Centers for Disease Control and Prevention. Mandatory immunizations for infants include hepatitis B, diphtheria, tetanus, and pertussis (DTaP); *Haemophilus influenzae* type B (HiB); measles, mumps, and rubella (MMR); varicella; pneumococcal vaccine (PCV); and inactivated polio virus (IPV). If certain risk factors are present, physicians may recommend additional vaccines.

Well-baby checkups also provide parents with anticipatory guidance regarding issues such as injury

and illness prevention, developmental expectations, and family and community issues. For newborns, anticipatory guidance topics may include putting infants to sleep on their backs to prevent sudden infant death syndrome, securing infants properly into car seats, and feeding infants. For older infants, physicians are likely to address issues such as home safety, setting rules and limits, and how to handle sibling interactions, as applicable. Discussion of these and other topics provides parents with important information and opens the door for parents to ask further questions about their child's health, development, and behavior. Physicians may also consider referring a family to community resources, if needed.

Well-baby checkups promote the prevention, early detection, and treatment of medical and developmental problems and help ensure a child's healthy growth. Checkups also allow parents the opportunity to ask questions about their child's health and development. Children should receive well-baby checkups at the times designated by the National Center for Education in Maternal and Child Health: at birth, within the first week of life, and at 1 month, 2 months, 4 months, 6 months, and 9 months of age. For young children, checkups should occur at 1 year, 15 months, 18 months, 2 years, 3 years, and 4 years of age.

## SUMMARY

Regular well-baby checkups serve several important functions, including monitoring children's growth and development, conducting necessary medical tests and interventions, and providing parents with anticipatory guidance.

## WHOLE LANGUAGE

Whole language, now largely discredited, was a popular educational philosophy and style of reading instruction that emerged in the late 1970s and flourished until the mid-1990s. Influential whole language theorists likened reading development to the natural and effortless emergence of oral language in young children, and a process that students would spontaneously acquire if they were immersed in a nurturing, literature-rich environment. Advocates such as Marie Clay, Kenneth Goodman, and Reggie Routman helped transform the teaching of reading by rhapsodically describing whole language classrooms as student centered (not teacher centered), meaning centered (not skill centered), and focused on literature (not on discreet letters and sounds or on phonics-based basal readers).

During the era of its popularity, whole language teachers rejected traditional instruction that used phonics, spelling lessons, and reading skill workbooks. Teachers came to embrace the idea that literacy concepts were to be discovered, not taught, and that learning to read should be natural, playful, easy, and meaningful. Professors in teachers' colleges, classroom teachers, and publishers quickly jumped on the whole language bandwagon.

## CLASSROOM PRACTICES

A variety of teaching practices were associated with the whole language movement. Whole language teachers were encouraged to read literature aloud to students, give "picture walks" (talk about story illustrations) before guided reading, affix labels to objects in the classroom, and read big books while sweeping their hands under the lines of text. Beginning readers were encouraged to memorize short stories, rhymes, and predictable books. Daily activities focused on literature appreciation, enjoyable projects, discussions, and writing activities.

Whole language classrooms were typically organized into learning centers or cooperative pods, rather than in rows facing the teacher. Words were often posted on "word walls" around the room. Many

schools mandated schoolwide DEAR (drop everything and read) or SSR (sustained silent reading) time to provide for independent student reading. Because whole language advocates railed against standardized testing and instead promoted the use of “authentic assessments,” teachers were urged to evaluate students based on portfolio evidence, conferences, and student reflections.

## FALLING OUT OF FAVOR

Although much was written about the ecstasy of the whole language classroom (and some reports did show increased student motivation with certain practices), several comprehensive meta-analytic reports of empirical reading research have compellingly debunked whole language ideology, pointing instead to the crucial importance of systematic, explicit instruction in phonemic awareness and phonics for beginning readers. Research shows that most students learn to read when they are carefully taught to read and not merely exposed to good literature and fun literacy experiences.

## WHOLE LANGUAGE LEAVES A LEGACY

Although many analysts blame whole language practices for years of plummeting reading achievement scores, the movement can actually be credited with bringing several benefits to the field. Whole language brought a renewed understanding of the importance of good literature in schools, a fresh emphasis on the importance of daily writing practice, the necessity for allowing “invented spelling” or “temporary spelling” while beginning writers practice sound and symbol generalizations, the idea that spelling is developmental, the essential importance of the teacher–learner relationship, and the necessity of reading instruction being exciting and pleasurable for students.

Although the U.S. government has now strongly endorsed phonemic awareness and phonics as essential components of beginning reading instruction, whole language practices persist in many classrooms. Certainly some teachers who identify themselves as whole language teachers artfully combine literature-based learning with more recently mandated research-based phonics instruction. But phonics experts (sometimes teasingly called *phonicators*) and whole language enthusiasts (sometimes termed *holy*

*languagers* or *holey languagers*) continue their pedagogical debates in the persistent so-called reading wars. The whole language movement inspired controversy that lingers today.

## WIDOWHOOD AND WIDOWERHOOD

---

The loss of a spouse is typically characterized as one of life’s most stressful events, and older adults often state that the loss of a spouse is the defining event of their later years. A wide range of reactions is possible when a person enters into widowhood or widowerhood. Although research has suggested that widowed individuals experience a variety of challenges, it is important to remember that each person’s reaction is highly influenced by his or her specific situation. Factors such as length of marriage, age of widow or widower, social and family support, financial resources, type of loss, and many other features make each situation unique.

According to the 2003 U.S. Census, about 2.5% of men (widowers) and 9.7% of women (widows) older than 15 years were classified as widowed. This translates into almost 14 million Americans who have lost a spouse and have not remarried. Research on widowhood and widowerhood has typically focused on the challenges faced by older widows. This is likely because about 62% of all widowed individuals are women older than 65. Conversely, there has been comparatively little research done on widowers, younger widows, and individuals who have lost a same-sex partner.

Both widows and widowers face significant challenges as they adjust to the loss of their partner. Studies have shown that widowed individuals face notably higher rates of health problems. Older widows and widowers also experience higher rates of disability and mortality than married controls. Not surprisingly, both widows and widowers have significantly higher rates of depression than their married counterparts. Often these elevated rates of depression can continue for many years.

It is difficult to determine whether men or women are affected more negatively by the loss of their spouse. Widowers tend to seek out and receive less social support. They are also less inclined to openly express their emotions regarding their loss. Conversely, widows tend to seek out social support and tend to openly convey their grief. Many researchers have argued that marriage tends to be more beneficial for men, and so the loss of their spouse has a greater negative impact. Additionally, many men expect to precede their spouse in death and therefore are surprised when the opposite occurs. Some men have difficulty dealing with the daily aspects of living alone, including eating healthy meals and maintaining a clean living environment. On the other hand, widows often have difficulty sustaining the same standard of living and managing their financial affairs.

An area of specific concern for widowers, especially older widowers, is the markedly increased rates of suicide. Older widowers have a suicide rate about 12 times as high as the rate for older widows. Widowers also demonstrate an increased rate of alcohol abuse compared with other men of the same age.

Some widowed individuals, especially younger widows and widowers, remarry at some point in their life. Research has shown that men are more likely than women to remarry, and younger widows are more likely than older widows to remarry. A significant

factor in remarriage is the availability of suitable partners, which explains the relatively low rate of remarriage by older widows. However, it is interesting to note that older widowers do not have a higher rate of remarriage than younger widowers. This suggests that some widowed individuals, especially older individuals, simply choose not to remarry.

## WISDOM

---

What comes to mind when thinking of wise people? Individuals might think of religious leaders, gurus, priests, medicine men, shamans, and sometimes politicians or therapists. These don't necessarily need to be famous people. On a personal level, someone might think of one's grandfather or grandmother and remember a situation in which their advice shed new light in a situation and was therefore eye opening.

What all these people have in common is a certain age. Rarely is wisdom attributed to a young woman or man. It is attributed to people in *late adulthood* who have had many experiences in life. This is the case in most cultures around the world. On the one hand, wisdom can be a goal of development, that is, something people strive for; on the other hand, wisdom can be the prerequisite for successful coping with life tasks during a certain life period. In any case, wisdom is something positive and admirable.

To get a better grasp of the concept, wisdom has often been discussed in the context of *intelligence*. Cattell distinguished between fluid and crystallized intelligence. Fluid intelligence is related to deductive reasoning, abstract thinking, heuristics for coping with new situations, and the speed of processing information. Fluid intelligence has its peak in young adulthood and declines with age. Crystallized intelligence refers to the whole body of experiences, skills, algorithms, and factual knowledge. Crystallized intelligence almost always increases with age. The increase in crystallized intelligence can make up for the loss in fluid intelligence. Crystallized intelligence can be seen as the basis of wisdom. However, there are some differences between crystallized intelligence and wisdom. First, crystallized intelligence is assessed in intelligence tests on information, vocabulary, facts, and school learning. Wisdom can hardly be measured because it is related to concrete knowledge about life experiences, including life's uncertainties and paradoxes. Second, contrary to intelligence, wisdom is less related to the current sociopolitical conditions. Wisdom encompasses a broader timeframe, learning from history, knowing the past to inform the future and to reflect on the present. Third, wisdom is more than just a body of theoretical knowledge. It has cognitive, motivational, affective, and interpersonal qualities.

For example, professors are often seen as very knowledgeable and bright, but not always necessarily as wise. The *cognitive* component of wisdom refers to experiential and practical knowledge of life. Wise advice is given with a profound understanding of the person and the situation. Wisdom is often connected with thinking outside the box and interpreting the situation from a different angle. It can be seen as the ability to deal successfully with the uncertainties, complexities, and problems of life. As the philosopher Karl Popper stated, "Living is problem solving. Problems and life entered the world together and with them problem solving." Wisdom often refers to creative strategies of problem solving. Strategies are abstract prescriptions on how to interpret and solve life problems, for example, being patient and sacrificing the immediate for the long-term good.

A wise person is not *motivated* by power, glory, or fame. Wise advice is given without considering one's own personal interest and benefits. The person in need or the society in need benefits from the wise advice. The motivation is to care and to be responsible for

others. This is the interpersonal component of wisdom. *Emotionally*, a wise person is often described as courageous, fearless, and calm, with a healthy distance from the situation.

The description of the different components of wisdom sheds new light on the question of whether wisdom has a strong *genetic* component or can be *learned*. Often, the genetic side of wisdom has been emphasized. However, wisdom could be partly acquired by being available for reflection and reflexivity in one's life experiences, learning values of responsibility for oneself and the community, learning that giving is sometimes more than receiving, deciding and acting on choices that benefit more people in the long term rather than focusing on the immediate and sole gratification of a few people, and understanding the essentials of life, including the paradoxes and realities, in more detail.

Wisdom of individuals can become part of the wisdom of a collective, for example, a cultural group's *sayings* or *proverbs*. Von Senger, for example, analyzed such proverbs in the Chinese language. Especially relevant today, yet conceived more than 2,300 years ago, Sun Tsu analyzed the art of war in China, according to successful and unsuccessful strategies, for example, "Know your enemy, know yourself, and your victory will not be threatened. Know the terrain, know the weather, and your victory will be complete." Or "No country has ever benefited from a protracted war." Or "The supreme art of war is to subdue the enemy without fighting." However, such sayings or proverbs do not always give clear prescriptions for acting because they are often contradictory, for example, "Don't put off until tomorrow what you can do today" but "Sleep on it," meaning either act right away or wait before you act. Wisdom refers to the ability to consider the demands of the situation. In some situations, it might be appropriate to wait. Time might lead to a clearer mental representation of the problem situation and thus be helpful for coming up with a solution. In other situations, it might be appropriate to act right away. The situation might change, the chance of the moment might be lost, or waiting might aggravate the problem. A wise person, then, is one who considers the value of timing and context of the situation, and adheres to the greater good of people.

To summarize, wisdom refers to the understanding of people in concrete life situations. Wisdom is based on a huge body of life experience and knowledge of

problem-solving strategies and on an emotional distance and fearlessness when giving advice without having one's own intentions in mind.

## WORK

---

Work is commonly defined as an activity that involves effort and sometimes reward. The result of work could be the achievement of a goal, the meeting of a demand, the completion of a task, or the generation of income. This variety of results of work reflects the different meanings that have been and continue to be attached to the activity of work. These differing results of work are associated with a range of psychological and development factors. Work can be considered from a historical perspective but also in terms of its developmental and psychological consequences. The sorts of activities that many in the Western world call work are very different from those pursued by our ancestors. However, some of our current approaches and attitudes toward work may be more than 2 million years old.

Evidence of work as a fundamental activity of human development is often inferred from discoveries of fossilized tools. Using this approach, work has

been documented occurring at least 2 million years ago in the Olduvai Gorge in Tanzania. The extinct species of the genus *Homo habilis* apparently used stone chopping tools to butcher dead animals. About 700,000 years ago, hand axes were in use, and thereafter, there is evidence of specialized industries being established based on crafting stone or flint into a variety of different tools.

Debate continues about the degree of organization that existed in production of these crude tools and about the degree of organization in the trade and deployment of such tools. The traditional view is that work was no more than an attempt to meet direct survival demands. Indeed, many accounts of early humans portray them as working as scavengers and behaving like savages. However, there are intriguing examples from relatively modern times that may point to a more sophisticated role of work in the earliest human groups. Aboriginal tribes in the Northern Territory of Australia did not develop tools beyond stone axes at the time of their first contact with white settlers in the 19th century. However, they had developed advanced trade and distribution networks for their tools.

It appears that even primitive forms of work were focused on more than just survival demands. Trade and distribution of tools require planning, logistics, and demarcation of roles. Passing on skills to the next generation requires training and development. Furthermore, it appears that survival demands were not as unrelenting and fraught as some have supposed. Studies of modern hunter-gatherer societies reveal that they often have time for activities other than those associated with the immediate survival of the group, such as hunting, gathering, and fighting rival groups. These other activities included social interactions within and beyond the group, ceremonies, rituals, and religious and aesthetic pursuits. All these activities tended to blend into a kind of “group or tribal life” and were not divided up as in modern developed societies. For example, such tribe people painted the animals they hunted, married and procreated for the survival of the group, and engaged in religious activities often to enlist the favor of the Spirit or Spirits for ongoing personal health and community well-being.

### WORK AND SLAVERY

As agrarian societies developed, work and all other aspects of farming life were determined by the seasons. Life and work were cyclical—sow, tend,

harvest, store. Amid the vicissitudes of climate (good and bad seasons, floods and droughts), there was a rhythm to existence. Agrarian societies initiated the establishment of private ownership of land. Agriculture also was more specialized and required markets for commodities. With a scarcity of labor and advances in technology, slavery was supplied through either conquest or purchase, and a life of work developed in various parts of the world.

Slavery underpinned some of the greatest civilizations in history. Although slaves predominantly engaged in manual labor, particularly agricultural work, some slaves worked as tradespeople, teachers, domestics, and doctors. Slavery is one of the most powerful examples of the stratification of society through the division of labor. Slaves were often seen by the ruling class as an unruly rabble that was temperamentally work-shy and untrustworthy. This “rabble mentality” was echoed in management theories of the early 20th century and is still evident in some current confrontational management practices. The dependency on slave labor has been associated with the decline of the Roman Empire because of the loss of a work ethic among the citizens.

Slavery reminds us of the central role of freedom and discretion in work. Slaves did not have freedom of expression, congregation, worship, representation, decision making, fear, or want. The distinction between slavery and freedom is not as clear-cut as it might seem. An interesting question is whether the slave of Roman times would identify with a modern executive living in a company-paid house, driving a company car, working 85 hours a week, espousing the company values and vision statement, and being at the beck and call of his or her employer by mobile telephone and email.

## WORK AND RELIGION

In less developed societies, religion served to foster the success of survival activities such as cultivation, gathering, hunting, and harvesting. However, in European civilization for about 1,000 years, the organizational prowess of the Christian Church resulted in large landholdings and massive building projects, which in turn afforded a range of work opportunities. These created significant wealth for the Church and with it material and mercantile temptations.

Protestantism provided a potent doctrine that combined religious devotion with the extolling of hard

work. The Protestant Work Ethic emphasized thrift, industry, wealth, and discipline as fundamental virtues. Whereas in the past, Roman Catholic orthodoxy had interpreted the Bible as presenting work as a curse, Protestants reinterpreted work as a blessing. For example, in the book of Genesis in the Old Testament, God is presented as a worker who creates the world in 6 days and ceases from his labors to rest on the 7th day. Moreover, Adam in his unfallen state is commanded to work, tending and ruling creation as God’s steward. It is a naïve misreading of the text (still prevalent in textbooks today) to interpret work as a curse after the Fall. Work was originally viewed as good and as part of what humans were made for; however, like every good thing, after the introduction of sin, its blessing became its curse. That is, work in Biblical terms is not a curse in itself; instead, work has become cursed in that we encounter frustration, toil, and obstruction. Protestantism, especially Puritanism and Quakerism, was exported to and flourished in America. The emphasis on hard work and community led to an unprecedented organization of labor into jobs and work shifts. In addition to manufacturing endeavors such as Cadburys in England and Hershey in America, Quakers opened banks and established lines of credit outside of the normal confines of the city.

## SPECIALIZATION OF WORK

As settled societies developed towns and new technologies, further specialization of work functions occurred. In particular, a stratum of society sat between the slaves, peasants, laborers, and serfs and the ruling classes of soldiers, lords, knights, and kings. These were the craftsmen who organized themselves along functional lines into part trade unions and part trade associations. In medieval Britain, they were called guilds, but similar organizations developed around the world. Hierarchies existed within these *guilds*, with long apprenticeships to reach the level of a journeyman. The highest level, Master, was achieved after many years of work and the production of a “masterpiece” accepted by the guild.

Guilds provided a powerful mechanism for the control of skilled labor. Guilds in some towns had significant political power as a result of their control of skilled labor. As guilds became more sophisticated, the emphasis moved toward trading the skills and away from the development of the skills. Masters of

guilds restricted the number entering and progressing through the guilds to maintain control over the supply of skilled labor. As a result of this, many workers were employed as “wagemen,” as opposed to apprentices or journeymen. This created a new class of employer-employee relationship.

The industrialization of Western societies in the late 18th and early 19th centuries dramatically severed the necessary nexus of work and the natural world. Increasingly, work became linked to technology, usually centralized in factories and mills, necessitating massive and unparalleled urbanization around the new sources of employment. Economic power determined the nature and conditions of the work available and, as a consequence, the life circumstances of millions of employees. As a result, employees eventually organized into unions to bargain over the pay and conditions of work. In the process, the field of industrial relations emerged and has remained one of the central characteristics of contemporary working life in developed economies. The change from an agrarian to an industrial era was difficult for many workers. Many resented the loss of autonomy of having a farm of their own, being forced to move to the city often to live in squalor, being underpaid and forced to work in dangerous conditions, having no control over the work process, and being consigned to repetitive and seemingly useless sets of duties. Work became associated with mass production and mass production with worker alienation, which sometimes found expression in industrial sabotage. As industrialism developed, work became increasingly fragmented, simplified, and repetitive.

## WORK AND TECHNOLOGY

Technology has profoundly influenced work practices throughout history. Two inventions in the past century that have generated dramatic change are the internal combustion engine and the microcomputer. The internal combustion engine greatly enhanced the mechanization of work. For the first time, workers were not necessarily undertaking the primary work tasks, but were instead tending, operating, or maintaining machines that did. This created an explosion in productivity as production was no longer directly related to worker effort or skill. The Ford Motor Company is often credited with the introduction of the production line method of working; however, Ford management had observed a Chicago meat-packing

business where carcasses were hung from moving hooks and were butchered as they moved along. Until 1909, cars were assembled in teams, with all the workers being involved in the process of construction from start to finish. When production lines were introduced, productivity jumped, and the cost of a Model T Ford halved in 3 years. Workers were reduced to doing one or two activities on a product as it moved along a conveyor belt. These same activities were repeated thousands of times per day, and yet at the end of the day, there was still an apparently endless stream of further products to be processed the same way. People often reported being treated either as part of one of the machines or like a monkey. Such work robbed the workers in many cases of a sense of achievement, a sense of ownership, a sense of skill and personal development, and a sense of meaning through work.

As the quality of working life declined in industrial societies, the value of nonwork time increased. The demarcation of work to a specific location and a number of hours per week delimited work and how it was understood by many in industrialized societies. The problem that increased production created for Ford was that supply outstripped demand because the working hours at the time were so long, individuals did not have time to devote to other activities for which a motor vehicle might be required. Henry Ford's solution was to cut the hours of work so that workers would be able to use the cars that he was producing. The widespread availability of motor vehicles to large portions of society further fueled the pace of change. Workers were able to live further from their place of work, creating suburbs and commuters. Furthermore, there was a large increase in tourism because ordinary people were now able to access distant parts of the country rapidly. This stimulated a nascent tourism and service industry that was already benefiting from enhanced rail infrastructure. The relationship between work and nonwork and leisure has become a major field of theory and research.

Communications technology also had a dramatic effect on work in the late 19th and 20th centuries. The telegraph and then the telephone made the world a smaller place and enabled information to be exchanged at a hitherto unheard-of pace. By the mid-20th century, the computer was developed, and it began to be used by governments and large organizations in the 1950s and 1960s. However, the development of the microprocessor chip led to the first personal computers

being widely available for business and home use. The IBM Personal Computer was launched with Microsoft software in 1981. The Apple Corporation had already released the Apple II computer. The impact of the introduction of the personal computer was almost instant. These machines were capable of doing many of the routine clerical tasks in offices faster and more accurately than human clerks. In the same way that machinery had led rapidly to redundancies in manufacturing jobs, computers cut a swathe through clerical jobs. Computers were also employed to control machines, creating robots for a range of tasks, including motor vehicle manufacture.

The combination of communication technology and computer technology has led to further rapid changes in how we work. Telecommuting is now a fact of life for many workers. Employees do not need to be physically present in the workplace; indeed, the notion of the workplace is changing. The mobile phone, laptop computer, and Internet have brought the workplace back into the home for the first time in hundreds of years for some sections of the workforce. This has further complicated the separation of work and nonwork.

With rapid growth in the use of technology, efficiency of production and process has very often come at the expense of employment opportunities and at the cost of nonwork time.

Technological advancement has significantly lengthened the hours of work for some well-educated people in the workforce while at the same time presented long-term unemployment for less-skilled workers. Furthermore, the employer-employee relationship is no longer as intimate as it once was because of globalization. Employees can no longer rely on the quality of their work or their personal qualities to ensure continuing employment but rather are subject to the fluctuations of the international money markets. The complexity and rapidly changing nature of work have spawned at least two specializations within the field of psychology—industrial and organizational psychology and vocational psychology. Central to these endeavors has been the notion of work adjustment and well-being of the worker and organization.

Improvements in manufacturing efficiency continued apace throughout the 20th century, which also saw the development of jet propulsion and affordable air travel and transport as well as large and reliable motorized shipping. This has greatly increased world

trade opportunities and development of global organizations.

## FORMAL AND INFORMAL WORK

About one third of our time available for living is taken up with work and 20% with leisure. Despite the central role work plays in most of our lives, its purpose, meaning, and psychological influence remain vexed questions. For instance, there is a plethora of research from social and organizational psychology that suggests that work is injurious. A recent study found that most people replied that they “wished they were doing something else” when asked while they were at work. In another study, 19% of women and 14% of men reported having unpleasant emotional strain for more than half of the previous working day. This suggests that many people do not enjoy the experience of work and may experience significant deleterious effects from work. However, other studies point to the benefits of work and our reluctance to forego work. A survey of more than 500 lottery winners concluded that people with psychologically and financially rewarding jobs continued working regardless of the amount they won, whereas those who worked in low-paying semi-skilled and unskilled jobs were far more likely to quit the labor force. In another study, 80% of Americans said they would not retire from working even if they had enough money to live off comfortably. Hence, we end up with the paradox that work is a source of frustration, yet one we are reluctant to forego. However, what constitutes work and leisure is increasingly difficult to define. For instance, whereas working as a mechanic would be seen as work to most people, is working at home tuning your car’s engine work or leisure? The difference perhaps is between formal and informal work.

Formal work tends to be associated with income and most commonly with monetary reward defined by some legal arrangement such as employee-employer, self-employed, business partners, subcontractor, agent, or representative. Generally in such arrangements there is a financial exchange between the worker and some other party, such as an employer or a customer or client. These forms of work have been studied extensively from many different perspectives, including industrial relations, sociology, psychology, philosophy, economics, and business studies.

Informal work constitutes activities that fall outside the definition of formal work but still possesses

at least one of the characteristics set out in the definition of work. Domestic chores around the house and garden would fall into this informal category, along with charity and voluntary work. In many societies, this work has been traditionally performed by women.

## WORK AND DEMOGRAPHY

In 1997, married women in Australia spent an average of 1 hour, 47 minutes per day more on domestic work than men. Women spent an average of 3 hours, 46 minutes on household work, compared with 2 hours, 30 minutes for men. There was evidence of clear demarcation in the type of household work done by men and women. Women did more food preparation and clean-up than men, 30 minutes more laundry work, and 30 minutes more general housework. Men did 25 minutes more grounds and animal care and 25 minutes more home maintenance. Large discrepancies between the amount of informal work done by men and women have been linked to divorce rates. The requirement to do domestic informal work is common for most people, with the exception of the very wealthy who have continued to employ domestic staff, thereby formalizing this type of work.

In 1870, 52% of employed women were engaged in paid domestic work. At the end of the 19th century, the figure was 1.5 million. By 1920, 28% of employed women were paid domestic workers; the proportion decreased further to 18% in 1940, which was the last time the job was at the top of the list of women's occupations. By 1970, the percentage had declined to 5.1%, and then to 2.5% in 1980. The decline in domestic jobs for women was in part due to the widespread availability of clerical roles. At the same time, some of this work was outsourced to restaurants and child care centers.

In American Colonial homes that produced goods, neighborhood girls helped the housewife with cooking, clothes making, baking bread, and producing dairy products in return for room and board and an apprenticeship in these skills. This position changed from a "helper" to a formalized "live-in servant" who was expected to do the household chores employing all of the new facilities, such as gas and electricity, and their attendant appliances. Typically, these were rural workers attracted to the higher wages available in the city.

Domestic work remained a low-status job and became identified with women of color as white

women moved into clerical occupations. Between 1920 and 1940, the proportion of African American women in domestic work rose from 46% to 60%. The most common form of domestic work by the 1980s was day cleaning, performed by a range of people of color. Teenage babysitters constituted the largest group of white Americans who were listed as domestic service workers.

Domestic work, whether formal or informal, was excluded from most legal protections and social security entitlements, and even denied protection in the form of a union until the 1970s, when the industry was in sharp decline. However, both formal and informal domestic work is becoming increasingly recognized as a valid form of work that may be associated with psychological outcomes. With women's dramatically increased participation in the workforce in the late 20th century, there has been a resurgence in the formalization of domestic work to assist busy dual income couples. There has been an increase in employment of cleaners, child care assistants, cooks, and butlers. This has been extended to dog walkers and "Saturday Dads" who take children to weekend sporting events. These changes in working patterns have caused a blurring between work and leisure. For instance, time spent with and caring for children is classified by some as work, whereas others classify this as leisure.

## WORK AND UNEMPLOYMENT

One way to look at the importance and role of work in human life and development is to examine what happens when people are deprived of the opportunity to work. In her classic research investigations into the effects of unemployment, Marie Jahoda delineated most of the major psychosocial benefits of work in addition to pay and conditions. She found that work performs five psychosocial functions for the individual and that those without work face the challenge of meeting these needs in some other way. First, work enables and often demands social contact. Such contact fosters the development of social skills, the establishing of social networks, and opportunities for mutual support. Second, work demands activity and almost always demands at least a minimal level of physical activity. There are many studies illustrating the physical and psychological benefits of regular activity in sustaining fitness, energy levels, mental alertness, and work conditioning. Third, work in most societies gives people a

social role and social identity. Knowing someone's occupation, especially when meeting him or her for the first time, usually gives us a great deal of information about him or her—education, intelligence, personality, success, income, social status, and how much he or she is or is not like us. Work is a major way in which people define themselves and others within the community. Fourth, work gives structure to people's time. Work usually demands that activities be undertaken at specific hours of employment. This benefit provides a pattern to people's lives, allowing them to make arrangements about nonwork tasks. Fifth, work links people with goals larger than themselves and their own immediate concerns. By having to direct attention away from self to another task external to our individual focus, work usually is an opportunity for external orientation to others and the work in general.

Other researchers have considered the less positive effects of work. In particular, the concept of occupational stress has been extensively researched and is probably the most commonly researched area of work now. Although definitions of stress appear in 16th-century dictionaries, it is generally agreed the term became popular after the Second World War. The term *stress* has passed into the modern idiom despite significant confusion over its meaning. Stress is classically defined as a nonspecific response of the body to any demand made on it. In this scheme, there are three stages of the stress reaction: alarm, resistance, and exhaustion. Other definitions focus on a range of negative affective and physiological responses. Some researchers, most notably Robert Karasek and Roy Payne, have considered the relationship between the characteristics of a person's job and his or her stress response. Both researchers have argued that perceived job demands and perceived control over meeting those demands will predict stress. Jobs that are high in demands and low in control are predicted to be the most stressful. The relationship among job demands, control, and stress has been well documented in the literature for more than 20 years. In addition, other factors, such as the degree of social support enjoyed in the workplace, have been shown to predict stress levels.

Work has been a central activity of all human societies and has provided significant material, societal, and psychological benefits. However, at the same time, it is clear that work in and of itself can be not only unsatisfying but also positively deleterious for psychological and physical well-being. Perhaps

John Paul Getty, the industrialist, best summed up the nature of jobs when he said, "if you haven't got a problem, you haven't got a job." Work is about solving problems, and employment is about delegating this task to others.

## SOME CONCLUDING COMMENTS

Work is now recognized as broader than merely having a job. Much essential work is carried on outside of the labor market. There is increasing recognition of the value of such activity for communities and nations as a whole. Moreover, as noted several times, the distinction between work and nonwork is often difficult to delineate—so much so that modern formulations of "career" typically encompass not only worker as employee but also all the multiple roles that individuals take up, shed, and resume at various times in their ongoing development. Writers about the future of work expect that work will continue to change with new occupations developing while old ones perish; that there will be an increasing emphasis in work on academic, creative, and intellectual skills, in comparison with manual and mechanical skills; that work training will become a lifelong learning process and will be conducted increasingly through distance education and the Internet; and that work will be conducted in increasingly globalized and multicultural contexts.

The paradox of work remains with us. Most of us get a sense of contribution and well-being from work as well as an income to help us live. We are confronted by frustration, toil, and boredom while working. We expose ourselves to significant risk: physical injury, stress, bullying, harassment, mockery, and reputation harm through work. Yet work also provides opportunities to turn preoccupations into occupations for growth, enlightenment, contribution, service, and achievement.

—Jim E. H. Bright and Robert G. L. Pryor

## WORLD HEALTH ORGANIZATION

---

The World Health Organization (WHO) was established in 1948 as a specialized agency for the United Nations devoted to issues of health. It is governed by the 192 Member States of the United Nations, with headquarters in Geneva, Switzerland. A nation can be a member of WHO without being a member of the United Nations. There are six regional offices throughout the world:

Regional Office for Africa in Brazzaville, Republic of Congo

Regional Office for Europe in Copenhagen, Denmark

Regional Office for South East Asia in New Delhi, India

Regional Office for the Americas/Pan American Health Organization in Washington, DC

Regional Office for the Eastern Mediterranean in Cairo, Egypt

Regional Office for the Western Pacific in Manila, Philippines

The main functions of the WHO are as follows:

1. To give worldwide guidance in areas related to health
2. To set global standards for health
3. To cooperate with governments in strengthening national health programs
4. To develop and transfer appropriate technology, information, and standards

The services include a day-to-day information database on the incidence of internationally significant diseases; publishing a list of diseases, injuries, and deaths; monitoring adverse reactions to drugs; and establishing world standards for antibiotics and vaccines. There is a strong training component and resources to strengthen the delivery of health services.

Efforts to control and eradicate infectious diseases have been a main focus for the WHO. One of the major accomplishments of the WHO was the elimination of smallpox. Smallpox was endemic in 31 countries and claimed almost 2 million lives a year. In 1967, a systematic effort to vaccinate selected populations in endemic countries was initiated. By 1972, the disease was present in only 8 countries. The last case of smallpox was discovered in Somalia in 1977. Today, the WHO is focusing on the eradication of polio, neonatal tetanus, leprosy, and iron-deficiency disease.

In 1977, the World Health Assembly, which consists of the member nations, set the goal of “health for all by the year 2000.” This slogan does not mean that there will be an end to all disease or disability, but rather that basic health care will be available to everyone. The focus is on health care in community settings, such as homes, schools, and the workplace.

In 1978, representatives from 134 countries met with WHO delegates in Almatay, Kazakhstan, and agreed to implement the “health for all” motto through primary health care. Primary health care emphasizes the responsibility of the community to use health strategies that are appropriate and affordable. Such services would include health education, adequate food supply, safe water, basic sanitation, maternal and child care, family planning, immunizations, prevention and control of local endemic diseases, appropriate treatment of common diseases and injuries, and provision of essential drugs.

Recognizing the threats to the public health posed by accidental or intentional release of harmful agents, the WHO in 2001 made specific recommendations regarding global health security. The WHO issued a resolution that every country should be able to detect, verify, and respond appropriately to epidemic-prone threats when they arise, resulting in the development of the Department of Communicable Disease Surveillance and Response (CSR). This unit aims to attain global health security through the containment of known risks, such as emerging infections; response to unexpected events, such as global outbreaks; and

improved preparedness by strengthening national capacity. The aspect of improved preparedness is addressed through an integrated approach providing expert assistance in epidemiology and enhancement of laboratory skills.

—Linda Spencer

## WRIGHT, JOHN C. (1933–2001)

---

John Cook Wright was born in Los Angeles and grew up in Washington, DC, and Tucson, Arizona. He graduated from Phillips Exeter Academy in 1950, received a bachelor's degree from Harvard University in 1954, and after a 2-year stint in the army, earned his doctoral degree in psychology from Stanford University in 1960. His dissertation was a study of noncontingent reinforcement, supervised by Alex Bavelis, and he also worked with Robert R. Sears on a classic study of child rearing and child development.

Wright spent his long career as a college professor, researcher, social activist, and advocate for the welfare of children. He taught at the University of Minnesota (1960–1968), the University of Kansas (1968–1996), and the University of Texas at Austin (1996–2001). With his wife, Dr. Aletha Huston, he founded and directed the Center for Research on the Influences of Television on Children (CRITC).

Employing innovative experimental methods, Wright applied developmental theories of perceptual attention to describe the mental processes of the

young television viewer. His research showed that children are active during viewing; they work deliberately to decode, interpret, and understand the content presented. The formal features of television (production techniques such as cuts, fades, pacing, and animation) are critical tools that children use to judge what content is interesting, comprehensible, and meets their viewing goals. Wright developed his traveling-lens model as a framework to explain that children dedicate the most time and attention to television segments that are both comprehensible and stimulating. As children mature, content that was previously incomprehensible becomes more desirable and engaging.

With a team of colleagues, Wright performed the premier longitudinal studies measuring the effects of early educational television viewing. This line of research revealed that viewing *Sesame Street* at ages 2 and 3 years is related to higher language abilities and better school preparation at age 5. These positive effects do not dissipate after kindergarten—especially for boys, preschool educational viewing predicts higher grades in high school. Wright claimed that early viewing of educational television helps set boys on a positive educational trajectory that begins at school entry and translates into higher levels of success in high school. Informed by the results of these studies, he argued that television as a medium is neither good nor bad—the content viewed determines the effects on the viewer. Contrary to Marshall McLuhan's famous dictum, "The medium is the message," Wright staunchly proclaimed, "The message is the message."

## Young Adulthood

*Youth cannot know how age thinks and feels. But old men are guilty if they forget what it was to be young.*

—J. K. Rowling

---

## YOUNG ADULTHOOD

---

What does it mean to become an adult? Most people rate the top criteria for marking the entry to adulthood as accepting responsibility for one's self, making independent decisions apart from parents, establishing egalitarian relationships with parents, and achieving financial independence. Although self-sufficiency has been attained in young adulthood, the period of the twenties and early thirties, young adults continue to grow and change in multiple arenas: biological, cognitive, psychosocial, and social.

### BIOLOGICAL CHANGES DURING YOUNG ADULTHOOD

Typically, full height is attained in middle to late adolescence. Yet growth is not complete; the size and shape of the body continue to change in young adulthood. Both accumulation of fat and growth of muscle continue such that women reach their full breast and hip size and men their full shoulder and arm size in their early twenties. Throughout the twenties, physical strength and athletic skill increase, peaking at about age 30 and declining thereafter. All the body systems

(e.g., the digestive, respiratory, circulatory, immune, and reproductive) reach peak levels of functioning in early adulthood. When physical growth stops, senescence, or age-related gradual physical decline, begins.

Generally, the first noticeable age-related changes occur in the skin. The connective tissue of the body, collagen, begins to decrease at about age 20, by about 1% each year. The skin thins and loses elasticity, making wrinkles visible, especially around the eyes. These age-related changes in the skin occur all over the body but are most noticeable on the face. At about 30, reductions in the number of pigment-producing cells in the head lead to the emergence of gray hair. At this age, hereditary baldness in men becomes apparent; hair also begins to thin because of hormonal changes and reductions in the blood supply to the skin.

There is a great deal of variability in the process and timing of aging. Connections between age and physical change in adulthood are loose and not as predictable as developments during earlier periods in life. Change varies widely across parts of the body, with some parts affected more than others. For example, a given individual's liver may age more quickly than his or her lungs, particularly if he or she consumes heavy amounts of alcohol. In addition, there are tremendous individual differences in the aging process. Some

individuals age more quickly than others, because of genetic and lifestyle differences.

## **COGNITIVE CHANGES DURING YOUNG ADULTHOOD**

Most of us recognize the changes in cognition that children and adolescents undergo, but cognition continues to develop in young adulthood.

### **Postformal Reasoning: From Dualism to Relativism**

During young adulthood, many people progress beyond Jean Piaget's formal operational stage of reasoning to postformal reasoning, entailing a shift from dualistic thinking to relativistic thinking. Dualistic thinking entails a belief in absolutes regarding information, authority, and values. Individuals who think in dualistic terms believe that there are concrete right and wrong answers to every question. Adolescents, for example, tend to think in dualistic terms, always looking for the one "right" answer. With time, experience, and exposure to diversity, young adults transition to relativistic thinking in which they realize that there are many perspectives on any given topic. Instead of one absolute truth, relativistic thinkers consider multiple truths, relative to given contexts and perspectives.

The postformal reasoner understands that an individual's perspective is one of many views and that there are few absolute answers; knowledge is not fixed, but changes. Therefore, postformal thinking is flexible, permitting us to attend to both the problem and its context, which is needed to adapt our cognitive problem-solving skills to real-world situations. Postformal reasoning combines objectivity, or abstract logic, and subjectivity, or situation- and individual-based feelings and experiences. In young adulthood, we are confronted with problems in work, marriage, and family life that do not have single correct solutions. Yet how we handle these problems influences our future and life course. Mature thinking entails integrating logical and objective processing with sensitivity to context and personal perspective.

### **Dialectical Thought**

At its best, the cognitive flexibility of formal operational reasoning reaches the level of dialectical thought, an advanced level of reasoning. Dialectical

reasoners understand that every idea also suggests the opposite idea. Dialectical reasoners are capable of considering both poles simultaneously, integrating and synthesizing them, and adapting to the resulting continual changes. Dialectical thinking entails integrating and synthesizing our experiences and ideas with the contradictions and inconsistencies we encounter, resulting in a constantly changing perspective of oneself and the world. It is understood that few questions have single unchangeable answers; however, unlike relativistic reasoners, dialectical reasoners recognize that although there are many perspectives or viewpoints on a given situation, some hold more merit or can be better justified than others and permit a more solid foundation for decision making.

Although we first become capable of postformal operational thinking in young adulthood, and many young adults transition to relativistic thinking, only some young adults develop the capacity for dialectical reasoning. Many people do not become dialectical thinkers until middle adulthood, if at all.

### **Effect of College on Cognition**

How does college influence thinking? With college education, people tend to become more tolerant of differing political, social, and religious views and more flexible in their attitudes and consideration of differing perspectives. Research suggests a progression by which the more exposure students have to college, the greater the level of cognitive development, from dualism, to relativism, and, in some individuals, dialecticism.

First-year college students, for example, tend to believe in absolute truth (dualistic thinking); they are often disappointed when professors answer their questions with lengthy generalities (i.e., "it depends on a variety of factors"). Then students enter a phase of extreme relativism in which they question the notion of a universal truth and become lost in a sea of perspectives, recognizing that there are multiple perspectives and each can hold merit, varying by context (relativistic thinking). Finally, students come to realize that although there are multiple perspectives, each can be weighed, and they differ in terms of overall merit. They become committed to particular values, can recognize multiple perspectives, and remain open-minded. True dialectical thought in which contradictions are synthesized into a complex and dynamic perspective occurs for some, but not most, college students.

The intellectual challenge, social interactions, and exposure to a variety of perspectives through class discussions, peers, books, and professors that is typical of a college education stimulate students to consider new questions and thoughts and thus progress cognitively. Generally, the more years of college education and life experience one has, the more likely one is to demonstrate advanced levels of reasoning. However, young adults who are not enrolled in college may advance cognitively if they are confronted with similar opportunities to be intellectually challenged, engage in social interaction and issue-focused discussions, and be confronted with multiple perspectives.

### **Expertise and Cognition**

During the college years, we not only develop our thinking skills but also gain expertise in a given field. We choose a college major, or a field in which to specialize. As we take courses in that field, we develop a knowledge base that influences how we process information. This is also true regarding life experience, regardless of education. As we gain more experiences within a given context, we develop expertise, enabling us to think in more complex and efficient ways. Compared with novices, experts remember and reason more quickly and effectively. We develop more abstract ways of thinking about the material within our area of expertise, which helps us better organize and reason with it.

### **Moral and Self-Concept Development**

Changes in cognitive development and in social experience also bring changes in moral development. We encounter moral dilemmas throughout our daily life. As we advance cognitively, we think in new ways about our lives. Events in our lives, such as committing to a relationship, job promotions, psychotherapy, and serious illness, can lead to a disequilibrium, a mismatch between our perspective and experience, and stimulate reflection. Reflecting on these experiences leads to deeper convictions about our values, self, and place in the world.

### **Vocation**

Vocational exploration and choice begins in childhood, when we fantasize and imagine what different careers are like. In adolescence, we explore and evaluate potential careers in light of our skills and

abilities, and choose educational experiences that prepare us for possible careers. In young adulthood, we narrow our options based on our experiences, interests, personalities, and opportunities. Our families and social contexts influence our vocational decisions in the sense that we tend to choose vocations similar to those to which we have been exposed. People who grow up in higher socioeconomic status homes and communities are more likely to select high status vocations such as lawyer, doctor, and scientist, whereas those who grow up in low-income homes and communities are more likely to consider less prestigious occupations. Those individuals who enter college often sample majors, to further exploration and determine where their interests lie. Then they choose a major and explore careers within that field. Some people may not choose an occupation until well after college. Occupational choice does not end with college graduation or entry into the first job. Unlike prior generations when adults could expect to put in a lifetime of work at the same company, retiring with a gold watch and a pension, most young adults can expect to be employed in a range of positions, even changing occupations several times through life. The consideration of various careers and vocational growth and change continues throughout young adulthood.

Young adults who do not attend college have more limited vocational choices. Twenty-five percent of young people with a high school diploma have no plans to go to college. North American young adults who do not attend college often find it hard to find a job other than the one held as a student. Of American recent high school graduates who do not continue their education, about 20% are unemployed. North American young adults who are not college bound have few alternatives to turn to for vocational counseling, training, and job placement. Many flounder after high school graduation because most North American employers perceive high school graduates as poorly prepared for occupations. When high school graduates find work, they often are limited to low-paid and unskilled jobs.

### **PSYCHOSOCIAL TASKS OF YOUNG ADULTHOOD**

Young adults are faced with several psychosocial tasks: solidifying autonomy, further shaping and committing to an identity, and developing a capacity for intimacy.

## Autonomy

Autonomy refers to self-governance, the ability to make decisions independently of others. Although the development of autonomy is a lifelong process beginning in toddlerhood and becoming more obvious in adolescence, many people do not establish a full sense of autonomy until young adulthood, when education is complete, work life has begun, and the individual is living on his or her own, apart from parents and formal institutions. A sense of autonomy permits young adults to maintain close bonds with family members, seek family members' advice in problem solving, and ultimately make and carry out their own decisions based on considering their values and opinions. The task for young adults is to gain experience and feel more comfortable in exerting their autonomy.

## Identity

Like autonomy, identity development begins in adolescence when individuals experiment with possibilities and explore alternatives in order to ultimately make enduring decisions in the areas of career, love, and worldview. Identity refers to a sense of self. In young adulthood, the individual has committed to an identity and the commitment strengthens. The identity also undergoes change and refinement as the young adult takes on new roles, such as worker, spouse, and parent.

## Intimacy

According to life-span development theorist Erik Erikson, the primary psychosocial task of young adulthood is developing a capacity for intimacy. The development of intimacy refers to the ability to establish close, committed relationships with others that will last a lifetime and that will support the individual's maturing identity throughout life. Managing this task entails balancing the opposing needs for independence, or autonomy, and connections, or intimacy. We learn to experience intimacy by making and maintaining important attachments with others. Intimacy entails giving of oneself, openness, and vulnerability—sharing without asking what will be received in return.

## SOCIAL CHANGES OF YOUNG ADULTHOOD

Young adulthood is a time of great social change—we progress to full independence and take on adult roles. As we take on adult roles, the impulsivity characteristic

of adolescence and emerging adulthood wanes. For example, after the early twenties, particularly college graduation, substance use, such as alcohol and marijuana consumption, declines.

## Friendship

Friendship is important at all ages in life because it is a source of emotional support, positive feelings, and self-esteem. Young adulthood is a time in which we sort through and solidify existing friendships and make new ones. The overall absence of marital and family obligations permits young adults time to form extensive and varied social networks, forming friendships at college or at work; among political, cultural, athletic, or religious groups; and even on the commute to work or on vacation. Young adults have many social opportunities from which they select people who provide information, advice, companionship, and empathy.

Friends are usually similar in age, sex, and socioeconomic status. They also share common interests, experiences, and needs. Friends share their thoughts and feelings with one another, revealing themselves and making themselves vulnerable. In adult friendships, trust and loyalty are important. Friends often come and go throughout life, but some adult friendships continue for many years. Women are more likely to experience lifelong friendships and tend to see their friends more often than do men.

Women friends get together to talk. Male friends get together to do things such as play sports. Men are more likely to report barriers to intimacy such as feeling in competition with other male friends. Because they are free of marital and family obligations, open to new people, and exposed to many people, young adults in their early to middle twenties experience low levels of loneliness comparable to other ages in life. Young adults who live alone tend to form an extensive circle of friends and spend nearly as much time with friends as they do alone.

As young adults enter the thirties, family obligations and changing lifestyles cause some friendships to intensify and others wane. A lack of time, caused by juggling work, home life, and child care, makes maintaining friendships more challenging. Because we tend to form friendships with people who are similar to us, a change in marital status or parenting status can change the dynamics of friendship. Some friends, therefore, drift apart, and new friendships are made based on similarities such as children,

occupation, and neighborhood. Despite the changes, most people report a few lifelong friends.

## Sexuality

In young adulthood, sexual activity increases in prevalence, with fewer people remaining virgins and more people regularly engaging in intercourse. Sexual activity increases through the twenties as people marry or cohabit. At around age 30, sexual activity begins to decline, despite few changes in hormonal levels. The decline in sexual activity is associated with the multiple roles and demands of adult life, work, family, and child care.

Males and females display a similar pattern of sexual activation, arousal, release through orgasm, refraction, and recovery. For males, sexual arousal and excitement can occur very quickly in response to many stimuli, in addition to or in lieu of an arousing partner. Over the course of young adulthood and particularly toward the end of young adulthood, males may notice a gradual increase in refractory period and slower arousal, requiring additional stimulation and additional time between arousal and full erection, erection and ejaculation, and orgasm and recovery.

Generally speaking, in females, sexual arousal, excitement, and orgasm take longer than in males. As females progress through young adulthood, arousal and orgasm become more likely. In adolescence, girls are often advised to protect their virginity and may be conditioned to resist their own desire, and instead emphasize their control over sexual experiences. In young adulthood, many women explore their sexuality through multiple partners and different sexual experiences, becoming more comfortable with and appreciating their sexuality, and experiencing orgasm on a regular basis.

Like friends, we tend to choose partners to date, cohabit, or marry based on similarity. Our partners tend to be similar in age (within 5 years), education, ethnicity, and often religion. We tend to meet our partners for long-lasting relationships through introductions by family or friends, at work, school, or through activities based on common interests.

## Cohabitation

Cohabitation refers to the lifestyle of unmarried couples who live together, sharing intimacy, a sexual relationship, and a residence. Cohabitation is more common today than ever before, especially among

young adults. For example, more than one half of all women aged 25 to 40 in the United States have lived with a man outside of marriage. Many couples view cohabitation as an opportunity to test the relationship and get used to living together. Others view it as an alternative to marriage, a long-term arrangement with the rewards of companionship while maintaining independence. Homosexual adults often find no alternative to cohabitation because few states recognize homosexual relationships in formal partnerships. Increasingly, cohabitation includes children.

## Marriage

Young adults are waiting longer than ever before to marry. The overall rate of first marriages in young adulthood is the lowest it has been in 50 years. Sixty percent of young adults aged 20 to 30 in the United States are not yet married, and 3% are already divorced. More young adults choose to remain single, cohabit, and, after divorce, do not remarry.

The transition to marriage itself is a challenge. The transition to marriage entails a great deal of work in defining the relationship and each person's roles within the relationship. For example, negotiating the marital relationship requires deciding who does what in completing the myriad details of daily life. Who will cook? What will be eaten? When is leisure time and what is on the agenda? How will the household and financial tasks be decided? These decisions may be particularly challenging for today's young adults and therefore make the transition to marriage more difficult because of changes in gender roles and the tendency of young adults to live farther away from family members (and thus have fewer sources of support and guidance) than prior generations. Cohabitation before marriage may make marriage less of a turning point; however, many young adults report transitional stress despite prior cohabitation.

Generally, spouses with similar backgrounds in terms of socioeconomic status, education, religion, and age tend to report higher levels of marital satisfaction. Overall stability in other areas of life, such as stable financial and employment status, are also associated with higher levels of marital satisfaction. Although similarity in interests and in background is ideal, most successful married couples share some critical values and interests and learn to compromise, adjust, and agree to disagree about others.

The maturity of the partners also contributes to the overall success of a marriage. Generally, the younger

the bride and groom, the less successful the marriage. A full sense of identity is needed before one can establish intimacy. Because many young adults in their early twenties are still determining and solidifying their identity, shared intimacy, compromise, and growth as a couple are difficult. Before a full sense of identity is achieved, passion may be valued over the true predictors of marital success: openness, trust, loyalty, intimacy, and commitment. Young adults who married early may find that their values and roles diverge with those of their spouses as they mature. Those who wait until their late twenties and thirties to marry are less likely to divorce.

### Divorce and Remarriage

About one half of all marriages in the United States end in divorce. Most divorces occur within 5 to 10 years of marriage. Divorce itself is a stressful experience for men and women, who both show signs of depression and anxiety, which typically declines within 2 years. Men show a more positive and quick adjustment when they remarry shortly afterward. Most women prefer their new single lives over unhappy marriages, despite increases in loneliness and reduced income. However, some women, particularly those who were in traditional marriages and who highly identified with their roles as wives, find divorce particularly challenging and are likely to remain anxious and depressed over time, experience drops in self-esteem, and tend to form other unsuccessful romantic relationships. Overall, the economic and psychological health of divorced women are enhanced by career advancement through education and job training and social support from family and friends.

After divorcing, two thirds of men and more than one half of women remarry. Typically, remarriage occurs within 4 years of divorce. Men remarry more quickly than do women. Remarriages face many of the same challenges of first marriages, with higher rates of divorce in the first few years. The practical reasons that often influence second marriages, such as financial security, social acceptance, relief from loneliness, and help in raising children, may not provide a basis for a solid marriage. Also, after a failed marriage, people may be more likely to view divorce as an acceptable solution when marital difficulties resurface. Finally, stepfamilies are stressful; children from prior marriages place stress on new marriages. Although the first few years of second marriages are

at higher risk for divorce than first marriages (about 7% higher), afterward the divorce rates are about the same.

### Parenthood

Recent generations of young adults have come to recognize parenthood as a choice. Some adults choose to remain childless and, because of changing cultural values, are less likely to experience social criticism and rejection than those of prior generations.

The physiological ability to produce children, reproductive capacity, is highest in the early twenties and declines with age. Females' ovulation is most consistent in young adulthood and becomes more erratic in the mid- to late thirties. Males, on the other hand, experience little to no change in sperm production throughout young adulthood. Despite their reproductive capacity, young adults are having children later in life than ever before. Most births occur to women older than 25. The number of women who give birth in their thirties is higher than ever. Families also are having fewer children, with the average number per couple at 1.8.

Young adults note many advantages of parenthood, particularly opportunities for love and change: the giving and receiving of warmth and affection, experiencing the stimulation and fun that children add to life, and the growth and learning opportunities that add meaning to life. They tend to report the sense of accomplishment and creativity from helping children grow and from someone to carry on after one's death as other advantages of parenthood. Parenthood is also an additional marker of adulthood; some young adults view parenthood as an opportunity to learn to be less selfish and to learn to sacrifice as well as to become accepted as a responsible and mature member of the community.

However, young adults also recognize that parenthood entails disadvantages, such as a loss of freedom, financial strain, and worries over children's health and well-being. Parenthood is associated with a decline in marital satisfaction; couples have less time to spend together and experience more stress and sleep loss. Parenthood is associated with a shift toward more traditional roles in the relationship such that the mother usually takes a larger role in child care. Women who have been very active in their careers before parenthood may find this transition particularly challenging and may experience a greater decline in marital satisfaction and mental health than men.

Couples who postpone parenthood until their late twenties and thirties tend to experience a less stressful and easier transition. Couples who have achieved some of their occupational goals and have acquired life experience and maturity navigate new parenthood more successfully and with less of a decline in marital satisfaction. Men in their late twenties and thirties tend to participate more actively in child care, and women this age are more likely to encourage their husbands to share in the housework and child care. Despite this, in most families, women manage most of the parenting, caregiving, and household responsibilities, which can lead to fatigue and stress and sometimes be a detriment to their careers.

## SUMMARY

The twenties and early thirties, young adulthood, is a time of biological, cognitive, psychosocial, and social change. Our body reaches the peak of maturation and begins senescence. Our mind undergoes further development, permitting us to think in new ways. Young adults become more comfortable asserting their autonomy, further refine their identities, and develop a capacity for intimacy. Young adulthood is also a time in which we begin to make decisions about relationships. More young adults choose to remain single, cohabitate, and, after divorce, do not remarry.

Those who marry do so at later ages than ever before, and about one half divorce. Likewise, young adults are waiting longer to become parents. In all, it appears that the social changes of young adulthood, the transition to marriage and parenthood, are delayed among today's young adults, as compared with prior generations. The nature of young adulthood itself is undergoing change as we proceed into the new millennium.

## Zone of Proximal Development

*What the child can do in cooperation today he can do alone tomorrow. Therefore the only good kind of instruction is that which marches ahead of development and leads it; it must be aimed not so much at the ripe as at the ripening functions.*

—Lev Vygotsky

---

### ZONE OF PROXIMAL DEVELOPMENT (ZPD)

---

The zone of proximal development (ZPD), as a concept, was introduced by the Russian psychologist Lev Semenovich Vygotsky (1896–1934) in the early 1930s. The ZPD is situated within the context of children’s education and cognitive development. It refers to an imaginary zone that represents the gap between what an individual can do independently with no assistance and what he or she can do with careful assistance by an adult or more competent member of his or her culture. Consistent with the Marxist principles of socialism and dialectical materialism of the time, Vygotsky’s ZPD emphasizes the importance of social interaction and children’s participation in sociocultural activities for learning and development.

The idea is that individuals learn best when working together with others during joint collaboration, and it is through such collaborative endeavors with more skilled persons that children learn and internalize new concepts, psychological tools, and skills. The main goal of education from this perspective is to keep children in their own ZPDs as often as possible

by giving them interesting and culturally meaningful learning and problem-solving tasks that are slightly more difficult than what they do alone, such that they will need to work together either with another, more competent peer or with a teacher or adult to finish the task. The idea is that after completing the task jointly, the child will likely be able to complete the same task individually next time, and through that process, the child’s ZPD for that particular task will have been raised. This process is then repeated at the higher level of task difficulty that the child’s new ZPD requires.

Vygotsky originally proposed the idea of the ZPD in the context of assessing the skills and abilities of children with special needs in the form of serious physical, developmental, or learning disabilities. During the late 1920s, the Soviet Union encountered record numbers of mentally retarded and physical disabled children. Although standard methods of intellectual assessment, such as Binet’s intelligence quotient (IQ) test, were becoming popular, Vygotsky’s views differed. He argued that such measures limited the assessment of children’s intellectual ability because they only assessed a child’s individual “static” functioning and therefore missed the really interesting story—what children are capable of learning in the

future with help. He argued that children's intellectual assessment should be based on what they are demonstrating with the help of another person, not just what they can already do well by themselves. The ZPD became the central theoretical grounding for a very important and fairly recent movement, called "dynamic assessment," that has endeavored to develop assessment instruments that assess children's learning potential and ongoing learning processes, rather than just their static IQ.

Vygotsky would often give an example similar to the following for why the ZPD is important and why we need to take a dynamic approach to intellectual assessment. Suppose there were two boys who came to the clinic for intellectual assessment due to parents' and teachers' concerns over their learning and academic progress. Each child was given a standard IQ test, and both children performed identically on the static test, yielding an IQ score of 73. According to the standard procedure, these two children would be seen as having the same intellectual potential, and the same educational recommendations would be made for both children. However, let's imagine that both children were then given a dynamic assessment procedure in which a challenging cognitive problem-solving task was first given to the children for them to complete individually and the experimenter noted how well the child could perform the task. Each boy then participated in a 20-minute interactive joint (adult and child) teaching session in which the adult carefully assisted the child on the task and taught the child how it works while they completed the task together. Afterward, the child was given the same task again and asked to complete it on his own, and the experimenter noted how well he did now. One of the boys, it turns out, was able to learn the task easily and made huge gains in what he could do with the task by himself before and after the teaching session. The other child, however, made little gains and never really understood what to do with the task. He continued to struggle even though he had participated in the same sensitive teaching session with the adult as the other child, and his postteaching individual performance score was basically the same as it was before the joint session. According to the static IQ score, these two children are the same intellectually. However, it becomes clear from the dynamic teaching session that these two children are very different in their learning potential and capacity to benefit from instruction. The former child has a much wider

ZPD than the latter, at least for this particular task, and the educational placement and curricular recommendations for the two boys are likely to be very different as well.

An important implication of Vygotsky's ZPD for teachers and parents is that it is the learning that takes place during social interaction between adults and children, and between children and other children, that spurs cognitive growth and development for the child. This places much responsibility on the part of teachers and parents as agents of development for children. The goal is to assess each child's ZPD for a given activity (know what the child's skill and motivation level are for a given task) and then pitch sensitive instruction to children at their upper limit of the zone. It is here where children learn with the support and guidance of capable instructors. As the child learns more and more and as his or her skill level increases, the teacher gradually reduces the assistance and gives the opportunity for the child to execute the task alone (a process called "scaffolding"). Eventually, the child masters the required skills needed to accomplish the task. Thus, it is through the teacher's guidance that the child is able to complete the task that he or she would otherwise not be able to complete. Once the task is accomplished, the result is the development of a new, higher ZPD.

A second important implication of Vygotsky's ZPD is the idea that we must assess children's cognitive potential dynamically, over time, and involving others providing assistance in the ZPD, as described earlier. Such assessment procedures provide information about what type of instruction works for the child and allow teachers to tailor their instruction to the student's actual needs rather than on the student's assumed needs based on his or her age or grade level, as is the case with standardized assessment procedures. Finally, the ZPD also suggests that children learn best in small groups, especially if the task is at the right level of difficulty.

Vygotsky's notion of the ZPD, originally developed in the 1930s in the Soviet Union, has much to offer contemporary educational and psychological practice. Indeed, the ZPD is probably the most widely known concept of all of Vygotsky's sociocultural theories, and it continues to inspire researchers and practitioners.

## ZYGOTE

---

At conception, a sperm from the father penetrates an egg from the mother, resulting in a zygote. A human

zygote contains 46 chromosomes in two sets. One set is donated from the sperm (father), and the other set is donated by the egg (mother). The zygote will develop into a male if the sperm that fertilized the egg carries a Y chromosome, and the zygote will develop into a female if the sperm carries an X chromosome. The zygote also contains the appropriate factors necessary to direct the proper formation of the early embryo.

Monozygotic twins (identical) derive from the same zygote and share all of the same genetic material. Dizygotic (fraternal) twins derive from different zygotes and share only 25% of their genetic material, the same amount that any two siblings share.

Zygotes that receive an abnormal number of chromosomes from the gametes that joined together may be unviable or may produce an individual with a genetic syndrome such as Down's syndrome (an extra chromosome number 21), Turner's syndrome (only one X chromosome), or Klinefelter's syndrome (more than two sex chromosomes).

—Therese Poole

## Tables and Figures on Selected Aspects of Human Development

Americans 65 Years and Older As a Percentage of Total U.S. Population, 1950–2050	1348
Annual Number of Births, 1946 to 2001	1349
Average Reading, Mathematics, and Science Literacy Scores of 15-Year-Olds, by Sex, 2000	1350
Basic Indicators of World Health Organization Members, 2001	1351
Child Care Arrangements of Preschool Children, by Age, Race/Ethnicity, and Type of Child Care Arrangement, 1999	1355
Death Rates for Leading Causes of Death for All Ages: United States, 1950–2002	1356
Enrollment in Grades K–8 and 9–12 of Elementary and Secondary Schools	1357
General Statistics of Public Libraries, by Population, 2000	1358
Health Insurance Coverage by Age Group in United States	1358
High School Graduates 1987–1988 to 2012–2013	1359
Life Expectancy in All Member States of World Health Organization in 2001	1360
Mortality Causes Under 5 Years Old in 2002	1364
Number of People Age 60 and Older	1364
Number of School-Associated Violent Deaths, 1992–2000	1365
Percent of Early Prenatal Care by Race: United States, 1980–2002	1365
Percent of Families With Income Below the Poverty Level	1366
Percent Overweight and Obesity by Age: United States, 1960–2002	1366
Percentage of Children Ages 3–5 Not Yet Enrolled in Kindergarten Who Participated in Home Literacy Activities With a Family Member Three or More Times per Week	1367
Selected Chronic Health Conditions Causing Limitation of Activity Among Working-Age Adults by Age: United States, 2000–2002	1367
Use of Illicit Drugs in the Past Month by Age, 2003	1368
Years of Life Lost in Thousands by Risk Factor and Sex, 2000	1369
