However, the quality of the information on medical Web sites is highly variable and thus some users are reluctant to utilize the information given on mainstream sites. Through social engineering, some Web sites exploit the public's weakness for trusting information on the Web. There are numerous cases of online financial transactions in which unsuspecting members of the public have lost large amounts of money as they have been victims of exploitation. As with a financial setting, there is a great potential for good use and misuse for health information. With e-health experiencing rapid growth, it is becoming increasingly important to consider the various ethical issues that are involved with this form of health information. Unlike financial transactions, inaccurate and unethical information on health informing Web sites could lead to greater complications and even death (Theodosiou & Green, 2003).

Medicine and those that practice it have always had ethics as a core component of their field. There should be no difference when the more traditional aspects of medicine are modernized and utilized as e-health. All those involved with the running of online health care sites have to realize that they are running a site that could potentially mean the difference between life and death for those who access it. It is imperative that such Web sites follow codes and guidelines to prevent individuals' personal medical information, including patterns of use and interests, from involuntarily entering the hands of unauthorized people.

This article focuses on a number of privacy issues that are associated with e-health. Among these are concerns about determining the quality of technologically mediated care, ensuring and managing privacy, and allowing freedom of choice. It is well known that the Internet has the potential of exposing the public to unregulated volumes of misleading information on health and illness. This article will give a short summary of the various regulatory bodies that have been set up to try and ensure that any health information that is put up on the Internet is accurate and in no manner misleading. The *Codes of Conduct* proposed by the Health on the Net Foundation, *URAC* guidelines, and the *e-Code of Ethics* are examples of some regulatory ventures. It has to be made clear that medicine is a practice in which the interests of the patient are the priority rather than the exception, and with rules and regulations e-health can be as "safe" as going to one's local general practitioner. With the exponential growth of e-health, the need to determine the safety, security, and ethical behavior in relation to the traditional services is of paramount importance.

BACKGROUND

The Impact of E-Health

The Internet is seen as the primary medium for the expansion of e-health (Maddox, 2002). This has already resulted in a shift away from the traditional health care delivery model. Patients need not rely on their health care provider for information, and the development of telemedicine has removed the geographic limits that have always been present in health care. The advent of electronic health records with decision support systems will enable medical records to be stored in large data warehouses, thus promoting easier disease management. Also the shift in financial and clinical relationships between all parties involved in health care are all a result of the e-health revolution.

The importance of the Internet in the e-health revolution is crucial. The expansion through this medium has produced eight different types of e-health Web sites. According to Sass (2003), these are:

- Internet-based medical education
- medical expert sites for patient management of a complex nature
- general health information sites for laypeople
- specialized medical sites where physicians play an active role
- cyber doctors who give second opinions for tests carried out in the real world
- sites provided by insurers and drug companies informing about various products
- community Web sites where people suffering from similar ailments share experiences and advice
- research Web sites that focus on new treatment techniques and methods

With such a large variety of e-health Web sites, it can be seen why more than 88 million people in America alone utilize the Internet to search for health information (Ansani et al., 2005).

This rapid expansion has led to the development of new challenges that will require a readjustment in current regulatory systems. Two primary concerns that are a direct result of the information explosion are the quality of information and the possibility of misinterpretation and deceit (Fried, Weinreich, Cavalier, & Lester, 2000). Health consumers and health care providers who access the Internet to obtain knowledge and information have to be able to trust the quality of information being presented to them. Also, with the large volume of content available, the chance of manipulating data and putting up incorrect information is a major concern and a real problem (Goldman & Hudson, 2000). It is this element of uncertainty that has proved to be the main barrier for the growth of e-health at an even faster rate (Fried et al., 2000). Apart from the problems with actual content, the major fear concerns the lack of privacy and security (Chhanabhai, 2005).

The fear arises from the inherent nature of the way business is run on the Internet. Currently most online businesses, especially health Web sites, utilize cookies to collect information about people that visit their Web sites. The other method in which information is collected is through the use of online registration forms. It is the collection of this information that consumers fear. As noted by Goldman and Hudson (2000):

The trail of transactional data left behind as individuals use the Internet is a rich source of information about their habits of association speech and commerce. When aggregated, these digital fingerprints could reveal a great deal about an individual's life. (Goldman & Hudson, 2000, p. 1)

As they lack trust, health consumers are reluctant to fully and honestly disclose health information. The *Ethics Survey of Consumer Attitudes About Health Web Sites* (2000) found that 75% of people surveyed are concerned about health Web sites sharing information without their permission. A large proportion of the survey sample stated that they refused to engage in any online health-related activity as a result of their privacy and security concerns. However, 80% of respondents also said that if there was a specific policy regarding their involvement in information sharing, they would be more willing to move towards the e-health system.

Health consumers' concerns are justified by the numerous reports of health information mismanagement within electronic systems. Win (2005) highlights the following reports:

- Kaiser Permanente accidentally sending e-mail responses to the wrong recipients. The e-mail contained sensitive information that was obtained through online activities
- Global-Healthtrax, an online health store, revealing all contact information including credit card numbers of their its customers on its Web site
- The University of Michigan Medical Center mistakenly placing thousands of its patients records for public access on its Web site

These are a few examples of the reasons that the health consumer is reluctant to fully embrace e-health. Despite that, health consumers are visiting online health Web sites for information and confirmation of various diseases and treatment plans. Thus their primary fear arises when they have to share personal and private information. As a consequence, privacy may not be an issue when only visiting Web sites for information. The issues of quality and misinterpretation hence take on a bigger role in this scenario.

Health Web sites may seem to have high-quality information, but because of the nature of the health information, even this may cause unintentional harm to users of that information. Risk and Dzenowagis (2001) report that unlike other information, health information on the Internet is very susceptible to the following problems:

- language and complexity barriers
- inappropriate audience or context
- unavailability of certain services or products in different parts of the world
- difficulty in interpreting scientific data
- accuracy and currency of information
- potential for source bias, source distortion, and self-serving information

The wide-ranging sources of potential problem areas and the nature of the health Web sites makes them vulnerable to numerous ethical problems. The key ethical issues surrounding e-health are privacy and confidentiality, and quality of information (Ansani et al., 2005; Eysenbach, 2001).

Privacy and Confidentiality

Privacy is found to be the major concern with e-health (Westin, 2005). Health consumers feel that placing information on the Internet or on any electronic system makes it easily accessible to unauthorized persons. Unauthorized persons may be people within the particular company to people such as hackers (Goodman & Miller, 2000). These persons may use the obtained information in various ways. The information is valuable to insurance companies, pharmaceutical organizations, and fraudulent individuals. The fear is that health information can be used to blackmail individuals, especially those in high-profile positions (Givens, 1996). For the average person, the fear is that the information may be used by insurance companies to deny coverage and claims or to increase premiums. Potential employers could use the service of hackers to obtain health information and health Web site surfing habits on current or potential employees, and use this information to fire or not even hire a person (Goodman & Miller, 2000). As systems may be insecure and health information is of high value, there is a great potential for unethical behavior.

There are numerous types of people that have tried and will try to obtain health information. Each of these people will use different ways to try to obtain this information. These methods can be grouped into five distinct categories, identified by the Committee on Maintaining Privacy and Security in Health Care Applications of the National Information Infrastructure (National Research Council, 1997):

1. insiders who make “innocent” mistakes and cause accidental disclosures
2. insiders who abuse their record access privileges
3. insiders who knowingly access information for spite or for profit
4. the unauthorized physical intruder
5. vengeful employees and outsiders

These categories are not clear cut, as an intruder may fall into all the categories depending on his or her time period or situation. Outside attackers and vengeful employees make up one of the five categories; the other four categories indicate that the people that one should fear are those on the inside. Unlike other attackers who might be more interested in the actual breaking of the system, the insider who is a trusted individual is after the information (Spitzner, 2003).

Computer systems by their nature are prone to many other problems other than those that involve an intrusive nature. Being a system that is based on software and various pieces of hardware, an EHR system is vulnerable to both software bugs and hardware failures. These failures have the potential of corrupting medical records and thus diminishing the integrity of the system. When the postal, fax, or telephone system fails, there is a clearly evident impact on the message that is meant to be delivered (Anderson, 1996). In an EHR, this corruption may not be as easily noticeable. Examples include altering numbers in a laboratory report or deleting large amounts of important information. Unlike in other systems where an error would mean a financial disadvantage, an error in the health care system, due to badly designed software or poor hardware construction, may have a detrimental effect on both the caregiver and the patient.

Quality of Information

The quality of Internet-based medical information is extremely variable as there is no peer review or mandatory standard for the quality of health information (Edworthy, 2001). Studies by Ansani et al. (2005), Butler and Foster (2003), and Smart and Burling (2001) have found that health Web sites, irrespective of the medical condition, vary widely in their quality of information. These studies found that there were many inconsistencies in the information provided as well as in the various treatment plans proposed. This is to be expected, as many of the Web sites are sponsored by companies selling specific products or are run by individuals who are sharing their own experiences. Health information carries with it opportunities to reap large cash profits, thus many e-health Web sites are profit driven. With monetary value being associated with health information, the potential for health consumer deceit, bias, or distraction is high (Edworthy, 2001). Also, information may not come from credible sources, thus making it potentially harmful to people who may use that information as a benchmark in their health care. The problem lies with basic human nature. When individuals are suffering from an illness, especially a chronic illness, they tend to try non-conventional therapies in order to improve their condition. With the Internet teeming with alternative therapies, whether provided by individuals or a wide variety of groups, the possibility of using potentially harmful advice is very high (Center for Health Information Quality, 2005). It is this drive towards the use of non-traditional therapies that drives the need for models that can assure that good quality and correct information is published on the Internet.

Apart from possible problems that are a direct result of the information on the Internet, other negative effects of e-health affect the doctor-patient relationship (Theodosiou & Green, 2003):

- health consumers may be better informed than their health care provider about medical findings in a specialized area,
- health consumers may have found disturbing information that may not apply to their situation at all,
- health consumers may choose to use alternative therapies that hinder or oppose the mainstream treatment methods, and
- health consumers may feel they are right and refuse to listen to their health care provider.

Despite the possible negative effects on the patient-doctor relationship, the advent of e-health also has an important role in the empowerment of the patient and thus addressing patients as health consumers rather than just patients. This again highlights the importance of ensuring that the standard of information that empowers patients is of the highest quality.

As can be seen, the possibility of unethical effects is limitless. A number of regulatory bodies have come into existence to try and reduce the chances of unethical activity. The next section will give a brief description of the main quality affirming bodies.

FOCUS

Regulating E-Health

Presently there are approximately 98 different rating schemes for medical Web sites (Ansani et al., 2005). With such a large number of schemes, there is no way of ensuring that one standard that can be trusted over another, thus leading to inconsistent information being posted on the Internet. The leading organizations that have established guidelines for online e-health initiatives are:

- E-Health Code of Ethics,
- Health on the Net Code (HONCode),
- Health Internet Ethics (Hi-Ethics), and
- American Accreditation Healthcare Commission (URAC).

The four above-mentioned schemes are recognized as the leaders in developing sustainable guidelines (Wilson, 2002). The Health Insurance Portability and Accountability Act (HIPAA) is legislation that aims to establish greater privacy rights for health consumers. However, it has a strong legal background that may affect ethical considerations. It is not discussed in this article.

E-Health Code of Ethics

Founded in May 2000 by the non-profit organization Internet Healthcare Coalition, the aim of the code is to provide a guiding set of principles aimed directly at e-health stakeholders worldwide. Its goal is:

to ensure that individuals can confidently and with full understanding of known risks realize the potential of the Internet in managing their own health and the health of those in their care. (Internet Healthcare Coalition, 2006)

The code, which can be found at http://www.ihealthcoalition.org/ethics/ethics.html, is based on eight basic principles: candor, honesty, quality, informed consent, privacy, professionalism in online health care, responsible partnering, and accountability.

Its principles are all based on ethical considerations. Unlike other guidelines, it does not focus on any legal considerations. This has allowed the code to be developed in a manner that provides an ethical foundation for both the providers and receivers of information. The strength of the code results from its development process. It was developed by a method similar to that of an open source project. The draft document was created by medical ethicists and persons involved in the area of ethical behavior. This draft document was then published for public comment, and the comments were incorporated into the final version of the code (Mack, 2002).

Despite its strong ethical base, the major downfall of the e-health Code of Ethics is that it places the final burden on the user of the Web site. As there are no real enforcement measures, the final responsibility is on the provider or the reader of the health information as to whether or not they should conform to the code.

Health on the Net Code (HONCode)

Developed by the Geneva-based Health on the Net Foundation in 1996, the HONCode is the earliest quality initiative for e-health. It is available in 17 different languages. Its inherent strength, simplicity, is also its weakness. Like the eCode of Ethics, the HONCode is based on a set of eight principles. These are (Health on the Net Foundation, 2006): authority, complementarity, confidentiality, attribution, justifiability, transparency of authorship, transparency of sponsorship, and honesty in advertising and editorial policy.

This code works by allowing Web sites that conform to all eight principles to display an active HONCode logo that is considered a Web site trustmark. The presence of this logo indicates that the Web site meets the set guide of standards and ethics. However, this is a self-certification system, and even though HON does periodically review the Web sites that apply for its logo, the Foundation still depends on users of the Web site to inform it if the Web site is not conforming to the HONCode of practice (Risk & Dzenowagis, 2001).

Once again the burden of responsibility is placed on the users of the site to inform HON if there are any breaches in the code; only then can that site have its link broken. The complete code of practice can be found at http://www.hon.ch.

Health Internet Ethics (Hi-Ethics)

Launched in May 2000, Hi-Ethics is a coalition of profit-making U.S. health Web sites. It is run by the non-profit organization Hi-Ethics Inc., with the aim to ensure that individual consumers can realize the full benefits of the Internet to improve their health and that of their families. It is based on 14 principles that are intended to increase the quality of information while ensuring that sound ethical principles are maintained (Mack, 2002). Its principles look at (Hi-Ethics Inc., 2006): privacy policies; enhanced privacy protection for health-related personal information; safeguarding consumer privacy in relationships with third parties; disclosure of ownership and financial sponsorship; identifying advertising and health information content sponsored by third parties; promotional offers, rebates, and free items or services; quality of health information content; authorship and accountability; disclosure of source and validation for self-assessment tools; professionalism; qualifications; transparency of interactions; candor and trustworthiness; and disclosure of limitations and mechanism for consumer feedback.

Web sites that conform to the principles are given URAC accreditation (see next section) and are listed on the Hi-Ethics Web site as trusted sites for health information (Kemper, 2001). Each Web site undergoes a third-party accreditation process before it is approved with the Web site trustmark. The problem with this is that it targets only American companies and Web sites, thus covering only a small portion of the Web sites that are available. This closed coalition and the importance of maintaining the currency of its principles are the main drawbacks of this guideline. (Mack, 2002; Kemper 2001).

American Accreditation Healthcare Commission (URAC)

Launched in August 2001, the URAC standards are based on the 14 Hi-Ethics principles. URAC also draws upon the eCode of Ethics in order to develop ethical frameworks for health Web sites. Unlike the eCode of Ethics, which is completely voluntary with no formal compliance assurance mechanism, URAC works in cooperation with Hi-Ethics to act as a third-party verification system. The standards address the following concerns (Mack, 2002): health content editorial process, disclosure of financial relationships, linking to other Web sites, privacy and security, and consumer-complaint mechanisms.

Any Web site that applies for accreditation with URAC undergoes a two-step review process. Initially the Web site is reviewed by a member of the URAC accreditation staff. The staff member travels to physically meet the owners of the site, to ensure that the online site and the people running it conform to their standards (URAC, 2006). Having passed that stage, the Web site is then assessed by the Accreditation and Executive Committees. Any Web sites that fail to comply with the guidelines after being accredited will have their accreditation withdrawn (Mack, 2002). Each Web site that wants to be accredited has to pay a fee that includes the cost of travel for URAC certifiers.

URAC also has a number of issues that have to be addressed. It is currently aimed at American Web sites, thus like the Hi-Ethics initiative, it is very limiting in its target market. Also it requires a substantial number of fee-paying members to make it truly viable. It cannot be considered to be a successful program if it only has a select group of Web sites conforming to its requirements.

There are numerous other guidelines and systems in place, and the report by Risk and Dzenowagis (2001) provides in-depth analyses of each of the different systems. These four mechanisms alone highlight that there is a problem in trying to control the type of health information that is made available on the Internet. The ideal solution would be to regulate the actual Internet itself. This move has been supported by the World Health Organization, which has called for tighter controls on the placing of health information on the Internet. However, this was opposed by Eysenbach (1998) who correctly stated that attempting to control information on the Internet is both unrealistic and undesirable. As the Internet cannot be controlled, the next best thing is to ensure that the guidelines that are available can and will do a good job. They must promote the rapid development of e-health by making available health information that is of high quality and conforms to stringent ethical standards.

CONCLUSION

The Internet was created to produce a medium of communication that is both flexible and under no specific governing body. By its nature, the Internet has grown extremely successful and has produced an environment that is difficult to regulate, as free speech is promoted. It is in this context that e-health has been developed, and its very nature is an adaptation of the nature of the Internet. The health consumer now has the opportunity to control the way their health is treated. This being so, an area has opened up for unscrupulous and unethical behavior. The problem is further heightened as health care itself suffers from unclear privacy rules. Thus e-health enjoys the benefits of both the electronic medium and medical treatment, but also suffers from the weakness of unclear privacy rules.

This article has highlighted a number of examples where e-health has suffered negative consequences resulting from fraudulent activity and incorrect information on the Internet. Quality of Internet health information is of utmost importance, as it can have both beneficial and fatal consequences for the wide audience that it reaches out to. The unclear definition of e-health does not help the cause either. With e-health not clearly defined, it leaves another question open, “What can be defined as good quality health information?” There are numerous standards and guidelines available, but none will work if there is no way of assessing what good quality health information is.

The four models discussed in this article aim to ensure the validity and reliability of e-health information while maintaining a strong ethical framework. The problems with the models are the lack of consistency and the often complex burden that is placed on the user of the Web site to understand and follow the different criteria. Also some of these models involve high costs to ensure accreditation (e.g., URAC), thus making it not viable for smaller and individual-run Web sites to subscribe to such standards. The models are focused on mainstream Web sites as well as mainstream therapies, thus they do not take into account alternative therapies or treatments plans; yet, it is in these alternative methods that the chances for unethical behavior arise.

E-health is unquestionably the future of health care. With e-health, health consumers will be empowered with deep knowledge and self-care strategies, and will be linked to large communities of other health consumers and health care providers. For the health care providers, e-health brings the opportunity to immediately access patients’ records while promoting evidence-based medicine and keeping updated with the most current treatment techniques. However, the full potential of e-health may not be realized, as there is great fear concerning the privacy, security, and unethical behavior connected with the Internet. Currently there are many alarming areas regarding e-health. What is needed is a single regulatory body that will ensure that ethics and privacy are essential elements in the design of e-health initiatives.

Promoters of e-health must remember that e-health is a branch of medicine and thus they should subscribe to the ethical practices that have been established through the Hippocratic Oath. They must remember that "the practice of medicine involves a commitment to service to the patient, not one to economic interests" (Dyer & Thompson, 2001, p. 1).

KEY TERMS

Consumer Health Informatics: "The branch of medical informatics that analyses consumers needs for information; studies and implements methods of making information accessible to consumers; and models and integrates consumers' preferences into medical information systems" (Eysenbach, 2000).

E-Health: "An emerging field in the intersection of medical informatics, public health and business, referring to health services and information delivered or enhanced through the Internet and related technologies. In a broader sense, the term characterizes not only a technical development, but also a state-of-mind, a way of thinking, an attitude, and a commitment for networked, global thinking, to improve healthcare locally, regionally, and worldwide by using information and communication technology" (Eysenbach, 2001).

Electronic Health Records: A longitudinal collection of health information about individual health consumers and populations which is stored in an electronic format. The stored information will provide a picture of "cradle to the grave" consumer health information.

Health Informatics (Medical Informatics): The emerging discipline in which information technology is applied to the medical field. It involves the development of structures and algorithms to enhance the treatment, management, and prevention of medical conditions.

Informed Consent: The process by which a health consumer is firstly given all the information about various procedures, which will possibly include information on how consumer information will be treated. The health consumer can then make a legally binding decision to carry on with the process or decline taking part.

Medical Ethics: The field that considers the activities, risks, and social effects that affect the field of medicine. It is strongly based on the Hippocratic Oath and uses this as a guideline to determine the ethical conduct of professionals in the field of medicine.

Medical Internet Ethics: "An emerging interdisciplinary field that considers the implications of medical knowledge utilised via the Internet, and attempts to determine the ethical guidelines under which ethical participants will practise online medicine or therapy, conduct online research, engage in medical e-commerce, and contribute to medical Web sites" (Dyer, 2004).

MEDLINE: A comprehensive electronic literature database of life sciences and biomedical information produced by the U.S. National Library of Medicine. It covers the fields of medicine, dentistry, nursing, veterinary medicine, health care administration, and the pre-clinical sciences dating back to 1966.

Telemedicine: The use of telecommunications technology to aid in medical diagnosis and consumer care when the health care provider and health consumer are separated geographically.

Chapter 7.9
Developing Trust Practices for E-Health

ABSTRACT

The number of people turning to the Internet to meet their various health needs is rising. As the prevalence of this form of e-health increases, so the issue of trust becomes ever more important. This chapter presents a brief overview of e-health and describes how and why people are using the Internet for health advice and information. In order to understand the trust processes behind this engagement, a staged model of trust is proposed. This model is explored through a series of in-depth qualitative studies and forms the basis for a set of design guidelines for developing trust practices in e-health.

INTRODUCTION

E-health is a term widely used by many academic institutions, professional bodies, and funding organizations. Rarely used before 1999, it has rapidly become a buzzword used to characterize almost everything related to computers and medicine. As its scope has increased, so have the trust issues associated with the term. A systematic review of published definitions identified a wide range of themes but no clear consensus about the meaning of the term e-health, other than the presence of two universal themes (health and technology) (Oh, Rizo, Enkin, & Jadad, 2005). Eysenbach's (2001) commonly cited definition allows a conceptualization that goes beyond simply "Internet medicine."

> *E-health is an emerging field in the intersection of medical informatics, public health and business, referring to health services and information delivered or enhanced through the Internet and related technologies.*

Despite an absence of any single definition of the concept, the key themes of health and technology allow a wider exploration of the domain from multiple standpoints. E-health can encompass a wide range of technologies (Internet, interactive television, personal, digital assistants, CD-ROMS), a range of health services and information types (family practitioner's surgeries, public settings, consultations, decision making), and a range of different stakeholders (medical professionals, patients and careers, business).

Sixty two percent of Internet users have gone online in search of health information, and it has been estimated that over 21 million people have been influenced by the information provided therein (Pew, 2000). Given the prevalence and use of Web sites concerned with health, the focus of this chapter is specifically on the use of the Internet for health advice and information. There has been a rapid increase in the use of technology, specifically the Internet, in health information and advice. Worldwide, about 4.5% of all Internet searches are for health related information (Morahan-Martin, 2004). Sieving (1999) lists a number of different push and pull factors that have led to this increase, at least from an American perspective. These include an increasingly elderly population and a change in emphasis from healthcare providers treating illness to patients having primary responsibility for maintaining and improving their own health. Meanwhile, a range of content providers have recognized the educational and financial benefits of providing online health information.

Given the range of health advice and information available and the possible delivery modes available, patients are faced with decisions about which information, providers, and technologies to trust. How do people make decisions about trust in this context and how can guidelines for trust practices help in this respect? This chapter aims to explore the issue of trust within the context of e-health. The rest of this chapter is organized as follows. In the next section, we discuss the role of technology in the context of health information and advice. In section "Trust and Mistrust in E-Health," we examine the context of trust in relation to e-health, and in particular online or Web-based health advice and information, and present a staged model of trust that helps reconcile differences in the literature. "Validating the Model" presents a validation of the staged model through in-depth qualitative work. "Guidelines for Developing Trust in E-Health" draws together the literature and the results of the qualitative work to present a set of guidelines addressing how trust practices can be promoted in e-health and especially Web-based e-health.

THE ROLE OF TECHNOOGY IN THE CONTEXT OF HEALTH INFORMATION AND ADVICE

Technology has traditionally played an important role within health care. Through physician focused systems such as telemedicine and more recently the development of an electronic patient record system within the UK to an increase in patient-focused information and advice channels, accessing information about health can now be achieved via the telephone, the Internet, or even via the television (BBC Online, 2004). The UK's National Health Service is one service provider exploring new ways of disseminating health information to the general public. The NHS Direct service allows patients to access information online, speak to a nurse on the telephone, or retrieve information via a public access kiosk (Dobson, 2003).

Increasingly, the Internet has been seen as a major source of advice and information on health. More and more patients prefer not to let physicians dictate medical care and as such, have turned to alternative sources of advice. An estimated 80% of adult Internet users in the US (Pew Research, 2003) and over two thirds of Internet users in Europe have turned to the Internet for health information and advice (Taylor & Leitman, 2002). People search online for health information and advice for a number of reasons. Some people want to be better informed, better prepared when meeting the doctor, or are searching for support, alternative answers, or reassurance (Rozmovitis & Ziebland, 2004). Over 40% of Europeans said they would like to discuss information found on the Internet with their doctor, and one in five European consumers has asked their doctor about a symptom or diagnosis after having read information online (WHA, 2002). Many people searching online for health advice believe that it will enable them to better deal with their health and will convey health benefits (Mead, Varnam, Rogers, & Roland, 2003).

Time constraints in the consulting room have also led to an increase in online searching. The average length of a doctor's appointment in the UK is currently about 8 minutes. In this short period of time, both the doctor and the patient often find it difficult to explain and discuss all their issues. Patients often find it difficult to recall the specifics of their discussions with the doctor after the consultation (Kalet, Roberts, & Fletcher, 1994). Young people, in particular, are turning to the Internet rather than to a family doctor or a parent to get health information and advice (Kanuga & Rosenfeld, 2004), and the appeal of the Internet is particularly strong for those people who wish advice on important but sensitive matters (Klein & Wilson, 2003). The Internet allows people to communicate and interact with a far greater variety of people across all walks of life. It provides up-to-date information as well as increased social support (Eysenbach, Powell, Englesakis, Rizo, & Stern, 2004). It allows information to be shared in the form of text and images and can put people in touch with the most up-to-date information from some of most eminent sources in the medical profession. The Internet can offer people second and even third opinions and, in short, can provide people with information and advice that they simply cannot find anywhere else.

The advice that health consumers are seeking online ranges from information and advice about treatment decisions, interpreting diagnoses, and understanding any long-term medical implications through to finding support groups, seeking alternative therapies, and understanding drug requirements and drug interactions (Bernhardt & Felter, 2004; Gray, Klein, Noyce, Sesselberg, & Cantrill, 2004; Peterson, Aslani, & Williams, 2003; Reeves, 2001; Ziebland, Chapple, Dumelow, Evans, Prinjha, & Rozmovits, 2004).

But does the Internet leave patients better informed, and does reading online information and following advice lead to better outcomes? Coulson (personal communication), for example, found that people using Internet resources for health topics such as HIV and Aids often took on medical advice that was incorrect. Another key issue is the extent to which users recognize quality advice and information. Despite there being at least 70,000 health related sites available on the Internet (Pagliari & Gregor, 2004) less than half of the medical information available online has been reviewed by the medical profession (Pew Research, 2000), and few sites provide sufficient information to support patient decision making, with many also being heavily jargon laden and difficult to read (Smart & Burling, 2001).

One of the benefits (and the disadvantages) of the Internet is the range of material available regarding health and lifestyle advice. Sites can vary in the type of advice and information they present (see Table 1) and in terms of their scope, health topic, ownership, country of origin, and levels of interactivity. To indicate the range of different sites available, Table 2 provides an overview of three different UK-based sites highlighting their main features and the range of services available on each site.

Given the huge variety of sites available, how are consumers searching for and evaluating the trustworthiness and quality of health Web sites? There is a large body of research assessing the quality of information available on the Internet (Jadad & Gagliardi, 1998; Smart & Burling, 2001; Wyatt, 1997), embracing diverse topics such as Viagra, rheumatoid arthritis, and diabetes. A systematic meta-analysis of health Web site evaluations noted that the most frequently used quality criteria included accuracy, completeness, and readability and design (Eysenbach, Powell, Kuss, & Sa, 2002). Seventy percent of the studies they reviewed concluded that quality is a problem on the Internet.

Almost all of these quality assessments have been conducted from a medical perspective. Relatively few studies have tried to understand the patient experience. Despite forming a cornerstone of NHS IT policy (NHS, 1998) and numerous studies reporting the widespread consumer use of the Internet for health information, relatively few have attempted to understand how different stakeholders access and evaluate the information and the way in which Internet sources affect the patients' experience or health outcomes. Notable exceptions are studies of the way in which patients with HIV or AIDS (Reeves, 2001), cancer (Ziebland et al., 2004), paediatric health information needs (Bernhardt & Felter, 2004), or medicine

Table 1. The range of health Web sites available to consumers

Type of site	Description of site
Web providers and portal sites	Information and advice supplied by Web provider rather than a physical organization. Portals act as catalogues of information providing a gateway to many other sites providing information and advice.
Support groups	Often run by individuals or on behalf of support groups. May be local, national, or global in scale. Often contains forums where consumers can read comments and contribute to discussions.
Charity sites	Registered charity sites provide information and advice on specific health issues and provide a focal point for fund raising activities.
Government Web sites	Provide patient information in the form of news, features, and fact sheets.
Pharmaceutical sites	Sponsored by pharmaceutical companies these sites are often biased in favour of their own drug remedies and regimes.
Sales sites	Sales sites promote and sell certain drugs, medical devices, or health plans, often in addition to some information.
Personal sites	Contains personal experiences of illness and health issues.
Medical databases	Provide access to research papers on health and illness issues.
Media sites	Extensions of print or television media sites that provide the latest news and commentary on health features.
Clinician sites	Information on specific health issues or specialist clinics run by medical professionals.

Table 2. Health Web sites and range of features/services

	Web site		
	Netdoctor http://www.netdoctor.co.uk	**Dipex** http://www.dipex.org	**NHS direct** http://www.nhsdirect.nhs.uk
Domain	General health	High blood pressure	General health
Owner	Web provider	Charity	Government
Type of advice	Patient fact sheets Ask the doctor service News Discussion boards	Personal accounts Medical information Frequently Asked Questions	Health encyclopaedia Self-help guide Clinical evidence-based research reports
Commercial aspects	Health related advertising	Donations requested	None
Notable features	SMS alert service (e.g., contraceptive pill reminder Discussion boards)	Video clips Links to support groups	Locate nearest NHS services facility

requirements (Peterson et al., 2003) use online information to help them make treatment decisions, interpret information, find support groups, and seek alternative therapies. Other studies have suggested that whilst the Internet can increase patients' knowledge about their health conditions, they can be left feeling too overwhelmed by the information available online to be able to make an informed decision about their own health care (Hart, Henwood, &Wyatt, 2004). Reviews of quantitative Web-based intervention studies have generally indicated beneficial effects of the Internet on health outcomes, although issues concerning the methodological quality of such studies remain (Bessell, McDonald, Silagy, Anderson, Hiller, & Sansom, 2002). A more recent meta-analysis by Wantland et al. (Wantland, Portillo, Holzemer, Slaughter, & McGhee, 2004) concluded that in the majority of studies, knowledge and or behavioural outcomes improved for participants using Web-based health interventions.

The paucity of research from the patient perspective is a problem, because we know that ordinary health consumers are likely to adopt different quality criteria to experts, being more readily influenced by the attractiveness of the design, for example (Stanford, Tauber, Fogg, & Marable, 2002). In an empirical study of over 2,500 people who had sought advice online, for example, most began their search via a general information portal—gaining access to information of variable quality indiscriminately (Briggs, Burford, DeAngeli, & Lynch, 2002). Eysenbach and Köhler (2002) noted that consumers (as opposed to experts) failed to check the authorship or owners of the Web site or read disclosure statements, despite suggesting these as important quality markers beforehand. Their study made use of an artificial search task, however, and the authors themselves suggested that people in a "real setting" with a greater stake in the outcome may well pay more attention to the content of the Web sites, in terms of markers of quality. This failure to engage with real Internet consumers in a realistic setting is a common problem in studies of online trust. Thus, there is a real need for systematic explorations of the ways in which people evaluate the trustworthiness of health information and advice online.

TRUST AND MISTRUST IN E-HEALTH

The literature suggests that trust is multifaceted, multidimensional, and not easy to tie down in a single space (Marsh & Dibben, 2003). A key point to note is that trust is intimately associated with risk; indeed, it is possible to argue that in the absence of risk, trust is meaningless (Brien, 1998). Even within seemingly simple acts of trust, complex sets of judgements are invoked and a risk assessment is involved. Indeed, some of the trust models that have been developed in recent years have explicitly included risk (Corritore, Kracher, & Wiedenbeck, 2003). In online advice, there is no doubt that people are more willing to trust a site if perceived risk is low. This came out very clearly in a study of over two and a half thousand people who said they had sought advice online (Briggs et al., 2002). Those that sought advice in relatively high risk domains (e.g., finance) were less likely to trust, and subsequently act on, the advice than those who sought advice in low risk domains (e.g., entertainment).

The literature regarding trust in an e-commerce setting provides a useful starting point for exploring the ways in which people evaluate the trustworthiness of health information and advice online (see Grabner-Krauter & Kaluscha, 2003 for a recent review.) Based on this literature, we can assume that various factors are likely to govern the extent to which individuals feel they can trust health advice online. Firstly, they may be influenced by the look and feel of the site; trusting, for example, those sites rated high in visual appeal and mistrusting those sites with poor visual design or with unprofessional errors. Secondly, they may be influenced by the branding of the site or by presence of familiar images or trusted logos. Thirdly, they may be influenced by the quality of information available on the site, trusting those sites with greater perceived expertise, and fourthly, they may be influenced by the extent to which the advice is personalized to the individual, that is, the extent to which the advice appears to come from and be directed to similar individuals (i.e., those with a shared social identity).

Whilst these different factors appear to be important, researchers disagree over their relative importance in fostering trust. For example, some researchers argue that consumer trust (or a related construct, credibility**)** is primarily driven by an attractive and professional design (Fogg, Kameda, Boyd, Marchall, Sethi, Sockol, & Trowbridge, 2002; Kim & Moon, 1998; Stanford et al., 2002) or is influenced by the presence or absence of visual anchors or prominent features such as a photograph or trust seal (Riegelsberger, Sasse, & McCarthy, 2003). Others argue that trust reflects the perceived competence, integrity predictability, and/or benevolence of the site (Bhattacherjee, 2002; McKnight & Chervany, 2001). A few authors also highlight the importance of personalisation in the formation of trust judgments (Briggs, De Angeli, & Simpson, 2004) or the notion of good relationship management (Egger, 2000).

One way of reconciling these different findings is to consider a developmental model of trust or the way in which trust develops over time. For example, it is worth distinguishing between the kinds of trust that support transient interactions and those that support longer-term relationships (Meyerson, Weick, & Kramer, 1996). Riegelsberger, Sasse and McCarthy (2005), in their model of trust, describe different stages of trust that develop over time: early, medium, and mature forms of trust. A number of authors (Egger 2000, 2001; Sillence, Briggs, Fishwick, & Harris, 2004a) have suggested that three phases are important: a phase of initial trust followed by a more involved exchange that then may or may not lead to a longer-term trusting relationship. If one considers trust in this developmental context, then some of the findings in the literature make more sense. In particular, consideration of a developmental context helps to reconcile the tension between those models of trust, which suggests that it is a concept grounded in careful judgment of institution and process factors such as vendor expertise and experience, process predictability, degree of personalization and communication integrity, and those models that suggest trust decisions depend much more heavily on the attractiveness and professional feel of a site.

A staged model of trust (see Figure 1) makes it possible to distinguish between relatively "hasty" and more "considered" processing strategies for the evaluation of trust in high- and low-risk environments. Chaiken (1980) identified two processing strategies by which an evaluation of trustworthiness may be made: firstly, a heuristic strategy that follows a "cognitive miser" principle, where people base decisions on only the most obvious or apparent information; and secondly, a systematic strategy that involves the detailed processing of message content. A number of other studies in the persuasion literature support the two-process model, namely that people use cognitively intense analytical processing when the task is an important or particularly engaging one, whereas they use affect or other simple heuristics to guide their decisions when they lack the motivation or capacity to think properly about the issues involved. Such different processing strategies also reflect the distinction between the preliminary stage of (1) *intention to trust* and the later stage of (2) *trusting activity* (McKnight & Chervany, 2001).

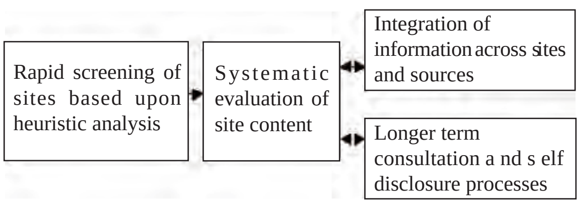
The process does not stop there, however, and a more realistic assessment of the development of trust should include a third stage in which a trusting relationship develops between the consumer and the Web site. This final stage has been rather overlooked in the trust literature, although it was originally proposed in the Cheskin/Sapient report (1999), and also appears in MoTEC (a Model of Trust for E-Commerce) (Egger, 2000, 2001), where the authors described a stage of trust maintenance. There is, however, little empirical evidence for a staged model of trust in e-commerce. Only two of the studies reviewed by Grabner-Krauter and Kaluscha (2003) investigated real transactions and these were limited to short-term interactions. Most published studies of trust do not investigate the act of trusting, but rather investigate the intention to trust (Briggs et al., 2004).

Stage 1: First Impressions and Heuristic Analysis

Some studies have asked participants to briefly visit a site or sites and then offer some evaluation of trustworthiness. According to Chaiken (1980), such participants would have very low involvement in this process, and we would expect that their trust judgements would be based on first impressions and as such, highly influenced by the attractiveness and ease of use of the site. A number of studies support this.

In their studies on credibility (a concept closely related to trust), Fogg et al. (2002) asked consumers to compare two sites drawn from 1 of 10 different domains, and to make a judgement about which of the sites was more credible. They were asked to

Figure 1. Staged model of trust



supplement this judgement with comments, and notably 46.1% of those comments reflected design qualities, as indicated by the following sample of comments drawn from four participants.

More pleasing graphics, higher quality look and feel.

Not very professional looking. Don't like the cheesy graphics. Looks childish and like it was put together in 5 minutes.

Such comments are remarkably similar to those elicited by Briggs et al. (2002) in a qualitative investigation of trust in sites offering advice and information to potential house buyers (Study 1). In that study, participants had to search for relevant information and then discuss which sites they would return to and which they would reject. Once again, a positive first impression was linked to good design and an absence of amateur mistakes as well as to indications of expertise, while a negative first impression was more explicitly tied to poor design.

Similar results have been noted within the health domain. Peterson et al. (2003) explored consumer experiences in searching for and evaluating information on medicines online. They found that participants reported quickly, rejecting sites that were slow to load, that contained too many graphics, and that had pop-up advertisements. Social cues are also important in the design of trustworthy Web sites. Appropriate graphics and photographs can add to a sense of social presence and inclusion, whilst inappropriate mission statements or alienating language can have the opposite effect (Wang & Emurian, 2005).

Faced with a vast array of information, it is likely that people, and in particular unmotivated students or people under time pressures, will fall back on heuristic processes. Sillence et al. (Sillence, Briggs, Fishwick, & Harris, 2004c) have shown that this rapid screening is very effective in the initial stages of contact with a health Web site. Within a 30-second window, participants were able to efficiently sift information, recognizing and rejecting general portals and sales sites quickly. This may be because such sites have distinctive design features associated with them, but some content processing is also underway.

Good design and credible information do not always go "hand in hand." Sillence et al. (2004c) noted that credible health sites such as those run by BUPA and the NHS were often rejected because they failed to convey through their design the right cues to their content. Well-designed sites with large financial backing, such as those owned by pharmaceutical companies or large sales companies, may well contain credible yet very biased information and advice. Fraudulent Web sites designed to be used in phishing scams are often very well-designed sites containing false information. Experts in the health domain warn against consumers' over reliance on the design of health Web sites as an indicator of credibility (Stanford et al., 2002).

Stage 2: FurtherInvolvement with the Site and Careful Evaluation of Site Content

Those investigations that involved real consumers or that required some protracted engagement with a site or that have asked customers about the general principles underpinning e-commerce transactions have generated a family of trust models with reasonable agreement. In general, the models suggest that trust, which supports online engagement, is influenced by perceived integrity and expertise, predictability, or familiarity of content and reputation (e.g., Bhattacherjee, 2002; Briggs et al., 2002, study 2; McKnight & Chervany, 2001). A number of studies also highlighted the importance of interface factors (ease of use and functionality) that help to reduce the transaction costs of an exchange (e.g. Egger, 2000, 2001; Lee, Kim, & Moon, 2000).

For example, Bhattacherjee (2002) developed a psychometric scale for trust in online transactions that was tested in two field trials and modified accordingly. The resultant seven item scale tapped into three trust elements:

1. **Ability:** both in terms of expertise and information access.
   Example: "Amazon has the skills and expertise to perform transactions in an expected manner."
2. **Integrity:** encompassing issues of fairness of conduct in transactions, customer service, and data usage.
   Example: Amazon is fair in its use of private user data collected during a transaction."
3. **Benevolence:** in terms of keeping the customers interests in mind in terms of showing empathy and responsiveness to customer concerns.
   Example: "Amazon is open and receptive to customer needs."

In a large scale study of credibility conducted at the Stanford persuasion laboratory, over 1,400 participants completed a questionnaire concerned with those factors they felt made Web sites more or less credible (Fogg, Marshall, Laraki, Osipovich, Varma, Fang, et al., 2001). The authors found that "commercial implications" of a Web site negatively affected its perceived credibility. Users penalized sites that had an aggressive commercial flavour. This included sites that required a paid subscription to gain access or sites that had a commercial purpose as opposed to an academic purpose. Bernhardt and Felter (2004) also noted that parents mistrusted commercial sales sites when searching online for health advice for their children. Conversely, sites that convey expertise through the inclusion of authors' credentials and references were viewed in a positive light. External links to outside materials and sources were also seen favourably as evidence of the site's honest and unbiased intention. (Fogg et al., 2001). Within a health context, however, research suggests that perceptions of credibility in relation to commercialism may be more flexible and are highly dependent on topic and content. Walther, Wang, and Loh (2004) found that the presence of advertising on health Web sites only had a deleterious effect on the credibility of sites with .org domains. It actually had a positive effect on .com and educational domains (.edu).

In the health domain, Peterson et al. (2003) found that consumers' opinions on credible sources of information on medicines varied, with some participants viewing pharmaceutical companies as the "official" information on a medicine and others preferring what they considered to be more impartial sources, such as Government organizations and educational establishments. Perceptions of impartiality vary according to the health domain (see our work on the Measles, Mumps, Rubella (MMR) vaccination (Sillence, Brigs, Fishwick, & Harris, 2004b), but remain a key factor in predicting trust. Bernhardt and Felter (2004) found that parents thought that ulterior motives of a site undercut the reliability of the health information they provided.

Stage 3: Subsequent Relationship Development and Integration

As previously mentioned, few studies within the e-commerce trust literature have looked at longer-term relationships between consumer and Web site. This is surprising given that early psychological models of trust between individuals focused explicitly on the build up of a relationship over time.

Trust is a consequence as well as an expectation of action, which means that initial trust judgements will be modified by experience. This interpretation of trust was evident in Rotter's (1967) original view of interpersonal trust, where trust in a generalized other could develop from successful and consistent exchanges with parents and siblings. Gambetta (1988) emphasized the developmental nature of trust by arguing that the point where we shift from saying, "I don't trust X" to "I trust X," is a threshold on this continuum that will vary with individual tendencies (e.g., a disposition to trust) and experience: "trust is not a resource that is depleted through use; on the contrary, the more there is the more there is likely to be" (Gambetta, 1988, p. 234).

Those online studies taking a longer-term perspective on trust emphasize the importance of shared values between customer and vendor. In these studies, trust in a longer term e-commerce relationship is a function not only of competence and predictability, but is highly influenced by the extent to which e-vendors are good communicators and show sensitivity to the personal values and circumstances of the consumer. In this way, good personalization practices are shown to be important for the development of a trusting relationship

In Florian Egger's (2000, 2001) studies of online customers, good personalized communication between customer and vendor was shown to be vital to the development of trust. Egger developed a model of trust for electronic commerce (MoTEC), where trust is initially determined by three factors: (a) the users knowledge of the domain and reputation of the vendor, (b) the impression made by the interface, and (c) the quality of the informational context as assessed by the consumer, but where a fourth factor, relationship management, becomes influential over time:

Relationship management reflects the facilitating effect of timely, relevant and personalized vendor-buyer interactions on trust development (pre-purchase) and maintenance (post-purchase). (Egger, 2001)

Fogg et al. (2001) also noted the influential role of good personalized transactions in their large-scale study of credibility. One of the scales in the questionnaire measured "tailoring" of content and included the following four items:

- The site sends e-mails confirming the transactions you make.
- The site selects news stories according to your preferences.
- The site recognizes that you have been there before.
- The site requires you to register or log in.

Tailoring was found to increase credibility, although the effect was more profound for the older users. In other words, older respondents reported higher credibility evaluations for sites that used some type of tailoring. The role of personalization in online trust was also apparent in a study in which people were asked about advice on the Internet (Briggs et al., 2002). This was an online questionnaire-based study in which a total of 2,893 respondents said they had actually sought advice online. These individuals were asked to give information about the site they had used in terms of issues related to trust as identified in an extensive review of trust literature. In a regression analysis, a clear three-factor model of trust emerged. Personalization was one of these factors and included items such as:

- Did the respondent feel involved in the process?
- Was the site interactive?
- Was the information tailored to the participant?
- Were different courses of action suggested?
- Was a peer commentary available?

Personalization then seems to be an important enabling factor for trust in online advice and indeed in other studies of trust in e-commerce that have explored full engagement with Web sites.

The online community literature also suggests that long-term relationships online are based upon a sense of trust that develops through the exchange of often personal information. The ability to personalize content and to build personalized content is important. The ability to share empathy is also key, especially in health-based communities (Preece & Ghozahti, 2001), but the community context allows individuals some control over disclosure (Gray et al., 2005). Studies within the health domain have examined people's motivations for continued use of the Internet. Rozmovits and Ziebland (2004) noted that in cancer patients, long-term support was the key factor. The Internet was often used to share experience and advice, and to contact support groups and chat rooms. In other health domains, for example, hypertension, personal experiences are also important (Sillence, Briggs, & Herxheimer, 2004).

There is some debate as to the impact of the Internet on health decision making and outcomes, for example, in terms of choosing one form of medication over another or choosing to make a lifestyle choice such as giving up smoking. Coulson (personal communication), for example, found that people using Internet resources for health topics such as HIV and Aids often took on medical advice that was incorrect. However, recent studies indicate that there is some interplay between an individual's use of the Internet and other personal health information sources. Gray et al. (2005) noted that adolescents using the Internet for health advice would check the information that they had received from personal sources on the Internet for consistency. Bernhardt and Felter (2004) also noted that information convergence is a strategy used by parents looking online for health advice about their children, to assess whether or not the information is trustworthy. Parents thought that information that they had read across a number of sites and across a range of different sources (off-line and online) was more trustworthy.

VALIDATING THE MODEL

The staged model of trust proposed by Briggs et al. (2004), and illustrated in Figure 1, reconciles the different findings with regard to the literature concerning online trust. It also allows for the development of guidelines that relate to the stage of engagement with a Web site. As discussed previously, the majority of online trust studies have suffered from using unrealistic settings, unmotivated participants, and from focusing purely upon initial impressions of trust. In keeping with the staged model of trust, we report on a longitudinal in-depth qualitative study that investigates first impressions of a Web site and early analysis of content, as well as longer-term engagement with health Web sites.

The qualitative study is a 4-week investigation of real consumers' attitudes towards online health advice. Four groups of consumers, all with an interest in a specific health issue, searched the Internet for advice over a 4-week period. A variety of data collection methods were used including data logging, log books, verbal protocols, and group discussion. The aim was to elicit the key themes surrounding initial trust and mistrust of health Web sites.

Qualitative Investigations of Trust in Online Health Advice

A novel methodology was developed in order to examine how genuine health consumers search for and appraise online health information and advice. The methodology allows for the examination of people's decision-making processes, in particular with respect to trust, to be observed through the first few seconds of interaction with a Web site to 1 year of engagement.

Four longitudinal studies examining groups of people faced with risky health decisions were undertaken. The health topics were menopause and HRT, hypertension, and healthy living. In addition, a small-scale study examining MMR was also carried out. The methodology is described in more detail in Sillence et al. (2004a). In total, 40 participants (30 females and 10 males) took part in four separate studies focusing on four different health topics. Despite including one solely female health topic, it was anticipated that the final sample would have been more balanced. We can only assume that the gender bias in our sample reflects the higher female interest in health advice within an online setting that has been noted in other studies (Briggs et al, 2002; Pew, 2000) and thus were more willing and committed to take part in the longitudinal study.

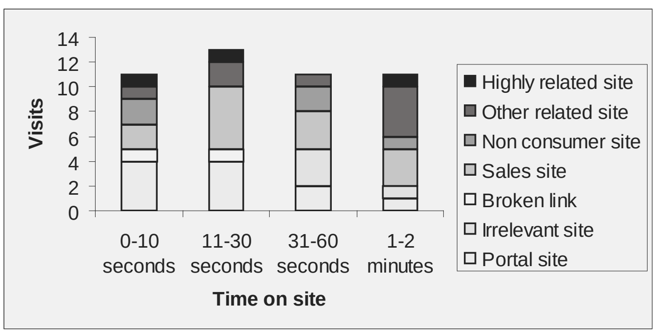
The methodology used was the same in each study. Participants were invited to attend a total of four 2-hour sessions at Northumbria University, UK. During all four sessions, participants used the Internet to search for information and advice on the health topic in question, followed by a group discussion with a facilitator. Participants were told to freely surf the Web during Sessions 1 and 4, and were directed to specific Web sites during Sessions 2 and 3. These specific sites were chosen for their trust design elements, and to reflect the range of sites actually used by consumers. All the Web sites visited by the participants were logged and the amount of time spent on each site was recorded. In addition, the participants were asked to record their perceptions of each site visited in a logbook and use this information during the discussion sessions. All the discussions were transcribed and subject to content analysis. At the end of the fourth week, the participants were given diaries in order to record their ongoing information and advice searches over a 6-month follow-up period.

Rejecting or Selecting Health Sites

The first study indicated that during the first 10 seconds of scanning Web sites, participants are keen to find something that is immediately relevant to them and to find content that they can "latch onto." Many of the rejected sites at this stage were portal sites. Portal sites often require participants to carry out a deeper search or to input additional search terms. At 30 seconds, the largest category of sites rejected at this point were sales based. Participants were clearly able to detect and reject signs of commercial activity and a sales orientation very rapidly. At 2 minutes, many sites rejected at this stage were either sales based or were classified as "other related." Some sales sites do not reveal their commercial element until the user has explored the site in some detail. Participants may search through the site and then make a decision to reject the site after discovering its commercial motivation. Figure 2 illustrates the time to reject sites and the type of content the site provided in the case of the HRT and menopause study.

The transcripts from the group discussions and the verbal protocols were examined in terms of the selection (trust) or rejection (mistrust) of Web sites. A number of themes relating to the first impressions of the Web site and characteristics of trustworthy sites emerged. In terms of rejection, the overwhelming majority of comments related to the design of the Web site. The look and feel of the Web site was clearly important to the participants. Visual appeal, plus design issues relevant to site navigation, appeared to exert a

Figure 2. Rejection time and content of sites



strong influence on people's first impressions of the site. Poor interface design was particularly associated with rapid rejection and mistrust of a Web site. In cases where the participants did not like some aspect of the design, the site was often not explored further than the homepage, and was not considered suitable for revisiting at a later date. Negative comments included an inappropriate name for the Web site; complex, busy layout; lack of navigational aids; and pop-up adverts (see P10 in Box 1).

The participants mentioned a number of factors in terms of the sites they had selected to explore in more depth. The participants liked sites that contained a great deal of information that was presented in such a manner that an individual could quickly pinpoint their own specific areas of interest. Participants trusted the selected sites because they demonstrated an in-depth knowledge of a wide variety of relevant topics, and put forward unbiased clear information. Participants were more likely to trust the information if they could verify it and cross-check it with other Web sites. Most individuals preferred sites that were run by reputable organizations or had a medical or expert feel about them. They trusted the information on such Web sites, especially when the credentials of the site and its authors were made explicit. Most participants showed some distrust of the advice and information on Web sites sponsored by pharmaceutical companies or those explicitly selling products. This is interesting given that medical expert reviews of HRT and menopause Web sites recommend pharmaceutical sites as providing a comprehensive and credible source of information (Reed & Anderson, 2002). Participants were looking for sites that were written by people similar to themselves, who shared similar interests. In this way, advice feels personalized for them.

Over the Longer Term

We asked the participants in our longitudinal studies to keep diaries over a 6-month period in order to assess how they followed up the information and advice they had read online. The participants were asked to record any sites that they visited during that time and to make a note of what prompted

Box 1. Examples of features associated with early rejection

Inappropriate sounding names

Well I didn't like it, I think it was possibly the name but I didn't hold out any confidence in something called Netdoctor at all, it sounds more like an IT company to me. (HRT study, P11, 59 years old)

Commercial

It's a very visual thing but then I am a very visual person it has to appeal and the flip side of that is that anything that's covered in ads and pop ups and stuff like that, it's the principle I'm just not interested. (HRT study, P10, 48 years old)

It just looked a bit cheaply made and the donations sign just put me off straight away. (MMR study, P2, Female, 35)

Nothing to latch onto

There was one in particular I was just I went into it and then after a couple of minutes I just thought its too complicated its just too much I can't be bothered with it. (Hypertension study, P13, Female, 52) them to go online. We also asked them to note any "off-line" interactions concerning this particular health topic, for example, interactions with health professionals and friends and family. They were asked to make a note of any other resources they had used, for example, television, radio, or newspapers. We were interested to find out when and where the Internet becomes involved in the decision-making process and to assess whether or not information integration had occurred.

Integration

We noted that the Internet was affecting decision making concerning treatments and lifestyle issues differentially across health topics and across individuals. For some participants, online information and advice was affecting their thinking on a week–by-week basis. For others, the affect on their decision-making processes was ongoing over the course of the following year. Here is an example that illustrates how one participant used the information online, how it was integrated with other sources, and overall, how it affected outcomes in terms of decision making.

DT took part in the hypertension study. He was taking medication for his high blood pressure and was unhappy with what he saw as the debilitating side effects. Discussions prior to the study had

Box 2. Examples of positive features associated with trusted sites

Clear and informative content

I found an absolutely marvellous site I was really, really taken with it, it went into so such clear explanations and with a breakdown of the different, oestrogen, progesterone, testosterone and what they actually do and how they link together all along the way it kind of encouraged you at the beginning to work through the site progressively if you wanted to get like a whole raft of background knowledge and then it would help you make decisions, it was great. (HRT, P1, 52 years old)

Impartial information

I suppose it was interesting in the sense that it was so biased against the MMR its useful to read it I mean but basically it was just a self help group website and so again it was like totally propaganda asking for donations and this kind of thing that I found it a bit disturbing actually I didn't like it, it was just so one sided I didn't like it. (MMR study, P1, Female, 33)

A Web site for someone like me

You can go on and find medical information, but what I want to find out is, you know, people giving reports of, right I've got high blood pressure and I've done this and I've done that and it brought my blood pressure down. (Hypertension study, P6, Female, 45)

Familiar language

I like sites that use familiar language, language I am comfortable with not lots of American terms that don't mean anything to me or probably mean different things like drug names for example. (Healthy living study, P2, Male, 35).

It was a British site I guess because it called hot flushes hot flushes not hot flashes like American sites do—that really annoys me that. (HRT study P4, 45 years old) left him frustrated since his doctor had advised him that side effects were very unusual for this medication. DT was convinced his symptoms were not normal. During the sessions, he came across one site in particular thta detailed other people's experiences of side effects whilst taking this particular medication. During the group discussions, he told everyone of his findings and his intention to show these results to his doctor. The diaries indicated that he returned to the Web site several times before he visited his doctor. In consultation with his doctor, he had agreed on a change in his medication.

During the follow-up interviews, all the participants expressed the opinion that they were now more careful evaluators of online and off-line content. They also reported a new found confidence with respect to doctors and medical information.

Registration and Self-Disclosure

KK took part in the healthy living study. She was interested in planning a new exercise regime. She looked at ivillage (http://www.ivillage.co.uk) during one of the free search sessions and liked the interactive features of the Web site, such as the calculators, the alert functions, and the large message boards facility. Her diary indicates that she engaged with the site over the longer term. She registered her details with the site in order to be able to post messages and receive e-mail alerts and reminders concerning her personalized exercise plan.

Overall, the participants expressed their desire for personalized advice, but thought that currently it was difficult to obtain online. Often the information on the Web site was felt to be limited and lacking in personal detail. The participants did suggest they would be prepared to disclose more personal information in return for more personalized advice. However, the nature of the personal information was important in this respect. Whilst sites such as BBC's Big Challenge <http://www.bbc.co.uk/bigchallenge> and ivillage <http://www.ivillage.co.uk> offer something more akin to human rather than automated personalized advice, very few of the participants wanted to subscribe to sites such as these or to register their contact details in return for more tailored advice (see Sillence, Briggs, Fishwick, & Harris, 2005c for more detail).

SUMMARY

Initial design appeal is important to users. The speed with which consumers will reject information should provide a salutary lesson regarding the importance of providing the right cues to site content in a highly visible manner. Social identity emerged as a major factor for building trust in online advice. General sites with few identity cues (NHS, Bupa) were seldom selected as trusted sources. Sites with home pages containing relevant information and that offered the opportunity to browse stories from like-minded individuals were viewed very positively. These results add to and extend previous work on trust by Briggs et al. (2002). Once again, personalization and credibility appear to be important factors in predicting whether or not a respondent will act upon the online health advice offered. Additionally, ease of access to useful information also has an important role to play in this respect. This extends the role of usability within online advice and online trust. Good designs combined with the stories that resonate with individual experience are very important factors in building initial trust. There is support for the staged model of trust in which heuristic evaluation and rapid screening is followed up by careful content evaluation and then longer-term engagement with a site. The important trust factors emerging from the studies provide a useful starting point for the development of guidelines for developing trust in e-health.

GUIDELINES FOR DEVELOPING TRUST IN E-HEALTH

A composite picture of trust guidelines (taken from the literature and from the studies reported previously) is offered next. The guidelines are split into three sections to reflect the staged model of trust and to suggest the point at which they are most influential in terms of interaction.

Stage 1: Heuristic evaluation

1. Use a professional and attractive design
2. Ensure good ease of use
3. Provide good cues to content on the homepage
4. Maximize the familiarity or predictability of the layout and interaction
5. Do not mix advertising and content—avoid sales pitches and banner adverts

Stage 2: Content evaluation

1. Include background information on the knowledge and expertise of the authors
2. Make clear the motivations of the authors—provide good links to independent Web sites in the same domain to provide reassurances on bias
3. Ensure that the Web site reflects the social identity of the user
4. Offer a personalized service that takes accounts of each user's health needs and preferences
5. Include peer contributions and the ability to contribute to the site

Stage 3: Longer term engagement

1. Ensure content is regularly updated
2. Provide interactive features on the site as well as alternative ways of engaging users, for example, e-mail or text message alerts
3. Enable users to register in order to obtain personalized advice— make clear the purpose of registration and the privacy and security implications
4. Facilitate integration with other Web sites—include good links to other Web sites within the same domain. Provide local off-line addresses and contact details
5. Provide clearly stated privacy policies

FUTURE TRENDS

We began this chapter with a discussion of some of the reasons why considerations of trust are important in the expanding field of e-health. Let us end the chapter with some explicit considerations of the trust issues raised by future visions of e-health. The changing nature of e-health and its supporting technologies means that the issue of trust becomes ever more important. Health information and advice will no longer solely be accessed from a PC in the home but from public access kiosks in a variety of locations. Health alert systems on mobile phones will mean people receive personal information in public settings. The development of networked health information and the electronic patient record system in the UK means that increasing numbers of people will have access to sensitive health information shared across large networks.

The demand for increasingly personalized e-health services also raises issues of trust and self-disclosure. The qualitative studies reported in this chapter indicate that people desire personalized health services but are reluctant to register their details with Web sites. Work by Sillence and Briggs (in press) also indicated that users found it more difficult to get personalized health advice online compared, for example, to financial advice. The increase in personalization coupled with increasing "public technologies" raises a number of important points regarding privacy and security. Burgoon (1982) described two kinds of privacy, informational privacy and physical privacy, both of which will have to be addressed in future work on e-health.

As increasingly sophisticated Web-based services are being developed, health consumers' trust in the information, and increasingly in the technology that facilitates the transfer of the information, will become of particular importance. Users must be prepared to place their trust not only in the people, but also in the technology that underpins an interaction. Understanding the context for trust, therefore, involves understanding issues of encryption and data security as well as understanding the development of a psychological bond. Bollier (1986), for example, argued that it is vital to distinguish between issues of "hard trust,"—involving authenticity, encryption, and security in transactions, and issues of "soft trust,"—involving human psychology, brand loyalty, and user-friendliness.

We are involved in several related research projects that address these issues, and some things have become clear. Firstly, we need to develop research methods that invite proper participation and involvement. The trust literature is peppered with investigations of users' intention to trust rather than explorations of their trusting behaviour. It is not simply enough to ask people about trust and related issues such as self-disclosure and privacy in the abstract – because, quite simply, what people say and what they do are two different things. Paradigms that allow researchers to investigate the whole cycle of trust from initial trusting dispositions through intention to trust and trusting behaviour have been developed over the past couple of years. These methodologies are currently being refined to include further ways of determining important trust factors in e-health, for example, incorporating measures of individual differences and personalization. The use of eye-tracking, for example, provides another tool in our kit to study the attitudes and behaviours of genuine health consumers engaged in different levels of risky decision making. We also need to know a great deal more about what happens following loss of trust and how the integration process with other sources, for example, healthcare providers, affects decision making. Such questions will be crucial for the development of e-health systems that people can genuinely use.

CONCLUSION

This chapter has proposed a staged model of trust to help explain the trust processes that are involved with consumers' use of online health advice and information. The studies presented in this chapter have documented some of the factors that can influence people's perceptions of the trustworthiness of online health advice and directly infleunce behaviour. The studies provide support for the staged model of trust and have assisted with the development of guidelines for trust practices in e-health. These guidelines relate to both the design and content features of health Web sites, and will assist in prediciting the uptake of health advice. Future work will focus upon the importance of individual differences and personalization in e-health, and will explore the consequences of a loss of trust.

INTRODUCTION

The special relationship of trust that needs to exist between a patient and his or her physician has been recognized since the origins of the profession, and the need for doctors to keep confidential any information disclosed to them is codified in the Hippocratic Oath. A distinctive feature of the health records which arises from this relationship is the intimate nature of the information that they may contain; consequently, it is vitally important to maintain the confidentiality of the records and to protect the privacy of the patients. Privacy has long been recognized as a fundamental right in most western societies (Westin, 2003), and unless a patient can be sure that personal information will not be distributed against his or her wishes, the patient may be reluctant to disclose information that may in fact be crucial to his or her correct treatment (Ford, Bearman, & Moody, 1999; NZHIS, 1995), or he or she may refrain from seeking treatment (Sankar, Moran, Merz, &

Jones, 2003). This is particularly true when health records contain sensitive information concerning issues like drug and alcohol problems, sexual behavior, mental health, or a genetic predisposition towards certain diseases. In such circumstances, the consequences of the inappropriate release of information could be extensive and might impact on many aspects of a person's life, such as the ability to gain employment, to maintain a marriage, or to obtain loans or life insurance (Chadwick, 1999; Woodward, 1995).

Within the healthcare sector there is a constant pressure to balance patients' requirements for personal privacy against the potential benefits that may accrue to society as a whole from the more widespread use of their personal information. This issue is particularly relevant in developed countries that have been seeking to use computer-based patient records (CPRs) (Dick & Streen, 1991), electronic medical records (EMRs), and electronic health records (EHRs) to improve both organizational efficiency and the quality of care provided for patients (AHRQ, 2006).[1]

The potential benefits of EHRs are widely accepted, but there are also serious problems concerning the potential threats to patient privacy (Carter, 2000). The move from paper-based records to electronic records has greatly increased the potential threats to patients' privacy in two ways. Firstly, it has increased the risk of unauthorized access to patients' information by people both within and outside of an organization, since it is now no longer necessary to manually search through individual patient's records and it is possible to systematically search through collections of records from a distance (Goldschmidt, 2005). Secondly, the development of communications networks has greatly increased to the extent to which patient information is now routinely exchanged between different healthcare organizations so more people have access to it (Kissinger & Borchardt, 1996).

This article will explore some of the privacy issues associated with the development and use of EHRs. The first part describes the background and development of EHRs and the various ways that patient health information can be used and distributed within modern healthcare systems. It discusses the benefits that may accrue to the individual patient and also to healthcare organizations due to improved access to information. The second part then reviews some issues that arise from the use of EHRs, and it reviews research into patient attitudes towards the distribution of their health information. The final part of the article discusses some technologies that address the security requirements of patients such as role-based security systems (Sandhu, Coyne, Feinstein, & Youman, 1996), smartcard systems (Rienhoff, 2003), and finally, e-consent systems (Coiera & Clarke, 2004; Galpottage & Norris, 2005; Scott, Jennett, & Yeo, 2004), which aim to provide patients with much greater control over the access to their information.

BACKGROUND

Electronic information systems are often justified on the grounds that having access to more complete, accurate, and timely information facilitates better decisions. In the case of health records, these benefits may accrue directly to the individual patient in terms of better treatment or to the population in general through improvements to healthcare practice or administration (Mount, Kelman, Smith, & Douglas, 2000). The application of data-mining techniques to large numbers of EHRs could facilitate epidemiological and evaluative studies (Bath, 2004; Payton, 2003), and the information may also benefit healthcare administrators and managers by providing them with more comprehensive information about service usage and costs (Hannan, 1999).

Despite the wide range of their potential benefits, the introduction of comprehensive EHRs has been relatively slow because of the complexity of the health sector from technological, organizational, and ethical perspectives (Goldschmidt, 2005). The use of computer-based information systems to store patients' records has been evolving since the 1970s. The early systems tended to focus on the administrative details of a patient and to deal with a single episode of care. Because of the high development and implementation costs, early systems were mainly used in larger hospitals (Goldschmidt, 2005; Reichertz, 2006), but as computing costs have fallen, sophisticated systems have become widespread, and systems are now found in most hospitals and in many primary care or GP practices (Didham & Martin, 2004).

In the late 1980s and throughout the 1990s, the potential benefits of an integrated lifelong electronic health record began to be recognized and explored (Haux, 2006). For the individual patient, major benefits arise from the improved continuity of care which is possible if all healthcare practitioners have a complete and detailed history of the patient's conditions and treatments on which to base their diagnoses and decisions. Easy access to a comprehensive patient history would be particularly useful when a patient is referred to a practitioner for the first time, if a patient needs treatment when he or she is traveling and is away from his or her usual practitioner, or in accident or emergency situations when the patient is unconscious or unable to answer questions (Mount et al., 2000; Hunt, Haynes, Hannah, & Smith, 1998). For example, comprehensive records will improve medication management by allowing the practitioner to quickly check whether a patient is known to be allergic to a particular medicine, or whether a particular drug might have adverse interactions with other medicines the patient may be taking (Ministry of Health, 2001).

Unfortunately, the widespread introduction of EHRs has been hampered by organizational problems caused by the dispersed nature of the healthcare sector in most countries. Since many organizations are involved in providing and funding care, a patient's information tends to get fragmented and dispersed (Goldschmidt, 2005; Kissinger & Borchardt, 1996). Treatment of a typical condition may involve a patient visiting a community-based practice, such as a general practitioner (GP), consultations and treatments by hospital-based specialists, and tests and analyses undertaken by various laboratories. Typically, information from each of these encounters will be stored by each organization within its own separate computer system, which will have been designed to support the specific requirements of each organization and its users. Furthermore, the payment for all these services may come in part or full from several sources, such as the patient, the government, or some private insurance scheme, so further inter-organizational information exchange is required to sort out the finances (Kissinger & Borchardt, 1996). Current developments of EHRs are therefore focusing on distributed structures with a centralized summary of a patient's information, with links to detailed information located in other computer systems (AHRQ, 2006). Developments of this kind are currently being supported by the governments of the UK (NHS, 2001, 2002a), Canada (CHII, 2006), Australia (NHIMAC, 1999), and New Zealand (Ministry of Health, 2000, 2001), which are all pursuing the development of nationwide EHRs to help manage their public health systems. In the United States where there is no public health system, the government is still involved in similar developments that aim to promote the efficient interchange of health information by funding the National Health Information Infrastructure (NHII) project (USDHHS, 2001) and through legislation such as the Health Insurance Portability and Accountability Act (HIPAA) of 1996 (USDHHS, 2006), which defines standards for health information structure, security, and privacy. These developments should benefit individual patients and also improve the overall efficiency of the health sector.

PRIVACY AND PATIENTS' ATTITUDES

The potential threats to the confidentiality of the information that EHRs contain and their implications for patient privacy are controversial (Carter, 2000), and large-scale health information systems have often been fraught with problems (Hannan, 1998; Sicotte et al., 1998). A classic example of this occurred within the British National Health

Service when doctors boycotted an inter-organizational network designed to improve the exchange of information on the grounds that it threatened patients' privacy (Davis, 1996; Willcox, 1995). Research in New Zealand into clinicians' attitudes towards the use of information contained within EHRs indicated that some of the potential uses were unacceptable and would also lead them to withhold information (Handy, Hunter, & Whiddett, 2001).

Despite the fact that many western countries have adopted privacy legislation that is based on the OECD principles (OECD, 1980) which should protect the confidentiality of health information, concerns about the uses made of the information are not unfounded. In the UK, the Caldicott Committee Report (1997) into patient privacy identified several breaches of confidentiality, and the report made wide-ranging recommendations to improve the security of patients' information. In a survey of Australians, Mulligan (2001) found that 1.9% of respondents reported harm arising from unauthorized disclosure of their information by health services. Anderson (2000) cites a number of cases where patient privacy has been breached in the United States. The U.S. pressure group *Patientprivacyrights* (2006) is also concerned that amendments to HIPAA will increase the abuse of patient information. The group claims that medical information is used to influence employment and promotion decisions, to determine eligibility for bank loans and insurance, and to market pharmaceuticals.

Despite the importance of personal privacy, there is a lack of research which addresses the issue from the patients' perspective. A recent review of the literature (Sankar et al., 2003) identified nearly 6,000 articles related to issues of patient privacy, but the vast majority of them were written from the practitioners' perspective or addressed legal or regulatory issues. Only 6% of the identified articles were written from the patients' perspective, and of these only 110 (2%) were based on research. Furthermore, most of this research focused on specific groups or particularly sensitive issues, such as adolescents who are concerned about their information reaching their parents or people who are having HIV tests. Very little work has addressed the perspective of ordinary patients.

Some research into attitudes of patients or the public towards the distribution of their information has been undertaken in the UK in association with the National Health Service's Electronic Record Development and Implementation Program (ERDIP) (NHS, 2002a), the PERIC (Patient Electronic Record: Information and Consent) project (Shickle, Carlisle, & Wallace, 2002), and the 'Share with Care' project (NHS, 2002b). Patients' attitudes have also been studied in New Zealand (Whiddett, Hunter, Engelbrecht, & Handy, 2006), and in Australia the issues of confidentiality of patient information and consent for access have been addressed as part of the Health*Connect* project (Health*Connect* Program Office 2002, 2003). These projects have recognized the increasing levels of concern about personal privacy among the general public and have begun to try to identify their expectations. However, to date the exploration of the attitudes of patients and the development of systems to meet their requirements has not received the attention that these issues would seem to warrant.

Although the various studies of patients' attitudes have addressed different specific issues and have used different research methodologies, such as questionnaires, interviews, telephone interviews, and focus groups, it is possible to draw some broad overall conclusions. A key finding of all the studies is that on many detailed issues there is little overall public consensus, and a wide range of views are often found, with some people being happy for their information to be used in certain a way, while others would be most upset by it. The studies usually find that there is little or no correlation between peoples' attitudes and demographic variables such as age, gender, ethnicity, and so forth. This means that it is virtually impossible to develop a standard system that will satisfy all patients, or even to predict the specific privacy requirement of any particular individual. However, the studies do reveal some general trends.

Firstly, the studies have all confirmed that people do want restrictions to be applied to access to their information. While most people are happy for their information to be accessed by practitioners who are treating them, there is much less consensus about information being accessed by other professionals for secondary purposes, such as clinical research or organizational management and planning.

Secondly, many people also wish for different levels of security to be provided for different parts of the record so that some information could be made available on a 'need to know' basis only, and for information about particularly sensitive issues to be hidden from general access. For example, the Share with Care project (NHS, 2002b) found that 32% of respondents had at least some sensitive information over which they would like particular control through the use of a 'virtual sealed envelope'.

Thirdly, people are more willing to allow their information to be used for purposes other than their care if the information is first made anonymous by removing any identifying features such as their name and address. However, many people expressed some reservations about sharing even anonymous information with people other than health professionals, and many people feel that they should still be consulted about the use of their information, even when it is anonymous. The desire for this level of control contrasts with some current practices which are permitted under the privacy legislations of the UK, Australia, and New Zealand (Galpottage & Norris, 2005) which do not control the use of unidentifiable data.

MANAGING ACCESS

Overall, the studies revealed that people would like to have more control over the uses that are made of their information. However, the mechanisms that are provided in most current computer systems operate at too coarse a level of granularity and are not sophisticated enough to meet patients' requirements. Typically, access control mechanisms provide entire classes of users with access to the set of applications that they need to fulfill their role within their organization (Sandhu et al., 1996). Protection of an individual's privacy tends to be based upon the integrity of the staff who are relied upon not to abuse their positions of trust rather than being based upon technological safeguards within the systems. However, technological solutions have been investigated by the health sector, particularly in the areas of smartcards and e-consent models.

The health sector has been experimenting with the use of smartcard technologies (credit card-sized devices with on-board memories and possibly microprocessors) to store patient information and to authenticate practitioners since the early 1990s, and several systems in the United States and Europe (particularly France and Germany) have used smartcards to store patient information with varying degrees of success (see Reinhoff, 2003, for a comprehensive review). Having a patient's information stored electronically on a card can be very convenient for organizations, and it can also give the patients a high level of control over who has access to their information (Marschollek & Demirbilek, 2006). However, there are often problems with compatibility and inter-operability of systems that limit the uptake and use of the smartcard-based EHRs (Reinhoff, 2003). The relatively limited memory that is available on the card means that systems tend to only contain a very restricted amount of information (Chan, 2000), and an alternative use of smartcards is to provide a method of authenticating users and controlling their access to other systems over a network (Blobel, Pharow, Spiegel, Engel, & Engelbrecht, 2001; Marschollek & Demirbilek, 2006). Overall it seems that smartcards on their own will not resolve all of the issues of patient privacy, but they may provide some components of the solution.

Recently, some researchers have been focusing on the design of systems which are capable of capturing and recording a patient's privacy requirements and their consent to share information at a fine level of granularity. This information would then be used by the 'e-consent systems' to mediate information requests and to enforce a patient's requirements depending on the intended recipient, the nature of the information, and the proposed use of the information (Coiera & Clarke, 2004; Galpottage & Norris, 2005; Scott et al., 2004). However, as Coiera and Clarke (2004) note, the process of consulting with each patient about future access to information needs to be managed carefully so that it does not place an undue burden on health professionals. One solution that has been proposed to overcoming this problem during the clinical consultation is to enable patients to log onto the EHR system at some other time and to set or update the access permissions for their own personal information (Galpottage & Norris, 2005), thus giving patients the ultimate control.

CONCLUSION

Healthcare systems are exceedingly complex environments that often deal with highly personal and intimate issues; consequently, the security and privacy requirements for EHRs are more demanding than most other information systems applications. To date, the magnitude of the technical difficulties of implementing EHRs has tended to dominate the attention of researchers, and the privacy issues which are associated with the wholesale exchange of patients' information have received comparatively little attention. However, privacy issues are important since they will also influence the acceptance of EHRs; a failure to address them may ultimately lead practitioners or patients to boycott or reject such systems.

Patients' privacy needs to be protected in several ways: by technological systems that enforce security and can restrict access to information, by organization and cultural systems that emphasize and respect patients' privacy, and finally by a legislative framework that can be used to enforce patients' rights to privacy.

KEY TERMS

Computer-Based Patient Record (CPR): Automated patient record designed to enhance and support patient care by providing access to complete and accurate data and to bodies of knowledge.

Confidentiality: Tacit understanding that information disclosed to care providers will remain protected.

Consent: Process by which an individual authorizes medical interventions or the processing of his or her information based on an informed understanding of the expected outcomes.

Data Mining: A set of techniques that explore large collections of data to discover new or unexpected relationships.

E-Consent System: Advanced computer-based system that can record a patient's consent and use it to mediate information requests from other systems.

E-Health: A term that encompasses a wide range of healthcare-related activities that involve the exchange of information using electronic communication systems.

Electronic Health Record (EHR): Integrated collection of health information relating to an individual's lifetime, stored in electronic format.

Electronic Medical Record (EMR): The health information for a patient contained within a given institution or organization stored in electronic format.

Master Patient Index (MPI): Module of a health information system used to uniquely identify a patient.

Smartcard: Credit card-sized device with on-board memory and possibly a microprocessor. Sometimes used to store a patient's personal information.

ENDNOTE

[1] There are no universally accepted definitions of the terms CPR, EMR, and EHR. The meanings of the terms have been constantly evolving and definitions often overlap; see Marietti (1998) for further discussion. This article will adopt the term EHR.

ABSTRACT

The problem of assuring secure and confidential access and transfer of medical records in health-care facilities can be partitioned into (a) secure storage and access of electronic records within a facility and (b) secure transfer of electronic records between facilities. To address the first issue, we propose a new tag-based data model for representation of electronic medical records along with patients' policy statements. This model helps to categorize the patient information as well as express patients' consent for a variety of domains, such as individual practitioner and facility. To address the second issue, this paper proposes a way of establishing a trust relationship between two interacting parties based on emerging trusted computing technologies, and describes its application and implementation in an electronic healthcare system. Our proposed

solutions have been demonstrated by developing a prototype system utilizing trusted computing components.

INTRODUCTION

There is a growing need for sharing patient records among health care providers and their associated facilities, in order to provide the best care and clinical outcomes for patients. Due to the increasing use of information technologies in health care industries, patient records are often produced and shared in an electronic form (Choudhri, Kagal, Joshi, Finin, & Yesha, 2003). The coordination of an individual's health care relies on the sharing of personal health information among health care providers and their facilities, such as clinics, test laboratories, and hospitals. It is well known that there are potential benefits and risks associated with the ease with which patients' electronic medical records may be shared (Task Force on Medical Informatics (TFMI), 1996). The ease of sharing information and its rapid dissemination by information technologies underscores the need to assure that the privacy and security requirements of the patient are met at all times and for all possible situations. For example, patients may not want to share or transfer any of their personal health information, without their knowledge and consent, and may want to retain the rights to both access and transfer of their information.

In order to address the issue of control of private medical information, the CSIRO ICT Centre was involved in the development of an electronic consent (e-consent) model (O'Keefe, Greenfield, & Goodchild, 2005) within the context of the Australian Government Department of Health and Aging (DoHA) Electronic Consent Project (Australian Government Department of Health and Aging (DoHA) Project, 2002). The term e-consent was coined to refer to a mechanism through which patients can express their consent policies for electronic records that are accessed and shared between health care facilities. The e-consent model was developed and demonstrated to stakeholders from the Australian health care sector for work commissioned by the DoHA. The most important outcome of the project is the concept of "placeholders," which were used as a means for ensuring privacy-preserving, anonymous electronic record transfer protocols. We make the following two observations on this e-consent model (referred to as the DoHA e-consent model).

First, any underlying data model must support adequate default consent statements and policies to ensure that the e-consent model can secure the privacy and confidentiality of medical data within a facility. The hierarchical data model used by the DoHA e-consent model has limitations on expressing a default policy set, as well as categorizing electronic patient records. This limitation led to the development of our new tag-based data model. In our model, each electronic medical record has a number of policy tags, which we call *e-tags* (electronic tags). Each e-tag has two fields: *category* and *policy*. The category field categorizes records into different groups, such as heart, head, and AIDS. The policy field, which we call an *e-co* (e-consent), contains a number of policy expressions. Unlike role-based access control (RBAC) (Crook, Ince, & Nuseibeh, 2003; Reid, 2003a) and the DoHA e-consent model, our approach allows the specification of access and transfer permissions in terms of (a) roles, (b) health care facilities, (c) health care providers, and (d) categories of information.

Second, in the DoHA e-consent model, the sender facility has to trust the receiver facility (and vice versa). That is, the sender as well as authenticating the identity of the receiver has to rely on the receiver having the right software and hardware system components and configuration to enforce the sender's policies on privacy and confidentiality. Similarly, the receiver also must ensure that it is always in the correct state and configuration for accepting any incoming record. Both facilities need to ensure and enforce the patients' consent policies for their electronic records, when these records are accessed and transferred. The DoHA e-consent model relies upon a person at the receiver facility entering a patient's consent requirements in the receiver facility's system. These limitations led to the development of a mutual attestation protocol to alleviate the mutual trust issue between senders and receivers.

The remainder of the paper is organized as follows. The second section presents a review of related work. We then present a motivating scenario in the third section. Our tag-based data model is presented in the fourth section. The fifth section presents two protocols: one for mutual attestation and one for transfer. We then illustrate our data model and mutual attestation protocol by describing the developed architecture and prototype implementation in the sixth section. The final section presents the concluding remarks.

RELATED WORK

In this section, we first discuss work related to protecting patient privacy in health informatics in general and then discuss the work closely related to our proposed model. This is followed by an overview of related work on remote attestation.

Security in Health Care Systems

Security and privacy of patient electronic medical records needs greater attention because of the wide adoption of electronic health care systems. Huston (2001) discusses the general security concerns of implementing electronic medical records and the technological and administrative tools that are available for safeguarding these records. Stein (1997) presents several scenarios in the use of electronic medical records and highlights the threats and opportunities in their adoption. One of the major privacy concerns is the secure transfer of electronic medical records from one service provider to another. TFMI (1996) discusses some issues related to the transfer of medical records. Chadwick and Mundy (2004) look at the security requirements for electronic transfer of prescriptions from the perspectives of confidentiality, integrity, and availability.

One of the most common privacy and security preserving techniques for sensitive medical data is the use of simple access control lists (ACLs). Evered and Bogeholz (2004) present a case study of the access control requirements for a health information system in a small aged-care facility. The study focused on the use of a static per-method ACL and found that the method was inadequate because the policy constraints became complex even for the small system considered in the case study. Effective use of an ACL system requires a carefully developed data model.

Access Control Data Model

Alternatives to simple ACLs also have been investigated and developed. Reid et al. (2003) examined the use of RBAC and found that the range of access policy expressions supported by RBAC was inadequate. Further, the paper proposed a model that supported access control through a consumer-centric role called the "care team." The advantage of this model was that a subgroup of entities within a role could be granted explicitly or denied access to health information. Motta and Furuie (2003) extended the RBAC reference model by introducing additional contextual authorization. The authorization module not only used positive and negative authorization, but also user affiliation, time, and location of access, user and patient relationship, patient status, and so forth.

Most of these hierarchical RBAC models cannot adequately represent the matrix nature of medical information. Khayat and Abdallah (2003) present a formal model for flat role-based access control, which we see as being closer to our model. Some of the access control problems are simplified because of the flat, nonhierarchical model. However, this model does not consider the problem-oriented approach, where the patient's medical condition may be divided into a list of discrete problems, such as diabetes, coronary artery disease, and lower back pain (Stein, 1997). The problem with this model is that only roles are considered. Our approach has overcome this problem by flattening, not only roles, but also the categories of medical records and medical information.

Mutual Trust

One way of establishing trust between interacting parties is to use an attestation protocol. Most of the earlier work on attestation protocols relied on software-based security, where the entire security feature is implemented in software systems. These solutions are often sufficient, but not always adequate (Trusted Computing Group (TCG), 2003). Classically, problems with key storage and management, and the location where secret keys may be stored in an accessible persistent store, remain open issues for most trusted system implementations. In recent times, integrating hardware-based solutions into software-based security systems has gained momentum because of a variety of political and economic requirements for enabling electronic commerce (e-commerce), such as those required to implement digital rights management systems. A general, hardware-based solution has been proposed by the TCG (2003). TCG first proposed a remote attestation protocol, using a trusted third party, called a privacy certifying authority (Privacy CA). One of the problems associated with a Privacy CA model is the lack of anonymity. In order to address this problem, direct anonymous attestation (DAA) was proposed as an alternative to the Privacy CA model (Brickell, Camenisch, & Chen, 2004). Yung (2005) presented a thorough analysis of implications of TCG-style remote attestation including Privacy CA, DAA, and combinations of both.

We next present a review of subsequent developments in remote attestation. There have been recent works on architectures that support enforcement of an owner's policy in client applications by attesting to the platform and integrity of the requesting applications (Sailer, Jaeger, Zhang, & Doorn, 2004a; Sandhu & Zhang, 2005). These researchers have developed and implemented such systems in a Linux environment, using the TCG remote attestation protocol and integrity measurement technologies. Several problems have been identified related to remote attestation (Halder & Franz, 2004; Reid et al., 2003). These include, for example, that remote attestation (a) makes no claims, statements, or assurances about program behaviors; (b) is static, inflexible, and inexpressive; (c) makes upgrades and patches to executable programs or operating systems difficult; and (d) is fundamentally incompatible with a widely varying, heterogeneous computing environments. Some techniques have been proposed to overcome these limitations, including semantic attestation (Halder &/ Franz, 2004), property-based attestation (Sadeghi & Stüble, 2004), virtual machines (Barham et al., 2003; Garfinkel, Pfaff, Chow, Rosenblum, & Bonch, 2003), and a fine grain attestation mechanism that measures only the required code (Shi, Perrig, & Van, 2005).

The most relevant work to our paper is the integrity measurement and attestation mechanism proposed by IBM (Sailer et al., 2004b). To perform an integrity measurement, IBM has modified the Linux boot loader and kernel to maintain the *chain of trust* from trusted platform module (TPM) to operating system to applications. The kernel maintains a list that represents the history of loaded processes and libraries. During attestation, the processes list is sent to the challenger, together with the reported platform configuration register (PCR) values. The challenger can then verify that whether the list is valid or not.

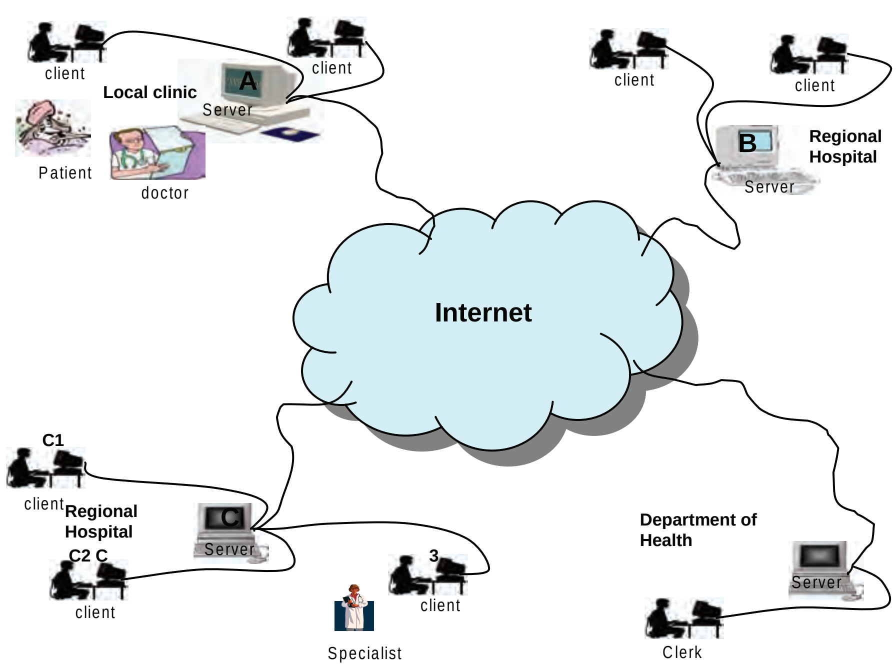
Our implementation and protocols differ from the IBM proposal as follows. First, our implementation is based on a Windows environment, rather than Linux, to explore what is achievable within the current, commercially installed infrastructure. Second, our approach suppresses the need for the facility to load the processes in a particular order, as the order is impossible to maintain in a dynamically loaded system, where software components are loaded and unloaded under application control. Third, our approach provides flexibility since each process can be specified as being in one of three states: *may*, *must*, or *must not* be loaded for the attestation to succeed. Finally, our approach can be used to force a facility to load the correct versions of the software, as we permit multiple valid digests for a process in order to support multiple versions of the same software.

A MOTIVATING SCENARIO

We consider an example from electronic health care environment that includes two hospitals, one medical clinic, and a governmental department of health as shown in Figure 1. The department of health issues credentials and permissions to operate the health care facilities, such as hospitals and medical clinics.

Though the basic set of policies are established by government rules and legislation, each facility may implement these policies differently. That is, each may have a different set of policies for different category of information. For example, Hospital A may have a different set of policies for AIDS-related records to that of Hospital B. Any data model must support a variety of default access policies for hospitals so that all medical records within that hospital are subject to these

Figure 1. Distributed health care environment



policies. However, it is a fundamental assumption of our paper, and the prior e-consent work, that patients are the ultimate owners of their own electronic medical records. Consequently, patients' privacy and consent policies may differ from those of a particular hospital. For example, patients can define a personal policy that all of the AIDS-related records are accessible to a personal doctor, but no other doctor in the hospital can access it, except in case of emergency. Similarly, patients' families can define their own policies for family members. For example, only family doctors can access immunization records of all family members. It is clear that the data model must support the definition of default family and patient policies. Similarly, patients' policies on AIDS-related records may say that only family doctors can access them, but they may want a particular blood test to be examined by an AIDS specialist. Furthermore, patients may not want to disclose their AIDS-related records to their family doctors though the families have policies that all records of family members are accessible to the family doctors.

Our access policies are defined at different granularity, based on entities, such as hospitals, patients, families, and medical records. However, some of the policies are defined for a group of medical records, such as AIDS-related records. This means medical records need to be *categorized* so that it is possible to define policies for a set of records within a category. For example, hospital default policies are normally expressed on *roles* (within the facility), rather than on *individuals.* As an illustration, Hospital A may have a policy that any individual doctor or nurse in an *emergency doctor role* can access all medical records and information. In contrast, patients' policies are less likely to depend on roles and may express their policies in terms of *individuals,* such as "grant access to AIDS-related records to Dr. Smith."

The hospitals may share patient medical information with each other to provide better services. Similar to access policies, we define *transfer policies* at the hospital, family, patient, and record levels. The hospital may have a certain policy for transferring information to another hospital. However, sharing of information is only possible if patients have given their consent. Therefore, the patients also must be able to define transfer policies. In addition to the specification of access and transfer policies, we also need to have policy enforcement mechanisms in place. This includes establishing a trust relationship between the clinic and hospital such that nothing undesirable (in terms of policy violations) ever occurs.

In summary, the data model must support (a) categorization of information, such as AIDS and heart, (b) policy expression for access and transfer, (c) default policy expression for hospitals, patients, and families, (d) default policy expression for different categories of information, and (e) policy expressions for both individuals and roles. Additionally, we need to define transfer and attestation protocols such that when the records are transferred from one facility to another, the defined policies are always enforced.

TAG-BASED DATA MODEL

This section discusses the tag-based data model and how it provides the features that are needed for modeling the health information scenario as discussed in the third section.

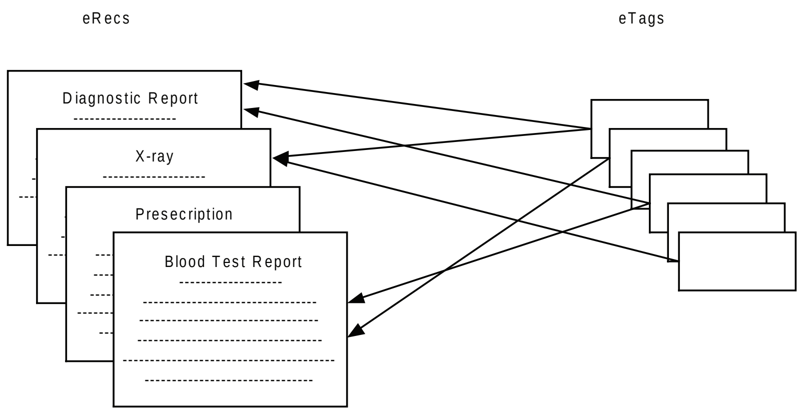
Data Model

An electronic record (e-rec) is a fundamental unit of information. It could be a diagnostic report, X-ray image, or prescription. An e-rec may have a number of electronic tags (e-tags) attached to it. Figure 2 shows the structure of an e-tag. Each e-tag has two fields: a *category* and a *policy expression* that we refer to as an e-consent. The category field consists of category *type* and *value.* The type determines whether the category is related to *patient, family,* or *facility.* The value

Figure 2. eTag structure

<Category Type, Value>	<eCo>

Figure 3. Relation between eRecs and eTags in the data model



provides the categorization within the category type. The e-consent field contains a set of access and transfer policies for the category.

Each e-tag can be grouped into one of three broad classes:

a. A special NULL category with a nonempty set of policies used to express record-specific policies. Such e-tags are defined for a specific medical record and are attached to it.
b. A category with an empty set of policies is used for categorization purposes.
c. A category with a set of policies used to group a set of records and specify group-related policies.

Figure 3 shows the many-to-many relation between e-tags and e-recs. Because this relation is many-to-many, each e-rec can be categorized into multiple groups by attaching multiple e-tags into it. Access and transfer of an e-rec is determined by the policies defined in its attached e-tags.

The category information is also sensitive, and unauthorized access to the e-tags attached to e-recs may reveal private and sensitive materials. For example, an e-tag with an AIDS category may reveal information that the patient has been visiting clinics for AIDS-related consultations. Our e-tags have an e-consent that applies both to the e-rec to which it is attached as well as to the e-tag itself. The implication of this is that the e-tag (and its associated e-rec) is inaccessible without suitable authorization, and so, for example, a medical practitioner will not have access to view the e-tags if the e-consent defined in the e-tag denies access to the practitioner.

We next provide some semiformal definitions in order to clarify the structures and relationships in the tag-based data model.

The following definitions assume the existence of some basic types:

STRING: the set of all finite-length strings composed of letters from an alphabet;
NAT: the set of natural numbers;
IMAGE: the set of all diagnostic and other images (charts, plots, etc.);
FTYPE: the set of types of facilities, such as hospitals, laboratories, and clinics;
CTYPE: the set of domain specific category types (such as facility, family, patient, and NULL);
ROLE: the set of occupational roles within a health care system, such as doctor, patient, nurse, specialist, and intern;
OPERATION: the set of permitted operations on an e-rec; and
POWERSET(S): the power set of a set S; that is, the set of all subsets of S.

We also define some identifying keywords associated with each of the defined entities in our model.

Definition 1: Subject (keyword: *Sub*)

A *subject* refers to a particular named human being or user. The identification is based on a pair: a key word *user* and unique name, expressed as a string taken from *STRING.*

$subject \in SUBJECT$
$SUBJECT = \{id \in STRING \mid (Sub, id)\}$

Definition 2: Facility (keyword: *Fac*)

A *facility* in our model is a named facility. *FACILITY* represents the set of all such possible facilities.

$facility \in FACILITY$
$FACILITY = \{f \in FTYPE, id \in STRING \mid (Fac, f, id)\}$

Definition 3: Electronic record (e-rec) (keyword: *Erc*)

An *e-rec* is a piece of information in the system for which access policies are defined, such as X-ray image, blood sample, and prescription. *EREC* represents the set of all such pieces of information.

$eRec \in EREC$
$EREC = \{e \in STRING \times IMAGE \mid (Eec, e)\}$

Definition 4: Roles (keyword: *Rol*)

Role is an occupational position in our system taken from a predefined set *ROLE.*

$role \in ROLE$
$ROLE = \{r \in ROLE \mid (Rol, r)\}$

Note that there is a many-to-many relationship between roles and subjects. A *subject* can be assigned to multiple *role*s, and, similarly, a *role* can be assigned to multiple *subjects.*

$ROLE \leftrightarrow SUBJECT$

Definition 5: Principal (keyword: *Prn*)

A *principal* is an entity for which an access can be granted.

$principal \in PRINCIPAL$
$PRINCIPAL = \{\bigcup \in SUBJECT \cup ROLE \cup FACILITY \mid (Prm, \bigcup)\}$

Definition 6: Operations (keyword: *Opn*)

Operations are the tasks that can be performed on an *e-rec*.

$operation \in OPS$
$OPS = \{o \in OPERATION, e \in EREC \mid (Opn, o, e)\}$

Definition 7: Category (keyword: *Cat*)

A *category* is either a tuple consisting of predefined types and associated values (effectively set of freely defined strings) or a special *NULL* category. Then we define the set of all categories as follows.

$category \in CATEGORY$
$VALUE \subset STRING$
$CATEGORY = \{k \in CTYPE \times VALUE \ \cup \{\mathrm{NULL}\} \ | (Cat,k)\}$

Definition 8: Policy (keyword: *Pol*)

A *policy* is a statement about operations that can be performed on an *e-rec* based on *principals*. Each policy has a time stamp associated with it (modeled as a natural number, *NAT*) that is used for conflict resolution and auditing purposes. *POLICY* is the set of all policies and we define it as follows.

$policy \in POLICY$
$POLICY = \{time \in NAT,\ \ OPERATION \times PRINCIPAL \, | (Pol,\ time,\ d)\}$

Definition 9: E-consent (keyword: *Ecn*)

An e-consent is a subset of all possible policy statements including the *NULL* policy, and *ECO* is the set of all policy statements.

$eCo \subseteq ECO$
$ECO = \{sp \in POWERSET(POLICY \ \cup \ \{\mathrm{NULL}\}) \ | (Ecn,sp)\}$

Definition 10: E-tag (keyword: *Etg*)

An e-tag is an e-consent defined for a category. *ETAG* represents all possible e-tags, except the one where all elements are empty.

$eTag \in ETAG$
$ETAG = \{t \in CATEGORY \times ECO \, | (Etg,t)\}$

When an e-tag is attached to an e-rec, it categorizes the e-rec and protects its access.

Definition 11: Object (keyword: *Obj*)

An *object* is a complete e-rec, along with its attached e-tags. *OBJECT* represents all e-recs with attached categorization and policy information.

$object \in OBJECT$
$OBJECT = \{ee \in ETAG \times EREC \, | (Obj,ee)\}$

Policy Expression Language

Our e-consent is used to express the transfer and access policies of a particular e-rec. One could define an e-consent using standard policy expression languages such as XACML (OASIS, 2005) or EPAL (Paul, Satoshi, Karjoth, Powers, & Schunter, 2003). However, most of the current policy expression languages primarily are used for expressing *access* policies, and languages that also are able to express *transfer* policies are a recent development. Examples of such languages are found in OMA 2.0 (Open Mobile Alliance (OMA), 2004) that came out of the family domain work within Motorola Research Laboratories (Messerges & Dabbish, 2003). These are rich, expressive languages allow generalized application to any digital rights management (DRM) application. However, as we did not require their full capabilities for this application, we decided to define and use our own simple application-specific policy expression language that supports both access and transfer policies.

Figure 4 shows our policy expression language. Each policy has a time stamp representing the time of creation of the policy.

The transfer policy grants or denies transfer to a certain facility (or hospital). The access policy grants or denies access to health practitioners (or subject), their roles, or facilities. The access permission can be granted with appended rights for health care practitioners or their roles as defined in the facility. A doctor can access an e-rec if, and only if, the access policies (a) allow access to the subject or to the role and (b) allow access to the facility. That is, both the facility and practitioners need to have access permission in order to access the medical records. Similarly, a doctor can transfer an e-rec if, and only if, (a) the

Figure 4. Policy expression language

```
policy :=
   policy_TRANSFER | policy_ACCESS
policy_TRANSFER :=
   (‘grant’ | ‘deny’) ‘transfer to’ (FACILITY)
policy_ACCESS:=
   policy_ACCESS_GRANT | policy_ACCESS_DENY
policy_ACCESS_GRANT:=
   ‘grant’ ‘access to’
   (((SUBJECT | ROLE)[‘with append right’]) | FACILITY)
policy_ACCESS_DENY :=
   ‘deny’ ‘access to’ (SUBJECT | ROLE | FACILITY)
```

access policies allow access to the subject and the facility and (b) transfer policies grant transfer permission to the destination facility.

Policy Enforcement and Conflict Resolution Mechanism

In order to determine whether a principal can access an e-rec or not, all the policies listed in the e-consent of all attached e-tags of an e-rec must first be evaluated. Not unexpectedly, there is a reasonable chance that there will be conflicting policies defined in different e-tags. For example, a patient's policy may state that the information is only accessible to a specific doctor at a particular, nominated hospital. However, the nominated hospital may have a conflicting policy to that of the patient, and allow any doctor or nurse, while acting in an emergency role at that hospital, to access all of the patient's information.

Our conflict resolution mechanism is based upon the following ordering on e-tag category types.

$$Facility \subseteq Family \subseteq Patient \subseteq NULL \quad (1)$$

This order ensures that any specific policies attached to a particular e-rec have a higher priority than the default policies that are attached to all the e-recs of the patient at a particular facility. Similarly, a patient default policy has priority over the facility default policy. This combination of priorities ensures that the patient always has a final say about access to their personal health information.

We now define our prioritized multistep conflict resolution mechanism as follows.

1. *Higher priority wins:* A check is first performed against the order in Equation 1. Unfortunately, this first step cannot resolve all conflicts, since a single e-consent may contain multiple policies. Similarly, an e-rec can have multiple e-tags at the same priority level. If resolution is not possible at this step, then the resolution moves onto step 2.
2. *More specific wins:* The conflict that results from multiple e-tags, possibly with the same priority, is resolved using a principle of "more specific wins." For example, a policy concerning a doctor wins over a policy concerning a role because a doctor is more specific than the role. Once again, this does not cover the situation where the policies are of the same priority and have identical specificities. If this step cannot resolve the conflict, we move onto step 3.

3. *Most recent wins:* In the case where step II cannot resolve the conflicts, we use the principle of "most recent wins," based on the time stamp attached to each policy. Finally, if the conflict still cannot be resolved using the time stamp, the resolution must be finalized at step 4.
4. *"Deny" wins over "grant":* If two policies have the same time stamp, the policy with "deny" wins over the policy with "grant."

Despite the fact that we expect that this conflict resolution mechanism will be able to resolve all of the conflicting policies, ultimately, for those that cannot be resolved by using this scheme, any implementation should provide for human intervention.

SECURE TRANSFER PROTOCOL

Secure transfer of an electronic medical record consists of two parts. First, mutual trust between interacting parties must be established so that they can be enforced to implement based on agreed access policies. Second, secure communication of electronic medical records between two parties using untrusted and unsecure public network infrastructure needs to be in place. We next describe the mutual attestation and transfer protocols we have developed to address these issues.

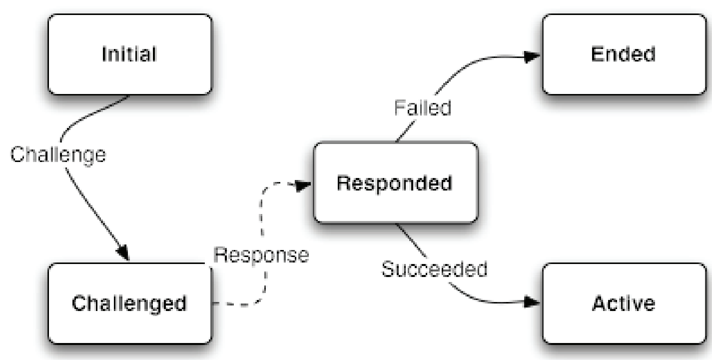
Mutual Attestation Protocol

TCG is an industrial standards body that produces a variety of specifications aiming to provide the best-practice software and hardware-based solutions to "help users protect their information assets (data, passwords, keys, etc.) from compromise due to external software attack and physical theft (2003)." One of the TCG specifications defines the cryptographic microcontroller hardware called the *trusted platform module* (TPM) that serves as a root of trust for authenticating a host's software configuration and protecting data by never releasing a root key outside itself.

The TPM chipset contains a set of *PCRs* that are used in measuring the characteristics and properties of the platform environment, such as integrity, system configuration, and executing states. For example, platform integrity (measured from boot time to the time at which applications are loaded) is kept in one of the PCRs. Any changes in the environment are reflected in a change to the PCR value (the update applies the cryptographic encryption algorithm SHA-1 to the current values concatenated with the new measured content).

The measured environment is then exchanged between the two parties wishing to establish a

Figure 5. TCG Remote attestation protocol



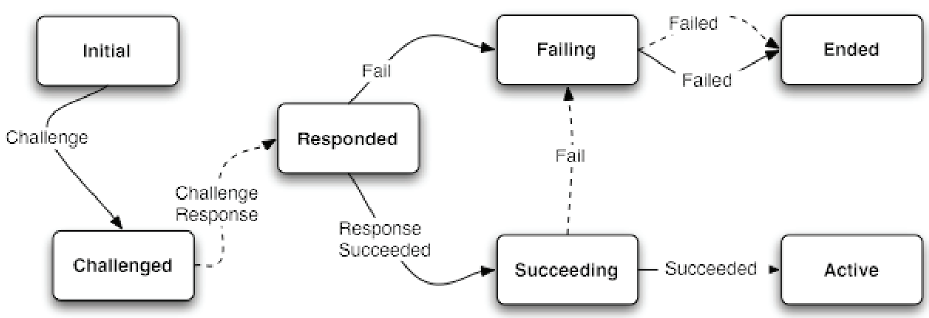
trust relationship, using a challenge-response attestation protocol. This attestation protocol is used to verify authenticity of the receiving party as shown in Figure 5. During attestation, the challenger platform (sender) sends an attestation challenge to the receiving (challenged) platform. The challenged platform then assigns one or more PCR values, using an *attestation identity key* (AIK) and sends this back to the challenger as a response. The AIK is protected by the TPM hardware[1] and the assigning is usually done using a special "*quote*" operation. The challenger then verifies that the received assigned values are the expected values, and so determines the authenticity of the challenged platform. After the successful attestation, the protocol reaches an active state, that is, the challenger trusts the platform configuration of the challenged facility and that the facility has a valid TPM. The challenger can then send encrypted messages to challenged facility, knowing that only the challenged facility can decrypt them (through the use of its TPM).

The TCG attestation protocol can support the remote authentication of a specific, challenged platform. However, in a general distributed health care environment, it is necessary to ensure that both the health care facilities engaged in a transaction have a valid TPM and that the facilities are in the correct software configuration. That is, the sender can trust the receiver, and the receiver can trust the sender for each possible transaction.

We extend the current remote attestation protocol and propose a mutual attestation protocol that permits two facilities to prove their validity to each other as shown in Figure 6. The full and dotted lines indicate the messages sent by sender and receiver facilities, respectively. The mutual attestation protocol is as follows. First, Facility A sends an attestation challenge to Facility B. Facility B then assigns one or more PCR values, representing its platform state using an AIK, and sends these values back to Facility A as a response, along with its attestation challenge to Facility A. Facility A then verifies the received assigned values with the expected values to determine whether the challenge is successful or not.

If the challenge is successful for Facility A, it then assigns one or more PCR values, representing its platform state using an AIK, and sends it/them to Facility B as a response, along with the successful result for its response to the earlier challenge. The receiver facility verifies the received assigned values with the expected values to determine whether the challenge is successful or not. The successful mutual attestation ends at the *active* state, where they can exchange electronic patient records, whereas unsuccessful attestation ends at the *ended* state.

Figure 6. Mutual attestation protocol



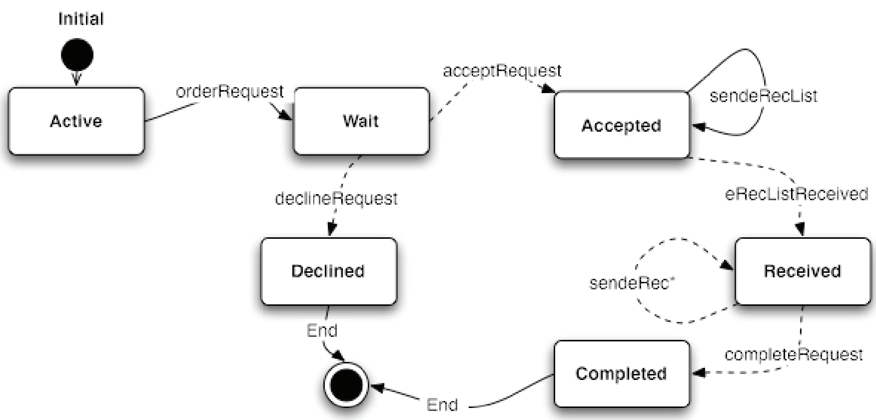
Transfer Protocols

Health care facilities exchange electronic medical records only when both facilities reach the active state. We next describe the transfer protocol we have defined for this purpose. Our transfer protocol is adapted and extended from the protocol proposed by O'Keefe et al. (2005). After successful mutual attestation, a doctor at a facility initiates a transfer by first creating and then sending an *order request* to another doctor at another facility as shown in Figure 7. The facility that initiates the transfer is called the originating facility, and the facility that receives the order request is called the destination facility. The order request is structured and contains the following information:

- Request identifier: This is a unique identifier for each request. The context of the interaction between facilities is always maintained by accompanying the protocol and data messages with the request identity.
- Short description: This is a string, for example, used by a doctor for description or other comments about a particular case. Note that this description is a permanently recorded and cannot be revoked or otherwise removed.
- Originating doctor and destination doctor identities: This is necessary to deliver messages to the right doctors.
- Policies: The originating facility also sends a set of policies that are applicable to medical records that will be created in the destination facility as part of the response to the request. These policies will be attached to any piece of information created as a response.
- Patient and family e-tags: It is necessary to register the patient in the destination facility in case they are not already in its system. This registration associates a repeatable, but anonymous, identity associated with the transferred patient record. Consequently, the e-tags are not transferred as part of the request in anonymous transfer but are replaced with anonymous tags (containing the patient and family policies and de-identifying the transferred information).

If the request is accepted by the destination facility, an *accept request* message is sent back to the originating facility. The originating facility can then fetch all the e-recs corresponding to the request in batch mode (resulting from the originating facility issuing an *e-rec list* message). All e-recs are preprocessed before being sent (as

Figure 7. State diagram illustrating the transfer protocol in originating facility



described later in our prototype system). In case of anonymous transfer, the name of the patient and the family e-tags are replaced with unique identifiers. As soon as the e-recs are received by the destination facility, the records are postprocessed (as described later in our prototype system) and stored in the facility. The destination facility then sends an acknowledgement message *e-rec list received* to the originating facility.

In case a response is required to a transfer, the destination facility can send back any number of e-recs by issuing a *send e-rec* message multiple times. Theses e-recs are similarly preprocessed and postprocessed by the destination and originating facilities, respectively. The send e-rec message contains, along with the e-rec, the request identifier. In postprocessing anonymous transfers, the anonymous identifier tags are replaced by the identifying family and patient e-tags. At the end of every transfer protocol, the destination facility sends an *end* message.

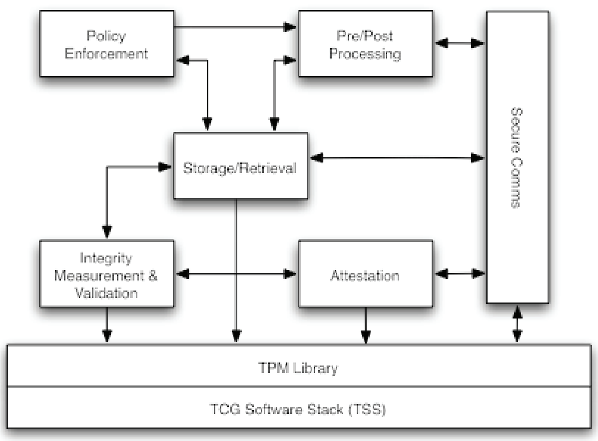
Figure 7 illustrates the transfer protocol for the originating facility for both cases—with and without a response. There is a complementary state diagram for the receiving facility, which is omitted here due to space limitations. The solid arrows represent sent messages, and the dashed arrows the received messages. The superscript star takes on the usual regular expression meaning and represents zero or more transitions (messages). In the case of a transfer without a response, such as transfer of a patient from one facility to another, the starred message is not received at all. In the case of a transfer with a response such as a referral of a patient to a specialist, it is possible to receive multiple e-recs in response to the referral.

PROTOTYPE IMPLEMENTATION

Figure 8 depicts the overall architecture of the "MedicClient" demonstration system, which is based on the concepts described in the fourth and fifth sections. The system has six major components.

- Policy enforcement: The system is responsible for enforcing policies and resolving conflicts, while accessing and transferring medical records. It is also responsible for generation and maintenance of transaction logs (required for auditing).
- Integrity measurement/validation: The system is responsible for measuring the current environment of the host computer

Figure 8. MedicClient architecture



and verifying that the measurements sent by other facility are as expected, and so can be trusted.

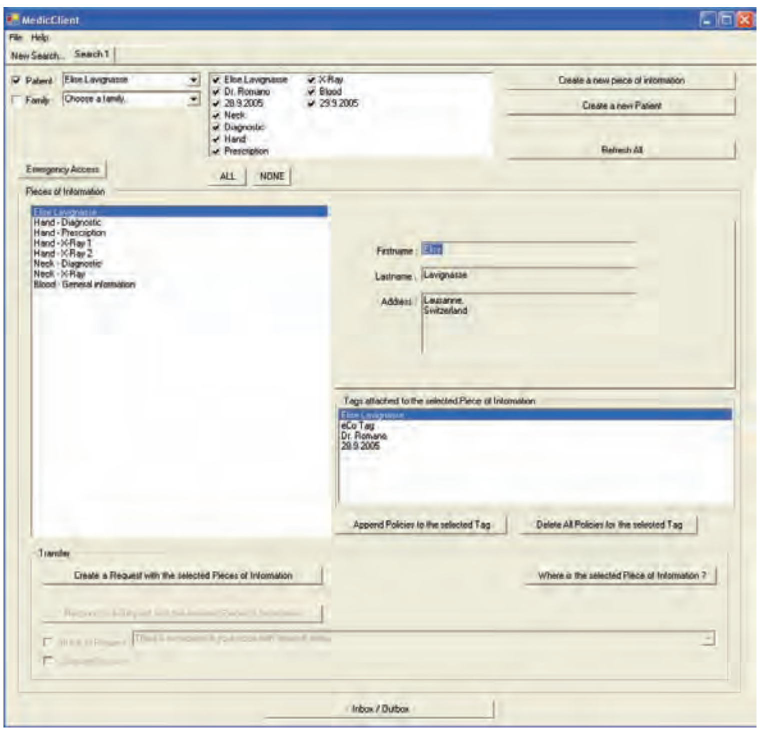
- Secure communication: The system is responsible for encrypting the outgoing information and decrypting the incoming information.
- Attestation: The system is responsible for authenticating and determining the identity of the remote facility.
- Pre/post processing: The system is responsible for processing e-tags for transfer.
- Storage and retrieval: The system is responsible for storing and retrieving e-recs from SQL databases.

Doctors access, create, and share medical information by use of the MedicClient software. Figure 9 shows a screenshot of the main interface for the system. Once a doctor is authorized to use the system and selects a patient, MedicClient displays the health-information view for the patient, as shown in Figure 9. We omit the details of operation of the system here due to the limitation of the space and focus on the technical details. Refer to Nepal, Zic, Jaccard, & Krahenbuehl (2006) and Nepal, Zic, Krahenbuehl, & Jaccard (2006) for a more comprehensive explanation of the system. We next describe the implementation details of major components.

Storage and Retrieval

Electronic medical records and all related data needed for the functioning of components are stored in a persistent, securely encrypted store and implemented using a SQL server. We use ADO.NET classes to connect data sources as well

Figure 9. MedicClient user interface for Dr. Romano



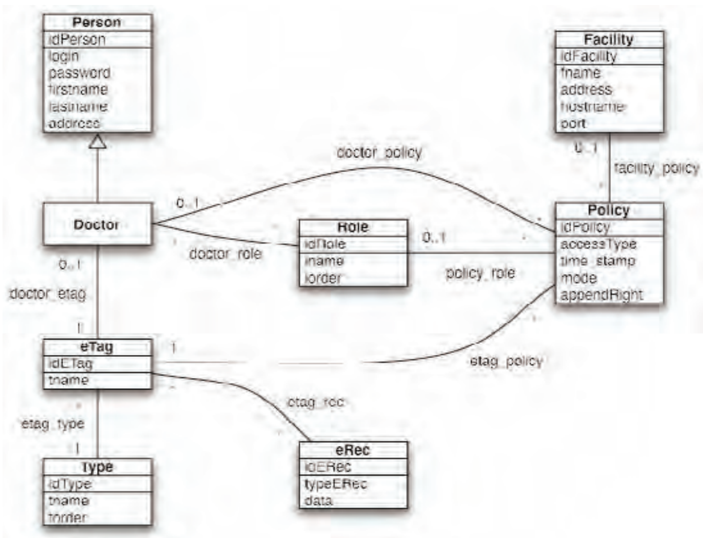
as to retrieve and update stored data. Figure 10 shows the relationships between the various entities involved in the tag-based data model. It can be seen from this figure that a policy is defined on the roles and facilities as well as individual doctors. It is worth noting that the doctor's e-tag is a *NULL* policy, as it does not have any relationship with the policy entities. The entities and their relationships were used to create the SQL tables that were held on the server. We utilized the trusted computing technology provided by the TPM microcontroller and its associated software stack to ensure the privacy and security of the SQL data. Database encryption and security is an area of research by itself, and this paper does not claim any contribution to this area. Our work was guided by the requirement that a patient's medical record privacy must be protected, which in turn suggests that at least the information held in a patient's e-rec table entry must be encrypted. This decision allowed a simple database implementation, as only the e-rec table entry data needs to be secured. Decryption of the information in an e-rec could be done without using another access to the database.

The e-rec data was encrypted using Triple DES. This requires the use of a symmetric key created at the time of installation of the MedicClient application. An asymmetric key is created and registered at the same time and is used for sealing the symmetric key to prevent unauthorized access. The seal is an encryption function that only allows the TPM and its specific software environment that created the object to decrypt it.

Policy Enforcement and Monitoring

We describe only one of the many implemented functions of this component, namely access policy enforcement. The access policy enforcement mechanism consists of two steps. The first step checks whether the doctor is allowed to access the information. The second step checks whether the facility, from which the doctor is trying to access the information, is allowed to access it. For both steps, all related policies for an e-rec are collected from e-tags in a list and checked against the conflict resolution mechanism specified in the fouth section to see whether the winner mode is grant or deny. Access is granted to the doctor in

Figure 10. E-R diagram for the tag-based model



the facility for the e-rec only if the policy for *both* doctor and the facility allows it. Otherwise, the access is denied.

Integrity Measurement

As explained earlier, in our distributed health care system scenario, a government health department provides the operational credentials and licenses for health care facilities. Our attestation protocol requires both parties to validate the issued credentials. In order to support this, we introduce a facility credential, digitally signed by the department of health or a similar authority, within the TPM credential architecture as shown in Figure 11. This credential is given to all facilities by the external authority after registration, and is linked to the endorsement credential of the registered facility.

The general principle of integrity measurement using a TPM-based system is that any software is measured using the SHA-1 digest of the executable code before being loaded and stored in PCR registers. The first (loaded) software that does the measurement is called c*ore root of trust for measurement* (CRTM), which in our case, is the machine BIOS. Our development platform was based on Microsoft's current version of the Windows XP operating system (OS), with the application development being done under the .Net environment. Despite the fact that the TPM chipset is found in most new PCs, the version of Windows XP (the most current released version at time of writing) did not support integrity *measurement* from CRTM. Further and because of this fact, there is no chain of trust that ties together the hardware BIOS to the application software.

Due to the lack of support at the OS level, we simulated the core root of trust by developing specialized loader software, called the *MedicLoader*, as shown in Figure 12. This loader intercepts calls to the loaded and unloaded applications and performs measurements on the executables before their execution. A fundamental assumption to our implementation is that the MedicLoader can be trusted to securely measure itself and the processes it loads before executing them. This means all components that are under this root of trust also must be trusted. Although this is useful for a concept demonstration, it is not a realistic solution for commercial applications. Realistic solutions must rely on OS support of both integrity measurement and being able to respond to a chain of trust.

The integrity measurements are performed as follows. For each executable file, we uniquely

Figure 11. The TPM credential architecture

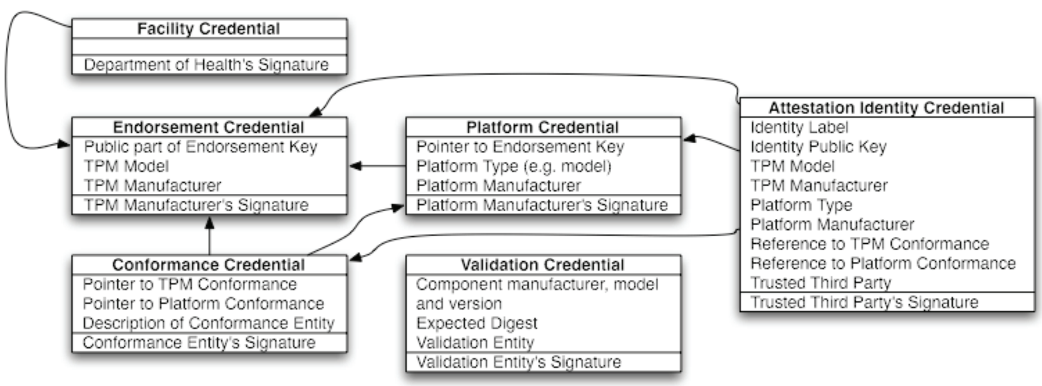


Figure 12. Raising the level of trust (for measurement)

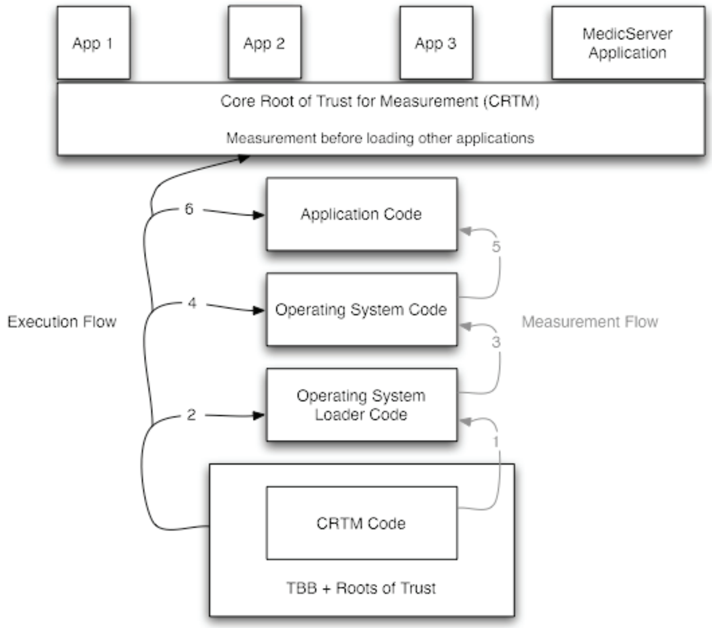


identify the executable and capture whether it is loaded or unloaded. We do this by extending the PCR values as a triple: the state of the code ("load" or "unload"), the file name of the executable, and SHA-1 digest value of the executable. Our implementation of this triple is simply a concatenation of these three values, and each of these resulting triples is kept as a list. Separate from this list, each facility keeps a database of processes that represents a register of "acceptable" process states. Each entry consists of the name, a calculated hash value for the executable, if it is loaded or unloaded, and the desired executable load state ("may," "must," "must not"). "May" signifies that the process may be loaded optionally, whereas "must" signifies that there is no option for loading the process—it must be present. We next describe the mutual attestation protocol between two server applications using this integrity measurement technique.

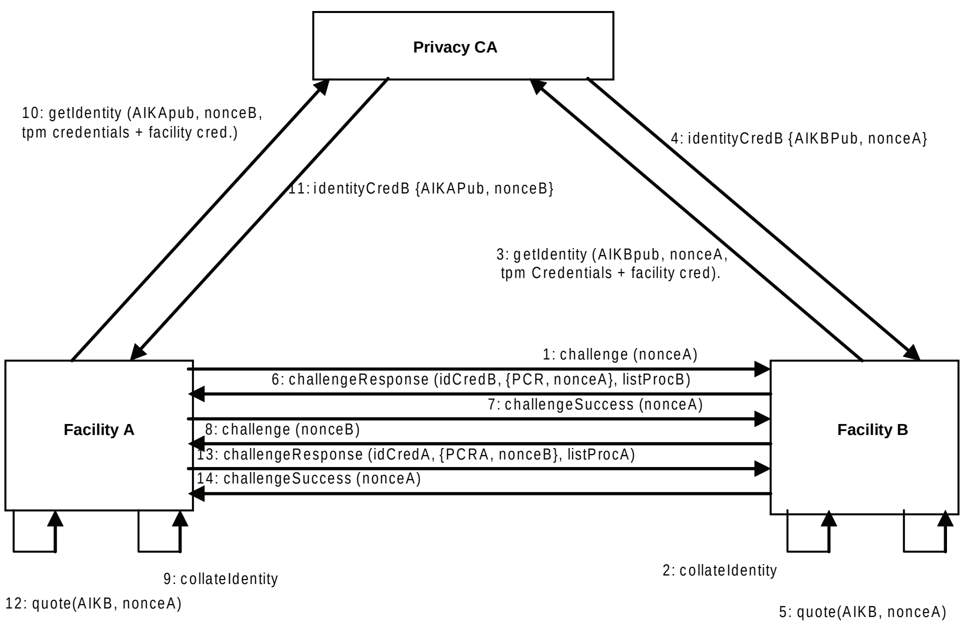
Mutual Attestation

The TrouSers FAQ (IBM Trousers, 2006) shows the existence of a dependency graph of trusted computing elements that are required to support remote attestation. Importantly, there are key elements that are missing in the current infrastructure; therefore, it is not possible to use some of the core functions provided by TCG's specifications for remote attestation, such as "CollateIdentityRequest" to collect TPM credentials or the "PCR_extend" operation. Because of this, we had to simulate these missing elements in our prototype demonstrator.

The TCG supports two remote attestation methods: one by use of a Privacy CA and the other by DAA (Yung, 2005). We chose the former in our prototype demonstration. Figure 13 illustrates the implemented mutual attestation protocol. The following explains the protocol steps when the originating Facility A wants to send a patient record to the destination Facility B.

1. Facility A sends a challenge to Facility B with an identifying nonce. We call this "nonceA."
2. Upon receiving the challenge, Facility B obtains its TPM credentials by calling the function "CollateIdentityRequest." This function also generates an AIK. The TPM credentials, facility credential, and the public part of the AIK are signed by the private part of the TPM endorsement key and then encrypted, using the public part of the Privacy CA key.
3. The encrypted blob is sent to the Privacy CA as an identity credential request.
4. The Privacy CA decrypts this blob with its private key. It verifies the signatures of the credential request, and then creates and sends an identity credential back to Facility B. This credential is a digital certificate containing the public part of the AIK, together with "nonceA," signed by the CA private key.
5. Facility B then performs an integrity measurement using the TPM "quote" function, using the AIK, "nonceA," and one or more PCR values, as input parameters. The AIK can only be used to sign the quoted PCR registers.
6. The message containing the output of the quote function, the identity credential received from the CA, and the list of recorded loaded and unloaded processes is then sent to Facility A from Facility B. On reception of this message, Facility A first checks the identity credential, verifying that the Privacy CA has signed it. This also reveals that Facility B has a TPM and that the AIK is an identity key in the TPM of Facility B. With this information, Facility A can then verify the signature of the PCR values and "nonceA." If the signature is verified successfully, then Facility A knows the PCR

Figure 13. Mutual attestation protocol



values of Facility B. Finally, Facility A does the following three verifications:
   a. All processes in the received list are in the database of acceptable processes with corresponding hash code.
   b. The expected PCR value is computed from the list of processes and compared with the PCR values of Facility B.
   c. All processes that are marked as "must" in the acceptable process database are loaded.
7. If all checks are successful, Facility A sends a challengesuccess message to Facility B. Otherwise, the attestation fails.
8. Facility B receives the challengesuccess message, and initiates the same procedure (steps 8-14 in Figure 13). At the end of these steps, both facilities are authenticated mutually and are ready to exchange medical records.

Preprocessing and Postprocessing

A patient medical record has a variety of e-tags attached to it. When a record is transferred from one facility to another, these e-tags sometimes may not be transferrable in their current form. For example, each facility may have different default policies for different categories of information, or in the case of anonymous transfers, the current e-tags must not be transferred. This requirement for processing tags indicates that there is a need for preprocessing and postprocessing of medical records, both just before sending them and just after receiving them. We defined and implemented the following preprocessing and postprocessing rules for a selection of e-tag types.

Facility default e-tags: Default facility *policies* are defined for a local facility only and must not be transferred. However, the *category* information itself must be transferred for classification purposes. That is, the originating facility will transfer e-tags together with categories but without policies. The destination facility will use its own default policies in the e-tag corresponding to the category.

Patient and family e-tags: Policies are always transferred for e-tags of type *patient* or *family*. In the case of anonymous transfer, the category value must be replaced with the anonymous identity as explained for the transfer protocol (see previous section).

E-rec specific policies: Specific policies attached to an e-rec are always transferred without any modification. As we assumed that roles, doctors, and facilities are globally identifiable, all policy expressions can be transferred and processed in every facility without any manual or automatic modification.

The developed prototype system was demonstrated to the Center for Networking Technologies for the Information Economy (CeNTIE) (2006) Enterprise System Focus Group and other stakeholders in September 2005. The demonstration has led us to the belief that our data model can be implemented using available technologies in databases. The demonstration also shows us that it is feasible to deploy mutual attestation protocols between two server applications in a distributed health care environment to enhance the trust for sharing electronic patient records.

DISCUSSIONS AND CONCLUSIONS

Previous e-consent data models were developed on a set of restricted assumptions. By widening the assumptions and examining the realistic use of e-consent within the health care system, we noted that these e-consent data models needed to be changed. Consequently, we developed a flexible data model for electronic medical records that we called the tag-based data model. The data model allows the representation of patients' medical records and incorporates their consent information. The model also allows categorization of medical records into different groups. This in turn allows the definition of default policies for each category. Unlike existing role-based access models, our data model supports both access and transfer policies on roles, categories of information, facilities, and health care practitioners.

Our experience has been that the data model allows a great deal of flexibility and autonomy for the end users and imposes a minimal set of semantic requirements on its use in specifying policies and categories. Because e-tags and e-recs are securely encrypted, indexing and searching requires the extension of the current data model to include metadata information.

Another important issue identified in previous e-consent demonstrators is the requirement for mutual trust between two interacting facilities. We believe that our mutual attestation protocol between two facilities provides a reflexive form of trust between two parties needing to support enforcement of policies. We explored the bounds of what is possible in the current Microsoft Windows environment; although the current Windows infrastructure lacks the necessary elements for remote attestation, such as chain of trust from hardware to operating system to applications.

Finally, we have developed a prototype system and demonstrated it to the CeNTIE (2006) Enterprise System Focus Group. The demonstration has led us to the belief that it is feasible to deploy such mutual attestation protocols between two server applications in a distributed health care environment to enhance the trust, while sharing electronic patient records. We also observed that the current implementation of mutual attestation protocol performance might be improved, as the protocol has to be run for each message sent or received by a facility. In future, we plan to tackle this problem by developing an application session-based mutual attestation protocol. Our preliminary study shows that such a protocol also will address the problem of discrepancy in time-of-use and time-of-attestation.

ACKNOWLEDGMENT

This work is supported by the Australian government through the Advanced Networks Program of the Department of Communications, Information Technology and the Arts. Discussions with Paul Greenfield of the prior e-consent model greatly assisted us in developing the tag-based data model.

Chapter 7.12
Reliability and Evaluation of Health Information Online

Elmer V. Bernstam

Funda Meric-Bernstam
University of Texas, M.D. Anderson Cancer Center, USA

ABSTRACT

This chapter discusses the problem of how to evaluate online health information. The quality and accuracy of online health information is an area of increasing concern for healthcare professionals and the general public. We define relevant concepts including quality, accuracy, utility, and popularity. Most users access online health information via general-purpose search engines, therefore we briefly review Web search-engine fundamentals. We discuss desirable characteristics for quality-assessment tools and the available evidence regarding their effectiveness and usability. We conclude with advice for healthcare consumers as they search for health information online.

INTRODUCTION

The healthy, the newly diagnosed, and the chronically ill turn to the Internet for health information. In spite of some controversy regarding the number of individuals that are accessing online health information at any given time, most experts agree that the numbers are enormous. Indeed, some have estimated that on any given day, more people consult the Internet for health information than see a physician (Fox & Rainie, 2002). Furthermore, there is evidence that patients are making treatment decisions based on the information that they encounter online (Helft, Hlubocky, Gordon, Ratain, & Daugherty, 2000). Therefore, researchers, clinicians, and the general public are increasingly concerned about the reliability of health information online that is directed toward consumers of healthcare. In this chapter, we consider the problem of how to enable healthcare consumers to evaluate online health information.

DEFINITIONS: INFORMATION QUALITY VS. INFORMATION ACCURACY

One of the major impediments to research into online information quality is the lack of clear, consistent, and generally accepted definitions. In this section, we define relevant terms to provide a vocabulary for discussion.

The factual correctness (accuracy) of health information online may be difficult to assess. Indeed, even experts often disagree regarding accuracy. Therefore, review of information content by a panel of experts is considered to be the gold standard of accuracy.

Most Internet users are not healthcare experts. Therefore, they cannot judge the accuracy of online health information. Since consumers cannot assess accuracy, surrogate measures that they can assess are appealing. We refer to these surrogate measures as measures of quality and collections of these measures as quality-assessment tools. Measures of information quality are useful to the extent that they (a) can be effectively assessed by healthcare consumers and (b) correlate with outcomes of interest such as whether the information is factually incorrect or whether the information has the potential to harm health (i.e., if the advice were followed).

An example of an information quality measure is authorship (i.e., is an author identified?). The JAMA benchmarks (Silberg, Lundberg, & Musacchio, 1997) are a commonly cited quality-assessment tool. The JAMA benchmarks consist of four quality measures: authorship, attribution, disclosure, and currency. These generally came to be known as the "clarity in publishing" criteria and are similar in spirit to the type of questions one might ask about a textbook or scientific paper.

Preferably, measures of quality should be based on meaning rather than presentation of information. In contrast, some studies tested superficial characteristics such as the claim of copyright (Fallis & Fricke, 2002). In this study, Web pages that claimed copyright were more likely to be accurate than pages that did not claim copyright. The authors point out, however, that it is simple to claim copyright. Even if such superficial measures correlate with accuracy, they are easy to manipulate. Web-site developers could simply claim copyright without modifying the information displayed on the Web site. Therefore, as superficial measures become more widely used, they will become less useful.

Unfortunately, quality measures are difficult to put into practice. A systematic review of studies assessing the quality of online health information determined that although 70% of the studies found quality to be a problem, there were wide differences in the quality measures used, their operational definitions,[1] and methods in which the analyses were carried out (Eysenbach, Powell, Kuss, & Sa, 2002).

Some have argued that a high-quality Web site should display information that is accurate, easy to understand, specifically tailored to the intended audience, and pleasing to the eye. However, in order to enable communication, more precise definitions are useful. Eysenbach et al.'s (2002) review of the literature distinguished the following: (a) technical quality criteria, defined as "general, domain-independent criteria, i.e., criteria referring to how the information was presented or what metadata[2] was provided," (b) design, which "includes visual aspects of the site such as the colors used or layout," (c) readability, meaning whether the language is easy to read and is understandable, (d) accuracy, or the "degree of concordance with the best evidence or with generally accepted medical practice," and (e) completeness, which refers to the portion of relevant material covered on the Web site. These five characteristics may be independent from each other. For example, it is possible for a high-quality Web site based on technical quality criteria to display false information, or a poor-quality Web site to display accurate information.

QUALITY-ASSESSMENT TOOLS

In response to widespread concern regarding the quality and accuracy of online health information, many organizations published quality-assessment tools. Consumers are encouraged to evaluate online health information using these quality-assessment tools. In spite of this and consumers' stated concern regarding the accuracy of the information that they see on the Internet, recent studies found little evidence that consumers are considering quality when searching for information online (Eysenbach & Kohler, 2002; Meric et al., 2002).

As mentioned above, quality measures often reflect clarity-in-publishing standards adapted from traditional media such as the display of authorship, attribution, disclosures of conflicts of interest, and so forth. Similarly, a television viewer or newspaper reader may want to look for an identified author and sponsorship information. When reading a scientific paper or book chapter, one looks for references to the published literature that support assertions. It is possible that these measures are less appropriate in some domains. Specifically, complementary and alternative medicine (CAM) is an important topic commonly addressed by health-related Web sites. The accuracy of CAM information is difficult if not impossible to define. By definition, CAM information may not reflect expert medical opinion or conventional standards of care. Furthermore, few CAM Web sites reference traditional biomedical literature (Sagaram, Walji, & Bernstam, 2002; Walji et al., 2004). An alternative is to consider the potential harm of the information if the advice were followed. Clinicians assessing the potential harm of online health information are able to do so with high interobserver reliability (see next paragraph; Walji et al.).

A recent review of quality-rating tools provided by the likes of the American Medical Association and Health on the Net (HON) Foundation, among others, found that no instrument reported interobserver reliability as a measure of its validity (Gagliardi & Jadad, 2002). The purpose of quality-rating tools is to allow those looking for health information to filter out poor-quality content. However, the criteria used must also be unambiguous so that different people using the same criteria will agree upon their usage. Therefore, it is important that different reviewers can agree upon and reproduce the results. In other words, quality measures must have high interobserver reliability. Unfortunately, evaluations of interobserver reliability have not been encouraging. Even trained informaticians are not able to consistently agree on the presence or absence of commonly cited quality criteria (Bernstam, Sagaram, Walji, Johnson, & Meric-Bernstam, 2005; Sagaram, Walji, Meric-Bernstam, Johnson, & Bernstam, 2004). It seems unlikely that consumers without informatics training fare any better. Furthermore, many quality-rating tools (composed of one or more quality criteria) are not practically usable by consumers. Many tools are not publicly available, are composed of criteria that cannot be reliably assessed, or have too many criteria (more than 10 questions to be answered per site; Bernstam, Shelton, Walji, & Meric-Bernstam, 2005). Table 1 provides examples of commonly cited quality criteria, their operational definitions, and expected interobserver reliability.

In addition to questionable usability, there is also conflicting evidence regarding the effectiveness of existing quality-assessment tools to identify false or misleading information online. Some studies show a correlation between quality and accuracy (Meric et al., 2002), while others do not (Walji et al., 2004). The reason(s) for this discrepancy is not clear. One possible explanation is that the correlation is domain dependent. Therefore, studies may differ depending on the specific topic tested (e.g., breast cancer vs. complementary and alternative medicine). For a comprehensive listing of commonly cited quality-assessment tools, see Eysenbach et al. (2002).

Is There Documented Harm from Online Health Information?

In spite of widespread concern regarding the potentially harmful effects of online health information, documented evidence of physical harm is scarce. A systematic review of harm from online information found few reported cases. However, the authors caution that this may be a result of underreporting rather than actual absence of harm (Crocco, Villasis-Keever, & Jadad, 2002). Consequently, some argue that concerns have been overemphasized and benefits to users have been underappreciated (D. Hoch & Ferguson, 2005). This issue remains controversial.

SEARCHING FOR HEALTH INFORMATION (WEB SEARCH ENGINES)

Few consumers are directed to specific Web sites by their healthcare provider (Reents, 1999; Tang & Newcomb, 1998). Therefore, left to their own devices, consumers use general-purpose search engines to find health information on the Internet (Eysenbach & Kohler, 2002; Fox & Rainie, 2002). Although their search strategies are often suboptimal and they rarely look beyond the first page of results, consumers are generally satisfied with their ability to find information on the Internet (Eysenbach & Kohler; Fox & Rainie, 2000). To a large extent, search engines determine what information is seen by consumers.

Search-engine technology is complex, changes quickly, and is often proprietary. Therefore, a detailed discussion of the inner workings of search engines is beyond the scope of this chapter. However, we will present a basic overview of relevant search-engine characteristics with particular emphasis on Google (http://www.google.com), the most popular search engine in the English-speaking world (Sullivan, 2004).

In general, to use a search engine, the user types in a few terms perceived to be related to his or her information need. An information need is an expression, in the user's own language, of the information that she or he desires. For example, "Should I use tamoxifen to keep my breast cancer from coming back?" is an information need. In order to satisfy this information need, a user may issue the following query: "breast cancer tamoxifen." A result set is retrieved in response to the query. The user can click on results that seem to be interesting. If none of the results seem interesting, users generally add or subtract terms from a query (Eysenbach & Kohler, 2002). For example, if "breast cancer tamoxifen" does not lead to a successful search, then "breast cancer tamoxifen recurrence" may be a reasonable query to try.

Before Google, most search engines used text-processing techniques to identify relevant Web sites. In other words, the search engine looked for Web pages that contained the query terms. This approach worked well when the Web was small. However, with many billions of Web sites, common queries now return too many results. Therefore, identifying results that are most likely to be useful became increasingly important. The designers of Google noted that the link structure of the Web was a rich source of information. Specifically, incoming links imply importance. Important sites tend to have many incoming links. Their algorithm, known as PageRank, makes use of links, or references from one Web page to another. This approach has proven so successful that most Web search engines now use some form of link analysis (Cho & Roy, 2004). Therefore, information displayed by popular Web sites is likely to be seen by healthcare consumers. Some studies found a correlation between popularity (Google rank) and accuracy (Fricke, Fallis, Jones, & Luszko, 2005) while others did not (Meric et al., 2002).

Search engines drive traffic on the Web. Therefore, Web sites compete for position on prominent search engines. Being ranked highly by Google, for example, will dramatically increase the number of users accessing a Web site (Cho & Roy, 2004). Many search engines, including Google, provide two types of results in response to a query. Algorithmic results are generated by the general-purpose search algorithm. In contrast, sponsored results are links to Web sites that have paid a fee to the search engine and are essentially advertisements. These are likely to contain commercial offers, often related to complementary and alternative medicine (Walji, Sagaram, Meric-Bernstam, Johnson, & Bernstam, 2005).

Unfortunately, not all search engines clearly identify sponsored results. Consumers are unaware of the existence of sponsored listings and do not differentiate them from nonsponsored results, which are retrieved algorithmically (i.e., using an algorithm that does not factor payment for placement). In fact, two in five (41%) links clicked by consumers are sponsored results (Marable, 2003). The Federal Trade Commission has recently recommended that search engines clearly identify sponsored listings (Hippsley, 2002).

ADVICE TO THOSE SEEKING HEALTH INFORMATION ONLINE

In this section, we consider the advice that can be offered to users searching for health information online in the absence of usable, reliable quality-assessment tools. Unfortunately, we cannot recommend a quality-assessment tool that can be used to identify problematic health information online. Similarly, we cannot recommend a Web search engine that lists only trustworthy information. In spite of this, we can recommend simple practices that are likely to minimize exposure to inaccurate information online.

Access Sites Known to be Trustworthy

Multiple government agencies such as the National Institutes of Health (NIH, USA) and the National Health Service (NHS) of the United Kingdom maintain Web sites with extensive libraries of health information intended for consumers. MedlinePLUS, maintained by the National Library of Medicine (USA), is a specific example. There are also disease-specific organizations that maintain high-quality content on every imaginable topic. Prominent examples include the National Cancer Institute (USA) and the American Heart Association (USA). Table 2 provides a small list of trustworthy Web sites with stable URLs (uniform resource locators). However, we emphasize that the Web is a dynamic medium and therefore any list of Web sites is dated by the time that it is published in print.

Distinguish Algorithmic from Sponsored Results

As discussed above, sponsored results are basically advertisements for particular Web sites that are often financed by commercial interests. Therefore, many sponsored links lead to Web sites attempting to sell products or services. To their credit, Google clearly identifies and separates sponsored results from algorithmic results. Searchers should be aware of how they encountered the Web site that they are viewing.

Consider the Source

Common sense tells us that information displayed by Web sites with commercial interests (i.e., those that are selling products) may not be entirely unbiased. Therefore, users would do well to consider the source, just as they would when evaluating non-health information. In general, government, organization, or academic Web sites are more likely to provide impartial advice compared to company (commercial) Web sites. However, this is a generalization and there may be exceptions.

Check with a Healthcare Professional

In some ways, online health information is no different from health information provided via any other medium. When in doubt, or when making important decisions, there is still no substitute for professional assessment and judgment. Therefore, the prudent health seeker will use online resources for education, but review important decisions with their healthcare provider.

FUTURE DIRECTIONS

As of this writing, traditional quality-assessment tools do not sufficiently address the concern regarding the quality and accuracy of health information online. Clearly, self-regulation (the status quo) does not prevent or identify false, misleading, or potentially harmful online health information. Regulation, whether by government(s) or nongovernmental organizations, does not seem viable. Indeed, even voluntary standards such as the HON code of conduct are difficult to enforce (Meric et al., 2002). In this section, we consider promising new approaches with the potential to address the shortfalls of traditional quality-assessment tools.

Distributed Human Annotation

There is too much Web content for any independent organization to evaluate and validate. Since content is constantly changing, evaluation and validation must be repeated to ensure compliance over time. A potential solution is to create a framework and process by which independent evaluators can collaboratively annotate content. Evaluators include the content providers (i.e., the Web-site developers), information specialists, and healthcare professionals. Therefore, the Web-site developer provides metadata such as authorship information. The metadata is checked by a nonmedical information specialist. Finally, the Web-site content is reviewed by a healthcare professional. Once the Web site has been evaluated, it is tagged with descriptors. Therefore, users can search for a Web site that has specific characteristics (e.g., has been evaluated by a healthcare professional). The MedCIRCLE (http://www.medcircle.org) project provides a vocabulary (HIDDEL, Health Information Disclosure, Description and Evaluation Language) to allow independent evaluators to describe a Web site in a consistent manner.

The advantage of this approach is that multiple independent evaluators can effectively collaborate. Consistent self-rating by Web-site developers may be better than no rating at all. However, as discussed above, self-regulation does not always ensure compliance with quality standards. In addition, independent manual Web-site evaluation is laborious. Although a distributed approach is likely to be more effective than one that relies on a single central authority, the Web is vast and constantly changing. Therefore, any validated subset of the Web is likely to be a very small percentage of all health information available online.

Reputation-Based Systems

Reputation-based systems explicitly model trust, which is hearsay evidence of predictable behavior. There are multiple examples of reputation-based systems in common use outside of healthcare. Perhaps the best known reputation-based system is the online auction company eBay (http://www.ebay.com) that brokers transactions (auctions) between buyers and sellers. After each transaction, feedback is solicited from both parties. Users who do not behave honorably acquire a bad reputation that is visible to the community. Similar systems have been developed for e-mail networks (Golbeck & Hendler, 2004). For online health information, one could develop algorithms to identify reliable sites using link analysis given a small set of verified (known to be good) sites such as those shown in Table 2.

Reproducibility

Unlike the traditional print media, Web sites do not exist independently of each other. In other words, a user has access to multiple Web sites from the same terminal. In contrast, when reading a book or journal article on paper, one may not have access to other books or articles on the same topic. It is easy to access multiple Web sites on the same topic to see if there is a consensus regarding specific information. One might hypothesize that if information is repeated on multiple independent Web sites, it is more reliable than information found on only a single Web site. However, this heuristic has not, to our knowledge, been systematically evaluated.

Self-Correction Hypothesis

The self-correction hypothesis refers to the possibility that users can identify and correct problematic health information online without professional guidance or supervision (Fennberg, Licht, Kane, Moran, & Smith, 1996; Ferguson, 1995; D. B. Hoch, Norris, Lester, & Marcus, 1999). In a sense, this is an extension of the approach used by open-source projects such as the online encyclopedia Wikipedia (http://www.wikipedia.org) and the open-source software movement where the user community identifies and corrects errors in content or computer code. Wikipedia allows any Web user to create and modify content. A recent analysis of Wikipedia content found that Wikipedia was generally accurate compared to a traditionally curated online encyclopedia like Britannica (Giles, 2005). In the context of online health information, we do not know whether self-correction really works. However, preliminary data are promising (Esquivel, Meric-Bernstam, & Bernstam, 2006). Therefore, it is possible that, given a sufficiently large and active forum, the Web can police itself.

CONCLUSION

Many Web users are searching for health information online and express concern regarding the quality and accuracy of online health information. Although there is evidence that online information affects healthcare decisions, there is little evidence that users are considering quality when accessing health information online. Helping users identify problematic health information online remains an open problem. Currently available quality-assessment tools cannot be reliably assessed by Web users and may not be effective at identifying problematic health information online. Fortunately, this is a young and dynamic field. Promising alternatives to currently available quality-assessment tools are subjects of ongoing research.

Chapter 7.13
The Effects of Confidentiality on Nursing Self-Efficacy with Information Systems

Diane Lending
James Madison University, USA

Thomas W. Dillon
James Madison University, USA

ABSTRACT

The objective of this study is to gain an understanding of nurses' perceptions of the confidentiality of computerized charts and determine if these perceptions influence nursing self-efficacy. A questionnaire was mailed to 600 hospital nursing staff just prior to the implementation of an integrated clinical and administrative hospital-wide information system. One hundred and thirty-nine questionnaires were returned for a response rate of 23%. The measurements consisted of perceived confidentiality, self-efficacy, self-reported technology use, self-assessed computer expertise, and attitude. We found that nurses recognize confidential information and that nurses do not think that computerized records are more or less confidential than paper records. Perceived confidentiality and self-efficacy are related. Because nurses that have lower self-efficacy also think that the data found in a computer is less confidential and that there is less of a need for confidentiality for computerized data, hospitals should take steps to improve self-efficacy by enhancing confidentiality training.

INTRODUCTION

Hospitals face countless constraints to fully implement information technology for nurses (Chang, Lutes, Braswell, & Nielson, 2006). The successful implementation of clinical and administrative information systems requires that attention be directed to both managerial and organizational issues (Dixon, 1999). These issues normally include, but are not limited to, the four components of a comprehensive technology assessment: safety, effectiveness, social impact, and cost/benefits (Happ, 1991; Pillar, Jacox, & Redman, 1990). This research focuses on the perceived confidentiality of the data, a safety factor, and the self-efficacy or confidence in their own use of technology of the nurses' that interact with the information system.

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 directed the secretary of the U.S. Department of Health and Human Services (HHS) to begin the process of establishing standards for health information, securing that information, and protecting the privacy of the individuals to whom that information refers (NCVHS, 2000.) Confidentiality of patient data, required by law, must be guaranteed. At the same time, this data must be easily available to the nurses and clinicians that are providing care (Priest, 1989). Neither manually produced paper records nor medical records stored within a computerized administrative and clinical system are totally secure from loss or unauthorized use, but problems of confidentiality can be anticipated and minimized if properly managed (Priest, 1989). This is emphasized in the summarized recommendations from the 2001 AMIA Spring Congress, where Yasnoff, Overhage, Humphreys, and LaVenture (2001, p. 535) write, "all stakeholders need to be engaged in coordinated activities related to public health information architectures, standards, confidentiality, best practices and research: and that informatics training is needed throughout the public health workforce."

Self-efficacy is a user's confidence that he or she has the ability to use an information system. Self-efficacy has been shown to have a strong influence on an individual's adoption of an information system. In this research, self-efficacy is used to assist in identifying the user's understanding of the privacy of confidential data and how it may affect the installation of a clinical information system.

Research is needed to determine the impact of administrative and clinical information systems on quality of care, the nurses' perceptions of the confidentiality of data and the affects of confidentiality on self-efficacy. The purpose of this study is to:

1. Develop and empirically test measures for perceptions of confidentiality.
2. Determine if the nurse's perceptions of computerized charts' confidentiality and paper charts' confidentiality differ.
3. Determine if nurses perceive that computerized charts and paper charts need the same level of confidentiality.
4. Establish that perceptions of confidentiality influence nurse's self-efficacy.

Demonstrating these relationships will help us understand if the implementation of HIPAA regulations is likely to influence nurse's acceptance of clinical information systems.

BACKGROUND

Self-Efficacy

Self-efficacy was introduced to the information systems (IS) literature by Compeau and Higgins (1991) based upon Social Cognitive Theory (Bandura, 1982). Social Cognitive Theory suggests that there are two types of forces that guide behavior: expectations relating to outcomes of the behavior, and beliefs about one's ability to perform that behavior. These beliefs about one's ability are called self-efficacy (Compeau & Higgins, 1991). Compeau and Higgins recognized that an individual's reactions to an information technology would be affected by that individual's self-efficacy or confidence that they could use the technology. They created a 10-item measure for computer self-efficacy which is widely used in the IS literature (Compeau & Higgins, 1995) and which we have used in this study.

Research has shown that self-efficacy has strong influences on many aspects of an individual's adoption of information systems. Self-efficacy has been shown to have affects on attitudes toward computer systems, including ease-of-use and usefulness (e.g., Compeau & Higgins, 1995; Venkatesh, 2000) and on behaviors such as system use and early adoption (Agarwal, Sambamurthy, & Stair, 2000.)

Henderson, Deane, and Ward (1995) included self-efficacy as part of an overall assessment of computer-related anxiety for nurses and clerical workers. They reported that nurses had poorer scores on all of the psychological variables that were thought to have some association with computer avoidance and use. This included more negative attitudes and a lower self-efficacy.

In a study of hospital personnel's adoption of a computer-based medical information system (CBMIS), management support and ease-of-use were shown to have significant effects on self-efficacy (Henry & Stone, 1995.) Self-efficacy was shown to have an effect on the staff's job satisfaction. Because job satisfaction is strongly linked to employee turnover (Hollenback & Williams, 1996), this is of major concern for hospital management. In a second study that emphasized user satisfaction of a CBMIS, Henry and Stone (1994) indicated that the end-user's sense of self-efficacy and outcome expectancy had a direct, meaningful, and positive impact on end-user satisfaction with the CBMIS.

Ammenwerth, Mansmann, Iller, and Eichstadter (2002) performed a quantitative 2-year study of factors that affect user acceptance of computer-based nursing documentation. They found two influencing factors; previous acceptance of the nursing process and the previous amount of self-confidence, a similar measure to self-efficacy.

Many variables have been shown to influence an individual's self-efficacy, including gender, age, educational level, computer ownership, computer experience, professional orientation, training, organizational support, management support, encouragement, and computer attitudes (Marakas, Yi, & Johnson, 1998). Ogletree and Williams (1990) found that computer ownership and level of computer usage predicted self-efficacy. In a study of college students, use of one technology increased self-efficacy in other technologies; for example, requiring the students to use e-mail to communicate with professors was found to increase self-efficacy in word processing and use of CD-ROM databases (Ertmer, Evenbeck, Cennamo, & Lehman, 1994). Based upon this research, we expect that computer usage and attitudes will have significant effects on nurses' beliefs about their ability to use the integrated clinical and administrative information system.

Finally, in a study looking at the introduction of a clinical and administrative information system, several factors were found to influence nurses' self-efficacy (Dillon, et al., 2003). Any familiarity with technology including home computers, answering machines, or VCRs was associated with higher self-efficacy. Additionally, self-assessed expertise in e-mail, Internet, or word processing was associated with nurses' having a higher self-efficacy toward the clinical information system (Dillon, et al., 2003.)

Confidentiality

There are a limited number of studies available that evaluate benefits or the impacts of the nurse's perception of confidentiality of the computerized record as compared to the traditional paper record. This is a particularly interesting finding because confidentiality has repeatedly been identified as a major concern when implementing a computerized record.

Curran and Curran (1991) explored privacy and confidentiality issues in electronic information systems. They reported that 76% of the nurses admitted that they used the computer to obtain patient information that was not in their assigned duty areas. This indicates that nurses may not be aware of the ethical issues related to accessing information without permission (Rittman & Gorman, 1992).

Brodt and Stronge's (1986) Nurses' Attitudes Toward Computers Questionnaire includes two items that possibly measure a nurses' attitude toward security. These were identified in a psychometric examination of the instrument by Stockton and Verhey (1995). They labeled the two items under "Computers and personal security," but did not identify confidentiality as a factor.

Privacy and confidentiality of health information were two issues reported in the Health Information Privacy Surveys of 1993 and 1996 conducted by Lou Harris and Associates (1993, 1996; Anderson, 2000; Goldman, 1998). The 1993 survey found that 27% of patient respondents believed that their health information had been made available to others without their consent. In addition, 24% of health care providers reported violations of patient's privacy, though no perceptions of privacy concerns were reported. The 1996 survey found that 18% of the general public felt that the use of patient records for medical research without the patients' permission was inappropriate.

Concerns have been raised about differences in perceptions of privacy of information based on cultural values (Milberg, Burke, Smith, & Kallman, 1995). In addition, concerns about security and confidentiality were summarized in the General Accounting Office's report to the Committee on Governmental Affairs, United States Senate, on automated medical records (General Accounting Office, 1991, p. 22), when the committee wrote, " (Because) Automated records . . . tend to be accessible to many users in many locations and these users could potentially search thousands of files with relative ease, problems with security and privacy are magnified."

More recently, privacy concerns by patients and health care providers have been addressed in the development of policy documents, issues concerning the Internet, and the increased use of bedside and portable technologies. Kluge (2000) established seven basic principles for the delivery of health care information. These principles include privacy, openness, accessibility, legitimacy, accountability, and security. Safran and Goldberg (2000) examined the impact of the Internet on electronic patient records emphasizing the changes in workflow and work patterns. Perception of privacy and confidentiality by health care workers were not included in either discussion. Fischer, Stewart, Mehta, Wax, and Lipinsky (2002) reviewed the literature for handheld computing devices and summarized issues, such as patient confidentiality, costs, and specialty specific uses of personal digital assistants.

Attitude

Attitude has long been used as a determinant for a user's intention to use or adopt an information system. Defined as a predisposition to respond in a consistently favorable or unfavorable manner, attitude concerns what the user knows or believes about the system, how much they like or dislike the system, and how they routinely act or behave regarding the system (Ajzen & Fishbein, 1980). Numerous studies have found a strong relationship between nurses' attitudes, efficacy, and systems use or adoption (e.g., Dillon et al., 2003; Dillon et al, 2005.)

In summary, the self-efficacy of nurses and their perceptions of data security and confidentiality are relatively unknown. Nursing research has investigated nurses' attitudes toward computers and effects on organizational procedures, but research is necessary to understand the nurse's self-efficacy, perceptions of the confidentiality of data from both paper and computerized systems, and the relationship for perceptions of confidentiality to efficacy.

METHOD

In order to explore if a nurse's perceptions of confidentiality influences self-efficacy, if nurses perceive that computerized and paper charts need the same level of confidentiality, and if the nurses' perceptions of computerized and paper charts' confidentiality differ we surveyed the nurses at a regional hospital center just prior to a system implementation. Our model was based upon Dillon, et al. (2003) which showed that self-reported computer use, self-assessed computer expertise, and nursing attitudes toward the information system predicted self-efficacy. We added three new factors to the model from McDowell, Dillon, Salimian, and Conklin (1998) for this study, including perceptions of (1) paper records confidentiality, (2) computerized records confidentiality, and (3) importance of confidentiality. Reliability and validity analysis were performed on all multi-item factors.

Setting

The survey was conducted at 350-bed regional hospital center in the south central United States just prior to the implementation of a new integrated clinical and administrative hospital-wide information system. All of the nursing staff at the hospital was aware that the information system was being installed. Within 30 days the new system would go "online" in most of the nursing units. The remaining units would "go live" in about 60 days after that. Prior to the new system implementation the only computerized nursing application was the ordering of medications from the hospital pharmacy. Nurses had no prior information systems experience. The hospital administration prepared the nursing staff by offering periodic training sessions. The nursing staff was kept abreast of the implementation timetable via the nurse managers that supervised each unit and information printed in a hospital-wide newsletter.

Data Collection Procedures

Surveys were distributed via home mail by the research team with the full support and assistance of the hospital. Institutional Review was approved by the hospital and the research team's university. All part-time (minimum of 12 hours per week) and full-time members of the hospital nursing staff (i.e., over 600 staff members) received the survey 30 days prior to the implementation of the integrated clinical and administrative hospital-wide information system. All participants received an addressed envelope that contained 1) a cover letter that solicited the respondents' cooperation and assured anonymity, 2) the survey instrument, 3) an entry form for a drawing ($100 gift certificate), and 4) a return envelope addressed to the research team. One hundred and thirty-nine surveys were returned prior to the drawing deadline, for a response rate of 23%. Ten of the 139 drawing-entries were selected randomly, the winning nurses were contacted, and prizes were delivered the following day. All hospital employees were informed of the drawing winners via the hospital newsletter. Table 1 shows the demographic characteristics of the respondents.

The Instrument

In order to better ascertain the factors that may affect the nurses' perception of confidentiality and self-efficacy, the questionnaire contained seven types of questions: perceptions of confidentiality with paper records, perceptions of confidentiality with computerized record, the importance of confidentiality, self-efficacy of the new information system, self-reported computer and electronic devices use, self-assessed computer expertise,

Table 1. Demographics of Survey Respondents

Variable		Number	Percentages
Work	Full Time	107	77.0%
	Part Time	32	23.0%
Sex	Female	132	95.0%
	Male	6	4.3%
	Unreported	1	.7%
Age	20-29	33	23.7%
	30-39	45	32.4%
	40-49	42	30.2%
	50-59	15	10.8%
	60 or over	2	1.4%

	RN Associates Degree	89	64.0%
	RN Bachelors	27	19.4%
	Masters Degree	4	2.9%

and general attitudes toward the information systems. In addition, a general comment question was provided.

MEASURES

Perceived Confidentiality

The confidentiality instrument was developed in an earlier study (McDowell et al., 1998). The current study marks the first empirical test of the instrument. The instrument began with eight forced choice items that were based on the literature review and the output from a seminar of nursing informatics graduate students. All nurses in the seminar had a wide range of experience with hospital information systems.

In the earlier study, these items were reviewed for content validity by eight nurses working in a critical care area of a regional medical center that had implemented a computer-based health care information system with a computerized patient record in the last 12 months. Nurses were asked to review item content for appropriateness in evaluating nurses' perception of confidentiality of the patient's medical record. In addition, the information systems nurse at the same medical center was asked to review the statements (McDowell et al., 1998).

Recommendations from these nine nurses were incorporated into a 10-item instrument. In each case, five identical questions were written for paper and computerized records. The questions were measured on a Likert-Scale with 1 indicating Strongly Agree and 7 indicating Strongly Disagree. We expected the questions to form three constructs, as shown in Table 2.

Reliability analysis was done with the 139 responses to see if these items associated as three separate constructs. In testing content validity with factor analysis, we found that the 10 items loaded on four factors using the principal components method with varimax rotation, as shown in Table 3. Table 4 interprets the factors and shows the Cronbach's alpha for each factor.

These factors were not exactly as expected, but were very interesting. The four items reflecting

Table 2. Confidentiality questions and expected constructs

Are Paper Records Confidential?	
If I were the patient, I would feel my traditional paper patient record was protected or secure from unauthorized use.	Papconf1
With the traditional paper patient record it is difficult for me to read information on patients that I am not currently caring for.	Papconf2
Visitors or patient's families can easily read confidential information written on various patient records (Reverse scored)	Papconf3

Are Computerized Records Confidential?	
If I were the patient, I would feel my computerized patient record was protected or secure from unauthorized use.	ISconf1
Visitors or patient's families will be able to easily view confidential information on the computer screen (Reverse scored)	ISconf2
With a computerized patient record it will be difficult for me to retrieve information on a patient that I am not currently caring for.	ISconf3

How Important is Confidentiality?	
Copies of pages from a patient's paper record are not considered confidential material.	Impconf1
Printouts of data from a computerized system that have a patient's name or number on them, but are not part of the patient record, do not need to be considered confidential information.	Impconf2
I feel it is not a breech of confidentiality if I read the chart of a patient that I am not caring for.	Impconf3
I feel it will not be a breech of confidentiality if I look up computerized data about a patient that I am not caring for.	Impconf4

need for records confidentiality did not load as a single construct. Rather, the like items loaded separately into two separate factors: Factor 1 items can be identified as "what is a breech of confidentiality?" and Factor 2 items loaded as "recognizing what was confidential?". Factor 2 also included whether it is easy for visitors to read paper confidential records, demonstrating that nurses recognize that easy-to-read records are still confidential.

Two of the three items reflecting the perception of information systems confidentiality clustered together in Factor 3. Two of the three items reflecting the perception of paper records confidentiality clustered together in Factor 4. However, Factor 4 has a very low Cronbach's alpha and should not be considered a reliable measure.

Self-Efficacy Toward the New Information System

Self-efficacy was measured using the 10 questions developed by Compeau and Higgins (1995), which are found in Table 5. A sample question was: "*I could complete the job using the <name omitted> system if there was no one around to tell me what to do as I go.*" The scale was a 10-point Likert scale ranging from 1 = Not at all Confident to 10 = Totally Confident. The self-efficacy score ranged from 1 to 100, a higher score displayed a

Table 4. Interpretation of factors

Factor	**Items**	**Cronbach's Alpha**
Factor 1: Confidentiality Breech	I feel it is not a breech of confidentiality if I read the chart of a patient that I am not caring for. I feel it will not be a breech of confidentiality if I look up computerized data about a patient that I am not caring for.	.7657
Factor 2: Recognize what is confidentiality	Copies of pages from a patient's paper record are not considered confidential material. Printouts of data from a computerized system that have a patient's name or number on them, but are not part of the patient record, do not need to be considered confidential information. Visitors or patient's families can easily read confidential information written on various patient records (Reverse scored)	.4194
Factor 3: Perceptions of computerized charts confidentiality	If I were the patient, I would feel my computerized patient record was protected or secure from unauthorized use. Visitors or patient's families will be able to easily view confidential information on the computer screen (Reverse scored)	.5564
Factor 4: Perceptions of paper charts confidentiality	If I were the patient, I would feel my traditional paper patient record was protected or secure from unauthorized use. With the traditional paper patient record it is difficult for me to read information on patients that I am not currently caring for.	.0735
Did not load on a factor	With a computerized patient record it will be difficult for me to retrieve information on a patient that I am not currently caring for.	N.A.

higher level of self-efficacy. Reliability analysis was done on the results of the survey to ensure that these items assessed a single construct. The Cronbach's alpha calculated for the 10 items was .9320, indicating excellent internal consistency. In testing content validity with factor analysis, we found that the 10 items loaded on two factors using the principal components method with varimax rotation. This indicated that the 10 items were two separate measures of self-efficacy. While most prior research reports unidimensionality of the self-efficacy construct, this finding is consistent with research such as Agarwal et al. (2000).

Self-Reported Computer and Electronic Devices Use

Two questions were asked to determine computer use. The first question requested the number of hours per week that the nurse used a home computer. The second question requested the number of years the nurse had used a computer for home or work. In addition, because self-efficacy has been related to the prior use of new technologies, information was gathered about the use of home and office electronic devices. The leading question was asked, *"Do you use any of the following at home or work?"* followed by: answering machine, cellular phone, VCR (video cassette recorder), and pager (beeper) (Settle, Dillon, & Alreck, 1999).

Self-Assessed Computer Expertise

Skill in various computer application uses was measured on a five-point Likert-scale. A sample question was "*Rate your ability to use… Word Processing*" with the available answers: beginner, novice, average, experienced, and expert. Questions were asked about computer expertise in general and word processing, Internet search, and e-mail ability.

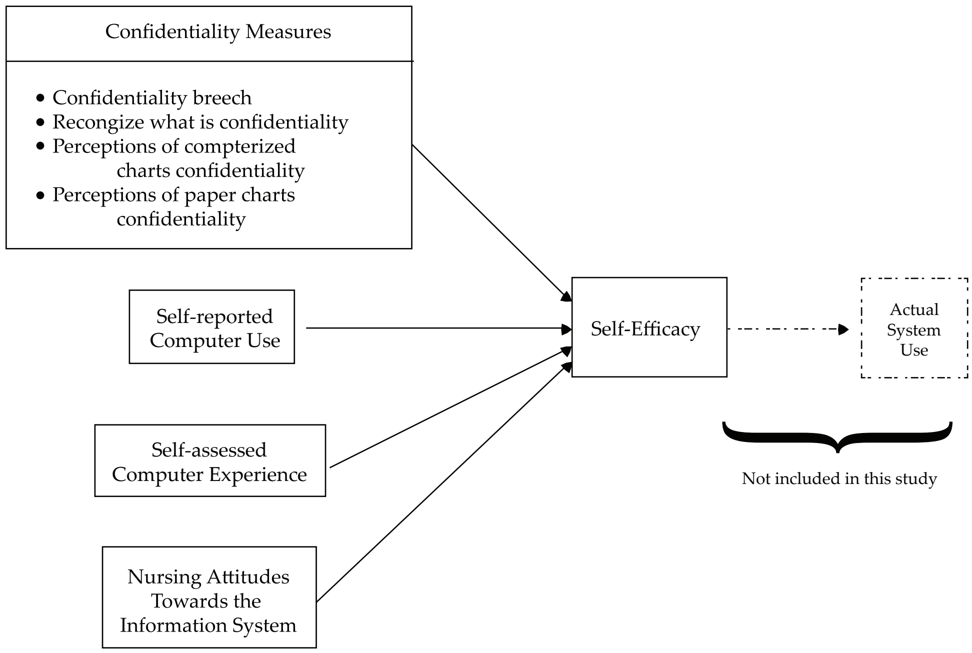
Attitudes

Attitudes toward the information systems were measured with five questions measured on a seven-point Likert scale. A sample question was: "*All things considered, using the new computerized <name omitted> patient record system is*" where 1 is Good and 7 is Bad. Reliability analysis

Table 5. Self-efficacy questions

I could complete the job using the <name omitted> system
1…if there was no one around to tell me what to do as I go
2…if I had never used a package like it before
3… if I had only the software manuals for reference
4…if I had seen someone else using it before trying it myself
5…if I could call someone for help if I got stuck
6…if someone else had helped me get started
7…if I had a lot of time to complete the job for which the software was provided
8…if I had just the built-in help facility for assistance
9…if someone showed me how to do it first
10…if I had used similar packages before this one to do the same job

Figure 1. Proposed reasearch model



was done to ensure that these items assessed a single construct. The Cronbach's alpha calculated for the five items was .9649, indicating excellent internal consistency. The five items loaded on a single factor using the principal components method with varimax rotation, supporting the unidimensionality of the attitude construct.

RESEARCH QUESTIONS AND MODEL

With the results of our reliability analysis, we slightly revised our research questions into the following questions:

- **Question 1:** Do nurses recognize what confidentiality is?
- **Question 2:** Are perceptions of computerized charts' confidentiality and paper charts' confidentiality different?
- **Question 3:** Are there differences in perceptions of breeches of confidentiality when looking at paper records or looking at computerized records for a patient the nurse is not caring for?
- **Question 4:** Is self-efficacy influenced by a nurse's perceptions of confidentiality or perceptions of the need for confidentiality? Prior research (Dillon et al., 2003) had shown that prior use of computers, computer expertise, and attitudes toward computers have a significant effect on self-efficacy. If the measures tested in research questions 1 through 3 show that perceptions of confidentiality are meaningful to nurses, can we improve the prediction of self-efficacy? In testing research question 4, we add perceptions of confidentiality to the self-efficacy model (Dillon et al., 2003) to get the model shown in Figure 1.

RESULTS

- **Question 1:** Do nurses recognize what confidentiality is?

The statements related to recognizing what confidentiality is were:

- Copies of pages from a patient's paper record are not considered confidential material
- Printout of data from a computerized system that have a patient's name or number on them, but are not part of the patient record, do not need to be considered confidential information.

Nurses strongly disagreed with both of these statements indicating that they recognize what confidential patient information is. The mean value for the first variable was a 6.56 (where 7 was highly disagree.) The mean value for the second variable was 6.12. A t-test to compare the means showed that there was a significant difference between these two means ($p < 0.001$.) This difference in means may be attributable to difference in wording between the two questions. The second question specifically indicates that the computerized information is not part of the patient record, while the first says that the paper information is part of the patient record.

- **Question 2:** Are perceptions of computerized charts' confidentiality and paper charts' confidentiality different?

Using a t-test, we compared the means of the three measures of record confidentiality. Our analysis shows that nurses consider it easier to read the records of a patient that they are not caring for if the records are on paper (a mean value of 4.75 for paper, as opposed to 3.56 for computerized records, $p < 0.001$). However, there was no significant difference in whether their perceptions of whether patients will think computerized records are more protected than paper records or whether visitors will be more able to see paper records than computer records. It may be that these second-hand perceptions are not salient to the nurses.

*Table 6. Best Model for Self-efficacy**

Model	R	R Square	Adjusted R Square	Std. Error of the Estimate
1	.644	.415	.387	13.499

Model	Sum of Squares	Df	Mean Square	F	Sign.

Answering Machine Use	7.648	3.522	2.172	.032

**dependent variable is self-efficacy*

- **Question 3:** Are there differences in perceptions of breeches of confidentiality in looking at paper records or looking at computerized records for a patient the nurse is not caring for?

Using a t-test, we compared the means of these two measures of perceptions of confidentiality breeches. There was a significant difference in these perceptions with the mean for reading paper records being 4.87 and the mean for reading computerized records 5.15 (where 7 = strongly disagree, $p < .05$.) Nurses consider that it is more of a breech of confidentiality to look at computerized patient charts than paper patient charts.

- **Question 4:** Is self-efficacy influenced by a nurse's perceptions of confidentiality or perceptions of the need for confidentiality?

We ran a multivariate analysis with self-efficacy as the dependent variable. The independent variables were the seven constructs in Figure 1: confidentiality breech, recognition of "what confidentiality is," the perception of confidentiality of paper records, the perception of confidentiality of computerized records, self-reported computer use, self-assessed computer expertise, and nursing attitudes toward the information system. Those variables that were significant in the relationship are shown in Table 6. Only one of the confidentiality factors was significant in the relationship, Factor 1, whether it was a breech of confidentiality to look at records for a patient that the nurse was not caring for. The less the nurse felt that it would be a breech of confidentiality, either on paper or from a computerized information system, the lower the nurse's self-efficacy about the new system. The adjusted R-square for this model is higher than the model without the Confidentiality factor.

While Confidentiality Factor 3, "Perceptions of computerized charts confidentiality," was not part of the best model predicting self-efficacy, a regression run between self-efficacy and Factor 3, "Perceptions of computerized charts confidentiality" was significant. Nurses that perceived computerized charts as more confidential had a higher self-efficacy than did nurses that perceived paper charts as more confidential. Table 7 shows this regression model.

DISCUSSION AND CONCLUSION

Hospitals are currently in the early stages of a move from paper to total electronic transactions and records. These new electronic information systems are closer to the patient and expand the number of clinical personnel that must interact with the new technology. By broadening the user base, there is an increasing need for an understanding of nurses' self-efficacy and perceptions of data confidentiality. The objective of this research was four fold. First, do nurses recognize what confidentiality is? Second, are perceptions of computerized charts' confidentiality and paper charts' confidentiality different? Third, are there differences in perceptions of breeches of confidentiality in looking at paper records or looking at computerized records for a patient the nurse is not caring for? And fourth, does self-efficacy influence a nurse's perceptions of confidentiality or perceptions of the need for self-efficacy?

Confidentiality Issues

Our findings contradicted those of Curran and Curran (1991) and Rittman and Gorman (1992), when we found that nurses do recognize what confidential patient information is. These findings may be the result of enhanced training programs provided by hospitals after privacy and confidentiality issues were publicized broadly by the General Accounting Office's report (1991) or the recent application of the Health Insurance Portability And Accountability Act of 1996.

*Table 7. Self-efficacy and confidentiality of computerized records**

**dependent variable is self-efficacy*

The goal of HIPAA as stated, is to "improve the portability and continuity of health insurance coverage in the group and individual markets, to combat waste, fraud, and abuse in health insurance and health care delivery, to promote the use of medical savings accounts, to improve access to long-term care services and coverage, to simplify the administration of health insurance, and for other purposes." A major function of the law is to prevent the wrongful disclosure of individually identifiable health information. Not adhering to HIPAA may result in financial penalties to the organization.

Recognition of the problems created by the accessibility of electronic patient records (Anderson, 2000; Safran & Goldberg, 2000) and changes in the laws concerning patient privacy (HIPAA, 1996) has lead to the acknowledged need and development of basic privacy and confidentiality principles (Kluge, 2000). These principles are now more fully integrated into all health care professions and organizations, enhancing the nurse's recognition of confidentiality issues (Kilbridge, 2003).

We found no significant differences in the level of confidentiality that nurses perceive in computerized and paper charts, although, nurses perceived that it was significantly easier to read the paper records of patients not in their care. We anticipated that paper-charting data would be considered more confidential because the setting of the study did not permit the nurses to use computerized data at this point in time and that the simplicity of search engines when using the Internet to retrieve general information via-keyword searches would sway respondents (Safran & Goldberg, 2000). A behavioral factor may be affecting this outcome. The computerized patient charting system is an unknown, but the nursing staff had been attending training sessions concerning the impending implementation. The realization that electronic patient records require specific identifiers, such as patient identification numbers, to access information as compared to simply reading the chart in hand may also be a factor.

Computerized charts and paper charts do need the same level of confidentiality, but the nurses surveyed in our research felt that it was more of a breech of confidentiality to access patient information from a computerized patient chart than information from a paper chart. This was in agreement with the previous findings that the nurses felt that information on paper records was easier to access (i.e., computerized patient data was more difficult to access, and thus is considered more confidential). Surprisingly, comments by those nurses that completed the survey were generally neutral when attempting to find a distinction between computerized and paper data. "Anything concerning a patient's information should be respected as confidential," was a comment made by a number of those providing comments on the survey.

Effects of Confidentiality Issues on Self-Efficacy

Previous research has identified a number of factors that affect a nurse's self-efficacy toward a computer system. For example, Dillon et al. (2003) found that familiarity with home electronic technology, such as a home computer or VCR, at least average levels of expertise with common software applications (Internet, e-mail, and word processing), and a positive attitude toward the computer system were associated with higher levels of self-efficacy. In addition, they also found that younger and better-educated nurses had a slight association to self-efficacy. A goal of this study was to extend these finding by determining if perceptions of confidentiality or perceptions of the need for confidentiality would also influence the nurse's self-efficacy of a computer system.

A nurse's perceptions of confidentiality and a nurse's perceptions of the *need* for confidentiality do influence the nurse's self-efficacy. We found that nurses that have lower self-efficacy also think that the data found in the computer is less confidential and that there is less of a *need* for computerized data to be confidential. Considering the importance of patient data confidentiality, we feel that these findings are important. Self-efficacy is a user's confidence that he or she has the ability to use an information system. Those showing a lower confidence with computerized charting are also showing a lower sense of worth for the data found in the computerized charting system. There are a number of steps that can be taken to improve the self-efficacy of the nursing staff. These include group or individualized training, availability of "practice" technology, and the accessibility of peer mentors.

In conclusion, self-efficacy refers to an individual's belief that he or she possesses the requisite skills and abilities to accomplish a given task. Self-efficacy determines the individual's level of persistence to learn a task and is influenced by the perceptions of the confidentiality for computerized patient data. Improvements of the nurses' self-efficacy toward an information system can be induced in several ways. The most obvious are to include tasks in training that foster self-confidence regarding their ability to use the system and enhance their understanding data confidentiality.

Limitations of the Study

Like any research, this study has limitations. First, the study was done at a single hospital in a single area. There may be something particular about this hospital or this area which affects the generalizability of the results. Second, the survey methodology used only allows us to find associations. We imply that confidentiality influences self-efficacy, but in actuality, we can only show that the two are associated. A time-series experiment would be needed to show causation. Finally, all measures are based upon perceptions prior to implementation of the system. We capture perceived confidentiality, attitudes, and self-efficacy after training, but prior to use. Future research could profitably study these measures after implementation.

Chapter 7.14
Standardization in Health and Medical Informatics

Josipa Kern
Andrija Stampar School of Public Health, Zagreb University Medical School, Croatia

ABSTRACT

Standard is a thing or quality or specification by which something may be tested or measured. The development of standards is organized on a global, international level, existing also on a national level, well harmonized with an international one. International developers are organizations working on this matter, like the International Organization for Standardization (ISO) or the European Committee for Standardisation (Comité Européen de Normalisation—CEN). Standards in health and medical informatics enable access to patient health records to read or to add some new data relevant to other healthcare providers taking care of a patient. Bad medical informatics can lead to patient deaths, and standardization in the field can prevent this from happening.

INTRODUCTION

When things go well, often it is because they conform to standards (International Organization for Standardization [ISO], 2005). In the Oxford Dictionary of Modern English, there is a lot of explanation of what the word standard means, but, in the context of the first sentence, the best meaning is the following: "standard is a thing or quality or specification by which something may be tested or measured." A personal computer is a standardized computer. This means that all of its components are made according to strictly defined specification. Consequently, it does not matter who produces the components or where they are produced.

Industry put in the first demand for standards. Standardization is especially important for electronics, and for ICT and its application in different areas. Nowadays, the developing of standards is organized on a global, international level, but it exists also on the national level, which is well harmonized with the international one.

Developers of standards are organizations and groups working on this matter. The leading standard developer in the world is the International Organization for Standardization. ISO is a nongovernmental organization that was established February 23, 1947. Its mission is to promote the development of standardization and related activities in the world with a view to facilitating the international exchange of goods and services, and to developing cooperation in the spheres of intellectual, scientific, technological, and economic activity (International Organization for Standardizaton, 2005). ISO collaborates with its partner in international standardization, the International Electrotechnical Commission (IEC), a nongovernmental body whose scope of activities complements ISO's. The ISO and the IEC cooperate on a joint basis with the International Telecommunication Union (ITU), part of the United Nations organization whose members are governments. The ISO standard can be recognized by the ISO logo, ISO prefix, and the designation "International Standard."

The European developer of standards is the European Committee for Standardisation (Comité Européen de Normalisation, CEN). It was founded in 1961 by the national standards bodies in the European Economic Community and EFTA countries. CEN promotes voluntary technical harmonization in Europe in conjunction with worldwide bodies and its partners in Europe, and the conformity assessment of products and their certification (Comité Européen de Normalisation, 2005). CEN cooperates with the European Committee for Electrotechnical Standardization (CENELEC) and the European Telecommunications Standards Institute (ETSI). A product of this cooperation is the European standard, which can be recognized by the prefix EN. Any added prefix to the existing one, for both the ISO and CEN standards, means that this standard is the result of cooperation with another standardization group or organization. The prefix ENV in European standardization means that this standard is not yet a full standard (it is under development by CEN).

ISO and CEN have technical committees working in specific areas. ISO/TC215, established in 1998, and CEN/TC251, established in 1991, are corresponding technical committees working on standardization in health and medical informatics. Both standardization bodies cooperate and mutually exchange their standards.

There are also a variety of other organizations and groups developing standards, either cooperating with ISO and CEN or acting as administrators and coordinators in standardization. For example, there are Health Level 7 (HL7); Digital Imaging and Communications in Medicine (DICOM); the American National Standards Institute (ANSI), a nonprofit organization that administers and coordinates the U.S. voluntary standardization and conformity assessment system, and so forth.

BACKGROUND

Definition

A standard is a set of rules and definitions that specify how to carry out a process or produce a product, or more precisely, a standard is a document established by consensus and approved by a recognized body that provides, for common and repeated use, guidelines or characteristics for activities or their results, aimed at the achievement of the optimum degree of order in a given context.

The main role of a standard is raising the levels of quality, safety, reliability, efficiency, and interchangeability, and consequently lowering costs (International Organization for Standardization, 2005).

Standard Creation Process

There are several phases in the process of standardization. The first phase of this process is characterized by demand for a standard. There must be someone who needs a standard. Most standards are prepared at the request of industry. The European Commission can also request the standards bodies to prepare standards in order to implement European legislation. This standardization is mandated by the Commission through the Standing Committee of the Directive in support of the legislation. Groups of users can also ask for a standard in the field of their interest. The second phase of standardization is the developing of standards by following specifications based on the needs defined in the first phase. Experts of a specific field work on related standards. After the standard has been approved by the standardization body, it becomes a prototype and goes through testing and evaluation. Positive test results imply the dissemination of standards, and they start to take effect. It should be highlighted that a standard is dynamic, and it changes time after time. Most standards require periodic revision. Several factors combine to render a standard out of date: technological evolution, new methods and materials, and new quality and safety requirements. To take account of these factors, the general rule has been established that all standards should be reviewed at intervals of not more than a predefined time period. On occasion, it is necessary to revise a standard earlier (Hammond & Cimino, 2001).

Standardization in Health and Medical Informatics: Why and What

Standardization has been a major factor in companies' financial and clinical success, enabling faster implementation, greater quality control, and significant cost savings (Ball, Cortes-Comerer, Costin, Hudson, & Augustine, 2004). The contribution of the standardization process in healthcare terminology initiated by CEN/TC251 and supported now by the work of CEN/TC215/WG3 to this new approach can be summarized as the practical realization of ontology (Rodrigues, Trombert Paviot, Martin, Vercherin, & Samuel, 2002). The standard CEN ENV 12924 contains a security categorization model for information systems in healthcare, distinguishing six categories plus some refinements. For each category, it specifies the required protection measures (Louwerse, 2002). Standards support interoperability and electronic-health-record (EHR) communication. They support cooperative work among health agents when it is necessary to share health-care information about patients in a meaningful way. Examples of requirements for EHR are provided in four themes: EHR functional requirements; ethical, legal, and security requirements; clinical requirements; and technical requirements. The main logical building blocks of an EHR use the terminology of CEN/TC251 ENV13606 (Lloyd & Kalra, 2003; Maldonado, Crespo, Sanchis, & Robles, 2004; Marley, 2002). Many specific medical records, like medical records of patients suffering from beta-thalassaemia, which are inevitably complex and grow in size very fast, are based also on ENV 13606 (Deftereos, Lambrinoudakis, Andriopoulos, Farmakis, & Aessopos, 2001). The wider electronic exchange of clinical information between heterogeneous information systems in the delivery of diabetes care demands a common structure in the form of a message standard and close cooperation with CEN/TC251 (Vaughan et al., 2000).

ISO 22857:2004	Health informatics—Guidelines on data protection to facilitate trans-border flows of personal health information

ISO/TS is a normative document representing technical consensus within an ISO committee.
ISO/TR is an informative document containing information of a different kind from that normally published in a normative document (Beolchi, 2003).
IEEE is the Institute of Electrical and Electronic Engineers, USA.

CURRENT STATUS OF STANDARDIZATION IN HEALTH AND MEDICAL INFORMATICS

All the standards developers work through their working technical committees in health and medical informatics and a number of working groups specialized in a specific area.

What are Specific Areas of Work and Results of the ISO/TC215?

Table 1 shows working groups acting in the ISO/TC215. Table 2 shows a list of standards given by this technical committee.

Table 3. CEN/TC251 working groups

CEN/TC251 WG 1 Communications: Information models, messaging, and smart cards
CEN/TC251 WG 2 Terminology
CEN/TC251 WG 3 Security, safety, and quality
CEN/TC251 WG 4 Technology for interoperability (devices)

Table 4. Standards in health and medical informatics given by CEN/TC251

EN 14484:2003 I	nternational transfer of personal health data covered by the EU data protection directive—High level security policy
EN 14485:2003 G	uidance for handling personal health data in international applications in the context of the EU data protection directive
EN 1828:2002 C	ategorial structure for classifications and coding systems of surgical procedures
EN ISO 18104:2003 I	ntegration of a reference terminology model for nursing (ISO 18104:2003)
EN ISO 18812:2003 C	linical analyser interfaces to laboratry information systems—Use profiles (ISO 18812:2003)
EN ISO 21549-1:2004	Patient healthcard data—Part 1: General structure (ISO 21549-1:2004)
EN ISO 21549-2:2004	Patient healthcard data—Part 2: Common objects (ISO 21549-2:2004)
EN ISO 21549-3:2004	Patient healthcard data—Part 3: Limited clinical data (ISO 21549-3:2004)
EN 12251:2004 S	ecure user identification for healthcare - Identification and authentication by passwords—Management and security
EN 12252:2004	Digital imaging—Communication, workflow and data management (which endorses all of DICOM as a European Standard)

What are Specific Areas of Work and Results of the CEN/TC251?

The work carried out by CEN/TC251 is mentioned in Table 3.

CEN/TC251 has been operating for 10 years. By October 2004, it had created 10 full standards or EN (Table 4).

FUTURE TRENDS IN STANDARDIZATION IN HEALTH AND MEDICAL INFORMATICS

There is no doubt that candidates for standardization in medical informatics will be core data sets for healthcare speciality groups, decision-support algorithms and clinical guidelines, and vocabulary. The identification of patients, content, and structure of electronic patient records, and messages being communicating in the healthcare system are also candidates for international standards. Standard formats need to be defined for special kinds of data like images, signals and waveforms, sound and voice, and video, including motion video. Data security, the security of objects and communication channels, and data archiving, especially in case of a catastrophe of any kind, should be standardized. Some of these standards exist or have been under way, but standardization is a continuous process, depending on the development of information and communication technology, and therefore all standards need to be improved and adapted to new technology coming day after day.

CONCLUSION

Standards in health and medical informatics are means to enabling better healthcare. Healthcare is supposed to be better if healthcare providers can access data in a patient's health record, and can read it or add some new data relevant for other healthcare providers taking care of the patient. Information technology used in diagnostics produces data about a patient as images, signals, or waves, as well as classic alphanumeric data. The format of such data should be standardized, usable, and readable on any instrument of the same kind wherever it is in the world. Medical language should be standardized, and coding systems should be universal. The transfer of medical data should be secure, as well as data storage and communication. Some patient data should be portable by health cards, especially for patients suffering from chronic diseases. Bad medical informatics can kill a patient, and standardization in the field can help make this not happen.

KEY TERMS

ANSI (American National Standards Institute): The private, nonprofit membership organization responsible for approving official American national standards.

CEN (Comité Européen de Normalisation, European Committee for Standardisation): The European authority for standards.

CEN/TC251: CEN technical committee for standardization in health and medical informatics.

EN: European standard made by CEN.

European Standardization: Activity of the European authority for standards.

International Standardization: Activity of the world authority for standards.

ISO (International Organization for Standardization): World authority for standards. It is also the international standard made by the organization.

ISO/TC215: ISO technical committee for standardization in health and medical informatics.

Standard: A set of rules and definitions that specify how to carry out a process or produce a product.

Standardization: Process of producing of standards.

Chapter 7.15
Biomedical Data Mining Using RBF Neural Networks

Feng Chu
Nanyang Technological University, Singapore

Lipo Wang
Nanyang Technological University, Singapore

INTRODUCTION

Accurate diagnosis of cancers is of great importance for doctors to choose a proper treatment. Furthermore, it also plays a key role in the searching for the pathology of cancers and drug discovery. Recently, this problem attracts great attention in the context of microarray technology. Here, we apply radial basis function (RBF) neural networks to this pattern recognition problem. Our experimental results in some well-known microarray data sets indicate that our method can obtain very high accuracy with a small number of genes.

BACKGROUND

Microarray is also called gene chip or DNA chip. It is a newly appeared biotechnology that allows biomedical researchers monitor thousands of genes simultaneously (Schena, Shalon, Davis, & Brown, 1995). Before the appearance of microarrays, a traditional molecular biology experiment usually works on only one gene or several genes, which makes it difficult to have a "whole picture" of an entire genome. With the help of microarrays, researchers are able to monitor, analyze and compare expression profiles of thousands of genes in one experiment.

On account of their features, microarrays have been used in various tasks such as gene discovery, disease diagnosis, and drug discovery. Since the end of the last century, cancer classification based on gene expression profiles has attracted great attention in both the biological and the engineering fields. Compared with traditional cancer diagnostic methods based mainly on the morphological appearances of tumors, the method using gene expression profiles is more objective, accurate, and reliable. More importantly, some types of cancers have subtypes with very similar appearances that are very hard to be classified by traditional methods. It has been proven that gene expression has a good capability to clarify this previously muddy problem.

Thus, to develop accurate and efficient classifiers based on gene expression becomes a problem of both theoretical and practical importance. Recent approaches on this problem include artificial neural networks (Khan *et al.*, 2001), support vector machines (Guyon, Weston, Barnhill, & Vapnik, 2002), k-nearest neighbor (Olshen & Jain, 2002), nearest shrunken centroids (Tibshirani, Hastie, Narashiman, & Chu, 2002), and so on.

A solution to this problem is to find out a group of important genes that contribute most to differentiate cancer subtypes. In the meantime, we should also provide proper algorithms that are able to make correct prediction based on the expression profiles of those genes. Such work will benefit early diagnosis of cancers. In addition, it will help doctors choose proper treatment. Furthermore, it also throws light on the relationship between the cancers and those important genes.

From the point of view of machine learning and statistical learning, cancer classification using gene expression profiles is a challenging problem. The reason lies in the following two points. First, typical gene expression data sets usually contain very few samples (from several to several tens for each type of cancers). In other words, the training data are scarce. Second, such data sets usually contain a large number of genes, for example, several thousands. That is, the data are high dimensional. Therefore, this is a special pattern recognition problem with relatively small number of patterns and very high dimensionality. To provide such a problem with a good solution, appropriate algorithms should be designed.

In fact, a number of different approaches such as k-nearest neighbor (Olshen and Jain, 2002), support vector machines (Guyon *et al.*,2002), artificial neural networks (Khan *et al.*, 2001) and some statistical methods have been applied to this problem since 1995. Among these approaches, some obtained very good results. For example, Khan *et al.* (2001) classified small round blue cell tumors (SRBCTs) with 100% accuracy by using 96 genes. Tibshirani *et al.* (2002) successfully classified SRBCTs with 100% accuracy by using only 43 genes. They also classified three different subtypes of lymphoma with 100% accuracy by using 48 genes. (Tibshirani, Hastie, Narashiman, & Chu, 2003)

However, there are still a lot of things can be done to improve present algorithms. In this work, we use and compare two gene selection schemes, i.e., principal components analysis (PCA) (Simon, 1999) and a t-test-based method (Tusher, Tibshirani, & Chu, 2001). After that, we introduce an RBF neural network (Fu & Wang, 2003) as the classification algorithm.

MAIN THRUST

After a comparative study of gene selection methods, a detailed description of the RBF neural network and some experimental results are presented in this section.

Microarray Data Sets

We analyze three well-known gene expression data sets, i.e., the SRBCT data set (Khan *et al.*, 2001), the lymphoma data set (Alizadeh *et al.*, 2000), and the leukemia data set (Golub *et al.*, 1999).

The lymphoma data set (http://llmpp.nih.gov/lymphoma) (Alizadeh *et al.*, 2000) contains 4026 "well measured" clones belonging to 62 samples. These samples belong to following types of lymphoid malignancies: diffuse large B-cell lymphoma (DLBCL, 42 samples), follicular lymphoma (FL, nine samples) and chronicle lymphocytic leukemia (CLL, 11 samples). In this data set, a small part of data is missing. A k-nearest neighbor algorithm was used to fill those missing values (Troyanskaya *et al.*, 2001).

The SRBCT data set (http://research.nhgri.nih.gov/microarray/Supplement/) (Khan *et al.*, 2001) contains the expression data of 2308 genes. There are totally 63 training samples and 25 testing samples. Five of the testing samples are not SRBCTs. The 63 training samples contain 23 Ewing family of tumors (EWS), 20 rhabdomyosarcoma (RMS), 12 neuroblastoma (NB), and eight Burkitt lymphomas (BL). And the 20 testing samples contain six EWS, five RMS, six NB, and three BL.

The leukemia data set (http://www-genome.wi.mit.edu/cgi-\\bin /cancer/publications) (Golub *et al.*, 1999) has two types of leukemia, i.e., acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL). Among these samples, 38 of them are for training; the other 34 blind samples are for testing. The entire leukemia data set contains the expression data of 7,129 genes. Different with the cDNA microarray data, the leukemia data are oligonucleotide microarray data. Because such expression data are raw data, we need to normalize them to reduce the systemic bias induced during experiments. We follow the normalization procedure used by Dudoit, Fridlyand, and Speed (2002). Three preprocessing steps were applied: (a) thresholding with floor of 100 and ceiling of 16000; (b) filtering, exclusion of genes with $max/min<5$ or $(max-min)<500$. *max* and *min* refer to the maximum and the minimum of the gene expression values, respectively; and (c) base 10 logarithmic transformation. There are 3571 genes survived after these three steps. After that, the data were standardized across experiments, i.e., minus the mean and divided by the standard deviation of each experiment.

Methods for Gene Selection

As mentioned in the former part, the gene expression data are very high-dimensional. The dimension of input patterns is determined by the number of genes used. In a typical microarray experiment, usually several thousands of genes take part in. Therefore, the dimension of patterns is several thousands. However, only a small number of the genes contribute to correct classification; some others even act as "noise". Gene selection can eliminate the influence of such "noise". Furthermore, the fewer the genes used, the lower the computational burden to the classifier. Finally, once a smaller subset of genes is identified as relevant to a particular cancer, it helps biomedical researchers focus on these genes that contribute to the development of the cancer. The process of gene selection is ranking genes' discriminative ability first and then retaining the genes with high ranks.

As a critical step for classification, gene selection has been studied intensively in recent years. There are two main approaches, one is principal component analysis (PCA) (Simon, 1999), perhaps the most widely used method; the other is a t-test-based approach which has been more and more widely accepted. In the important papers (Alizadeh *et al.*, 2000; Khan *et al.*, 2001), PCA was used. The basic idea of PCA is to find the most "informative" genes that contain most of the information in the data set. Another approach is based on t-test that is able to measure the difference between two groups. Thomas, Olsen, Tapscott, and Zhao. (2001) recommended this method. Tusher *et al.* (2001) and Pan (2002) also proposed their method based on t-test, respectively. Besides these two main methods, there are also some other methods. For example, a method called Markov blanket was proposed by Xing, Jordan, and Karp

(2001). Li, Weinberg, Darden, and Pedersen (2001) applied another method which combined genetic algorithm and K-nearest neighbor.

PCA (Simon, 1999) aims at reducing the input dimension by transforming the input space into a new space described by principal components (PCs). All the PCs are orthogonal and they are ordered according to the absolute value of their eigenvalues. The k-th PC is the vector with the k-th largest eigenvalue. By leaving out the vectors with small eigenvalues, the input space's dimension is reduced.

In fact, the PCs indicate the directions with largest variations of input vectors. Because PCA chooses vectors with largest eigenvalues, it covers directions with largest variations of vectors. In the directions determined by the vectors with small eigenvalues, the variations of vectors are very small. In a word, PCA intends to capture the most informative directions (Simon, 1999).

We tested PCA in the lymphoma data set (Alizadeh *et al*., 2000). We obtained 62 PCs from the 4026 genes in the data set by using PCA. Then, we ranked those PCs according to their eigenvalues (absolute values). Finally, we used our RBF neural network that will be introduced in the latter part to classify the lymphoma data set.

At first, we randomly divided the 62 samples into two parts, 31 samples for training and the other 31 samples for testing. We then input the 62 PCs one by one to the RBF network according to their eigenvalue ranks starting with the PC ranked one. That is, we first used only a single PC that is ranked 1 as the input to the RBF network. We trained the network with the training data and subsequently tested the network with the testing data. We repeated this process with the top two PCs, then the top three PCs, and so on. Figure 1 shows the testing error. From this result, we found that the RBF network can not reach 100% accuracy. The best testing accuracy is 93.55% that happened when 36 or 61 PCs were input to the classifier. The classification result using the t-test-based gene selection method will be shown in the next section, which is much better than PCA approach.

The t-test-based gene selection measures the difference of genes' distribution using a t-test based scoring scheme, i.e., t-score (TS). After that, only the genes with the highest TSs are to be put into our classifier. The TS of gene *i* is defined as follows (Tusher *et al*., 2001):

$$TS_i = \max\left\{ \left| \frac{\bar{x}_{ik} - \bar{x}_i}{d_k s_i} \right|, k = 1, 2, \ldots K \right\}$$

where:

$$\bar{x}_{ik} = \sum_{j \in C_k} \bar{x}_{ij} / n_k$$

$$\bar{x}_i = \sum_{j=1}^{n} x_{ij} / n$$

$$s_i^2 = \frac{1}{n-K} \sum_k \sum_{j \in C_k} \left(x_{ij} - \bar{x}_{ik} \right)^2$$

$$d_k = \sqrt{1/n_k + 1/n}$$

There are K classes. max $\{y_k, k = 1,2,..K\}$ is the maximum of all y_k, $k = 1,2,..K$. C_k refers to class k that includes n_k samples. x_{ij} is the expression value of gene i in sample j. is the mean expression value in class k for gene i. n is the total number of samples. $\bar{x}_i$ is the general mean expression value for gene i. s_i is the pooled within-class standard deviation for gene i. Actually, the t-score used here is a t-statistics between a specific class and the overall centroid of all the classes.

To compare the t-test-based method with PCA, we also applied it to the lymphoma data set with the same procedure as what we did by using PCA. This method obtained 100% accuracy with only the top six genes. The results are shown in Figure 1. This comparison indicated that the t-test-based method was much better than PCA in this problem.

An RBF Neural Network

An RBF neural network (Haykin, 1999) has three layers. The first layer is an input layer; the second

Figure 1. Classification results of using PCA and the t-test-based method as gene selection methods

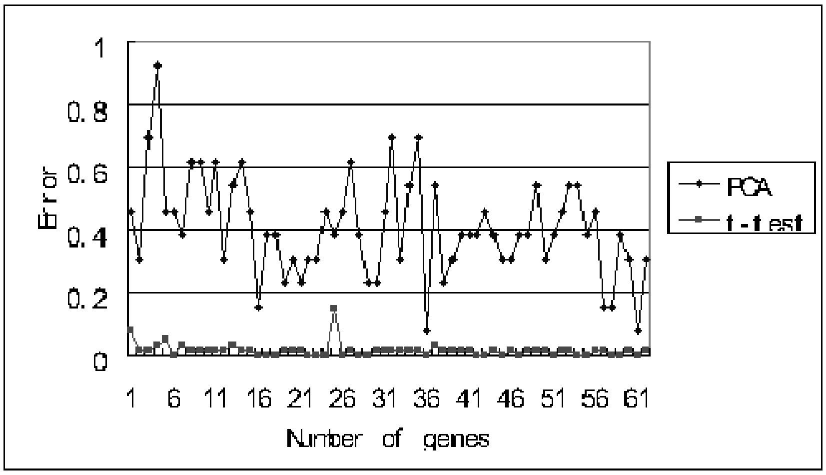

Figure 2. The testing result in the SRBCT data set

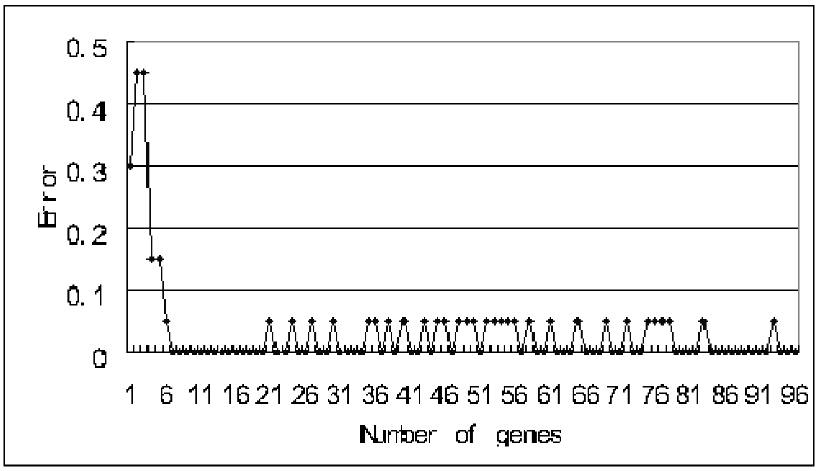


layer is a hidden layer that includes some radial basis functions, also known as hidden kernels; the third layer is an output layer. An RBF neural network can be regarded as a mapping of the input domain X onto the output domain Y. Mathematically, an RBF neural network can be described as follows:

$$y_m(x) = \sum_{i=1}^{N} w_{mi} G(\|x - t_i\|) + b_m,$$

$i=1,2,\ldots,N;\ m=1,2,\ldots M$

Here $\|\cdot\|$ stands for the Euclidean norm. M is the number of outputs. N is the number of hidden kernels. $y_m(x)$ is the output m corresponding to the input *x*. t_i is the position of kernel *i*. w_{mi} is the weight between the kernel *i* and the output *m*. b_m is the bias on the output *m*. b_m is the kernel function. Usually, an RBF neural network uses Gaussian kernel functions as follows:

$$G(\|x-t_i\|) = \exp(-\frac{\|x-t_i\|^2}{2\sigma_i^2})$$

where σ_i is the radius of the kernel *i*.

The main steps to construct an RBF neural network include: (a) determining the positions of all the kernels (t_i); (b) determining the radius of each kernel (); and (c) calculating the weights between each kernel and each output node.

In this paper, we use a novel RBF neural network proposed by Fu and Wang (Fu and Wang, 2003), which allows for large overlaps of hidden kernels belonging to the same class.

Results

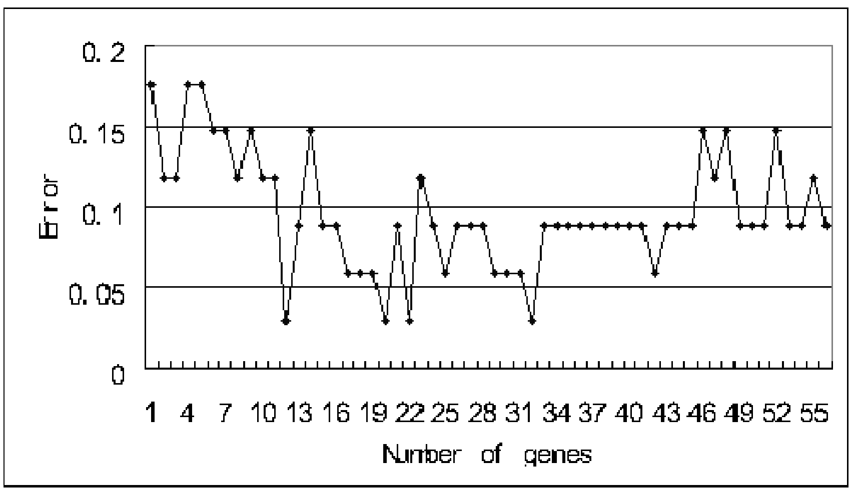
In the SRBCT data set, we first ranked the entire 2308 genes according to their TSs (Tusher *et al.*, 2001). Then we picked out 96 genes with the highest TSs. We applied our RBF neural network to classify the SRBCT data set. The SRBCT data set contains 63 samples for training and 20 blind samples for testing. We input the selected 96 genes one by one to the RBF network according to their TS ranks starting with the gene ranked one. We repeated this process with the top two genes, then the top three genes, and so on. Figure 2 shows the testing errors with respect to the number of genes. The testing error decreased to 0 when the top seven genes were input into the RBF network.

In the leukemia data set, we chose 56 genes with the highest TSs (Tusher *et al.*, 2001). We followed the same procedure as in the SRBCT data set. We did classification with 1 gene, then two genes, then three genes and so on. Our RBF neural network got an accuracy of 97.06%, i.e. one error in all 34 samples, when 12, 20, 22, 32 genes were input, respectively.

FUTURE TRENDS

Until now, the focus of work is investigating the information with statistical importance in microarray data sets. In the near future, we will try to incorporate more biological knowledge into our algorithm, especially the correlations of genes.

Figure 3. The testing result in the leukemia data set



In addition, with more and more microarray data sets produced in laboratories around the world, we will try to mine multi-data-set with our RBF neural network, i.e., we will try to process the combined data sets. Such an attempt will hopefully bring us a much broader and deeper insight into those data sets.

CONCLUSION

Through our experiments, we conclude that the t-test-based gene selection method is an appropriate feature selection/dimension reduction approach, which can find more important genes than PCA can.

The results in the SRBCT data set and the leukemia data set proved the effectiveness of our RBF neural network. In the SRBCT data set, it obtained 100% accuracy with only seven genes. In the leukemia data set, it made only one error with 12, 20, 22, and 32 genes, respectively. In view of this, we also conclude that our RBF neural network outperforms almost all the previously published methods in terms of accuracy and the number of genes required.

KEY TERMS

Feature Extraction: Feature extraction is the process to obtain a group of features with the characters we need from the original data set. It usually uses a transform (e.g. principal component analysis) to obtain a group of features at one time of computation.

Feature Selection: Feature selection is the process to select some features we need from all the original features. It usually measures the character (e.g. t-test score) of each feature first, then, chooses some features we need.

Gene Expression Profile: Through microarray chips, an image that describes to what extent genes are expressed can be obtained. It usually uses red to indicate the high expression level and uses green to indicate the low expression level. This image is also called a gene expression profile.

Microarray: A Microarray is also called a gene chip or a DNA chip. It is a newly appeared biotechnology that allows biomedical researchers monitor thousands of genes simultaneously.

Principal Components Analysis: Principal components analysis transforms one vector space into a new space described by principal components (PCs). All the PCs are orthogonal to each other and they are ordered according to the absolute value of their eigenvalues. By leaving out the vectors with small eigenvalues, the dimension of the original vector space is reduced.

Radial Basis Function (RBF) Neural Network: An RBF neural network is a kind of artificial neural network. It usually has three layers, i.e., an input layer, a hidden layer, and an output layer. The hidden layer of an RBF neural network contains some radial basis functions, such as Gaussian functions or polynomial functions, to transform input vector space into a new non-linear space. An RBF neural network has the universal approximation ability, i.e., it can approximate any function to any accuracy, as long as there are enough hidden neurons.

T-Test: T-test is a kind of statistical method that measures how large the difference is between two groups of samples.

Testing a Neural Network: To know whether a trained neural network is the mapping or the regression we need, we test this network with some data that have not been used in the training process. This procedure is called testing a neural network.

Training a Neural Network: Training a neural network means using some known data to build the structure and tune the parameters of this network. The goal of training is to make the network represent a mapping or a regression we need.

Chapter 7.16
Mining BioLiterature:
Toward Automatic Annotation of Genes and Proteins

Francisco M. Couto
Universidade de Lisboa, Portugal

Mário J. Silva
Universidade de Lisboa, Portugal

ABSTRACT

This chapter introduces the use of Text Mining in scientific literature for biological research, with a special focus on automatic gene and protein annotation. This field became recently a major topic in Bioinformatics, motivated by the opportunity brought by tapping the BioLiterature with automatic text processing software. The chapter describes the main approaches adopted and analyzes systems that have been developed for automatically annotating genes or proteins. To illustrate how text-mining tools fit in biological databases curation processes, the chapter presents a tool that assists protein annotation. Besides the promising advances of Text Mining of BioLiterature, many problems need to be addressed. This chapter presents the main open problems in using text-mining tools for automatic annotation of genes and proteins, and discusses how a more efficient integration of existing domain knowledge can improve the performance of these tools.

INTRODUCTION

Bioinformatics aims at understanding living systems using biological information. The facts discovered in biological research have been mainly published in the scientific literature (BioLiterature) since the 19th century. Extracting knowledge from such a large amount of unstructured information is a painful and hard task, even to an expert. A solution could be the creation of a database where authors would deposit all the facts published in BioLiterature in a structured form. Some generic databases, such as UniProt, collect and distribute biological information (Apweiler et al., 2004). However, different communities have different needs and views on specific topics, which change over time. As a result, researchers do not look only for the facts, but also for their evidence. Before a researcher considers a fact as relevant to his work, he checks the evidence presented by the author, because facts are normally valid only in a specific context. This explains why Molecular Biology knowledge continues to be mainly published in BioLiterature. Another solution is Text Mining, which aims at automatically extracting knowledge from natural language texts (Hearst, 1999). Text-mining systems can be used to identify the following types of information: entities, such as genes, proteins and cellular components; relationships, such as protein localization or protein interactions; and events, such as experimental methods used to discover protein interactions. Bioinformatics tools to collect more information about the concepts they analyze also use Text Mining. For example, information automatically extracted from the BioLiterature can improve gene expression clustering (Blaschke, Oliveros, & Valencia, 2004).

Text Mining of BioLiterature has been studied since the last decade (Andrade & Valencia, 1998). The interest in the topic has been steadily increasing, motivated by the vast amount of publications that curators have to read in order to update biological databases, or simply to help researchers keep up with progress in a specific area. Text Mining can minimize these problems mainly because BioLiterature articles are quite often publicly available. The most widely used BioLiterature repository is MEDLINE, which provides a vast collection of abstracts and bibliographic information. For example, in 2003, about 560,000 citations have been added to MEDLINE. Reading 10 of these documents per day, it would take around 150 years to read all the documents added in 2003. Moreover, the number of new documents added per year increased by more than 20,000 from 2000 to 2003. Hence, text-mining systems could have a great impact in minimizing this effort by automatically extracting information that can be used for multiple purposes and could not possibly be organized by other means.

This chapter starts by providing broad definitions used in Text Mining and describes the main approaches. Then, it summarizes the state-of-the-art of this field and shows how text-mining systems can be used to automatically annotate genes or proteins. Next, the chapter describes a tool designed for assisting protein annotation. Finally, the chapter discusses future and emerging trends and presents concluding remarks.

TEXT MINING

Text Mining aims at automatically extracting knowledge from unstructured text. Usually the text is organized as a collection of documents, or corpus.

TextMining = NLP + DataMining

Data Mining aims at automatically extracting knowledge from structured data. (Hand, Mannila, & Smyth, 2000). Thus, Text Mining is a special case of Data Mining, where input data is text instead of structured data. Normally, text-mining systems generate structured representations of the text, which are then analyzed by Data Mining tools. The simplest representation of a text is a vector with the number of occurrences of each word in the text (called a bag-of-words). This representation can be easily created and manipulated, but ignores all the text structure. Text-mining systems may also use Natural Language Processing (NLP) techniques to represent and process text more effectively. NLP is a broad research area that aims at analyzing spoken, handwritten, printed, and electronic text for different purposes, such as speech recognition or translation (Manning & Schütze, 1999). The most popular NLP techniques used by text-mining systems include: tokenization, morphology analysis, part-of-speech tagging, sense disambiguation, parsing, and anaphora resolution.

Tokenization aims at identifying boundaries in the text to fragment it into basic units called tokens. The first step in a text-mining system is to identify the tokens. The most commonly used token is the word. In most languages, white-space characters can be considered an accurate boundary to fragment the text into words. This problem is more complex in languages without explicitly delimiters, such as Chinese (Wu & Fung, 1994). Morphology analysis aims at grouping the words (tokens) that are variants of a common word, and therefore are normally used with a similar meaning (Spencer, 1991). This involves the study of the structure and formation of words. A common type of inflectional variants results from the tense on verbs. For example, "binding" and "binds" are inflectional variants of "bind." Some other word variants result from prefixing, suffixing, infixing, or compounding.

Part-of-speech tagging aims at labeling each word with its semantic role, such as article, noun, verb, adjective, preposition, or pronoun (Baker, 1989). This involves the study of the structure and formation of sentences. The tagging is a classification of words according to their semantic role and to their relations to each other in a sentence. Sense disambiguation selects the correct meaning of a word in a given piece of text. For example, "compound" has two different senses in the expressions "compound the ingredients" and "chemical compound." Normally, the part-of-speech tags are used as a first step in sense disambiguation (Wilks & Stevenson, 1997)

Parsing aims at identifying the syntactic structure of a sentence (Earley, 1970). The syntactic structure of a sequence of words is composed by a set of other syntactic structures related to smaller sequences, except for the part-of-speech tags that are syntactic structures directly linked to words. Normally, the syntactic structure of a sentence is represented by a syntax tree, where leafs represent the words and internal nodes the syntactic structures. Algorithms to identify the complete syntactic structure of a sentence are in general inaccurate and time-consuming, given the combinatorial explosion in long sentences. An alternative is shallow-parsing, which does not attempt to parse complex syntactic structures. Shallow-parsing only splits sentences into phrases, in other words, subsequences of words that represent a grammatical unit, such as noun phrase or verb phrase. Anaphora (or co-reference) resolution aims at determining different sequences of words referring to the same entity. For example, in the sentence "The enzyme has an intense activity, thus, this protein should be used", the noun phrases "The enzyme" and "this protein" refer to same entity.

Some of the NLP techniques described above can be implemented using algorithms also used in Data Mining. For example, part-of-speech taggers can use Hidden Markov Models (HMMs) to estimate the probability of a sequence of part of speech assignments (Smith, Rindflesch, & Wilbur, 2004). Not all NLP techniques improve the performance of a given text-mining system. As a result, designers of text-mining systems have to select which NLP techniques would be useful to achieve their ultimate goal.

After creating a structured representation of texts, text-mining systems can use the following approaches for extracting knowledge (Leake, 1996):

rule-based or case-based

The rule-based approach relies on rules inferred from patterns identified from the text by an expert. The rules represent in a structured form the knowledge acquired by experts when performing the same task. The expert analyzes a subpart of the text and identifies common patterns in which the relevant information is expressed. These patterns are then converted to rules to identify the relevant information in the rest of the text. The main bottleneck of this approach is the manual process of creating rules and patterns. Besides being time-consuming, in most cases, this manual process is unable to devise from a

Table 1. Categorization of some recent text-mining systems designed for automatic annotation of genes and proteins; for each system, the table indicates the mining approach taken, the proportion of NLP techniques used and the proportion of manual intervention needed to generate rules, patterns, or training sets

System	Mining	NLP	Manual
Andrade and Valencia (1998)	Rule-based	nil	nil
Pérez et al. (2004)	Rule-based	nil	nil
Corney et al. (2004)	Rule-based	Low	High

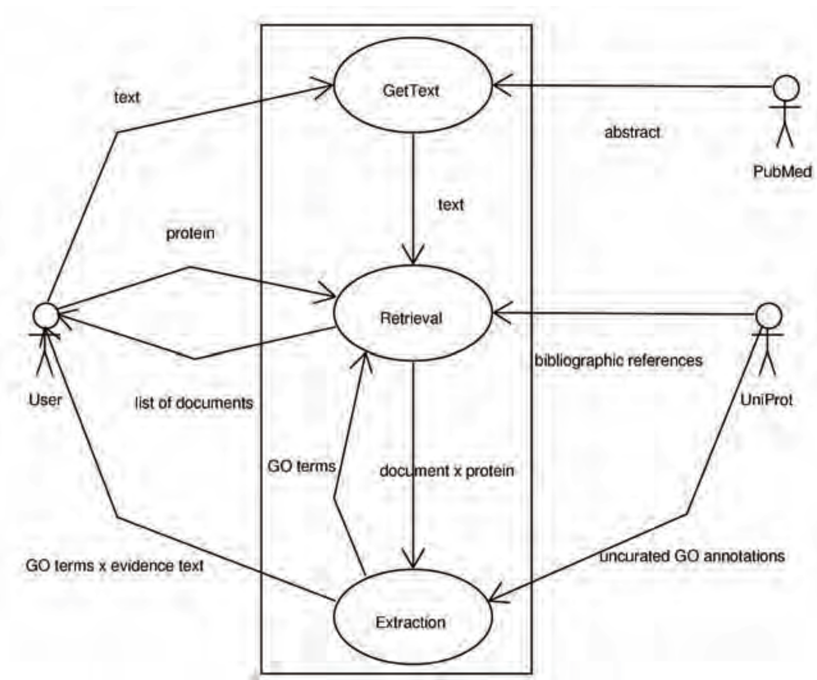
Kim and Park (2004)	Rule-based	Medium	Medium
Koike et al. (2005)	Rule-based	High	Medium
Palakal et al. (2003)	Case-based	Medium	Low
Chiang and Yu (2003)	Case-based	Medium	Low

Figure 1. UML use case diagram of GOAnnotator



subpart of the text the set of rules that encompass all possible cases.

The case-based approach relies on a predefined set of texts previously annotated by an expert, which is used to learn a model for the rest of the text. Cases contain knowledge in an unprocessed form, and they only describe the output expected by the users for a limited set of examples. The expert analyzes a subpart of the text (training set) and provides the output expected to be returned by the text-mining system for that text. The system uses the training set to create a probabilistic model that will be applied to the rest of the text. The main bottleneck of this approach is the selection and creation of a training set large enough to enable the creation of a model accurate for the rest of the text.

The manual analysis of text requires less expertise in the case-based approach than in the rule-based approach. In the rule-based approach, the expert has to identify how the relevant information is expressed in addition to the expected output. However, rule-based systems can use this expertise to achieve high precision by selecting the most reliable rules and patterns.

STATE OF THE ART

The main problem in BioLiterature mining is coping with the lack of a standard nomenclature for describing biologic concepts and entities. In BioLiterature, we can often find different terms referring to the same biological concept or entity (synonyms), or the same term meaning different biological concepts or entities (homonyms). Genes, whose name is a common English word, are frequent, which makes it difficult to recognize biological entities in the text.

Recent advances in Text Mining of BioLiterature already achieved acceptable levels of accuracy in identifying gene and protein names in the text. However, the extraction of relationships, such as functional annotations, is still far from being solved. Recent surveys report these advances by presenting text-mining tools that are not only run in different corpora but also perform different tasks (Hirschman, Park, Tsujii, Wong, & Wu, 2002; Blaschke, Hirschman, & Valencia 2002; Dickman, 2003; Shatkay & Feldman, 2003).

On the other hand, recent challenging evaluations compared the performance of different approaches in solving the same tasks using the same corpus. For example, the 2002 KDD Cup (bio-text task) consisted on identifying which biomedical articles contained relevant experimental results about Drosophila (fruit fly), and the genes (transcripts and proteins) involved (Yeh, Hirschman, & Morgan, 2003). The best submission out of 32 obtained 78% F-measure in the article decision, and 67% F-measure in the gene decision.

A similar challenging evaluation was the 2004 TREC genomics track, which consisted on identifying relevant documents and documents with relevant experimental results about the mouse (Hersh et al., 2004). The first task was a typical Information Retrieval task. A list of documents and a list of topics were given as input. The goal was to identify the relevant documents for each topic. The best submission out of 47 obtained 41% precision. The second subtask comprised the selection of documents with relevant experimental information. The best submission out of 59 obtained 27% F-measure. In addition to document selection, the task also comprised automatic annotations of genes. The best submission out of 36 obtained 56% F-measure.

Another challenging evaluation was BioCreAtIvE (Hirschman, Yeh, Blaschke, & Valencia, 2005). This evaluation comprised two tasks. The first aimed at identifying genes and proteins in BioLiterature. The best submission out of 40 obtained 83% F-measure. The second task addressed the automatic annotation of human proteins, and involved two subtasks. The first subtask required the identification of the texts that provided the evidence for extracting each annotation. From 21 submissions, the highest precision was 78% and

Figure 2. A list of documents related to the protein "Ras GTPase-activating protein 4" provided by the GOAnnotator. The list is sorted by the similarity of the most similar term extracted from each document. The curator can invoke the links in the "Extract" column to see the extracted terms together with the evidence text. By default, GOAnnotator uses only the abstracts of scientific documents, but the curator can replace or add text (links in the "AddText" column).

the highest recall was 23%. The second subtask consisted on automatic annotation of proteins. From 18 submissions, the highest precision was 34% and the highest recall was 12%.

AUTOMATIC ANNOTATION

One of the most important applications of text-mining systems is the automatic annotation of genes and proteins. A gene or protein annotation consists of a pair composed by the gene or protein and a description of its biological role. Normally, descriptions use terms from a common ontology. The Gene Ontology (GO-Consortium, 2004) provides a structured controlled vocabulary that can be applied to different species (GO-Consortium, 2004). GO has three different aspects: molecular function, biological process, and cellular component. To comprehend a gene or protein activity is also important to know the biological entities that interact with it. Thus, the annotation of a gene or protein also involves identifying interacting chemical substances, drugs, genes and proteins.

Text-mining systems that automatically annotate genes or proteins can be categorized according to: the mining approach taken (rule-based or case- based), the NLP techniques applied, and the amount of manual intervention required.

Rule-Based Systems

AbXtract was one of the first text-mining systems attempting to characterize the function of genes and proteins based on information automatically extracted from BioLiterature (Andrade & Valencia, 1998). The system assigns relevant keywords to protein families based on a rule comprising the frequency of the keywords in the abstracts related to the family. In addition to using a rule-based approach, AbXtract relies in only one rule that does not require human intervention. A similar approach is taken by the system proposed by Pérez, Perez-Iratxeta, Bork, Thode, and Andrade (2004), which annotates genes with keywords extracted from abstracts based on mappings between different ontologies.

An example of a system based on a large number of rules is BioRAT (Corney, Buxton, Langdon, & Jones, 2004). Given a query, BioRAT finds documents and highlights the most relevant facts in their abstracts or full texts. However, the rules are exclusively derived from patterns inserted by the user. Textpresso is another rule-based system that finds documents and marks them up with terms from a built-in ontology (Müller, Kenny, & Sternberg, 2004). The system assigns to each entry of the ontology regular expressions that capture how the entry can be expressed in BioLiterature. Textpresso is not so dependent on the user as BioRAT, since many of the regular expressions are automatically generated to account for regular forms of verbs and nouns.

BioIE is a system that takes more advantage of NLP techniques. It extracts biological interactions from BioLiterature and annotates them with GO terms (Kim & Park, 2004). The system uses morphology, sense disambiguation, and rules with syntactic dependencies to identify GO terms in the text. BioIE uses 1,312 patterns to match interactions in the sentences, so it also requires substantial manual intervention. Koike, Niwa, and Takagi (2005) propose a similar system that annotates gene, protein, and families with GO terms extracted from texts. The system uses morphology, part-of-speech tagging, shallow parsing, and simple anaphora resolution. To extract the relationships, it uses both automatically generated and manually inserted rules.

Case-Based Systems

A text-mining system using the case-based approach was proposed by Palakal, Stephens, Mukhopadhyay, and Raje (2003). The system extracts relationships between biological objects (e.g. protein, gene, cell cycle). The system uses sense disambiguation, and a probabilistic model to find directional relationships. The model is trained using examples of sentences expressing a relationship.

MeKE is another system that extracts protein functions from BioLiterature using sentence alignment (Chiang & Yu, 2003). MeKE also uses sense disambiguation. The system uses a statistical classifier that identifies common patterns in examples of sentences expressing GO annotations. The classifier uses these patterns to decide if a given sentence expresses a GO annotation.

Discussion

The systems described above show how Text Mining can help curators in the annotation process. Most rely on domain knowledge manually inserted by curators (see Table 1). Domain knowledge improves precision, but it cannot be easily extended to work on other domains and demands an extra effort to keep the knowledge updated as BioLiterature evolves. This approach is time-consuming and makes the systems too specific to be extended to new domains. Thus, an approach to avoid this process is much needed.

GOAnnotator

This section illustrates how text-mining can be integrated in a biological database curation process, by describing GOAnnotator, a tool for assisting the GO annotation of UniProt entries (Rebholz-Schuhmann, Kirsch, & Couto, 2005). GOAnnotator links the GO terms present in the uncurated annotations with evidence text automatically extracted from the documents linked to UniProt entries.

Figure 1 presents the data flow involved in the processing steps of GOAnnotator and in its interaction with the users and external sources. Initially, the curator provides a UniProt accession number to GOAnnotator. GOAnnotator follows the bibliographic links found in the UniProt database and retrieves the documents. Additional documents are retrieved from the GeneRIF database (Mitchell et al., 2003). Curators can also provide any other text for mining. GOAnnotator then extracts from the documents GO terms similar to the GO terms present in the uncurated annotations.

In GOAnnotator the extraction of GO terms is performed by FiGO, a tool that receives text and returns the GO terms detected (Couto, Silva, & Coutinho, 2005). FiGO is rule-based, does not use any NLP technique and does not require manual intervention. FiGO assigns a confidence value to each GO term that represents the terms' likelihood of being mentioned in the text. The confidence value is the product of two parameters. The first, called local evidence context (LEC), is used to measure the likelihood that words in the text are part of a given GO term. The second parameter is the inverse of their frequency in GO. GO terms are similar if they are in the same lineage or if they share a common parent in the GO hierarchy. FiGO uses the semantic similarity measure of (Lin, 1998) to compute the degree of similarity between two GO terms.

GOAnnotator ranks the documents based on the extracted GO terms from the text and their similarity to the GO terms present in the uncurated annotations (see Figure 2). Any extracted GO term is an indication for the topic of the document, which is also taken from the UniProt entry.

GOAnnotator displays a table for each uncurated annotation with the GO terms that were extracted from a document and found similar to the GO term present in the uncurated annotation (see Figure 3). The sentences from which the GO terms were extracted are also displayed. Words that have contributed to the extraction of the GO terms are highlighted. GOAnnotator gives the curators the opportunity to manipulate the confidence and similarity thresholds to modify the number of predictions.

FUTURE TRENDS

The performance of text-mining tools that automatically annotate genes or proteins is still not acceptable by curators. Gene or protein annotation is more subjective and requires more expertise than simply finding relevant documents and recognizing biological entities in texts. Moreover, an annotation tool can only perform well when it is using the correct documents and the correct entities. Errors in the retrieval of documents or in the recognition of entities will be the cause of errors in the annotation task.

Existing tools that retrieve relevant documents do not always provide what the curators want. On the contrary, curators spend a large amount of their time finding the right documents. This is probably the main reason why many curators are still not using text-mining tools for gene or protein annotation. Another reason is that quite often the full texts are not electronically available. Curators need additional information that is not usually present in the abstracts, such as the type of experiments applied and the species from which proteins originate. Finally, another reason is that most text-mining tools depend on domain knowledge manually inserted by curators, which is also very time-consuming.

Text-mining tools acquire domain knowledge from the curators in the form of rules or cases. The identification of rules requires more effort to the curators than the evaluation of a limited set of cases. However, a single rule can express knowledge not contained in a large set of cases. Neither source of knowledge subsumes the other: the knowledge represented by a rule is normally not well-represented by any set of cases, and it is difficult to identify a set of rules representing all knowledge expressed by a set of cases.

Couto, Martins, and Silva (2004) proposed an approach to obtain the domain knowledge that does not require human intervention. Instead of obtaining the domain knowledge from curators, they propose acquiring it from publicly available databases that already contain curated data. Text-mining systems could consider these databases as training sets from which rules, patterns, or models can be automatically generated. Besides avoiding direct human intervention, these automated training sets are usually much larger than individually generated training sets. Another advantage is that the tools' training data does not become outdated as public databases can be tracked for updates as they evolve.

SUMMARY

Bioinformatics aims at understanding living systems by inferring knowledge from biological information, such as DNA and protein sequences. The role of Text Mining in Bioinformatics is to automatically extract knowledge from BioLiterature. This field is new and has evolved over the last decade, motivated by the opportunity brought by tapping the large amount of information that has been published in BioLiterature with automatic text processing software.

Researchers will tend to use databases to store and find facts, but the evidence substantiating them will continue to be described as unstructured text. As a result, text-mining tools will continue to have an important role in Bioinformatics. Recent advances in Text Mining of BioLiterature are already promising, but many problems remain. In our opinion, the future of text-mining tools for gene or protein annotation will mainly depend on a better use of NLP techniques, and in an efficient integration of existing domain knowledge available in biological databases and ontologies.

ABSTRACT

Approximately 57 different types of clinical annotations construct a patient's medical record. These annotations include radiology reports, discharge summaries, and surgical and nursing notes. Hospitals typically produce millions of text-based medical records over the course of a year. These records are essential for the delivery of care, but many are underutilized or not utilized at all for clinical research. The textual data found in these annotations is a rich source of insights into aspects of clinical care and the clinical delivery system. Recent regulatory actions, however, require that, in many cases, data not obtained through informed consent or data not related to the delivery of care must be made anonymous (as referred to by regulators as harmless), before they can be used. This article describes a practical approach with which Cincinnati Children's Hospital Medical Center (CCHMC), a large pediatric academic medical center with more than 761,000 annual patient encounters, developed open source software for making pediatric clinical text harmless without losing its rich meaning. Development of the software dealt with many of the issues that often arise in natural language processing, such as data collection, disambiguation, and data scrubbing.

INTRODUCTION

Hospitals typically produce millions of text-based medical records over the course of a year. These records are essential for the delivery of care but underutilized or not utilized at all for clinical research. Digitized clinical data are a rich lode of possibilities for advances in biomedical research, because, in aggregate, they contain information about the variation in the delivery and quality of care.

Inherent in such research, however, is the use of data without the patient's consent. Recognizing this problem, the United States Department of Health and Human Services (HHS) has issued rules defining Protected Health Information (PHI) as part of the Health Insurance Portability and Accountability Act of 1996 (HIPAA) (Annas, 2002). In order for researchers to access such data, either they must have the patient's consent, or, as in most retrospective cases, the data must be made harmless, and the governing board must provide a waiver.

The HHS provides guidance for making health-care data harmless (HIPAA Standards for Privacy of Individually Identifiable Health Information: An Introduction to the Consent Debate, 2002). Data can be made harmless through three steps: (1) deidentification (i.e., the removal or modification of data fields that could identify a patient, such as name and social security number); (2) rendering the data ambiguous by ensuring that every data record in a public data set has a non-unique set of characterizing data (Berman, 2002a; Bouzelat, Quantin, & Dusserre, 1996; Quantin et al., 1998); and (3) data scrubbing (i.e., the removal or transformation of those tokens in text that can be used to identify persons or that contain information that is incriminating or otherwise private) (Berman, 2003; Sweeney, 1996). Although each of these methods has the potential to render the medical record harmless for its use by natural language processing investigators, attempts to design a fully anonymous system continue.

This article describes how Cincinnati Children's Hospital Medical Center (CCHMC), a large pediatric academic medical center with more than 761,000 pediatric patient encounters per year, has taken a practical approach to this challenge by developing, evaluating, and implementing the Encryption Broker (EB) software. The EB has a number of uses. First, it is essential for the ongoing development of a large pediatric corpus for pediatric natural language processing research and decision support (Pestian, Itert, & Duch, 2004). This corpus serves as an artificial intelligence training set for classifying text into the appropriate clinical domain, such as rheumatology or neonatology. Without the EB, these data could not be retrieved from the electronic portion of the medical records. Second, the EB ensures that research-needing text conforms to federal regulations. It does so through data disambiguation algorithms, deidentification, and data scrubbing.

The EB has another role. A key strategy of the organization is personalized medicine research that requires genomic and clinical delivery data to predict or prevent disease or to personalize treatment. This research requires substantial amounts of knowledge to be gleaned automatically from these data in real time. To do so, machine-learning systems that conceptually map the data into some ontology are required. The EB provides natural language scientists with large repositories of harmless clinical text for developing these systems.

The EB is recognized by CCHMC's Risk Management group as a tool to gather clinical text without violating HIPAA regulations. This approval is institution-specific; each institution using the EB is responsible for seeking its own internal certification. The EB essentially acts as a broker for investigators who wish to do retrospective analysis of clinical text and potentially makes it easier to receive approval for these purposes. CCHMC makes the EB software, the associated decision rules, and the related data files fully available for academic purposes by e-mailing joan.taylor@cchmc.org. The remaining sections of this article discuss methods and challenges for making these data harmless, CCHMC's approach, and the evaluation of this methodology.

LITERATURE REVIEW

It is beyond the scope of this article to describe fully the rich history of research in the areas of natural language processing; this review highlights those areas that have contributed to developing the conceptual approach underpinning the research presented: word sense disambiguation and data scrubbing.

WORD SENSE DISAMBIGUATION

Examining tokens in their context and determining exactly what sense is being used is the task of Word Sense Disambiguation (WSD). WSD is a difficult task and, as such, receives considerable theoretical and practical attention. To disambiguate (i.e., OR to operating room) requires an understanding of the surrounding tokens. In other words, "You shall know a word by the company it keeps" (Firth, 1957). There are two ways to do this. One is a supervised approach that integrates rule-based information into the semantic analysis. The other is an unsupervised stand-alone approach, where sense disambiguation is performed independent of and prior to compositional semantic analysis.

For this research, integrated rule-to-rule approach was used, because raw clinical notations are heavily packed with jargon, and unsupervised methods are traditionally used with well-formed text. Ng and Zelle (1997) note:

For each token to be disambiguated, the appropriate inference knowledge must be handcrafted. It is difficult to come up with a comprehensive set of the necessary disambiguation knowledge. Also, as the amount of disambiguation knowledge grows, manual maintenance and further expansion become increasingly complex. Thus, it is difficult to scale up manual knowledge acquisition to achieve wide coverage for real-world sentences.

This summary points out the limitations and provides future research guidance. That is, since rule-to-rule WSD requires substantial effort at some point, it will be necessary to integrate this work into a stand-alone unsupervised machine learning system.

Determining the optimal window size for token analysis is another important task. The linguistic tools used for WSD can be divided into two general classes: collocation and co-occurrence. Co-location, a quantifiable position-specific relationship between two lexical items, encodes local

Figure 1. Trigram analysis neighborhood

Analysis Neighborhood

Notation	B_{T3} B	$_{T2}$ B	$_{T1}$	τ	A_{T1} A	$_{T2}$ A	$_{T3}$
Example	John	was	born	FT	with	no	complications

Before	After
Fred Thompson* is an 8 y/o AAM with a hx of asthma. He presented in the ED with a laceration on his R radius approx 3 in. long.	John Johnson is an eight-year-old African American male with a history of asthma. He presented in the emergency department with a laceration on his right radius approximately 3 inches long.

** Fred Thompson is not the patient's name.*

lexical and grammatical information that often can accurately isolate a given sense (Jurafsky & Martin, 2000). In collocation, the assumption is that some tokens often are found together (e.g., emergency room or breast milk).

Co-occurrence data focus on the frequency of the same token within a particular range of tokens while ignoring its position. For example, "John's parents were in the *emergency room* while the *emergency room* physician treated John." Co-occurrence focuses on the fact that *emergency room* occurred twice. Collocation focuses on the fact that *emergency* is located next to *room*.

These tools enable selection of specific domain tokens from a larger generalized corpus (Jurafsky & Martin, 2000). This study formally uses local collocations to disambiguate terms. In particular, +/- three tokens around the target token (**t**) were analyzed. This window of tokens is referred to as a trigram. This strategy was based on previous research that notes:

[L]ocal co-location provides the most important source of disambiguation knowledge, although the accuracy of disambiguation achieved by the combined knowledge sources exceeds that obtained by using any one of the knowledge sources alone. That local collocation is the most predictive seems to agree with past observation that humans need a narrow window of only a few tokens to perform WSD. (Ng & Zelle, 1997)

DATA SCRUBBING

The literature describes many forms of data scrubbing. Scientists use data-scrubbing methods to de-identify pathology data (Berman, 2003), threshold cryptographic protocols (Berman, 2002b), automate record hash coding and linkages for epidemiological follow-up data confidentiality (Quantin et al., 1998), object-oriented software components (Herting & Barnes, 1998), cryptographic framework for document objects resulting from multiparty collaborative transactions (Goh, 2000), use personal identifiers while retaining confidentiality in child abuse cases (Kruse, Ewigman, & Tremblay, 2001), and describe data hiding techniques (Chao, Hsu, & Miaou, 2002).

Although research in the area of deidentification has been active over the last few years, scholars are still undecided as to whether it is possible to fully de-identify data. For example, Sweeney and Dreiseitl conclude that most data can be reidentified by linking or matching the data to other databases or by looking at unique characteristics found in the fields and records of the database itself (Dreiseitl, Vinterbo, & Ohno-Machado, 2001; Sweeney, 1997a). Sweeny, after reviewing a number of data-scrubbing systems, concludes that removing all explicit identifiers from medical data does not guarantee anonymity; rather, complementary policies will be necessary (Sweeney, 1997b). Others, however, regard those processes as too onerous to yield any practical consideration (Fisher, Baron, DJ, Barett, & Bubolz, 1990). Until the optimal set of strategies is found, each institution must address problems with deidentification as it finds best.

METHODS

A patient's medical record is comprised of approximately 57 different types of documents (Zweigenbaum, Jacquemart, Grabar, & Habert, 2001). These documents contain both structured data (e.g., computerized order entry data) and unstructured data (e.g., clinical dictations). Some data are confidential; others are a matter of public record. Computerized or handwritten notes include birth and death records, discharge summaries, imaging reports, short problem descriptions, and letters (Friedman, 1997; Grefenstette, 1994; Sager, Friedman & Lyman, 1987; Zweigenbaum & Menelas, 1994). The content of these documents has a great deal of variation not only between the documents but also within the documents

themselves (Biber & Finegan, 1994). This study concentrates on unstructured clinical text found in discharge summaries, radiology reports, surgical reports, and pathology reports.

The minimum regulatory standards for making PHI harmless require removal of up to 16 specific pieces of information (Madsen, Masys, & Miller, 2003). In the case of unstructured text, simply removing or encrypting these identifiers will disrupt the ability to understand the PHI and its meaning, thus rendering it useless for natural language processing research.

The remaining sections of this article outline the methods for collecting data, development of rules, three stages of software development, and the evaluation of the software.

DATA COLLECTION

From 2000 to 2002, CCHMC's division of Biomedical Informatics developed the Discovery System (DS), a centralized research repository (Pestian, Aronow, & Davis, 2002). The DS is populated regularly with new and updated clinical, research, and administrative data generated by the medical center. Substantial amounts of these clinical data are text from such specialties as pathology and radiology and from discharge summaries and surgical notes. The DS combined with other data are used for studying genotypic prediction of pharmacological responses and microarray expression of newborn hearing testing, sepsis onset in intensive care patients, the onset and severity of juvenile rheumatoid arthritis,

Table 3. Descriptive statistics

Description	Total
Total tokens in data set	19,924,949
Total sentences in data set	1,263,271
Average tokens/sentence (standard deviation)	15.33 (9.93)

Correct number of non-changes (% of Total Tokens)	132,670 (98.93)
Incorrect number of non-changes (% of Total Tokens)	770 (0.58)

quality assurance, financial reporting, and other activities.

Access to the data for research is governed by HIPAA regulations and controlled by the organization's Institutional Review Board (IRB). Prospective studies receive approval before the study begins. Access to retrospective data also must receive approval from the IRB. Requests for text that are not part of a formal research study sanctioned by the IRB can only be approved only after the data have been made harmless by using the EB or some other method.

DATA CLEANSING METHOD

The data-cleansing algorithm relies on two steps in order to render the unstructured clinical text harmless and preprocess it for use. The first step is to disambiguate the unstructured clinical text that is dense with jargon and acronyms. The second step is data scrubbing or deidentification. Each of these steps is described in subsequent paragraphs.

WORD SENSE DISAMBIGUATION

"All grammars leak" (Sapir, 1921). This is because people are always stretching and bending the rules to meet their communicative needs (Manning & Schutze, 1999). It should be no surprise that extensive jargon and acronyms have leaked into clinical text. The language of clinicians, though fundamental to patient care, lacks the structure and clarity necessary for natural language analysis. For example, in a clinical text, the token FT can be an abbreviation for *full-term*, *fort* (as in Fort Sumter), *feet or foot*, *field test*, *full-time*, or *family therapy*. Until these text data are disambiguated, there is no certainty that data scrubbing is accurate.

To resolve the ambiguities found in the text, a series of clinical disambiguation rules were made. The first step for developing these rules was to create a reference dataset that contained known ambiguous terms, clinical acronyms, and abbreviations. After developing a dataset of known acronyms and abbreviations, clinical experts reviewed the text for ambiguous terms. Ambiguous terms were added to the dataset. This review was done three times until the experts believed that most ambiguous terms were included in the dataset.

This reference dataset was then used to create a dataset of trigrams. Software was developed to extract from the all the data the trigrams for each ambiguous term. Clinical experts then reviewed these trigrams to create the disambiguation rules. Figure 1 presents a schematic of this approach. In the figure, one term, *FT,* is being evaluated by looking at the three tokens before *FT* and the three tokens after *FT.* The experts then reviewed all the trigrams and developed the disambiguation rules, using a majority/minority approach. That is, all instances of a specific term (i.e., *FT*) remain as a specific term (i.e., *FT*), unless an evaluation parameter is met. For example, one rule is *If FT* is proceeded by *born*; then FT = *Full-Term*. When developing rules, the use of expert(s) with subject matter knowledge substantially decreases the likelihood of disambiguation error. For example, based on the trigram in Figure 1, one may develop the rule: *if FT* is followed by *with*; then FT = *Full-Term*. Keeping in mind that FT can be an acronym for, say, *family therapy* or *foot*, this rule would be incorrect. Examples such as *patient attended family therapy with Dr. Johnson* or *laceration on right foot with decrease pedal pulses* would also meet the described conditions, thus voiding the rule.

DATA SCRUBBING

Once the data were disambiguated, they were reviewed for the presence of any of the 16 possible Protected Health Information (PHI) data elements. Limited PHI was found in the unstructured text fields. What were found were the patient and physician names and, rarely, a date of service; all other PHI was located in other structured database fields and could be eliminated by excluding those fields from the original query. Next, systematic bias was introduction into the data as a method of encryption; all female names were changed to *Jane*, all male names were changed to *John*, and all surnames were changed to *Johnson*. Table 1 provides an example of how the input data were changed.

TOKEN EVALUATION

The token evaluation criteria are based on the n-gram approach where n = the number of tokens to be evaluated before and after the token under consideration. The default value is NGRAM = 3, or a trigram. Thus,

τ;||| ||||;δ

is the syntax to evaluate a particular token, where τ represents the token under consideration, and δ represents its replacement. In this case, because NGRAM = 3, the series of pipes (|) symbolize the trigram of three tokens preceding and the three tokens following τ; seven pipes yield six points to evaluate τ. Bigrams would have five pipes, and so forth. In this case, the positions are |1|2|3|4|5|6|.

Numbers 1, 2, and 3 are positions of tokens preceding τ; numbers 4, 5, and 6 are positions of tokens that occur after the τ. Consider the following sentence.

The patient stayed in OR for one hour.

Each token is assigned a position:

Patient/1/ stayed/2/ in/3/ for/4/ one/5/ hour/6/

τ = *OR* it is excluded from the position assignment.

Next is the syntax for the rule to evaluate the abbreviation *OR* based on its collocation to *IN* using one of the more than 40 predefined conditions and placed at the NGRAM position. Detailed software documentation is included.

or;|||CONDITION(in)|||;operating room

If the condition is fulfilled, then the abbreviation *OR* will be replaced with *operating room* in text. If the condition is not fulfilled, then the next condition is considered. This occurs until the last condition is evaluated via an exit criterion.

A typical rule for the mentioned example could look like this:

or;|||IS(in)|||;operating room
or;||||IS(for)||;operating room
or;||||FINAL()|||;or

The first condition evaluates if the token *in* is before *operating room*. If this condition is not satisfied, the second condition is analyzed. If *OR* is followed by *for*, then *OR* is replaced with *operating room*, but if this is not true, the last condition says that the token should remain as *OR*. There are more than 40 predefined conditions (e.g., IS, PRE_NUM, POST_NUM) that can be used for testing. By default, all abbreviations are converted to lower case. Table 2 shows the pseudo code and the corresponding syntax.

EVALUATION

Evaluation of the EB consisted of randomly selecting encrypted sentences and pairing them with the original sentences. Clinical experts then reviewed these data and classified each token into one of four categories: a correct replacement, an incorrect replacement, a correct miss, and an incorrect miss. Proportions were then computed.

RESULTS

Processing scripts were written in Perl 5.0. Processing took place on a Sun Microsystems E6500, using 12 900-Mhz processors with 24 GB RAM.

DATA COLLECTION

All 2002 clinical texts were extracted from the DS. Table 3 provides the descriptive statistics for these data.

DISAMBIGUATION

Tokens of 915 candidate-ambiguous terms included all approved hospital acronyms, unapproved acronyms, and terms that were found. Clinical experts reviewed 715,518 trigrams that included these ambiguous terms. From this review 1,146 distinct rules for resolving ambiguity of the tokens were developed. Each rule was based on reviewing an average of 781 trigrams for a particular ambiguous token. These rules were then added to the EB's rules file to enable ambiguity resolution during data parsing.

DATA SCRUBBING

A review of the text fields found that the PHI present in the text clinical annotations was the patient's name, physician's name, and various dates. This finding made the algorithm for data scrubbing rather straightforward; by the introduction of systematic bias, data could be changed without compromising their meanings. The software's algorithm changed all male names to John, all female names to Jane, all surnames to Johnson, and all dates to 01/01/2005. This version of the software does not deal with neutral names (e.g., Pat). Future versions will.

EVALUATION RESULTS

The EB was evaluated by randomly selecting 348 records (a 0.05, 95% CI) from the original data and pairing these data with the corresponding data output from the EB. Table 4 shows the results of this comparison. A total of 10,240 (paired) sentences were reviewed by clinical experts. Ninety-eight percent of the time, the EB correctly changed a token; equally important, 99% of the time, when a token should not be changed, it was not. Of those tokens that were incorrectly changed (0.58%), a clear pattern emerged. The majority of these errors were related to ambiguous names. For example, the token *may* can mean the given name *May*, the month of *May*, or the command that *he may play sports in two weeks*. Errors in the output were found when any of the supporting files were not kept current.

SUMMARY

Protecting health information always has been a responsibility of healthcare organizations. Now that HIPAA regulations require additional levels of accountability, healthcare organizations must be creative when rendering such data harmless for research purposes. This approach shows that this is possible, but it has taken considerable effort, expense, and resources to develop and to evaluate the appropriate software. For example, to develop the first set of rules, the process includes collecting data, manually reviewing more than 700,000 trigrams to develop more than 1,000 disambiguation rules.

An important next step will be to determine the possibility of migrating from a hand-crafted rules approach to rules that are made based on supervised or unsupervised machine learning algorithms. A recent paper by Liu et al. (2004) best describes this discussion: “Supervised WSD is suitable only when we have enough sense-tagged instances with at least a few dozens of instances for each sense." Here, sense-tagged refers to ambiguous tokens that have been clarified via various methods like collocation or co-occurrence. "The combination of collocations and neighboring tokens are appropriate selections for the context. For terms with biomedical unrelated senses, a large window size such as the whole paragraph should be used, while for general English words a moderate window size between four and ten should be used" (Liu, Teller, & Friedman, 2004). Thus suggesting that the optimal method by be a combination of hand-crafter rules, and machine learning.

Other questions remain unresolved. First, how generalizable are disambiguation rules? That is, is the jargon used by clinicians in one part of the country or in one hospital, for that matter, different from the jargon used in another part of the country or another hospital? Second, how generalizable are disambiguation rules from the pediatric population to adult populations? While it is conjectured that there is little differences, certain differences will be inherent in the populations (i.e., adults will not be diagnosed with atrial septal defects; likewise children will not have coronary artery bypass grafts procedures). Third, how will a patient's longitudinal records be linked with this approach?

ABSTRACT

In some real-world areas, it is important to enrich the data with external background knowledge so as to provide context and to facilitate pattern recognition. These areas may be described as data rich but knowledge poor. There are two challenges to incorporate this biological knowledge into the data mining cycle: (1) generating the ontologies; and (2) adapting the data mining algorithms to make use of the ontologies. This chapter presents the state-of-the-art in bringing the background ontology knowledge into the pattern recognition task for biomedical data.

INTRODUCTION

Data mining is traditionally conducted in areas where data abounds. In these areas, the task of the data mining is to identify patterns within the data, which may eventually become knowledge. To this end, the data mining methods used, such as cluster analysis, link analysis and classification and regression, typically aim to reduce the amount of information (or data) to facilitate this pattern recognition. These methods do not tend to contain (or bring to the problem) specific domain specific information. In this way, they may be termed "knowledge-empty." However, in some real-world areas, it is important to enrich the data with external background knowledge so as to provide context and to facilitate pattern recognition. These areas may be described as data rich but knowledge poor. External background information that may be used to enrich data and to add context information, and facilitate data mining is in the form of ontologies, or structured vocabularies. So long as the original data can be linked to terms in the ontology, the ontology may be used to provide the necessary knowledge to explain the results and even generate new knowledge.

In accelerating quest for disease biomarkers, the use of high-throughput technologies, such as DNA microarrays and proteomics experiments, has produced vast datasets identifying thousands of genes whose expression patterns differ in diseased vs. normal samples. Although many of these differences may reach statistical significance, they are not biologically meaningful. For example, reports of mRNA or protein changes of as little as two-fold are not uncommon, and although some changes of this magnitude turn out to be important, most are attributes to disease-independent differences between the samples. Evidence gleaned from other studies linking genes to disease is helpful, but with such large datasets, a manual literature review is often not practical. The power of these emerging technologies—the ability to quickly generate large sets of data—has challenged current means of evaluating and validating these data. Thus, one important example of a data rich but knowledge poor area is biological sequence mining. In this area, there exist massive quantities of data generated by the data acquisition technologies. The bioinformatics solutions addressing these data are a major current challenge. However, domain specific ontologies such as gene ontology (GO Consortium, 2001), MeSH (Nelson & Schopen, 2004) and protein ontology (Sidhu & Dillon, 2005a, 2006a) exist to provide context to this complex real world data.

There are two challenges to incorporate this biological knowledge into the data mining cycle: (1) generating the ontologies; and (2) adapting the data mining algorithms to make use of the ontologies. This chapter presents the state-of-the-art in bringing the background ontology knowledge into the pattern recognition task for biomedical data. These methods are also applicable to other areas where domain ontologies are available, such as text mining and multimedia and complex data mining.

GENERATING OONTOLOGIES: CASE OF PROTEIN ONTOLOGY

This section is devoted to the practical aspects of generating ontologies. It presents the work on building the protein ontology (Sidhu et al., 2006a; Sidhu & Dillon, 2005a, 2006b; Sidhu et al., 2005b) in the section "Protein Ontology (PO)." It then compares the structures of the protein ontology and the well established gene ontology (GO Consortium, 2001) in the section "Comparing PO and GO."

Protein Ontology (PO)

Advances in technology and the growth of life sciences are generating ever increasing amounts of data. High-throughput techniques are regularly used to capture thousands of data points in an experiment. The results of these experiments normally end up in scientific databases and publications. Although there have been concerted efforts to capture more scientific data in specialist databases, it is generally acknowledged that only

20% of biological knowledge and data is available in a structured format. The remaining 80% of biological information is hidden in the unstructured scientific results and texts. Protein ontology (PO) (Sidhu et al., 2006a; Sidhu et al., 2006b; Sidhu et al., 2005a; Sidhu et al., 2005b) provides a common structured vocabulary for this structured and unstructured information and provides researchers a medium to share knowledge in proteomics domain. It consists of concepts, which are data descriptors for proteomics data and the relations among these concepts. Protein ontology has (1) a hierarchical classification of concepts represented as classes, from general to specific; (2) a list of attributes related to each concept, for each class; and (3) a set of relations between classes to link concepts in ontology in more complicated ways then implied by the hierarchy, to promote reuse of concepts in the ontology. Protein ontology provides description for protein domains that can be used to describe proteins in any organism. Protein ontology framework describes: (1) protein sequence and structure information, (2) protein folding process, (3) cellular functions of proteins, (4) molecular bindings internal and external to proteins and (5) constraints affecting the final protein conformation. Protein ontology uses all relevant protein data sources of information. The structure of PO provides the concepts necessary to describe individual proteins, but does not contain individual protein themselves. Files using Web ontology language (OWL) format based on PO acts as instance store for the PO. PO uses data sources include new proteome information resources like PDB, SCOP, and RESID as well as classical sources of information where information is maintained in a knowledge base of scientific text files like OMIM and from various published scientific literature in various journals. PO database is represented using OWL. PO database at the moment contains data instances of following protein families: (1) prion proteins, (2) B.Subtilis, (3) CLIC and (4) PTEN. More protein data instances will be added as PO is more developed. The complete class hierarchy of protein ontology (PO) is shown in Figure 1. More details about PO is available at the Web site: http://www.proteinontology.info/

Semantics in protein data is normally not interpreted by annotating systems, since they are not aware of the specific structural, chemical and cellular interactions of protein complexes. Protein ontology framework provides specific set of rules to cover these application specific semantics. The rules use only the relationships whose semantics are predefined to establish correspondence among terms in PO. The set of relationships with predefined semantics is: {SubClassOf, PartOf,

AttributeOf, InstanceOf, and ValueOf}. The PO conceptual modelling encourages the use of strictly typed relations with precisely defined semantics. Some of these relationships (like SubClassOf, InstanceOf) are somewhat similar to those in RDF schema but the set of relationships that have defined semantics in our conceptual PO model is small so as to maintain simplicity of the system. The following is a description of the set of predefined semantic relationships in our common PO conceptual model.

- **SubClassOf:** The relationship is used to indicate that one concept is a subclass of another concept, for instance: SourceCell SubClassOf FunctionalDomains. That is any instance of SouceCell class is also instance of FunctionalDomains class. All attributes of FunctionalDomains class (_FuncDomain_Family, _FuncDomain_SuperFamily) are also the attributes of SourceCell class. The relationship SubClassOf is transitive.
- **AttrributeOf:** This relationship indicates that a concept is an attribute of another concept, for instance: _FuncDomain_Family AttributeOf Family. This relationship also referred as PropertyOf, has same semantics as in object-relational databases.
- **PartOf:** This relationship indicates that a concept is a part of another concept, for instance: Chain PartOf ATOMSequence indicates that Chain describing various residue sequences in a protein is a part of definition of ATOMSequence for that protein.
- **InstanceOf:** This relationship indicates that an object is an instance of the class, for instance: ATOMSequenceInstance_10 InstanceOf ATOMSequence indicates that ATOMSequenceInstance_10 is an instance of class ATOMSequence.
- **ValueOf:** This relationship is used to indicate the value of an attribute of an object, for instance: "Homo Sapiens" ValueOf OrganismScientific. The second concept, in turn has an edge, OrganismScientific AttributeOf Molecule, from the object it describes.

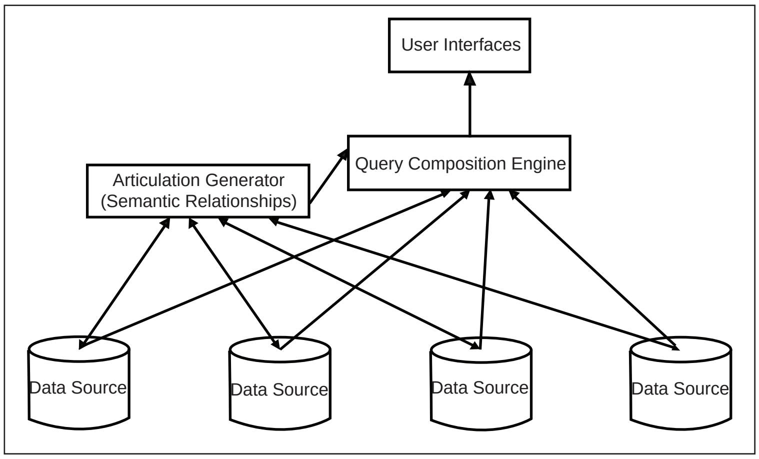
Comparing PO and GO

Gene ontology (GO Consortium, 2001) defines a structured controlled vocabulary in the domain of biological functionality. GO initially consisted of a few thousand terms describing the genetic workings of three organisms and was constructed for the express purpose of database interoperability; it has since grown to a terminology of nearly 16,000 terms and is becoming a de facto standard for describing functional aspects of biological entities in all types of organisms. Furthermore, in addition to (and because of) its wide use as a terminological source for database-entry annotation, GO has been used in a wide variety of biomedical research, including analyses of experimental data (GO Consortium, 2001) and predictions of experimental results (GO Consortium & Lewis, 2004)). Characteristics of GO that we believe are most responsible for its success: community involvement; clear goals; limited scope; simple, intuitive structure; continuous evolution; active curation; and early use.

It is clear that organisms across the spectrum of life, to varying degrees, possess large numbers of gene products with similar sequences and roles. Knowledge about a given gene product (i.e., a biologically active molecule that is the deciphered end product of the code stored in a gene) can often be determined experimentally or inferred from its similarity to gene products in other organisms. Research into different biological systems uses different organisms that are chosen because they are amenable to advancing these investigations. For example, the rat is a good model for the study of human heart disease, and the fly is a good model to study cellular differentiation. For each of these model systems, there is a database employing curators who collect and store the body of biological knowledge for that organism. This enormous amount of data can potentially add insight to related molecules found in other organisms. A reliable wet-lab biological experiment performed in one organism can be used to deduce attributes of an analogous (or related) gene product in another organism, thereby reducing the need to reproduce experiments in each individual organism (which would be expensive, time-consuming, and, in many organisms, technically impossible). Mining of scientific text and literature is done to generate list of keywords that is used as GO terms. However, querying heterogeneous, independent databases in order to draw these inferences is difficult: The different database projects may use different terms to refer to the same concept and the same terms to refer to different concepts. Furthermore, these terms are typically not formally linked with each other in any way. GO seeks to reveal these underlying biological functionalities by providing a structured controlled vocabulary that can be used to describe gene products, and shared between biological databases. This facilitates querying for gene products that share biologically meaningful attributes, whether from separate databases or within the same database.

Challenges faced while developing GO from unstructured and structured data sources are addressed while developing PO. Protein ontology is a conceptual model that aim to support consistent and unambiguous knowledge sharing and that provide a framework for protein data and knowledge integration. PO links concepts to their interpretation, that is, specifications of their meanings including concept definitions and relationships to other concepts. Apart from semantic relationships defined in "Protein Ontology (PO)," PO also model relationships like sequences. By itself semantic relationships described in "Protein Ontology (PO)" does not impose order among the children of the node. In applications using protein sequences, the ability of expressing the order is paramount. Generally protein sequences are a collection of chains of sequence of residues, and that is the format protein sequences have been represented unit now using various data representations and data mining techniques for bioinformatics. When we are defining sequences for semantic heterogeneity of protein data sources using PO we are not only considering traditional representation of protein sequences but also link protein sequences to protein structure, by linking chains of residue sequences to atoms defining three-dimensional structure. In this section we will describe how we used a special semantic relationship like *Sequence(s)* in protein ontology

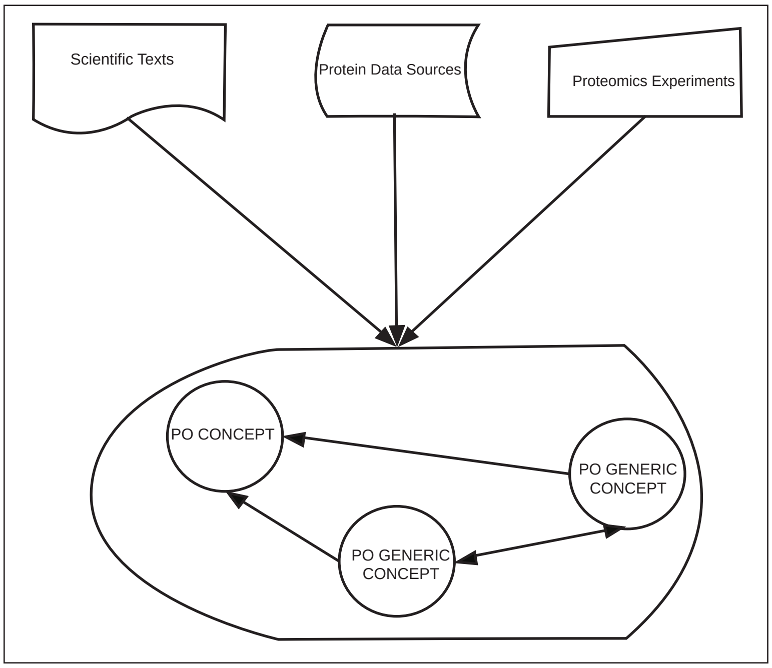
Figure 2. Semantic interoperability framework for PO



to describe complex concepts defining structure, structural folds and domains and chemical bonds describing protein complexes. PO defines these complex concepts as *Sequences* of simpler generic concepts defined in PO. These simple concepts are *Sequences* of object and data type properties defining them. A typical example of *Sequence* is as follows. PO defines a complex concept of *ATOMSequence* describing three dimensional structure of protein complex as a combination of simple concepts of *Chains*, *Residues*, and *Atoms* as: *ATOMSequence Sequence (Chains Sequence (Residues Sequence (Atoms)))*. Simple concepts defining ATOMSequence are defined as: *Chains Sequence (ChainID, ChainName, ChainProperty)*; *Residues Sequence (ResidueID, ResidueName, ResidueProperty)*; and *Atoms Sequence (AtomID, Atom, ATOMResSeqNum, X, Y, Z, Occupancy, TempratureFactor, Element)*. Semantic interoperability framework used in PO is depicted Figure 2.

Therefore, PO reflects the structure and relationships of protein data sources. PO removes the constraints of potential interpretations of terms in various data sources and provides a structured vocabulary that unifies and integrates all data and knowledge sources for proteomics domain (Figure 3). There are seven subclasses of protein ontology (PO), called generic classes that are used to define complex concepts in other PO classes: *Residues*, *Chains*, *Atoms*, *Family*, *AtomicBind*, *Bind*, and *SiteGroup*. Concepts from these generic classes are reused in various other PO classes for definition of class specific concepts. Details and properties of residues in a protein sequence are defined by instances of *Residues* class. Instances of chains of residues are defined in *Chains* class. All the three dimensional structure data of protein atoms is represented as instances of *Atoms* class. Defining *Chains*, *Residues* and *Atoms* as individual classes has the benefit that any special properties or changes affecting a particular chain, residue and atom can be easily added. Protein *Family* class

Figure 3. Unification of protein data and knowledge



represents protein super family and family details of proteins. Data about binding atoms in chemical bonds like hydrogen bond, residue links, and salt bridges is entered into ontology as an instance of *AtomicBind* Class. Similarly the data about binding residues in chemical bonds like disulphide bonds and CIS peptides is entered into ontology as an instance of *Bind* class. All data related to site groups of the active binding sites of proteins is defined as instances of *SiteGroup* class. In PO the notions classification, reasoning, and consistency are applied by defining new concepts or classes from defined generic concepts or classes. The concepts derived from generic concepts are placed precisely into class hierarchy of protein ontology to completely represent information defining a protein complex.

As such PO can be used to support automatic semantic interpretation of data and knowledge sources, thus providing a basis for sophisticated mining of information.

CLUSTERING FACILITATED BY DOMAIN ONTOLOGIES

In this section we demonstrate how to modify clustering algorithms in order to utilise the structure of ontology. In the section “Challenges with Clustering Data Enriched with Ontological Information” we present the differences between clustering data items with associated ontological information compared to clustering data items without this information. In “A Distance Function for Clustering Ontologically Enriched Data,” we show how these differences must be met in a clustering algorithm. Finally, “Automatic Cluster Identification and Naming” describes an automatic method of naming and describing the clusters found with the domain ontology.

Challenges with Clustering Data Enriched with Ontological Information

Many algorithms exist for clustering data (Duda, Hart, & Stork, 2001; Theodoridis & Koutroumbas, 1999). However, one of the primary decisions to be made when applying cluster analysis to data, and before choosing a specific algorithm, is the way of measuring distances between data items. Generally this involves defining some distance or similarity measure between data items defined in terms of their attributes.

Just as many clustering algorithms have been defined over a wide variety of data types, so to has a large set of potential similarity and distance functions been devised for comparing data items (Theodoridis & Koutroumbas, 1999). In general, a similarity function measures the degree to which two items are similar to one another. Conversely, a distance function measures how two data items are dissimilar. The choice of distance function for data items is often orthogonal to the particular clustering algorithm used as many clustering algorithms take as input a distance matrix, which contains the results of applying a distance function to each combination of data items. The distance matrix is a square symmetric matrix with each cell *i*, *j* measuring the distance between data items *i* and *j*. The particular distance function used with data items is generally dependent on the type of data being compared. For example, the distance between vectors of real valued data is often defined with the Euclidean distance function, whereas more elaborate functions are required for the sequence data types often found in biomedical datasets.

Thus, the first question we must address when devising a distance function for data enriched with information from ontologies is: what form does the data take? Details will, of course, depend on the particular ontology applied to the data. However, we can make some general comments and apply them in an example of comparing genes based on the associated gene ontology terms. In this example, the "knowledge-poor" or raw data items consist solely of gene names, for example, AA458965 or AA490846, using the GenBank accession codes. These gene names are essentially class labels with no knowledge embedded in them. Hence, there is no useful way to compare them on their own. Ontological information from the gene ontology may be associated with each gene by using the gene ontology database or with the use of a search engine such as SOURCE (Diehn et al., 2003). In our example, the gene ontology associations are shown in Table 1.

Two characteristics regarding the enriched data are apparent. First, there are different numbers of terms from the gene ontology associated with each gene. For the first gene there are four terms whilst the second has six associations. In general, this will be the norm for associations. Second, we do not seem to have accomplished much from the data enrichment. The associated terms can still be regarded as individual class labels for a very large number of classes (more than 16,000). The terms only have meaning in their relationships within the ontology hierarchy.

Thus, algorithms to cluster ontology enriched data items (1) must be able to handle different numbers of terms associated with data items; and (2) must be able to compare terms based on relationships in the ontology.

A Distance Function for Clustering Ontologically Enriched Data

Given the requirements for the clustering of ontologically enriched data developed in the last section, what kind of similarity measure or distance measure is appropriate? Standard measures like Euclidean distance are not applicable because the data contains different numbers of attributes and there is no natural way to define a distance between classes.

One possible approach is suggested by an analogy to comparison of documents in the field of computational linguistics. A common approach in this field is to transform a free form document into a sparse vector of word counts where each position in the vector refers to a different word in the corpus (see, e.g., Chapter 10 of Shawe-Taylor & Cristianini, 2004). This simplified knowledge representation of the text document ignores relationships between words. In the same way that this representation views a document as a vector of word counts, the ontologically enriched data items may be thought of as a vector of occurrences of gene ontology terms. We could devise a long sparse binary vector with each position referring to the presence or absence of an association with each of the thousands of gene ontology terms to the data item. The problem with this knowledge representation is that most of the gene ontology terms apply to only a very few genes in the database. This means that very few similarities could be found between the vectors for different data items. The solution to this difficulty lies in incorporating the relationships within the ontology into the knowledge representation.

Referring back to the example of the two genes in the last section, there is another characteristic of the enriched data that are not, at first, apparent. We can retrieve further enriched data for the genes by tracing back up the gene ontology

Table 1. Enriched data. First column lists "knowledge-poor" data in the form of GenBank identifiers. Second column lists associated Gene Ontology term identifiers for each gene.

AA458965	GO:0005125, GO:0005615, GO:0006955, GO:0007155

	5: GO:0008150

Note: Some terms are seen multiple times at the same distance or at further distances

hierarchy. In the gene ontology, parent terms are more general concepts of child terms. For example, for the gene AA458965 the term GO:0006952 (defense response) can be derived from the term GO:0006955 (immune response) by following the is-a relationship in the ontology. This allows us to retrieve more general terms describing the genes. These more general terms give a sort of background knowledge for the genes. As we trace back terms higher in the hierarchy we successively build up more general background knowledge for the genes. The complete set of associations for the genes in our example is shown in Table 2. It should be clear that the terms associated with the genes differ in importance. Terms that are lower in the hierarchy are more specific to the data items and should be treated as more significant for comparisons between data items. Conversely, terms that are far from the original terms (in terms of distance up the hierarchy) are more general and should play a less significant role in comparison of data items. Furthermore, different child terms may have the same parent term or terms. This means that as we trace back up the ontology hierarchy we may draw in the same term more than once. Consequently, the background knowledge of terms may, and usually will, have duplicated terms.

This observation suggests a method of applying a similar knowledge representation to that used in the field of computational linguistics. Rather than using a binary vector to represent the presence or absence of an association between data item and gene ontology term, we use a real value measure or weighting of the degree of significance of the term to the data item. Terms directly associated with each data item, for example those listed in Table 1, receive a weight value of 1, terms indirectly associated with the data item (i.e., higher in the hierarchy) are given a lower weighting and terms that cannot be reached from terms associated with the data item are assigned 0. This leads to a less sparse vector where comparisons may be made.

A straightforward method of deriving the distance between terms using a weighting scheme like this is to adapt a similarity measure called the Tanimoto measure (Theodoridis & Koutroumbas, 1999). The Tanimoto measure defines a measure of similarity between sets:

$$\frac{n_{X \cap Y}}{n_X + n_Y - n_{X \cap Y}} = \frac{n_{X \cap Y}}{n_{X \cup Y}}$$

where X and Y are the two sets being compared and n_X, n_Y and $n_{X \cap Y}$ are the number of elements in the sets X, Y and $X \cap Y$ respectively.

However, in the current situation, the "sets" being compared are the gene ontology terms for the two genes. As there may be duplicated terms in the lists associated with each data item we adapt the Tanimoto measure to give similarities between bags rather than sets.

Also, as the terms higher in the ontology are less significant in terms of comparison than the more specific terms towards the bottom, we weight the contribution of terms by the distance from the descendent gene ontology term directly associated with the gene. In effect, this results in a "weighted" cardinality of the bag of gene ontology terms. Furthermore, as we are interested in a distance rather than a similarity, we subtract the similarity from 1. The final distance function used, then, is:

$$D_{X,Y} = 1 - \frac{n'_{X \cap Y}}{n'_X + n'_Y - n'_{X \cap Y}} = 1 - \frac{n'_{X \cap Y}}{n'_{X \cup Y}}$$

where X and Y are the bags of terms being compared and n'_X, n'_Y and $n'_{X \cap Y}$ are the weighted cardinalities of the bags X, Y and $X \cap Y$ respectively given by:

$$n'_X = \sum_{i \in X} c^{d_i}$$

where X is the bag of gene ontology terms, d_i is the distance of term of X with index i from its associated descendent in the original set of gene ontology terms for the gene, and c is the weight constant. The weighted cardinality of the other bags is similarly defined.

The more general gene ontology terms provide a context for the understanding of the lower level terms directly associated with genes. The c weight constant allows variation of the importance of the "context" to the comparison. A value of $c = 0$ means that higher level are ignored. A value of 1 considers all terms equally irrespective of their position in the hierarchy and regards the very general terms as overly significant. The c parameter may be viewed as a sort of "constant of gravity" for the clusters. The higher the value of c, the more that distantly related genes are gathered into a cluster. A choice of $c = 0.9$ gives reasonable results.

A similar graph-based approach for determining similarity based on gene ontology relationships to our described above is given in Lee, Hur, and Kim (2004). That approach involves transformation of the gene ontology from a directed acyclic graph into a tree structure and encoding of gene ontology accession codes to map into the tree.

Our similarity function contains several assumptions about ontologies. It treats distances between levels in the ontology as the same. This means that terms that are the same distance away from the terms directly associated to data items have the same effect on the similarity measure. This may not necessarily reflect the knowledge encoded in the ontology. The level of fan-out from a parent to child in the ontology may be an indication of the concentration of knowledge in the ontology. For example, when the fan-out from parent to child is large, this may indicate that the parent concept has been investigated more or is understood better than parents with less fan-out. This and other measures could conceivably be incorporated into the similarity function.

Automatic Cluster Identification and Naming

Once clusters have been identified, the ontology can facilitate inference of cluster descriptions. The descriptions say how data items in the cluster are similar to one another and different to other clusters using the vocabulary of the ontology.

Cluster descriptions are inferred for each cluster using the method shown in the pseudo code in Figure 4. At lines 1 and 2 the algorithm starts with an empty set of definitions and a list of all terms directly associated with the data items in the given cluster. The ontology hierarchy is traversed upwards replacing terms with their parent (more general) terms. Terms are replaced (line 12) only if the parent term is *not* associated with data items in another cluster (or is one of any of the ancestor terms in another cluster). At lines 8 and 14 the algorithm chooses a term to be added to the class description. Line 8 is the case when the top of the hierarchy is reached and line 14 is the case when no parent terms could be found that referred only to the cluster of interest. The output of the algorithm is a list of terms for a cluster that describe in the most general way possible the data items in the cluster (but not so general that it describes another cluster).

Insight into structure within clusters can be gained by examining which data items are associated with terms in the cluster description. It can happen that a subset of the data items in a cluster may have a description that is more concise than the description for all the data items in the cluster. This may be an indication of poor clustering of the data items.

CASE STUDY

This section presents a case study of enriching bio-medical data with the protein ontology. The case study discusses the results of six data mining algorithms on PO data. The protein ontology database is created as an instance store for various protein data using the PO format. PO provides technical and scientific infrastructure to allow evidence based description and analysis of relationships between proteins. PO uses data sources like PDB, SCOP, OMIM and various published scientific literature to gather protein data. PO database is represented using OWL. PO database at the moment contains data instances of following protein families: (1) prion proteins, (2) B.Subtilis, (3) CLIC and (4) PTEN. More protein data instances will be added as PO is more de-

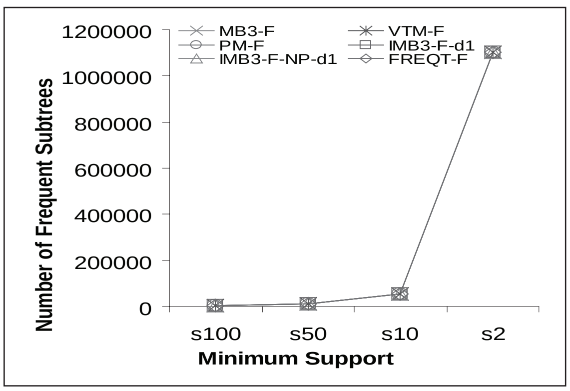
veloped. The PO instance store at moment covers various species of proteins from bacterial and plant proteins to human proteins. Such a generic representation using PO shows the strength of PO format representation.

We used some standard hierarchical and tree mining algorithms (Tan & Dillon, in press) on the PO database. We compared MB3-Miner (MB3), X3-Miner (X3), VTreeMiner (VTM) and PatternMatcher (PM) for mining embedded subtrees and IMB3-Miner (IMB3), FREQT (FT) for mining induced subtrees of PO data. In these experiments we are mining prion proteins dataset

Figure 6. Number of frequent subtrees for prion dataset of PO data



described using protein ontology framework, represented in OWL. For this dataset we map the OWL tags to integer indexes. The maximum height is 1. In this case all candidate subtrees generated by all algorithms would be induced subtrees. Figure 5 shows the time performance of different algorithms. Our original MB3 has the best time performance for this data.

Quite interestingly, with prion dataset of PO the number of frequent candidate subtrees generated is identical for all algorithms (Figure 6). Another observation is that when support is less than 10, PM aborts and VTM performs poorly. The rationale for this could be because the utilized join approach enumerates additional invalid subtrees. Note that original MB3 is faster than IMB3 due to additional checks performed to restrict the level of embedding.

CONCLUSION

We discussed the two challenges to incorporate this biological knowledge into the data mining cycle: generating the ontologies, and adapting the data mining algorithms to make use of the ontologies. We present protein ontology (PO) framework, discuss semantic interoperability relationships between its concepts, and compare its structure with gene ontology (GO). We also demonstrate how to modify clustering algorithms in order to utilize the structure of GO. The results of six data mining algorithms on PO data are discussed, showing the strength of PO in enriching data for effective analysis.

Chapter 7.19
A Haplotype Analysis System for Genes Discovery of Common Diseases

Takashi Kido
HuBit Genomix, Inc., Japan

ABSTRACT

This chapter introduces computational methods for detecting complex disease loci with haplotype analysis. It argues that the haplotype analysis, which plays a major role in the study of population genetics, can be computationally modeled and systematically implemented as a means for detecting causative genes of complex diseases. In this chapter, the author provides a review of issues on haplotype analysis and proposes the analysis system which integrates a comprehensive spectrum of functions on haplotype analysis for supporting disease association studies. The explanation of the system and some real examples of the haplotype analysis will not only provide researchers with better understanding of current theory and practice of genetic association studies, but also present a computational perspective on the gene discovery research for the common diseases.

INTRODUCTION

In recent years, much attention has been focusing on finding causative genes for common diseases in human genetics. (Badano & Katsanis, 2002; Daly, 2001; Fan & Knapp, 2003; Gabriel et al., 2002) These findings of causative genes of common diseases including diabetes, hypertension, heart disease, cancer, and mental illness are expected to be opening doors for realizing new diagnoses and drug discoveries. A promising approach for the gene discovery on common diseases is to statistically examine genetic association between the risk of common diseases and DNA variations in human populations. While single nucleotide polymorphisms (SNPs), the most common genetic variation, are widely used for this genetic association study, haplotypes, the combination of closely linked SNPs on a chromosome, has been shown to have pivotal roles in the study of the genetic basis of disease (Clark, 2004; Niu, 2004; Schaid, 2004). The main purpose of this report is to provide a comprehensive review of haplotype analysis in genetic association studies on complex, common diseases and provide the computational framework which enables us to carry out successful high-throughput genome-wide association study.

In addition to the review of the recent developments of haplotype analysis, the author presents the design, implementation, and application of a haplotype analysis system for supporting genome-wide association study. While there are some useful tools or programs available for haplotype analysis (Kitamura et al., 2002; Niu, Zin, Zu, & Liu, 2002; Sham & Curtis, 1995; Stephens, Smith, & Donnelly, 2001), little work has been reported for a comprehensive analysis pipleline for large-scale and high-throughput SNPs screening which fully integrate these functions. HAPSCORE (Zhang, Rowe, Struewing, & Buetow, 2002) is one of the few examples of those pipeline systems; however, it does not include some analysis functions such as automatic linkage disequilibrium (LD) block partitioning and disease association analysis tools. In this report, the author presents a system, LDMiner (Higashi et al., 2003), which represents the pioneer pipeline system that integrates a comprehensive spectrum of functions related to haplotype analysis. This report introduces the details of LDMiner and shows some examples of haplotype analysis with LDMiner, which helps to explain the theory and practice on population-based association study for common diseases.

BACKGROUND

Genetic Variations and Common Diseases

The progress on human genome science is opening doors for the discovery of new diagnostics, preventive strategies, and drug therapies for common complex diseases including diabetes, hypertension, heart disease, cancer, and mental illness. Analysis of human genome primarily focuses on variations in the human DNA sequence, since these differences can affect the potential risk of disease outbreaks or the effectiveness of a drug treatment of the diseases.

A common method for determining the genetic differences between individuals is to find single nucleotide polymorphisms (SNPs). A SNP is defined as a DNA sequence variation referring to an alteration of a single nucleotide (A, T, G, C). SNPs represent the most common genetic variations. In fact, there are millions of SNPs in the human genome (Kruglyak & Nickerson, 2001), and it is estimated that there will be on average one SNP every 1,000 base pairs. SNPs are caused when nucleotides replicate imperfectly or mutate. Although most of these SNPs have no ostentatious impacts on the survival of the species, certain SNPs may confer beneficial effects allowing species to evolve and to adapt to new environments more successfully, while certain others may be detrimental. These SNPs are passed on from generation to generation. After hundreds of years, some SNPs become established in the population.

A number of instances are known for which a particular nucleotide at a SNP locus (i.e., a particular SNP allele) is associated with an individual's propensity to develop a disease. For example, it has been reported that functional SNPs in the lymphotoxin-alpha gene were associated with susceptibility to myocardial infection by means of a large-scale case-control association study using 92,788 SNP markers (Ozaki et al., 2002). There have also been a number of reports that show some SNPs in certain genes can determine whether a drug can treat a disease more effectively in individual with certain genotypes compared to those who do not carry such SNPs. For example, Cummins et al. (2004) reported that there is a strong association in Han Chinese between a genetic marker, the human leukocyte antigen HLA-B*1502, and Stevens-Johnson syndrome induced by carbamazepine, a drug commonly prescribed for the treatment of seizures. These SNPs are often linked to the causative genes, but may not be themselves proved to be causative. These are often called surrogate markers for the disease. These disease-associated SNPs are expected to be validated by a number of investigations including biological experiments and epidemiological studies in the next several years.

Why Study Haplotypes?

A haplotype is a set of closely linked alleles (SNPs) inherited as a unit. For example, let's assume that there is a gene containing three SNPs. We now represent two alleles of each SNP with A and B (A is minor allele). The number of possible combinations of the three SNPs is eight (i.e. A-A-A, A-A-B, A-B-A, A-B-B, B-A-A, B-A-B, B-B-A, B-B-B). However, the total number of common (i.e. frequency > 5%) haplotypes in the population usually converge to a number less than eight, for example, three (A-A-A, A-B-A, B-B-B). Also, the number of common haplotypes varies depending on the chromosome regions. The recent empirical findings in human genetic studies show that genomic sequence is comprised of parts; cold spots (LD blocks) having much less variations than other regions and hot spots having more variations (Cardon & Abecasis, 2003). Some recombination hot spots tend to include a large number of haplotypes, while cold spots (or LD blocks) include only small number of haplotypes.

Haplotypes play important rules for searching the causative sites associated with several common diseases. As Clark (2004) discussed the role of haplotypes in candidate gene studies, there are three primary reasons for considering the haplotype configuration, which are listed as follows.

- **Biological function:** Haplotypes may be defined as functional units of genes; the protein products of the candidate genes may depend on particular combinations of amino acid. For example, ApoE is a protein whose function is influenced by a pair of polymorphic amino acids (Fullerton et al., 2000). The two-site haplotypes best describe the functional differences of carious ApoE protein isoforms rather than those of individual SNPs in the gene.
- **Tracing past evolutionary history:** The variation in populations is inherently structured into haplotypes. The haplotypes cover the informative small segments on ancient ancestral chromosome that may harbor a disease locus. Therefore the information on haplotype structure is useful for localizing and for tracing the past historical events on causative sites. For example, we can trace the evolutionary events by classifying haplotypes into clusters on the basis of the idea of population genetic theory, which gives us a useful insight on the origin of the disease. (Kido et al., 2003; Templeton, 1995)
- **Statistical power advantage:** The haplotype-based analysis, which combines the information of adjacent SNPs into multilocus haplotypes, may increase statistical power of conventional SNP-based analysis to detect disease associated sites. Bader (2001) showed that haplotype-based association tests can have greater power than SNP-based association tests in the case when the disease locus has multiple disease-causing alleles.

Linkage Disequilibrium and Haplotype Analysis

The case-control study, which compares a group of people with disease to a similar group of people without disease, is commonly used in population-based association study design. If we have a strong hypothesis about the special causative alleles, causal alleles can be directly evaluated. For common complex diseases, however, strong hypotheses about the specific causal alleles are generally not available, so the "indirect" association approach has become widespread. In "indirect" association studies, we expect that the actual causative allele is not genotyped but might be located near another marker that is genotyped.

LD is an important concept for indirect association study, which is defined as the lack of independence among different polymorphisms. That is, alleles A and B are said to be in LD if the frequency of pairs of alleles AB is not equal to the product of the frequencies of A and B alleles. In LD analysis, we assume that causative alleles at tightly linked markers will remain in significant LD for extended periods of time from ancestors. Various statistical metrics can be used to summarize the extent of pairwise LD between two linked markers, such as D' and r^2.

One of the important questions for indirect association studies is "how much LD is needed to detect a disease allele using its nearby genetic markers?" Krina and Cardon (2004) discussed the complex interplay among factors that influence allelic association. They outlined the four parameters that affect an odds ratio test of association with a single SNP: (1) the odds ratio of true disease-causing SNP, (2) LD between markers and the causal SNP, (3) the marker allele frequency, and (4) the disease allele frequency. Ideally a disease allele can be detected provided that the extent of LD between the marker and the causative allele is high and the marker allele frequency matches with the allele frequency of the disease allele.

Since haplotype analysis captures regional LD information of SNPs, characterization of LD patterns is important. Characterization of LD patterns across the human genome is at present an area of highly active research. International HapMap project gathers information on LD structure of variation in human populations (The International HapMap Consortium, 2003). This will facilitate genome-wide association analysis and the search for the genetic determinations of complex diseases.

Computational Algorithms for Haplotype Analysis

Defining LD Blocks

The recent finding in human genetics shows that human genome is broken up into regions of weak LD (called hot spots) and strong LD (called cold spots or LD blocks). Strong LD within a genomic region implies that most of the variation of that region can be captured by just a few informative SNPs, called tag SNPs. It is hoped that the regions of strong LD will facilitate the discovery of genes related to common diseases through association studies.

There are a variety of proposed empiric definitions for haplotype blocks. For example, Gabriel et al. (2002) developed a descriptive approach to comparing block boundaries across different populations. They examined adjacent pairs of SNPs in at least two populations, and labeled SNP pairs as concordant or discordant, based on the strength of linkage disequilibrium between two populations. They then calculated the percentage of concordant pairs among all pairs to define the block boundaries. Liu et al. (2004) propose several similarity measures to compare haplotype boundaries across populations. They found that haplotype block boundaries vary among populations and the definition of haplotype blocks is highly dependent on the density of SNPs and the method used to find blocks. The understanding of the similarities and differences of haplotype blocks between different populations will be important for future genome association studies.

Inferring Haplotype Phases

In most cases, haplotypes are not read directly when multiple human SNPs are genotyped, but must be inferred from unphased genotype data. Although a spectrum of molecular haplotyping methods such as single-molecule dilution, long-range allele-specific PCR were developed, these methods are not widely used because of their low-throughput performance and important technical problems remain unresolved. Therefore a number of algorithms for inferring haplotypes from unphased genotype data have been developed.

Niu et al. (2004) provides a good review of recent computational methods of population-based haplotype inference methods. Clark's algorithm is based on the principle of maximum parsimony which resolves the haplotypes by starting with identifying all unambiguous haplotypes (all homozygotes and single-site heterozygotes) and repeatedly adding a new haplotype to the resolved haplotype. (Clark, 1990) Although Clark's algorithm is a relatively straight-forward procedure, the algorithm does not give unique solutions, because the phasing results are dependent on the order of genotypes that need to be phased. Expectation-maximization (EM) algorithm estimates population haplotype probabilities based on maximum likelihood, finding the values of the haplotype probabilities which optimize the probability of the observed data, based on the assumption of Hardy-Weinberg equilibrium (HWE). (Excoffer & Slatkin, 1995) Actually, EM algorithm is based on solid statistical theory and are quite effective as simulation studies demonstrate that its performance is not strongly affected by the departures from HWE. (Niu et al., 2004). Some disadvantages of EM algorithm, however, are that the iteration may lead to locally optimal point when there are many distinct haplotypes, and it cannot handle a large number of loci. Stephens et al. (2001) proposed a coalescence-based Markov-chain Monte Carlo (MCMC) approach: a pseudo-Gibbs sampler (PGS) for reconstructing haplotypes from genotype data. This algorithm is implemented as program named PHASE. Niu et al. introduced a divide-conquer-combine algorithm: partition-ligation (PL), which can handle a large number of loci. This algorithm is implemented as programs named Haplotyper (Bayesian implementation) and PLEM (EM implementation).

Although there is an ongoing debate in regard to whether the best haplotype phasing algorithm exits, different algorithms perform differently in different populations with their own strengths and limitations. Niu et al. demonstrates that different algorithms have different degrees of sensitivity to various extends of population diversities and genotyping error rates using empirical simulations based on real genome data sets.

Statistical Advantages and Methods for Haplotype-Based Disease Association

Haplotype analyses can sometimes provide greater power than single-marker analyses for genetic disease associations, due to the ancestral structure captured in the distribution f haplotypes. Whether haplotype analyses outperform single locus analyses varies depending on the assumptions about the number of disease causing SNPs, the amount of LD among SNPs from the marker and disease causing SNPs. Schaid (2004) reviews the recent works on the statistical advantages of haplotypes. Bader (2001) reports that when the set of measured SNPs includes causative SNPs, single-locus tests are more powerful than haplotype-based tests when the number of causative SNPs is less than the number of haplotypes. In contrast, haplotype analyses can be more powerful than single-locus analyses when the SNPs are in LD with a causative diallelic locus. (Akey & Xiong, 2001) Both single-locus analyses and haplotype analyses lose power when there are multiple alleles at a causative locus, but comparatively speaking haplotype analyses lose less power. In this situation, the power advantage for haplotype analyses is greatest when the marker alleles are not in strong LD with each other, yet in strong LD with the causative alleles.

Schaid provides a comprehensive review on how to evaluate the association of haplotypes with human traits. When haplotypes are directly observed, then statistical methods can be applied to compare the frequencies of haplotypes between cases and controls. If the haplotype- phases are unknown, haplotype frequencies for the cases and controls can be estimated by EM algorithm. One of the common methods for haplotype-based disease association is to use likelihood ratio statistic test (LRT) which tests the equality of haplotype frequencies between cases and controls (Zhao & Sham, 2002). Although LRT is a practical method, one of the disadvantages of LRT is that it may not be adequate when there are many haplotypes, it lacks adjustment for environmental covariates. In order to solve this problem, Schaid introduces regression models for haplotypes in which haplotypes are treated as categorical covariates with other environmental covariates. Schaid also reviews recent developments of statistical regression methods for haplotype analyses.

A HAPLOTYPE SYSTEM ANALYSIS

LDMiner: The Pipeline System for SNP Analysis

We have developed a system named LDMiner that supports disease association studies to detect genes that may cause complex diseases (Higashi et al., 2003). The main functions of LDMiner are as follows:

1. LDMiner is a total analysis system for SNPs, LD blocks haplotypes, and disease association.
2. LDMiner automatically combines SNPs located in the vicinity with respect to each other on a chromosomal region and constructs LD block, and accordingly haplotypes within the block using the EM algorithm (Kitamura et al., 2002).
3. LDMiner automatically assesses the association of haplotypes and diplotypes between cases and controls. By combining SNPs together into LD blocks, we can improve the statistical power for association study.
4. LDMiner visualizes the analyzed results along with a genome viewer. The main viewer displays the genomic structure and is linked to another main viewer showing the in-depth analysis result. These viewers allow the user to easily check and make interpretations of the results.

LD analysis and some advanced association studies can be efficiently performed using LDMiner with handy tools for eliminating the inadequate data and so on. Consequently, the number of SNPs the system can analyze is about 30 to 50 times higher than by the standard manual procedures per unit of time (Higashi et al., 2003).

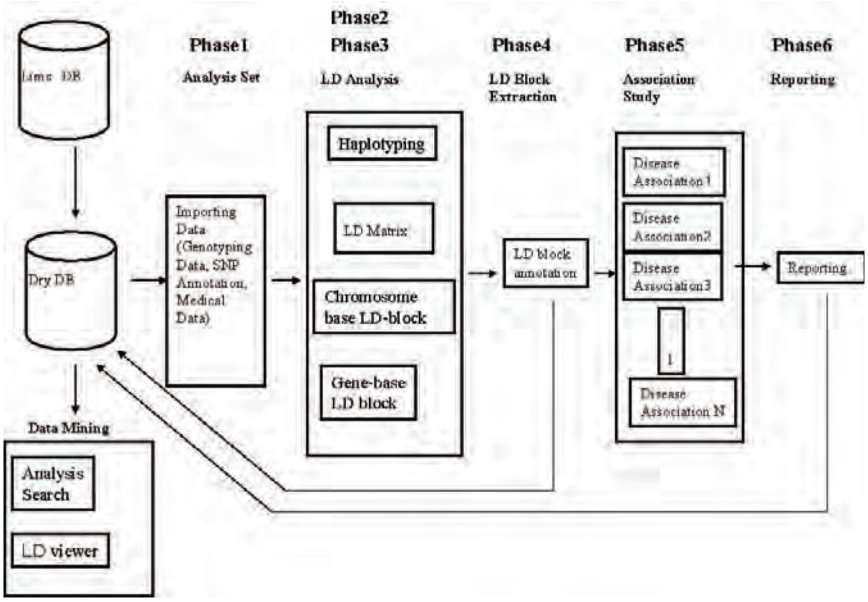
The system design of the LDMiner analysis pipeline is shown in Figure 1. In phase 1, we import genotype and medical data with SNP annotation for the analysis. In phases 2 and 3, we examine the extents of LDs among SNPs within the same genes or the same chromosomal regions as well as to estimate haplotypes and diplotypes using EM algorithm. In phase 4, LD blocks are automatically constructed by a sliding-window approach in searching for strong LD regions as discretized LDblocks. In phase 5, we perform several association tests for either individual SNPs or haplotypes within LD blocks. In phase 6, all association results are automatically annotated with SNPs and LD blocks information in order to easily retrieve and compare. These analysis results are visualized by linking the genome browser which maps LD status into genome structure.

Algorithms

Haplotyping

Given the genotypes of the individuals in a sample, the frequencies of the haplotypes in the population can be estimated. There are primarily three categories of algorithms for the inference of haplotype phases of individual genotype data;

Figure 1. Analysis pipeline with LDMiner

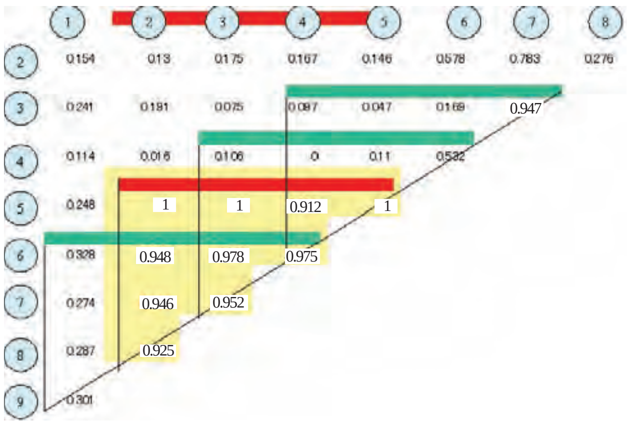


these categories are Clark's algorithm (Clark, 1990), the EM algorithm (Kitamura et al., 2002) and Bayesian algorithm (Stephens et al., 2001). Niu et al. reports the performance comparison of these algorithms and conclude that EM algorithm is shown to be accurate and practical. Furthermore they proposed PL algorithm, which is an extended version of a stochastic sampling algorithm incorporating the idea of "divide-conquer-combine", implemented the program called HAPLOTYPER which is applicable to a large number of SNPs. Although our system can incorporate several haplotyping programs as module, we mainly use EM algorithm implemented as LDSupport programs by Kamatani et al. (2002) and then determine the posterior probability distribution of diplotype configuration (diplotype distribution).

Automatic LD Block Extraction

We define the LD block based on the idea that SNPs within each LD block are tightly linked, which means that most of the pairwise LD measurement of two SNPs within the LD block is high, for example D' ≥ 0.8 Because our major purpose of LD block extraction is to improve the performance of haplotype association analysis, the number of SNPs in the LD block should be limited in order to keep down the degree of freedom of the association study. For example, based on our experience, three to five SNP markers are appropriate for our association study when the majority of the pairwise LD values across all SNPs within the same LD block is strong enough. Otherwise, if we select too many SNPs for the LD block, the power of the multi-locus association test becomes smaller because of the inflation of the number of haplotypes as well as the fact that the posterior probability of the diplotype determination becomes smaller. For these reasons, we propose the window-sliding method for LD block construction where the maximum number of SNPs in the LD block is always lower than predefined window size. One of the examples of

Figure 2. Window-sliding method for LD block extraction



the window-sliding method is shown in Figure 2. In this example, SNP2, 3, 4, 5 were extracted to be within a single LD block because all pairwise LDs among the four SNPs is strong enough (D' > 0.9). Although D' is the quite popular measure of LD, appropriate LD measures and parameters should be selected depending on the situation. LDminer provides a variety of LD measures and parameters for flexibly defining the LD block. We implement this method for both of gene-base and chromosome-base LD block extraction.

Disease Association for Multi-Locus Haplotypes

After building LD blocks, our system automatically performs both single-locus tests and haplotype /displotype association tests. In haplotype / diplotype association tests, we have options to select several multi-locus association tests such as Log Likelihood Test (LRT) (Zhao & Sham, 2002), Monte Carlo tests. (Sham & Curtis, 1995)

LRT is the nonparametric tests for homogeneity in haplotype / diplotype frequencies between cases and controls. For example, the fast EH program (FEHP) developed by Zhao and Sham can be used for this purpose. In their statistics, the maximum log-likelihood was calculated for cases alone, for controls alone, and for cases and controls pooled altogether. Denoting these maximum log-likelihoods as, and, LRT statistic was defined as 2(+ -), which is asymptotically chi-squared with the degree of freedom of, where is the number of haplotypes / diplotypes. Then we obtain asymptotic p-values as well as empirical p-values by the use of permutation procedures.

In Monte Carlo tests, some programs are well known such as CLUMP by Sham and Curtis (1995), which outputs the results of four different association tests from T1 to T4. In order to estimate the odds ratio (OR: a measure of the degree of association which estimates the relative risk of the disease in case-control study) and 95%CI for each haplotype/diplotype, we perform the Fisher's exact test for each haplotype by constructing a 2 × 2 table which consists of the number of haplotype holders /others in the column and the number of case/control in the row.

Viewer for Genome Structure and Tools for Analysis Interpretation

LDMiner also has a supplicated vitalization tool (Higashi et al., 2003). The main viewer displays the genomic structure and is linked to another main viewer showing the in-depth analysis result. As real causative polymorphisms are likely to be located in the vicinity of the analyzed polymorphisms rather than themselves, it is important to examine the surrounding genes and polymorphisms. For this purpose, we also proposed the algorithm on haplotype classification for detecting disease-associated sites (Kido et al., 2003). These viewers and tools allow the user to easily check and make an interpretation of the results.

EXAMPLES OF HAPLOTYPE ANALYSES

Experimental Setting: Genotype Data Used

To evaluate our methods, we performed a simulation study based on observed SNPs from genes around NPHS1 in chromosome 19 regions with a Japanese population of 375 independent individuals, a Caucasian population of 49 individuals and an African-American population of 49 individuals. This enables us to base our study on real patterns of LD within those genes. Some genes were genotyped in both exonic and intronic regions. We chose a subset of 10 SNPs mainly from NPHS1 genes denoted by 1 to 10 as shown in Figure 3.

Experimental Setting for the Simulation Study for Association Study

In order to examine whether the multi-locus association tests of LD0blocks have more statistical power than that of single-locus marker and how LD status influences the power of association, we evaluated it with simulated data sets. We designed a disease model for typical common disease described in report by Jannot, Essioux, Reese, & Clerget-Darpoux (2003) and phenotypic trait distributions were simulated under the samples of Japanese 375 (case 148, control 227) individuals, keeping our SNP typing information. In this model, we assumed that SNP 7, which allele frequency is 0.068, is the causative with prevalence rate of 0.08. We then compared the multi-locus haplotype tests with single-locus tests.

Single-Locus Analysis

The results of the single-locus analysis of allelic and genotype association are shown in Figure 4. As we designed, the causative SNP7 shows significant difference between case and control allele frequencies with a p-value is less than 0.00001. SNP9 also has a low p-value in allelic association. This is because LD between SNP7 and SNP9 is strongly high (|D'|=0.978) and the discrepancy between SNP7 and SNP9 frequencies is very small (SNP7 minor allele frequency [MAF]=0.068, and SNP9 MAF = 0.064). LD theory introduced by Zondervan and Cardon (2004) estimates that the expected OR of locus 9 is 2.06 and this fits with our simulation result. However, the SNP6, SNP8, SNP10 are also in the strong LD with locus, their p-values are not significant. This can be explained by the discrepancy between the disease SNP (locus 7) and marker SNP frequency is not small. The MAF of SNP6 is 0.135, that of SNP8 is 0.120 and that of SNP10 is 0.056. This case shows that common variant marker which has high allele frequency can not detect the effect of row variant causative SNP even though they are in the same LD block.

In LD mapping, the red part shows the strong LD (D' is higher than 0.8) and the blue part shows weak LD. Read parts can be extracted as LD block.

Haplotype Analysis

Selecting SNPs for Haplotype Analysis

First we selected 5 SNPs - SNP6, SNP7 (causative), SNP8, SNP9, SNP10 that are in the strong LD block as show in Figure 4. The average of |D'| in this LD block is 0.964. We then select 3 SNPs - SNP6, SNP8 SNP10. This is because, minor allele frequencies of SNP7 and SNP9 are small (less than 0.1) and they are usually considered as inappropriate SNP markers. Here, an interesting question for us is whether haplotype analysis consisting of three SNPs can detect the causative region or not, although all three SNPs are not positive in single-locus analysis.

Results of Haplotype Association: Single-Locus Analysis vs. Haplotype Analysis

The p-value distributions of the haplotype association and comparisons with those of single-locus analysis are shown in Figure 5. The HAP5 consisting of five SNPs has a significant overall p-value by FEHP program; empirical p-value is less than 0.001. However it is not higher than those of single-locus analysis at SNP7 and SNP9. Interestingly, HAP3 consisting of three SNPs has also significant overall p-value, which is less than 0.01. (The empirical p-value by FEHP program with 20000 permutations is 0.0022, and the asymptotic p-value is 0.0007. In Figure 3, we plot the empirical p-value of FEHP.) Furthermore this p-value is higher than those of single-locus analysis at SNP6, SNP8 and SNP10. This is a good example to show the advantage of haplotype analysis; although three SNPs in HAP3 are not positive in single-locus analysis, haplotype analysis can detect the significant difference in the HAP3 block.

Table 1 shows the results of haplotype analysis with three SNP markers (HAP3). Only six haplotypes are estimated by EM algorithm, major haplotype 'BBB' dominates 85.8 % over the population. For the major haplotype 'BBB', the difference of frequencies between case and control is not significant with a p-value obtained by Fisher's exact test of 0.085. The frequency of the minor haplotype 'AAB' - 6.5 %, is significant (p-value is less than 0.0001). It works as a risk haplotype, such that its frequency among cases (11%) is much higher than in controls (3%). The Fisher's p-value of 'AAB' is less than 0.0001 and the OR is 3.75 and its 95% confidence interval is 1.99 – 7.03. Because the posterior probability for determining diplotype is almost 100% (represented by blue bar) or more than 99% (represented by green bar) in most haplotypes, we can validate that haplotype estimation is mostly reasonable.

Diplotype Analysis

We also perform three-locus diplotype association as well as haplotype association study. This is done by determining individual's diplotype after estimating haplotype by EM algorithm (Kitamura et al., 2002). We only choose them from which posterior probability is more than 80%, otherwise we rule out from our analysis. The results are

Table 1. The results of haplotype analysis with 3 SNP markers

Table1:Haplotype Infomation

Haplotype ID	Sequence	Control Case	Frequency in case/control	Posterior probability distribution	Frequency	2x2 Fisher's p-value	Odds ratio	Odds ratio 95% confidence interval
0	Missing	0%(1) 0%(2)			0	0.0	0.0	null

Diplotype[1:6]	0%(1) 0%(1)				1.000000	1.565517	0.097154 - 25.226514
Diplotype[2:2]	0%(0) 3%(5)				0.008690	17.763251	0.974761 - 323.702877
Diplotype[3:3]	0%(2) 1%(2)				0.645199	1.569444	0.218627 - 11.266481
Diplotype[4:4]	0%(1) 0%(0)				1.000000	0.517634	0.020944 - 12.793105
Diplotype[4:5]	0%(1) 0%(1)				1.000000	1.565517	0.097154 - 25.226514

shown in Table 2. Minor diplotype [1:2] which represents the combination of haplotype1 ('BBB') and haplotype2 ('AAB') works as risk diplotype (Fisher's p-value is 0.005, OR=2.65). The diplotype also works as risk diplotype in our analysis (Fisher's p-value is 0.008, OR=17), although it is in the rare cases.

SUMMARY

The main purpose of this chapter was to review the roles of haplotype analysis for association study on complex common diseases and provide the computational framework that enables to realize high throughput genome-wide association study. The motivation, background and computational methods for finding causative genes by use of haplotype and LD information have been reviewed. A Haplotype Analysis System, LDMiner, has been introduced with some real examples of association studies. Although there have been significant advances in this area, further developments of computational methods for the genome-wide association studies and the detection of complex gene-gene interactions have been pursued. (Meng, Zaykin, Zu, Wanger, & Ehm, 2003; Ritchie et al., 2001; Toivonen et al., 2000) It is hoped that this report will entice further research and developments in bioinformatics for finding causative genes.

ACKNOWLEDGMENT

We would like to thank Dr. Tianhua Niu at Harvard University for useful discussions and comments.

Chapter 7.20
Computational Fluid Dynamics and Neural Network for Modeling and Simulations of Medical Devices

Yos S. Morsi
Swinburne University, Australia

Subrat Das
Swinburne University, Australia

ABSTRACT

This chapter describes the utilization of computational fluid dynamics (CFD) with neural network (NN) for analysis of medical devices. First, the concept of mathematical modeling and its use for solving engineering problems is presented followed by an introduction to CFD with a brief summary of the numerical techniques currently available. A brief introduction to the standard optimization strategies for NN and the various methodologies in use are also presented. A case study of the design and optimization of scaffolds for tissue engineering heart valve using the combined CFD and NN approach is presented and discussed. This chapter concludes with a discussion of the advantages and disadvantages of the combined NN and CFD techniques and their future potential prospective.

MATHEMATICAL MODELING

Introduction

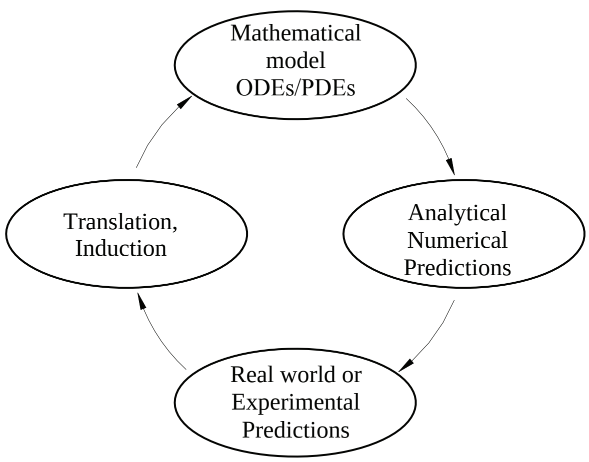
Many engineering systems are of a complex nature and require techniques that relate the relevant variables in the system under consideration. Equations that express physical phenomena between quantities require absolute numerical and dimensional equality. Historically, the use of dimensional analysis of the physics observed experimentally has been very successful in adding to our understanding of the complexity of the problem in hand. Generally speaking, all physical relationships can be expressed in terms of quantities such as mass M, Length L, and time T or other related quantities such as force F, pressure P, stress τ, and so on. The application of such a system may include converting one system of units to another, developing relations or equations, reducing the number of variables required for an experimental program and, in some cases, determining the principles of model design. It should be noted that for a physical system, dimensional analysis can only indicate variables or groups of variables that are functionally related, and it does not give insight of the nature of the correlation and its complexity. One of the most common uses of dimensional analysis is in experimental planning of examining a particular phenomena or system. Moreover, the dimensional analysis does not estimate the actual behavior of the system. This requires the development of a more comprehensive mathematical model which often requires a solution to the governing equations, either ordinary differential equations or partial differential equations (ODEs/PDEs).

The Governing Equations

In recent years, the utilization of mathematical modeling to solve engineering problems has been advanced greatly by the availability of fast and user-friendly software packages. However, these models, even today, still require experimental or physical modeling results to validate and verify the numerical results. However, in general, the process of mathematical modeling may require a continuing four-stage cycle, as illustrated in Figure 1 to have a solution.

The mathematical model is constructed based on fundamental laws of physics, often by making quite a number of assumptions. Some are justified quite rigorously on scientific grounds, while others render the problem tractable or solvable within an economically acceptable time frame. In any case, the mathematical assumptions formulate a mathematical model, and the next two stages of the cycle are intended to test this model and modify it if need be (Figure 1). To test a model, one needs to draw certain conclusions about the real problem at hand. Such terminations are often of two types, those related to previously observed situations (*explanatory in nature*) or those related to new, not previously observed situations (*predictive in nature*). Both types are important for validating a mathematical model, though for purposes of discussion, it is reasonable

Figure 1. The typical loop of mathematical modeling



to refer to both types as predictions. To obtain these outcomes, one first makes mathematical predictions, using mathematical tools, which have been previously developed or are developed for a particular mathematic model. These mathematical predictions are then translated back from the language of the model to the language of the real problem and interpreted as real-world predictions or conclusions. In the final stage, the predictions are checked against real data, either old (in the case of tests of the explanatory power of the model) or new (in the case of tests of its predictive power). On the basis of the new data, which includes the performance of the model's predictions, the model is modified, and the cycle repeats. The cyclical process is continuous and newly generated data must be validated against the explanatory power of the model or against its predictive power.

Mathematical models provide a fundamentally based quantitative relationship between process variables that provide a general insight into the overall behavior of a given system. For a new process, a mathematical model can provide guidance with respect to the general feasibility and the consistency of a new concept with both the physical and theoretical laws. If the process concept is found feasible, the model may identify critical areas that require further validation through possibly experimental investigation.

Traditionally, mathematical model development has relied on individual effort, where a scientist may have worked for a very long period of time to develop customized algorithms or a computer program, often understood by the developer alone. This imposes a major difficulty in extending the theory for further development of the program. However, in the last few decades with availability of software packages, the ready access to inexpensive computers, and the much more widespread application of modeling as a technical tool has assisted greatly in the advancement of mathematical modeling packages.

A mathematical model generally consists of algebraic or differential equations that quantitatively represent a system or process. For example, it may be a relationship that defines the time, pressure, and velocity in a pipe, defines swirling flow in an annulus, or defines the circulation patterns, fluid-structure interactions, composition of two phases in chemical equilibrium, stress distributions, and pressure drops along and across a valve or within a pump.

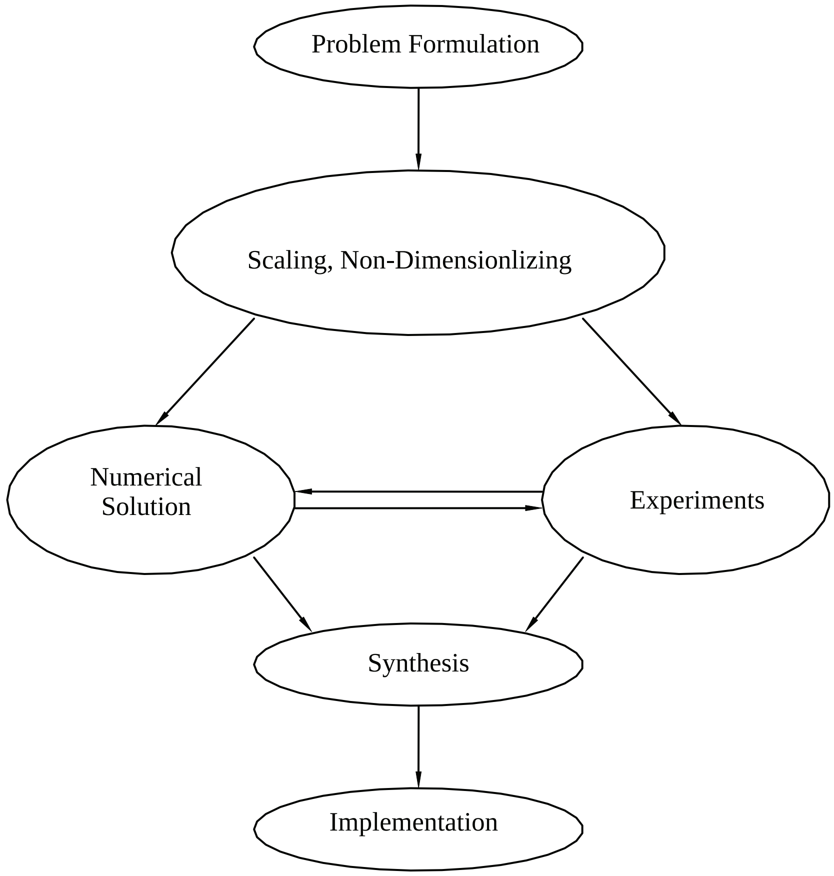
From the above discussion, it follows that a mathematic model may be simple differential equations or a complex set of equations, such as the coupled Navier Stokes equations with turbulence closures which may require certain expertise and advanced computer hardware to solve.

General Methodology for Model Development

A typical flowchart of a model development and implementation is shown in Figure 2. The model development involves the translation of a previously constructed physical picture into concrete mathematical terms, or more precisely, differential equations. Traditionally, problem formulation was usually performed "from scratch" by establishing a control volume and thus developing the appropriate governing equations in a differential form, by letting the dimensions of the control volume shrink to an infinitesimal size. While such a development is instructive and may indeed be appropriate for certain simple systems, at present there are rather easier and speedier ways to proceed:

- Drawing on prior experience with related systems (the rapidly growing body of modeling literature makes this possible);
- Using the "ready-made" building blocks of the key differential relationships;
- Navier-Stokes equations for fluid flow;
- Fourier's equation for heat transfer;
- Fick's equation for diffusion;

Figure 2. General methodology of model development



- Maxwell's equations for deformation processing turbulence models;
- Constitutive equations for deformation processing turbulence models.

It should be stressed that many problems involve some non-standard building blocks, such as meniscus effects, surface waves, hydrodynamic instability, surface tension, and so forth. The modeler will need to take care not to ignore these factors because the effects may have a dominant influence on the problem.

It has been shown that the critical examination of the governing equations represents the next logical step. These equations usually involve several scaled parameters as mentioned previously. Thus, the functional relationships between key process parameters, such as the solidification time proportional to the square of the characteristic dimension, the linear dependence of the melt velocities on current in induction furnaces, the relationship between the Rayleigh number and the characteristic velocity in buoyancy driven flows, Reynolds number effect on wall shear stress, and so forth, do provide a framework for interpreting data, which is unlikely to emerge from the computer output. Furthermore, the analytical solutions or functional relationships provide an excellent means for evaluating the consistency of computed solutions. The computer-generated solutions will make a much greater degree of precision possible to a whole range of process problems, such as the details of the velocity field, the thermal gradients, local values of the heat and mass transfer coefficients, and the details of mixing. Therefore, these two approaches are complementary rather than orthogonal.

At this point, it is important to stress the need to employ the correct boundary conditions because the software packages essentially solve the same types of conservation equations, and the principal factor that distinguishes individual cases is usually associated with the boundary conditions. These numerical solutions need to be checked for internal consistency, that is, by performing overall heat, mass, and momentum balances, testing sensitivity to different starting points and grid sizes, and, most importantly, checking the predictions against analytical asymptotes. The predictions will then have to be compared with experimental measurements to establish the discrepancies between these results by critical examination. If the deviation between these results is large, then it is necessary to check the appropriateness of the assumptions and to update the model.

Outline of the General Mathematical Procedures

The general principle of mathematical procedures, which can hold for any systems, can be outlined as follows:

- Define the quantity conserved, the control volume for which the equations are to be written, and select the independent and dependent variables. If only one independent variable appears, an ordinary differential equation will result.
- Apply the physical laws that yield the input and output expressions for the quantity conserved.
- Substitute these expressions into the appropriate terms in the equation.
- Develop the necessary boundary conditions.
- Solve the resulting differential equation and boundary conditions.

The above procedures can be applied to various engineering problems for design and optimization of various cardiovascular devices such as blood vessels, rotary blood pumps, ventricular assist devices, lung ventilation unit, modeling of liver stent, kidney and various other medical devices. In the following section, a case study is given to illustrate the necessary steps needed for design and optimization of model of artificial heart valves.

The success or failure of mathematical treatment of blood flow problems within cardiovascular devices depends mainly on our ability to solve the governing equations of continuity, momentum, and energy as accurately as possible. These equations contain non-linear terms and a large number of unknown variables, which makes an exact solution extremely difficult to obtain. Therefore, some assumptions of the physical phenomena must be made in order to reduce the number of unknown variables in the equations. In complex turbulent flow, a complete solution is still extremely difficult to obtain and, in attempting to solve the equations of motion, it is necessary to consider the following factors:

- The solution techniques available for the problem and their reliability;
- The methods of approximating the equations;
- The degree of accuracy requiring the validity of assumptions employed.

In general, the exact solutions for complex medical devices are difficult to obtain; moreover, the correctness of the results obtained analytically are somewhat limited due to their simplifying assumptions. With this in mind, numerical analyses have been widely used for several decades. As a result, numerical techniques have been developed to solve different combinations of ordinary/partial differential equations for various engineering and science applications. These methods are briefly summarized below:

Numerical Methods

Finite difference method (FDM), finite-volume method (FVM), and finite-element method (FEM) are widely employed to solve flow and heat transfer problems. Generally, the choice of a particular technique depends on factors such as non-linearity, geometry of boundary, and type of boundary conditions. FDM is a common and successful method used to deal with orthogonal geometries involving simple boundary conditions. In FDM methodology, discretization of the governing equations in 3D problems is simpler and the accuracy can readily be examined by the order of the truncation error in the Taylor's series expansion. However, for problems involving irregular geometry in the solution domain, FVM is more suitable. On the other hand, arbitrary and more complex geometries, involving gradient boundary conditions, FVM can be more cumbersome, and the application of FEM is preferred. Another important use of FEM is as a generalized computer algorithm, making it more advantageous than the other methods (Das & Morsi, 2003). However, development of a computer code that employs FEM is more time consuming compared to an equivalent code that uses FDM or FVM. It should be noted that the topic of "which method is good" is still the subject of debate among researchers. In reality, the choice of a particular method depends on the type of partial differential equations (PDEs) and the computational domain.

Partial Differential Equations (PDEs)

PDEs representing the physical problem may be classified as elliptic, parabolic, and hyperbolic and can be expressed in two-dimensional Cartesian form as

$$A\frac{\partial^2\phi}{\partial x^2}+B\frac{\partial^2\phi}{\partial x\partial y}+C\frac{\partial^2\phi}{\partial y^2}+D\frac{\partial\phi}{\partial x}+E\frac{\partial\phi}{\partial y}+F\phi+G(x,y)=0 \quad (1)$$

Where ϕ is the dependent variable that becomes velocity and temperature in fluid flow and heat transfer problems respectively? The mathematical character of the PDE is defined by the coefficients of A, B, and C. Other coefficients, D and E, can be functions of the spatial coordinates (x, y). The source term is represented by G. All fluid flow and heat transfer problems use a set of PDEs that are the same as the general equation shown above. However, in some situations of complex geometry, typical boundary conditions and the coefficient in the equation (1) can represent a formidable challenge in computational ability.

Computational fluid dynamics (CFD) and computer hardware during the last decade provide researchers in the field with various commercial codes of FVM and FEM such as CFX-TASCflow, FLOW3D, CFX4, CFX5, STAR-CD, Flotran, and so forth. They have helped significantly in various area of engineering to obtain reasonable approximations. However; other researchers have developed their own source codes for specific applications in fluid flow and heat transfer.

Recent improvements in the coupling library MpCCI (previously called COCOLIB) are taking place in cooperation between Computational Dynamics, Intes, GMD, and Daimler Chrysler. This capability will provide a general interface between a flow solver and a structural analysis code for estimating the fluid loads on a defined structure, particularly in multiphysics problems. Many have used this MpCCI interface to couple either their own codes or commercial codes such as fluid dynamics (CFX) with structure analysis (ANSYS, ADINA, ABACUS) and successfully simulated fluid induced large deflection problems. Several CAD development packages, such as Unigraphics, Solid-Edge, AutoCAD, Pro-Engineer, and 3D-CAD, have become an additional advantage for developing the accurate geometries of the computational domain. The development of CPU speed has also helped to simulate more sophisticated turbulence modeling that deals with realistic geometries. Traditionally, the results generated from these codes are validated with qualitative and quantitative information gained from experimental diagnostics techniques such as partical images velocitmatry (PIV) and laser Doppler anemometry (LDA).

In general, despite all the advances in the field, the CFD approach to some typical situations remained computationally expensive in terms of time. On the other hand, it is not suitable for system simulations, particularly for optimization purposes. Moreover, when the solution demands an interactive procedure, numerical solution usually fails to provide the solutions in real time due to its iterative procedure. The major shortcomings of CFD analysis can be listed:

- The system is usually depicted in terms of the set of ordinary differential equations or partial differential equations. The mathematical representation in terms of OPDEs/PDES usually involves approximations that are not relevant to the physical model. Moreover, due to a lack of precise knowledge of the physics of the processes involved or the properties of the materials used, the mathematical model represents an ideal situation rather than a real one.
- There may be several external *disturbances*, such as a change in environmental conditions that affect the response of the system.
- The exact initial conditions to determine the state of the system may not be accurately known.
- The model may be too complicated for exact analytical solutions. Computer-generated numerical solutions may have small errors that are magnified over time.
- The solution may be inherently sensitive to small perturbations in the state of the system, in which case, any error will magnify over time.
- Numerical solutions may be too slow to be of use in real time. This is usually the case if PDEs or a large number of ODEs are involved.

Although the CFD is now increasingly used to model thermal and fluid system performance as a part of the design and engineering process, in nearly all cases, the computational time required for CFD limits its use to providing insight into the physical phenomena investigated after the basic design is chosen rather than as a design and optimization tool. This is the case where NN can be thought of as another alternative tool where a collective set of neurons can be trained with a prior knowledge database obtained from numerical CFD calculations. Thus, it was required to define an intelligent system and its collectiveness.

SYSTEM APPROACH

A *system* may be defined as a small part of the universe that we are interested in and that has some intelligence. At this point, it is difficult to quantify the mode or the degree of intelligence that can be given to a system. However, the existing CFD/experimental data are enormous and can be one of the most important tools to create a system with some knowledge-based intelligence through various evolutionary algorithms (EAs). There are several areas where knowledge-based training approaches are applied to construct intelligent systems through evolutionary algorithms. These include instrument landing systems, automatic pilot, collision-avoidance systems, antilock brakes, smart air bags, intelligent road vehicles, medical diagnostic devices, image processing, pattern recognition, intelligent data analysis, temperature and flow control, process control, intelligent CAD, smart materials, smart manufacturing, Internet search engines, and machine translators. Neural network (NN) is one of approaches through which a knowledge-based system can be constructed.

Neurophysiologists spent many years searching for the engram, that is, the precise location in the brain for specific memories. The brain memory system has a specific structure that consists of many elements (neurons) working in parallel and in connection with one another. These sets of neurons act as a computing system for the brain. Thus, a neural network science based largely on the notion of "brain-style computation" has evolved in which a large number of very simple processing units act simultaneously on a distributed pattern of data. A trained neuron can be thought of as an expert system or a knowledge-based system in the category of information it has been given to analyze. Thus, NN that consists of several neurons has a remarkable ability to derive meaning from complicated or imprecise data that can be used to extract patterns and detect trends that are too complex to be recognized by humans or computer techniques. The application of NN to a variety of engineering applications appears to be a recent development, and a brief discussion on system development is outline below.

Simple System

A system has an input $u(t)$ and an output $y(t)$ where t is the time. A schematic representation simple open system is shown in Figure 3.

One can represent an input-output relationship by $y = \nabla(u)$ where∇ is an operator (addition, substraction, differential, or integral). Thus, if we know the input u(t), then the operations represented by ∇ must be carried out to obtain the output. In some situations, we may have a set of values for u(t) and y(t) and we would like to know what ∇ is. This is a *system identification* problem. If the system identifies the physics precisely, then it is called an expert/intelligent system.

For *closed-loop control*, there is a *feedback* from the output to the input of the system, as shown in Figure 4. The output of the NN model is compared with some standard value (base value). This base value can be from CFD simulation, experimental data, or analytical solution. The difference between the output and the base value can be treated as an error and minimized through a feedback closed loop approach.

Complex systems are made up of a large number of such opened/closed simple systems, each of which may be easy to understand or to solve for. Together, however, they pose a formidable modeling and computational task, and from a neurophysics point of view, each simple system behaves like a neuron.

NEURAL NETWORK IN CFD APPLICATION

Neural networks (NNs) have emerged as an alternative tool (Cao et al., 2004; Parlos et al., 1992) to first principle-based approaches for modeling complex systems in a variety of engineering applications. In a particular area of CFD analysis, the volume flow rates obtained by the two-dimensional CFD analysis were used as target values for learning a neural network. By learning neural network with the target values, the values of learning results were obtained, which almost coincide with the values of CFD (Han, 2003). The authors have used backpropagation rule as a learning method with hyperbolic tangent sigmoid transfer function for connecting the input layer with the first hidden layer. Even in a particular natural convection problem, u, v, p and T, Ra, Pr can be considered as inputs and Nusselt number can be considered (heat transfer rate) as an output. Yuen and Bau (1998) used the same approach for a natural convection problem. Diaz (2000) used

Figure 3. Schematic representation of an open system

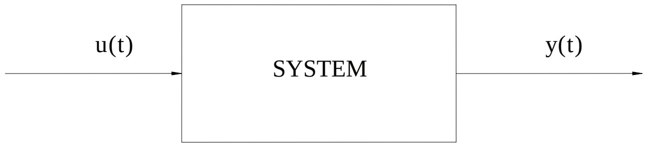


Figure 4. Closed system

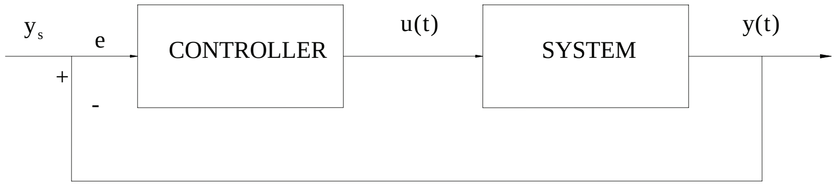


NN model for heat exchanger problem. Turbulence model using NN models were also reported (Gillies, 1998; Lee et al., 1997).

NN-based fluid field estimation with dimensional inputs and output has been studied by Xue and Watton (1998). The non-linear transient behavior of fluid power elements was also identified through NN modeling based upon input-output observations only. Xu et al. (1996) applied NN to model a flow through an orifice. Schreck et al. (1994) reported a non-dimensional NN configuration to characterize the unsteady, vortex-dominated flow as it develops over the wing and splitter plate of aircraft using surface pressure measurements and flow visualization. The neural network models were shown to accurately predict both temporal and spatial variations for both the unsteady separated flow fields and the aerodynamic loads. The inputs and output of the NN model were non-dimensionalized according to previous empirical and theoretical results. More recently, Cao et al. (2004) reported a non-dimensional artificial neural network (NDANN) model for accurate predictions of flow force and flow rates under the broad operating conditions of a hydraulic valve. Because of its non-dimensional characteristics, the NDANN fluid field estimator also exhibits accurate input-output scalability, which allows the NDANN model to estimate the fluid force and flow rate even when the operating condition parameter or design geometry parameters are outside the range of the training data. Sablani et. al. (2003) developed an explicit calculation of the friction factor in pipeline flow of Bingham plastic fluids. Their NN approach involved the establishment of an explicit relationship between the Reynolds number, (Re), and the friction factor, (f), under both laminar and turbulent flow conditions. In addition, EAs have also been applied to various optimization problems in thermofluid devices including airfoils, heat exchangers, fluid-structure interaction problems, and missile nozzle inlets for high-speed flow.

The overall modeling approach in NN is a black box approach, since (in principle) the development of NN models does not require prior knowledge of the process. It is sufficient to provide the network with the set of input data and the corresponding outputs. The objective is to train a model with prior knowledge input (PKI) (Chao et al., 2001; Watson et. al., 1999). However, having some idea about such relationship may provide for the fine-tuning of the NN model. In some instances, these ideas have shown exceptional improvements in NN model performance (Porru et al., 2000; Shayya & Sablani, 1998; Sablani, 2001). It is also capable of dealing with uncertainties, noisy data, and non-linear relationships. Brasquet and Le Cloirec (2000) conducted an experimental study and measured air and water pressure drops through a layer of several textile fabrics. Their study focused on the influence of specific parameters of clothes on their dynamic behavior. Using NN, they correlated fluid properties (i.e., viscosity, density, and Reynolds number) and fabric characteristics (i.e., thickness, density, number of openings, and raw material) as input neurons with pressure drop as the output neuron. The NN model they developed predicted pressure drops that closely followed the experimental values. A hybrid neural network modeling approach (Porru et. al., 2000) was proposed for the identification of the dynamic behavior of chemical reactors. They used a multilayer, feedforward neural network to correlate bulk carbon monoxide concentration and temperature with reaction rate. Their NN model was capable of describing the system kinetics over the entire range of the investigated operating conditions whereas a conventional Langmuir–Hinshelwood rate law failed to provide the correct representation. These and other studies reported in the literature underscore the importance of NN in tackling wide range of problems. However, in most of the applications of NN in modeling, a feedforward neural network is used to get a non-linear input/output mapping. A detailed methodology in the development of NN model for cardiovascular application is outlined below.

Case Study Overview: The Use of Artificial Neural Network for the Design and Optimization of Heart Valve

One of the most important applications of this area is prosthetic heart valves, which are commonly used to replace natural heart valves and are also widely used in ventricular assist devices (VAD) in total artificial hearts (TAH). The clinical success of any valve design is based on many factors including the fluid flow phenomena, particularly *in vitro* velocity profiles, shear stresses, regurgitation, and energy losses (Baldwin & Tarbell, 1991; Chandran & Cabell, 1983; Morsi et al., 2001). Thus, the optimization of the valve leaflet or wall-stress development patterns relates various parameters (Qiong et al., 2003). Moreover, if a prosthetic heart valve is to be used, the valve-related problems such as blood cell damage, thrombus formation, calcification, and infection, as well as valve durability, need consideration. In such areas, the fluid-phase is most conveniently described with respect to a Eulerian reference frame, while a Lagrangian formulation is more appropriate for the solid phase. These two formulations are not compatible, and, as a result, the numerical complexity increases manyfold. Several numerical techniques, such as arbitrary Lagrangian Eulerian (ALE), fictitious domain/mortar element (FD//ME), and immersed boundary (IB), have been proposed recently. All these techniques solve the problem (fluid-structure) sequentially. The solution of fluid forces are obtained using conservation of law of mass and momentum equations and then the structural solution follows for each time step. In all the methods mentioned above, the deformation of the mesh poses a formidable computational task, particularly in the case of the complex geometric problems like cardiovascular application.

In the study of hemodynamics and, in particular, vascular disease, one of the most important variables is the shear stress, τ [N/m^2], at the vessel wall. Wall shear stress has considerable clinical relevance because it provides information about both the magnitude of the force that the blood exerts on the vessel wall as well as the force exerted by one fluid layer on another. Shear stress varies with flow conditions (cardiac output, heart rate, etc.) as well as with the local geometry of the vessel (curves, branches, etc.). Excessively high levels of shear stress caused, for example, by atherosclerotic lesions or artificial heart valves, may damage red blood cells (a condition called haemolysis) or the endothelium of the vessel wall. Other abnormal shear stresses, such as very low or strongly oscillatory shear stresses, may also change the biological behavior of some cells or platelets in the blood stream (leading to thrombus formation) or endothelial cells on the vessel wall. Thus, the rheology of the blood, along with the laws of conservation (basic physical laws), is important in the design and development of artificial devices.

A typical solution procedure of fully open valve is shown in Figure 5.

The mesh quality changes as the solution proceeds, as shown in Figure 6(a). Most of the time, the solution diverges due to the poor quality of mesh, and this is the case with cardiovascular problems where it needs a large deflection phenomenon. The flow dynamics are also very complex, shown in Figure 6(b), as the valve deflects from its original position.

A three dimensional mesh generation of complete tri-leaflet valve is shown in Figure 7 to give an idea of its numerical complexities (Morsi & Das, 2004). Nevertheless, few modeling approaches have been proposed using sequential weak coupling. The knowledge gained from the experimental findings also has increased our understanding in the same area.

At this point, it is impossible to carry out any numerical procedure to achieve an optimized design with the variable mentioned above. However, a neural network model can be thought of as an alternative method to deal with such optimization problems with existing numerical/experimental data. A solution can be achieved by building a model of the cardiovascular system of an individual and comparing it with the real time physiological measurements or with existing CFD simulation data. The aim is to exploit the benefits of NNs by developing an improved neural network methodology from the prior knowledge inputs for the qualitative and quantitative visualization of flow development on deformed structures.

The development of an NN model involves two basic steps. These include the generation of (or compilation of available) data required for training, the training of NN networks, and the evaluation and validation of the optimal configuration of the NN model. The procedure used for the development of the NN model is outlined below.

Step 1. Data from CFD/Experiments for Training of Artificial Neural Networks

PIV and LDA are powerful experimental techniques that enable full field velocity vectors of seeding particles suspended in a fluid to be visualized. It is effective for obtaining both qualitative and quantitative information of a flow. Particle tracking velocimetry (PTV) also uses the images of seeding particles for analysis and can give data for wide range of variables. Both these visualization data and CFD data from the numerical techniques can be used (PKI Method) to create an NN model to mimic the actual cardiovascular system for given boundary conditions.

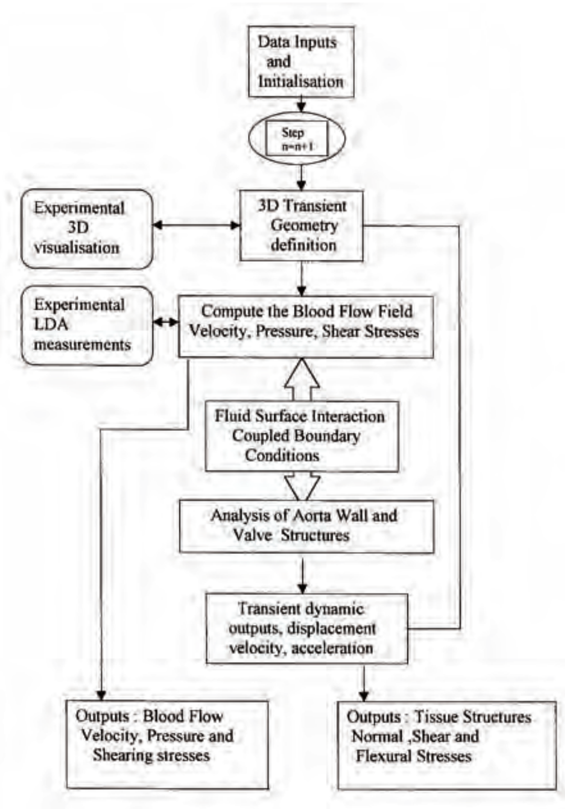
The overall objective of the proposed NN model is to devise and evaluate an explicit procedure for estimating the heart valve leaflet deflection with time. An accurate training of a system of NN model may save computational time substantially for such a complex problem as the fluid-structure interaction of the leaflet of heart valve.

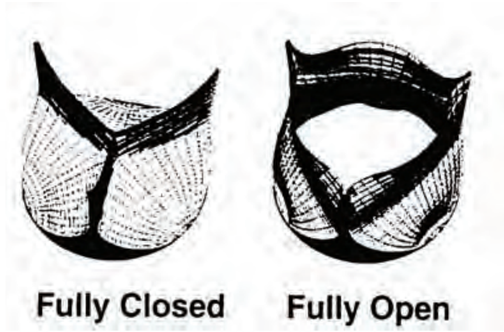
Step 2. Algorithm for Selection and Training of Neural Networks

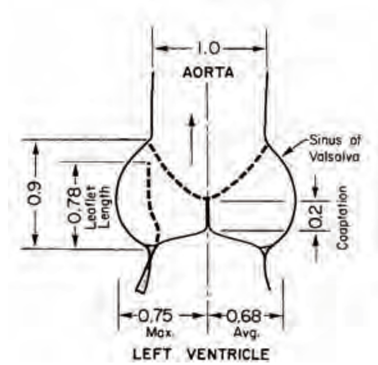
It is necessary to design an NN model to represent the desired input-output mapping for which the following considerations should be taken into account.

- *Type of system output:* stochastic or deterministic;

Figure 5. Typical tri-leaflet configurations for closed and open valve





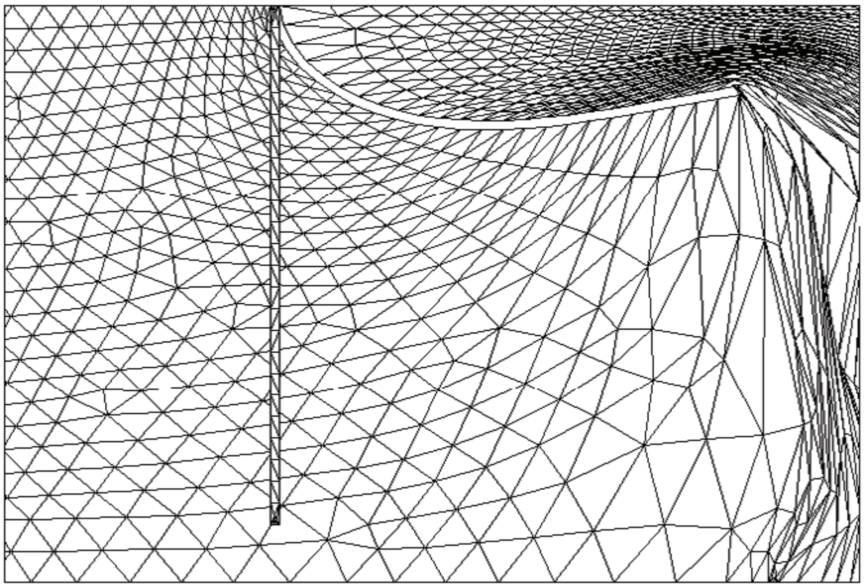


- *Type of neural network connectivity:* feed-forward, recurrent, or something else. This is a critical factor, especially when dealing with dynamical systems or with very large data quantities;
- *Layer transfer functions that depend on system behavior:* non-linear or linear;
- *Training routine:* gradient-based schemes or non-gradient-based schemes (Genetic Algorithms);
- *Scaling of input CFD data and output data:* both must be of constant order of magnitude.

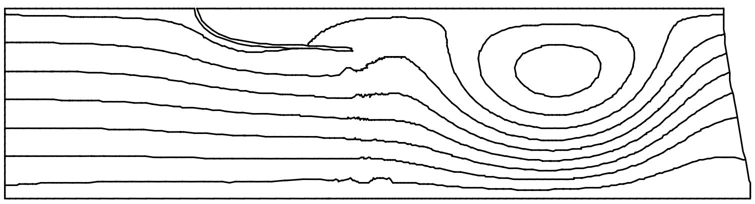
A typical NN structure trained for modeling purposes is shown in Figure 8. A scaling unit is needed to carry the system parameters and responses into a range meaningful for NN structure considered. Once training is over, the weights and bias terms of trained NNs are saved, and NN model is used for design purposes. It has to be pointed out that even though the training phase is long, using NN model takes a very short time, as there are no complex calculations.

The feedforward network structure, as a possible NN model, is shown in Figure 9. There are several ways one can select the input data depending upon objective functions (Outputs). A dataset

Figure 6. (a) Mesh deformation in 2D fluid-structure analysis; (b) streamline plot at peak flow condition



(a)



(b)

of fluid variables (u_f, v_f, P_f,) and structure varibles (u_s and v_s) at all points, along with tube diameter (D), leaflet thickness (d), Reynolds number (Re), and so forth, can be used as input parameters to an NN model with deflection (δ) as an output variable. These points cover the entire domain of solution with Re varied in a large range. It is to be noted that training the NN model with a limited dataset may not capture all the information (modes non-linearities) of the physical phenomena. The input layer consisted of five neurons that corresponded to u_f, v_f, Re, D, and d, while the output layer had one neuron representing the leaflet deflection, δ. However, selecting input data in the case of a dynamic situation of fluid flow is a crucial factor because the flow changes from laminar to turbulent as time increases. Thus, enormous amounts of data are required to train an NN model with all the non-linearities that are associated with a fluid and structural member. However, the use of surface force, that is, instantaneous pressure force (as a polynomial) on the leaflet as input and the deflection as an output may reduce the number of data for a specific optimization. Neural networks are proven to be more sophisticated in analyzing

Figure 7. Computational domain for a typical fluid-structure analysis of tri-leaflet heart valve

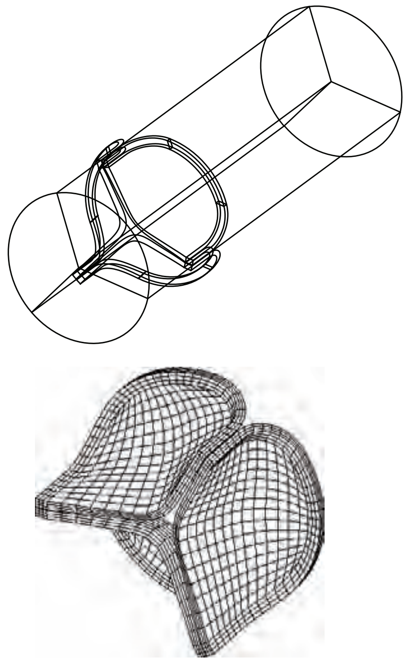


Figure 8. Neural network structure during training phase for model generating

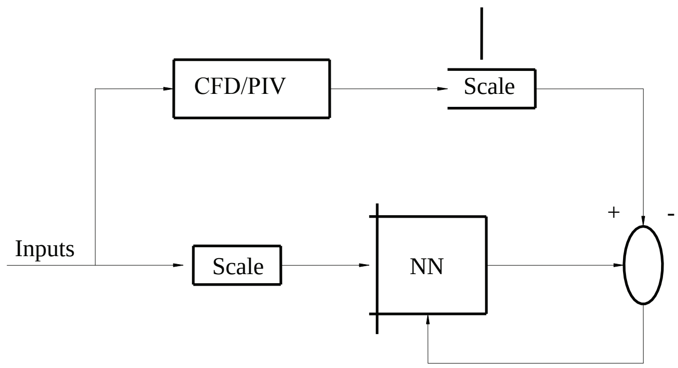
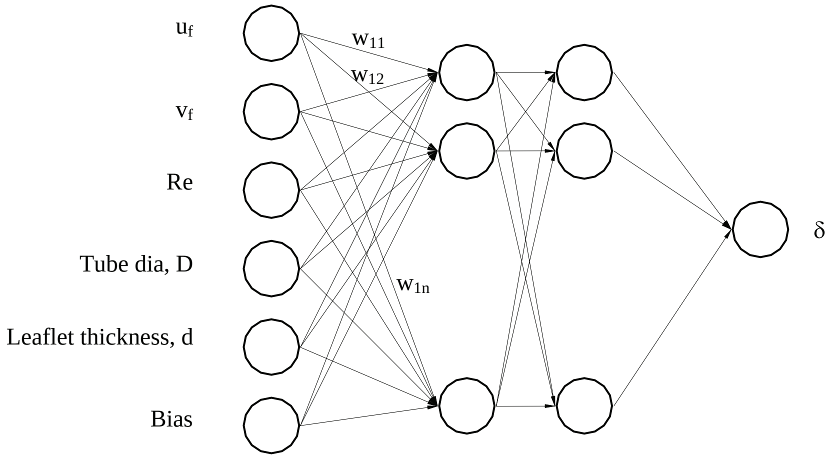


non-linear functions operating on polynomial expansions.

Backpropagation algorithm is a well-known method (Haykin, 1999), as discussed above. It can be utilized for development and training. The building of a backpropagation network involved the specification of the number of hidden layers and the number of neurons in each hidden layer. Hidden layers, which can be more than one, are formed using neurons having continuously differentiable non-linear activation functions, while output neurons have linear activation functions.

Figure 9. A multilayer perceptron structure (MLP)



The number of neurons on the last layer is equal to the number of objective functions. However, in Figure 9, only one objective function is shown. All the neurons are connected to the neurons of the previous and next layers. In addition, several parameters including the learning rule, the transfer function, the learning coefficient ratio, the random number seed, the error minimization algorithm, and the number of learning cycles can be specified to improve the learning strategy. As the problem involves several non-linearities, that is, fluid flow and large material deformation, the accurate choice of these parameters is very difficult. However, a trial and error method can be used and for which several standard procedures are provided by any NNs software. Input data move ahead through the layers according to the connections, and, at the output layer, output of the NN is obtained. Thus, the major step is called training and consists in determining adequate values for these connection. The training is performed by minimizing the evaluation errors of the NN for the known points of the database entries. These outputs, y, are compared to desired values (base value), and weights are changed by means of backpropagation algorithm minimizing error functions depending on error, *e*, between desired and obtained outputs. This stage is crucial and often tedious, since this optimization exercise involves a large number of variables. It is usually performed through gradient-based methods and may suffer from local minimization, resulting in a weak training which provides a poor approximation. Moreover, the results may depend strongly on the number of layers and neurones, which is a real disadvantage for the present application, since the training should be performed automatically.

In general, as the number of hidden layers and the number of neurons within each hidden layer increased, the prediction capabilities of the network also increased. However, the number of connection weights increased significantly as the number of neurons and hidden layers increased, thereby increasing the chances of memorization of the behavior among the dataset (rather than generalization). Hence, the number of hidden layers and the neurons in the hidden layers need to be selected carefully.

The applications of NN models in fluid-structure problems may have to predominantly use the backpropagation network as it depends mostly on existing input and output data. Without the priory knowledge input (CFD data), NN model may be impossible to achieve. Thus, CFD still plays a major role in providing this information for NN models. However, developing the model through these data may save the computational or optimization time significantly.

CONCLUSION

In this chapter, development of an NN model with the existing CFD/experimental results is discussed particularly in the area where a multiphysics phenomena (fluid-structure) along with a complex geometry. Emphasis is given to the backpropagation technique with multilayer perceptron (MLP) because backpropagation techniques are the most suitable for training non-linear data structures. At this stage, the NN models are not widely used in CFD analyses because of the longer time involved in the training procedure with such a large non-linear data range. However, soon we will achieve a convenient mode of training procedure with evolutionary algorithms.

Chapter 7.21
Genome-Wide Analysis of Epistasis Using Multifactor Dimensionality Reduction:
Feature Selection and Construction in the Domain of Human Genetics

Jason H. Moore
Dartmouth Medical School, USA

ABSTRACT

Human genetics is an evolving discipline that is being driven by rapid advances in technologies that make it possible to measure enormous quantities of genetic information. An important goal of human genetics is to understand the mapping relationship between interindividual variation in DNA sequences (i.e., the genome) and variability in disease susceptibility (i.e., the phenotype). The focus of the present study is the detection and characterization of nonlinear interactions among DNA sequence variations in human populations using data mining and machine learning methods. We first review the concept difficulty and then review a multifactor dimensionality reduction (MDR) approach that was developed specifically for this domain. We then present some ideas about how to scale the MDR approach to datasets with thousands of attributes (i.e., genome-wide analysis). Finally, we end with some ideas about how nonlinear genetic models might be statistically interpreted to facilitate making biological inferences.

THE PROBLEM DOMAIN: HUMAN GENETICS

Human genetics can be broadly defined as the study of genes and their role in human biology. An important goal of human genetics is to understand the mapping relationship between interindividual variation in DNA sequences (i.e., the genome) and variability in disease susceptibility (i.e., the phenotype). Stated another way, how does one or more changes in an individual's DNA sequence increase or decrease their risk of developing a common disease such as cancer or cardiovascular disease through complex networks biomolecules that are hierarchically organized and highly interactive? Understanding the role of DNA sequences in disease susceptibility is likely to improve diagnosis, prevention and treatment. Success in this important public health endeavor will depend critically on the degree of nonlinearity in the mapping between genotype to phenotype. Nonlinearities can arise from phenomena such as locus heterogeneity (i.e., different DNA sequence variations leading to the same phenotype), phenocopy (i.e., environmentally determined phenotypes), and the dependence of genotypic effects on environmental factors (i.e., gene-environment interactions or plastic reaction norms) and genotypes at other loci (i.e., gene-gene interactions or *epistasis*). It is this latter source of nonlinearity, *epistasis*, that is of interest here. Epistasis has been recognized for many years as deviations from the simple inheritance patterns observed by Mendel (Bateson, 1909) or deviations from additivity in a linear statistical model (Fisher, 1918) and is likely due, in part, to canalization or mechanisms of stabilizing selection that evolve robust (i.e., redundant) gene networks (Gibson & Wagner, 2000; Waddington, 1942, 1957; Proulx & Phillips, 2005).

Epistasis has been defined in multiple different ways (e.g., Brodie, 2000; Hollander, 1955; Philips, 1998). We have reviewed two types of epistasis, biological and statistical (Moore & Williams, 2005). Biological epistasis results from physical interactions between biomolecules (e.g., DNA, RNA, proteins, enzymes, etc.) and occur at the cellular level in an individual. This type of epistasis is what Bateson (1909) had in mind when he coined the term. Statistical epistasis on the other hand occurs at the population level and is realized when there is interindividual variation in DNA sequences. The statistical phenomenon of epistasis is what Fisher (1918) had in mind. The relationship between biological and statistical epistasis is often confusing but will be important to understand if we are to make biological inferences from statistical results (Moore & Williams, 2005).

The focus of the present study is the detection and characterization of statistical epistasis in human populations using data mining and machine learning methods. We first review the concept difficulty and then review a multifactor dimensionality reduction (MDR) approach that was developed specifically for this domain. We then present some ideas about how to scale the MDR approach to datasets with thousands of attributes (i.e., genome-wide analysis). Finally, we end with some ideas about how nonlinear genetic models might be statistically interpreted to facilitate making biological inferences.

CONCEPT DIFFICULTY

Epistasis can be defined as biological or statistical (Moore & Williams, 2005). Biological epistasis occurs at the cellular level when two or more biomolecules physically interact. In contrast, statistical epistasis occurs at the population level and is characterized by deviation from additivity in a linear mathematical model. Consider the following simple example of statistical epistasis in the form of a penetrance function. Penetrance is simply the probability (P) of disease (D) given a particular combination of genotypes (G) that was inherited (i.e., P[D|G]). A single genotype is determined by one allele (i.e., a specific DNA sequence state) inherited from the mother and one allele inherited from the father. For most single nucleotide polymorphisms or SNPs, only two alleles (e.g., encoded by *A* or *a*) exist in the biological population. Therefore, because the

Table 1. Penetrance values for genotypes from two SNPs

	AA (0.25)	*Aa* (0.50)	*aa* (0.25)
BB (0.25)	0	.1	0
Bb (0.50)	.1	0	.1
bb (0.25)	0	.1	0

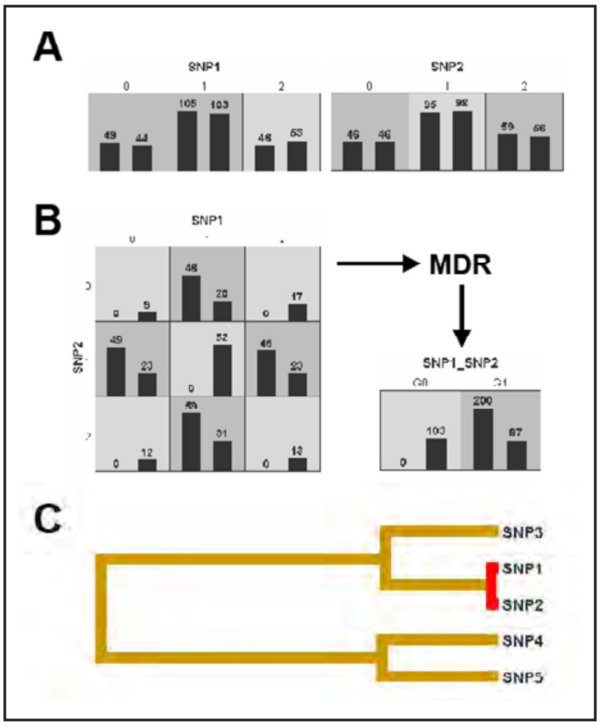
order of the alleles is unimportant, a genotype can have one of three values: *AA*, *Aa* or *aa*. The model illustrated in Table 1 is an extreme example of epistasis. Let's assume that genotypes *AA*, *aa*, *BB*, and *bb* have population frequencies of 0.25 while genotypes *Aa* and *Bb* have frequencies of 0.5 (values in parentheses in Table 1). What makes this model interesting is that disease risk is dependent on the particular *combination* of genotypes inherited. Individuals have a very high risk of disease if they inherit *Aa* or *Bb* but not both (i.e., the exclusive OR function). The penetrance for each individual genotype in this model is 0.5 and is computed by summing the products of the genotype frequencies and penetrance values. Thus, in this model there is no difference in disease risk for each single genotype as specified by the single-genotype penetrance values. This model is labeled M170 by Li and Reich (2000) in their categorization of genetic models involving two SNPs and is an example of a pattern that is not linearly separable. Heritability or the size of the genetic effect is a function of these penetrance values. The model specified in Table 1 has a heritability of 0.053 which represents a small genetic effect size. This model is a special case where all of the heritability is due to epistasis. As Freitas (2001) reviews this general class of problems has high concept difficulty. Moore (2003) suggests that epistasis will be the norm for common human diseases such as cancer, cardiovascular disease, and psychiatric diseases.

MULTIFACTOR DIMENSIONALITY REDUCTION

Multifactor dimensionality reduction (MDR) was developed as a nonparametric (i.e., no parameters are estimated) and genetic model-free (i.e., no genetic model is assumed) data mining strategy for identifying combinations of SNPs that are predictive of a discrete clinical endpoint (Hahn & Moore, 2004; Hahn, Ritchie, & Moore, 2003; Moore, 2004; Moore et al., 2006; Ritchie, Hahn, & Moore, 2003; Ritchie et al., 2001). At the heart of the MDR approach is a feature or attribute construction algorithm that creates a new attribute by pooling genotypes from multiple SNPs. The process of defining a new attribute as a function of two or more other attributes is referred to as constructive induction or attribute construction and was first developed by Michalski (1983). Constructive induction using the MDR kernel is accomplished in the following way. Given a threshold *T*, a multilocus genotype combination is considered high-risk if the ratio of cases (subjects with disease) to controls (healthy subjects) exceeds *T*, else it is considered low-risk. Genotype combinations considered to be high-risk are labeled G_1 while those considered low-risk are labeled G_0. This process constructs a new one-dimensional attribute with levels G_0 and G_1. It is this new single variable that is assessed using any classification method. The MDR method is based on the idea that changing the representation space of the data will make it easier for a classifier such as a decision tree or a naive Bayes learner to detect attribute dependencies. Open-source software in Java and C are freely available from www.epistasis.org/software.html

Consider the simple example presented above and in Table 1. This penetrance function was used to simulate a dataset with 200 cases (diseased subjects) and 200 controls (healthy subjects) for a total of 400 instances. The list of attributes included the two functional interacting SNPs (SNP1 and SNP2) in addition to three randomly

Figure 1. (a) Distribution of cases (left bars) and controls (right bars) across three genotypes (0, 1, 2) for two simulated interacting SNPs; (b) distribution of cases and controls across nine two-locus genotype combinations**; (c) an interaction dendrogram summarizing the information gain associated with constructing pairs of attributes using MDR****



*Note: * The ratio of cases to controls for these two SNPs are nearly identical. The dark shaded cells signify "high-risk" genotypes. ** Considering the two SNPs jointly reveals larger case-control ratios. Also illustrated is the use of the MDR attribute construction function that produces a single attribute (SNP1_SNP2) from the two SNPs. *** The length of the connection between two SNPs is inversely related to the strength of the information gain. Red lines indicate a positive information gain that can be interpreted as synergistic interaction. Brown lines indicate no information gain*

generated SNPs (SNP3 – SNP5). All attributes in these datasets are categorical. The SNPs each have three levels (0, 1, 2) while the class has two levels (0, 1) that code controls and cases. Figure 1a illustrates the distribution of cases (left bars) and controls (right bars) for each of the three genotypes of SNP1 and SNP2. The dark-shaded cells have been labeled "high-risk" using a threshold of T = 1. The light-shaded cells have been labeled "low-risk." Note that when considered individually, the ratio of cases to controls is close to one for each single genotype. Figure 1b illustrates the distribution of cases and controls when the two functional SNPs are considered jointly. Note the larger ratios that are consistent with the genetic model in Table 1. Also illustrated in Figure 1b is the distribution of cases and controls for the new single attribute constructed using MDR. This new single attribute captures much of the information from the interaction and could be assessed using a simple naïve Bayes classifier.

The MDR method has been successfully applied to detecting epistasis or gene-gene interactions for a variety of common human diseases including, for example, sporadic breast cancer (Ritchie et al., 2001), essential hypertension

(Moore & Williams, 2002; Williams et al., 2004), atrial fibrillation (Moore et al., 2006; Tsai et al., 2004), myocardial infarction (Coffey et al., 2004), type II diabetes (Cho et al., 2004), prostate cancer (Xu et al., 2005), bladder cancer (Andrew et al., 2006), schizophrenia (Qin et al., 2005), and familial amyloid polyneuropathy (Soares et al., 2005). The MDR method has also been successfully applied in the context of pharmacogenetics and toxicogenetics (e.g., Wilke, Reif, & Moore, 2005).

Consider the following case study. Andrew et al. (2006) carried out an epidemiologic study to identify genetic and environmental predictors of bladder cancer susceptibility in a large sample of Caucasians (914 instances) from New Hampshire. This study focused specifically on genes that play an important role in the repair of DNA sequences that have been damaged by chemical compounds (e.g., carcinogens). Seven SNPs were measured including two from the *X-ray repair cross-complementing group 1* gene (*XRCC1*), one from the *XRCC3* gene, two from the *xeroderma pigmentosum group D* (*XPD*) gene, one from the *nucleotide excision repair* gene (*XPC*), and one from the *AP endonuclease 1* gene (*APE1*). Each of these genes plays an important role in DNA repair. Smoking is a known risk factor for bladder cancer and was included in the analysis along with gender and age for a total of 10 attributes. Age was discretized to > or ≤ 50 years.

A parametric statistical analysis of each attribute individually revealed a significant independent main effect of smoking as expected. However, none of the measured SNPs were significant predictors of bladder cancer individually. Andrew et al. (2006) used MDR to exhaustively evaluate all possible two-, three-, and four-way interactions among the attributes. For each combination of attributes a single constructed attribute was evaluated using a naïve Bayes classifier. Training and testing accuracy were estimated using 10-fold cross-validation. A best model was selected that maximized the testing accuracy. The best model included two SNPs from the *XPD* gene and smoking. This three-attribute model had a testing accuracy of 0.66. The empirical p-value of this model was less than 0.001 suggesting that a testing accuracy of 0.66 or greater is unlikely under the null hypothesis of no association as assessed using a 1000-fold permutation test. Decomposition of this model using measures of information gain (see Moore et al., 2006; see below) demonstrated that the effects of the two *XPD* SNPs were non-addtive or synergistic suggestive of nonlinear interaction. This analysis also revealed that the effect of smoking was mostly independent of the nonlinear genetic effect. It is important to note that parametric logistic regression was unable to model this three-attribute interaction due lack of convergence. This study illustrates the power of MDR to identify complex relationships between genes, environmental factors such as smoking, and susceptibility to a common disease such as bladder cancer. The MDR approach works well in the context of an exhaustive search but how does it scale to genome-wide analysis of thousands of attributes?

GENOME-WIDE ANALYSIS

Biological and biomedical sciences are undergoing an information explosion and an understanding implosion. That is, our ability to generate data is far outpacing our ability to interpret it. This is especially true in the domain of human genetics where it is now technically and economically feasible to measure thousands of SNPs from across the human genome. It is anticipated that at least one SNP occurs approximately every 100 nucleotides across the $3*10^9$ nucleotide human genome. An important goal in human genetics is to determine which of the many thousands of SNPs are useful for predicting who is at risk for common diseases. This "genome-wide" approach is expected to revolutionize the genetic analysis of common human diseases (Hirschhorn & Daly, 2005; Wang, Barratt, Clayton, & Todd, 2005) and is quickly replacing the traditional "candidate gene" approach that focuses on several genes selected by their known or suspected function.

Moore and Ritchie (2004) have outlined three significant challenges that must be overcome if we are to successfully identify genetic predictors of health and disease using a genome-wide approach. First, powerful data mining and machine learning methods will need to be developed to statistically model the relationship between combinations of DNA sequence variations and disease susceptibility. Traditional methods such as logistic regression have limited power for modeling high-order nonlinear interactions (Moore & Williams, 2002). The MDR approach was discussed above as an alternative to logistic regression. A second challenge is the selection of genetic features or attributes that should be included for analysis. If interactions between genes explain most of the heritability of common diseases, then combinations of DNA sequence variations will need to be evaluated from a list of thousands of candidates. Filter and wrapper methods will play an important role because there are more combinations than can be exhaustively evaluated. A third challenge is the interpretation of gene-gene interaction models. Although a statistical model can be used to identify DNA sequence variations that confer risk for disease, this approach cannot be translated into specific prevention and treatment strategies without interpreting the results in the context of human biology. Making etiological inferences from computational models may be the most important and the most difficult challenge of all (Moore & Williams, 2005).

Combining the concept difficulty described above with the challenge of attribute selection yields what Goldberg (2002) calls a *needle-in-a-haystack* problem. That is, there may be a particular combination of SNPs that together with the right nonlinear function are a significant predictor of disease susceptibility. However, individually they may not look any different than thousands of other SNPs that are not involved in the disease process and are thus noisy. Under these models, the learning algorithm is truly looking for a genetic needle in a genomic haystack. A recent report from the International HapMap Consortium (Altshuler et al., 2005) suggests that approximately 300,000 carefully selected SNPs may be necessary to capture all of the relevant variation across the Caucasian human genome. Assuming this is true (it is probably a lower bound), we would need to scan $4.5 * 10^{10}$ pair wise combinations of SNPs to find a genetic needle. The number of higher order combinations is astronomical. What is the optimal approach to this problem?

There are two general approaches to selecting attributes for predictive models. The filter approach pre-processes the data by algorithmically or statistically assessing the quality of each attribute and then using that information to select a subset for classification. The wrapper approach iteratively selects subsets of attributes for classification using either a deterministic or stochastic algorithm. The key difference between the two approaches is that the classifier plays no role in selecting which attributes to consider in the filter approach. As Freitas (2002) reviews, the advantage of the filter is speed while the wrapper approach has the potential to do a better job classifying. We discuss each of these general approaches in turn for the specific problem of detecting epistasis or gene-gene interactions on a genome-wide scale.

A FILTER STRATEGY FOR GENOME-WIDE ANALYSIS

There are many different statistical and computational methods for determining the quality of attributes. A standard strategy in human genetics is to assess the quality of each SNP using a chi-square test of independence followed by a correction of the significance level that takes into account an increased false-positive (i.e., type I error) rate due to multiple tests. This is a very efficient filtering method but it ignores the dependencies or interactions between genes. Kira and Rendell (1992) developed an algorithm called Relief that is capable of detecting attribute dependencies. Relief estimates the quality of attributes through a type of nearest neighbor algorithm that selects neighbors (instances) from the same class and from the different class based on the vector of values across attributes. Weights (W) or quality estimates for each attribute (A) are estimated based on whether the nearest neighbor (nearest hit, H) of a randomly selected instance (R) from the same class and the nearest neighbor from the other class (nearest miss, M) have the same or different values. This process of adjusting weights is repeated for m instances. The algorithm produces weights for each attribute ranging from -1 (worst) to +1 (best). The Relief pseudocode is outlined below:

```
set all weights W[A] = 0
for i = 1 to m do begin
    randomly select an instance R_i
    find nearest hit H and nearest miss M
    for A = 1 to a do
        W[A] = W[A] − diff(A, R_i, H)/m
        + diff(A, R_i, M)/m
    end
```

The function diff(A, I_1, I_2) calculates the difference between the values of the attribute A for two instances I_1 and I_2. For nominal attributes such as SNPs it is defined as:

diff(A, I_1, I_2) = 0 if genotype(A, I_1) = genotype(A, I_2),
1 otherwise

The time complexity of Relief is $O(m{*}n{*}a)$ where *m* is the number of instances randomly sampled from a dataset with *n* total instances and a attributes. Kononenko (1994) improved upon Relief by choosing *n* nearest neighbors instead of just one. This new ReliefF algorithm has been shown to be more robust to noisy attributes (Kononenko, 1994; Robnik-Šikonja & Kononenko, 2001, 2003) and is widely used in data mining applications.

ReliefF is able to capture attribute interactions because it selects nearest neighbors using the entire vector of values across all attributes. However, this advantage is also a disadvantage because the presence of many noisy attributes can reduce the signal the algorithm is trying to capture. Moore and White (2007a) proposed a "tuned" ReliefF algorithm (TuRF) that systematically removes attributes that have low quality estimates so that the ReliefF values if the remaining attributes can be reestimated. The pseudocode for TuRF is outlined below:

```
let a be the number of attributes
for i = 1 to n do begin
    estimate ReliefF
    sort attributes
    remove worst n/a attributes
end
return last ReliefF estimate for each attribute
```

The motivation behind this algorithm is that the ReliefF estimates of the true functional attributes will improve as the noisy attributes are removed from the dataset.

Moore and White (2007a) carried out a simulation study to evaluate the power of ReliefF, TuRF, and a naïve chi-square test of independence for selecting functional attributes in a filtered subset. Five genetic models in the form of penetrance functions (e.g., Table 1) were generated. Each model consisted of two SNPs that define a nonlinear relationship with disease susceptibility. The heritability of each model was 0.1 which reflects a moderate to small genetic effect size. Each of the five models was used to generate 100 replicate datasets with sample sizes of 200, 400, 800, 1600, 3200 and 6400. This range of sample sizes represents a spectrum that is consistent with small to medium size genetic studies. Each dataset consisted of an equal number of case (disease) and control (no disease) subjects. Each pair of functional SNPs was combined within a genome-wide set of 998 randomly generated SNPs for a total of 1000 attributes. A total of 600 datasets were generated and analyzed.

ReliefF, TuRF and the univariate chi-square test of independence were applied to each of the datasets. The 1000 SNPs were sorted according to their quality using each method and the top 50, 100, 150, 200, 250, 300, 350, 400, 450 and 500 SNPs out of 1000 were selected. From each subset we counted the number of times the two functional SNPs were selected out of each set of 100 replicates. This proportion is an estimate of the power or how likely we are to find the true SNPs if they exist in the dataset. The number of times each method found the correct two SNPs was statistically compared. A difference in counts (i.e., power) was considered statistically significant at a type I error rate of 0.05. Moore and White (2007a) found that the power of ReliefF to pick (filter) the correct two functional attributes was consistently better ($P \leq 0.05$) than a naïve chi-square test of independence across subset sizes and models when the sample size was 800 or larger. These results suggest that ReliefF is capable of identifying interacting SNPs with a moderate genetic effect size (heritability=0.1) in moderate sample sizes. Next, Moore and White (2007a) compared the power of TuRF to the power of ReliefF. They found that the TuRF algorithm was consistently better ($P \leq 0.05$) than ReliefF across small SNP subset sizes (50, 100, and 150) and across all five models when the sample size was 1600 or larger. These results suggest that algorithms based on ReliefF show promise for filtering interacting attributes in this domain. The disadvantage of the filter approach is that important attributes might be discarded prior to analysis. Stochastic search or wrapper methods provide a flexible alternative.

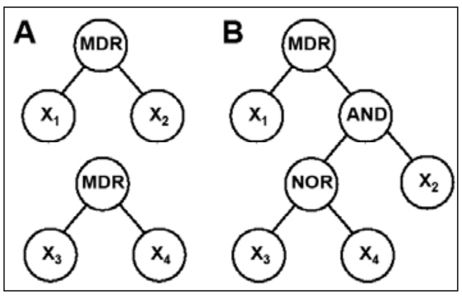
A WRAPPER STRATEGY FOR GENOME-WIDE ANALYSIS

Stochastic search or wrapper methods may be more powerful than filter approaches because no attributes are discarded in the process. As a result, every attribute retains some probability of being selected for evaluation by the classifier. There are many different stochastic wrapper algorithms that can be applied to this problem. Moore and White (2007b) have explored the use of genetic programming (GP). Genetic programming (GP) is an automated computational discovery tool that is inspired by Darwinian evolution and natural selection (Banzhaf, Nordin, Keller, & Francone, 1998; Koza 1992, 1994; Koza, Bennett, Andre, & Keane, 1999; Koza et al., 2003; Langdon, 1998; Langdon & Poli, 2002). The goal of GP is evolve computer programs to solve problems. This is accomplished by first generating random computer programs that are composed of the basic building blocks needed to solve or approximate a solution to the problem. Each randomly generated program is evaluated and the good programs are selected and recombined to form new computer programs. This process of selection based on fitness and recombination to generate variability is repeated until a best program or set of programs is identified. Genetic programming and its many variations have been applied successfully in a wide range of different problem domains including data mining and knowledge discovery (e.g., Freitas, 2002), electrical engineering (e.g., Koza et al., 2003), and bioinformatics (e.g., Fogel & Corne, 2003).

Moore and White (2007b) developed and evaluated a simple GP wrapper for attribute selection in the context of an MDR analysis. Figure 2a illustrates an example GP binary expression tree. Here, the root node consists of the MDR attribute construction function while the two leaves on the tree consist of attributes. Figure 2b illustrates a more complex tree structure that could be implemented by providing additional functions and allowing the binary expression trees to grow beyond one level. Moore and White (2007b) focused exclusively on the simple one-level GP trees as a baseline to assess the potential for this stochastic wrapper approach.

The goal of this study was to develop a stochastic wrapper method that is able to select attributes that interact in the absence of independent main effects. At face value, there is no reason to expect that a GP or any other wrapper method would perform better than a random attribute selector because there are no "building blocks" for this problem when accuracy is used as the fitness measure. That is, the fitness of any given classifier would look no better than any other with just one of the correct SNPs in the MDR model. Preliminary studies by White, Gilbert, Reif, and Moore (2005) support this idea. For GP or any other wrapper to work there needs to be recognizable building blocks. Moore and White (2007b) specifically evaluated whether including pre-processed attribute quality estimates using TuRF (see above) in a multiobjective fitness function improved attribute selection over a random

Figure 2. (a) Example of a simple GP binary expression with two attributes and an MDR function as the root node; (b) example of what a more complex GP tree might look like



search or just using accuracy as the fitness. Using a wide variety of simulated data, Moore and White (in press) demonstrated that including TuRF scores in addition to accuracy in the fitness function significantly improved the power of GP to pick the correct two functional SNPs out of 1000 total attributes. A subsequent study showed that using TuRF scores to select trees for recombination and reproduction performed significantly better than using TuRF in a multiobjective fitness function (Moore & White, 2006).

This study presents preliminary evidence suggesting that GP might be useful for the genome-wide genetic analysis of common human diseases that have a complex genetic architecture. The results raise numerous questions. How well does GP do when faced with finding three, four or more SNPs that interact in a nonlinear manner to predict disease susceptibility? How does extending the function set to additional attribute construction functions impact performance? How does extending the attribute set impact performance? Is using GP better than filter approaches? To what extent can GP theory help formulate an optimal GP approach to this problem? Does GP outperform other evolutionary or non-evolutionary search methods? Does the computational expense of a stochastic wrapper like GO outweigh the potential for increased power? The studies by Moore and White (2006, 2007b) provide a starting point to begin addressing some of these questions.

STATISTICAL AND BIOLOGICAL INTERPRETATION

Multifactor dimensionality reduction is powerful attribute construction approach for detecting epistasis or nonlinear gene-gene interactions in epidemiologic studies of common human diseases. The models that MDR produces are by nature multidimensional and thus diffuct to interpret. For example, an interaction model with four SNPs, each with three genotypes, summarizes

81 different genotype (i.e., level) combinations (i.e., 3^4). How do each of these level combinations relate back to biological processes in a cell? Why are some combinations associated with high-risk for disease and some associated with low-risk for disease? Moore et al. (2006) have proposed using information theoretic approaches with graph-based models to provide both a statistical and a visual interpretation of a multidimensional MDR model. Statistical interpretation should facilitate biological interpretation because it provides a deeper understanding of the relationship between the attributes and the class variable. We describe next the concept of interaction information and how it can be used to facilitate statistical interpretation.

Jakulin and Bratko (2003) have provided a metric for determining the gain in information about a class variable (e.g., case-control status) from merging two attributes into one (i.e., attribute construction) over that provided by the attributes independently. This measure of *information gain* allows us to gauge the benefit of considering two (or more) attributes as one unit. While the concept of information gain is not new (McGill, 1954), its application to the study of attribute interactions has been the focus of several recent studies (Jakulin & Bratko, 2003; Jakulin et al., 2003). Consider two attributes, A and B, and a class label C. Let H(X) be the Shannon entropy (see Pierce, 1980) of X. The information gain (IG) of A, B, and C can be written as (1) and defined in terms of Shannon entropy (2 and 3).

$$IG(ABC) = I(A;B|C) - I(A;B) \quad (1)$$

$$I(A;B|C) = H(A|C) + H(B|C) - H(A,B|C) \quad (2)$$

$$I(A;B) = H(A) + H(B) - H(A,B) \quad (3)$$

The first term in (1), I(A;B|C), measures the *interaction* of A and B. The second term, I(A;B), measures the *dependency* or correlation between A and B. If this difference is positive, then there is evidence for an attribute interaction that cannot be linearly decomposed. If the difference is negative, then the information between A and B is redundant. If the difference is zero, then there is evidence of conditional independence or a mixture of synergy and redundancy. These measures of interaction information can be used to construct interaction graphs (i.e., network diagrams) and an interaction dendrograms using the entropy estimates from Step 1 with the algorithms described first by Jakulin and Bratko (2003) and more recently in the context of genetic analysis by Moore et al. (2006). Interaction graphs are comprised of a node for each attribute with pairwise connections between them. The percentage of entropy removed (i.e., information gain) by each attribute is visualized for each node. The percentage of entropy removed for each pairwise MDR product of attributes is visualized for each connection. Thus, the independent main effects of each polymorphism can be quickly compared to the interaction effect. Additive and nonadditive interactions can be quickly assessed and used to interpret the MDR model which consists of distributions of cases and controls for each genotype combination. Positive entropy values indicate synergistic interaction while negative entropy values indicate redundancy.

Interaction dendrograms are also a useful way to visualize interaction (Jakulin & Bratko 2003; Moore et al., 2006). Here, hierarchical clustering is used to build a dendrogram that places strongly interacting attributes close together at the leaves of the tree. Jakulin and Bratko (2003) define the following dissimilarity measure, D (5), that is used by a hierarchical clustering algorithm to build a dendrogram. The value of 1000 is used as an upper bound to scale the dendrograms.

$$D(A,B) = \begin{cases} |I(A;B;C)|^{-1} & \text{if } |I(A;B;C)|^{-1} < 1000 \\ 1000 & \text{otherwise} \end{cases} \quad (5)$$

Using this measure, a dissimilarity matrix can be estimated and used with hierarchical cluster analysis to build an interaction dendrogram. This facilitates rapid identification and interpretation of pairs of interactions. The algorithms for the entropy-based measures of information gain are implemented in the open-source MDR software package available from www.epistasis.org. Output in the form of interaction dendrograms is provided. Figure 1c illustrates an interaction dendrogram for the simple simulated dataset described above. Note the strong synergistic relationship between SNP1 and SNP2. All other SNPs are independent which is consistent with the simulation model.

SUMMARY

We have reviewed a powerful attribute construction method called multifactor dimensionality reduction or MDR that can be used in a classification framework to detect nonlinear attribute interactions in genetic studies of common human diseases. We have also reviewed a filter method using ReliefF and a stochastic wrapper method using genetic programming (GP) for the analysis of gene-gene interaction or epistasis on a genome-wide scale with thousands of attributes. Finally, we reviewed information theoretic methods to facilitate the statistical and subsequent biological interpretation of high-order gene-gene interaction models. These data mining and knowledge discovery methods and others will play an increasingly important role in human genetics as the field moves away from the candidate-gene approach that focuses on a few targeted genes to the genome-wide approach that measures DNA sequence variations from across the genome.

ACKNOWLEDGMENT

This work was supported by National Institutes of Health (USA) grants LM009012, AI59694, HD047447, RR018787, and HL65234. We thank Mr. Bill White for his invaluable contributions to the methods discussed here.

Chapter 7.22
Gene Expression Programming and the Evolution of Computer Programs

Cândida Ferreira
Gepsoft, UK

ABSTRACT

In this chapter an artificial problem solver inspired in natural genotype/phenotype systems — gene expression programming — is presented. As an introduction, the fundamental differences between gene expression programming and its predecessors, genetic algorithms and genetic programming, are briefly summarized so that the evolutionary advantages of gene expression programming are better understood. The work proceeds with a detailed description of the architecture of the main players of this new algorithm (chromosomes and expression trees), focusing mainly on the interactions between them and how the simple yet revolutionary structure of the chromosomes allows the efficient, unconstrained exploration of the search space. And finally, the chapter closes with an advanced application in which gene expression programming is used to evolve computer programs for diagnosing breast cancer.

EVOLUTIONARY ALGORITHMS IN PROBLEM SOLVING

The way nature solves problems and creates complexity has inspired scientists to create artificial systems that learn by themselves how to solve a particular problem. The first attempts were done in the 1950s by Friedberg (1958; Friedberg et al., 1959), but ever since highly sophisticated systems have been developed that apply Darwin's ideas of natural evolution to the artificial world of computers and modeling. Of particular interest to this work are the Genetic Algorithms (GAs) and the Genetic Programming (GP) technique, as they are the predecessors of Gene Expression Programming (GEP), the most recent development in evolutionary computation and the theme of this chapter. A brief introduction to these three techniques is given below.

Genetic Algorithms

Genetic algorithms were invented by John Holland in the 1960s and they also apply biological evolution theory to computer systems (Holland, 1975). Like all evolutionary computer systems, GAs are an oversimplification of biological evolution. In this case, solutions to a problem are usually encoded in strings of 0s and 1s (chromosomes), and populations of such strings (individuals or candidate solutions) are used in order to evolve a good solution to a particular problem. From generation to generation candidate solutions are reproduced with modification and selected according to fitness. Modification in the original genetic algorithm was introduced by the genetic operators of mutation, crossover, and inversion.

It is worth pointing out that GAs' individuals consist of naked chromosomes or, in other words, GAs' individuals are simple replicators. And like all simple replicators, the chromosomes of genetic algorithms function simultaneously as genotype and phenotype: they are both the object of selection and the guardians of the genetic information that must be replicated and passed on with modification to the next generation. Consequently, the whole structure of the replicator determines the functionality and, therefore, the fitness of the individual. For instance, in such systems it would not be possible to use only a particular region of the replicator as a solution to a problem: The whole replicator is always the solution: nothing more, nothing less.

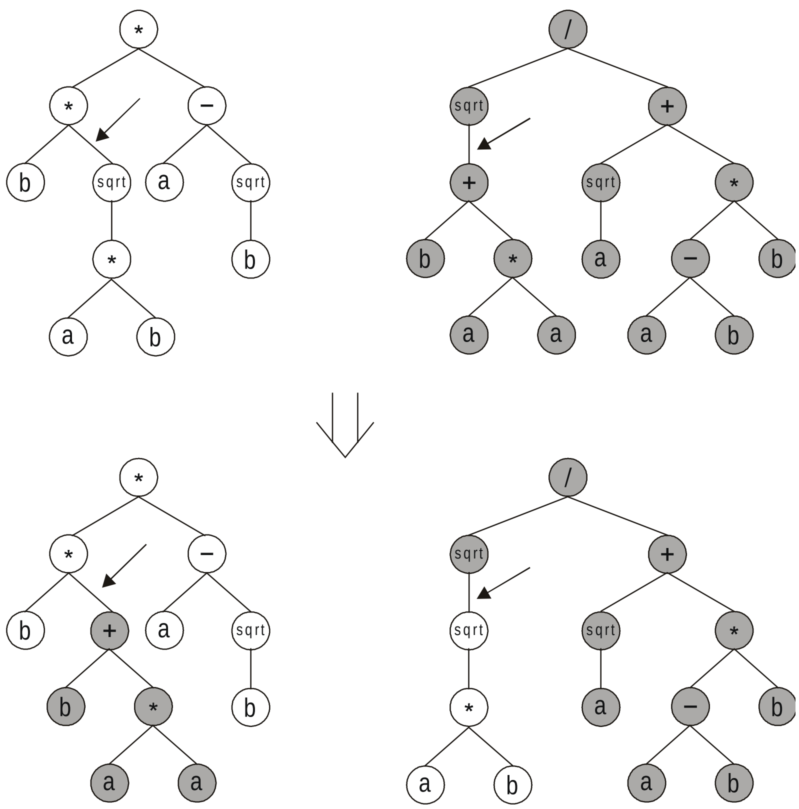

Figure 2. Tree mutation in genetic programming (The arrow indicates the mutation point. The new branch randomly generated by the mutation operator in the daughter tree is shown in gray.)

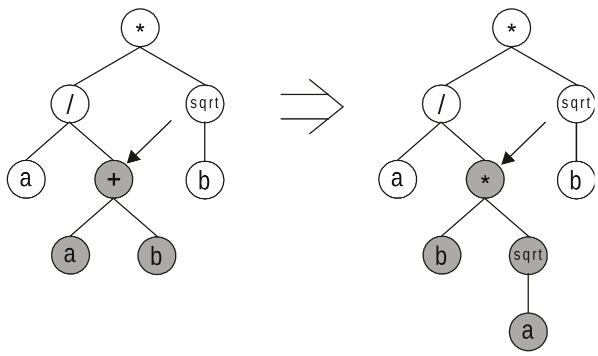

Figure 3. Permutation in genetic programming (The arrow indicates the permutation point. Note that the arguments of the permuted function traded places in the daughter tree.)

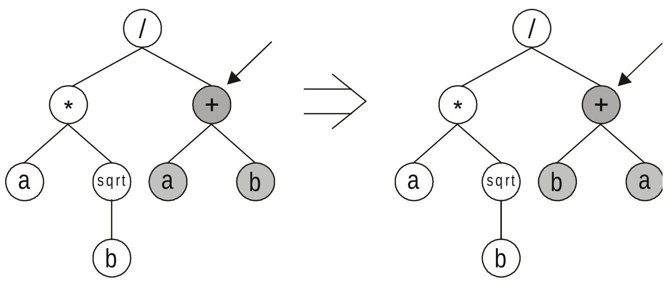

Figure 4. Illustration of a hypothetical event of point mutation in genetic programming (The arrow indicates the mutation point. Note that the daughter tree is an invalid structure.)

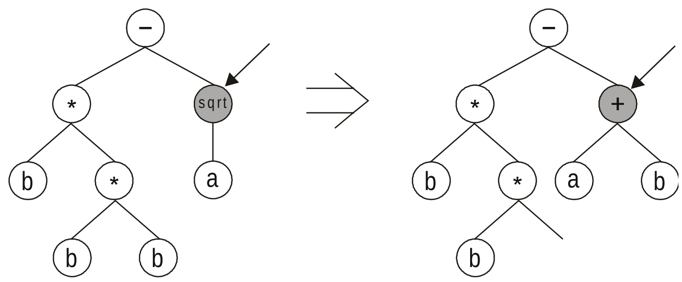


Genetic Programming

Genetic programming, invented by Cramer in 1985 (Cramer, 1985) and further developed by Koza (1992), solves the problem of fixed length solutions through the use of nonlinear structures (parse trees) with different sizes and shapes. The alphabet used to create these structures is also more varied, creating a richer, more versatile system of representation. Notwithstanding, the created individuals also lack a simple, autonomous genome. Like the linear chromosomes of genetic algorithms, the nonlinear structures of GP are also cursed with the dual role of genotype/phenotype.

The parse trees of genetic programming resemble protein molecules in their use of a richer alphabet and in their complex and unique hierarchical representation. Indeed, parse trees are capable of exhibiting a great variety of functionalities. The problem with these complex replicators is that their reproduction with modification is highly constrained in evolutionary terms because the modifications must take place on the parse tree itself and, consequently, only a limited range of modification is possible. Indeed, special kinds of genetic operators were developed that operate at the tree level, modifying or exchanging particular branches between trees.

Although at first sight this might appear advantageous, it greatly limits this technique (we all know the limits of grafting and pruning in nature). Consider for instance crossover, the most used and often the only search operator used in genetic programming. In this case, selected branches are exchanged between two parent trees to create offspring (Figure 1). The idea behind its implementation was to exchange smaller, mathematically concise blocks in order to evolve more complex, hierarchical solutions composed of smaller building blocks.

The mutation operator in GP is also very different from natural point mutation. This operator selects a node in the parse tree and replaces the branch underneath by a new randomly generated branch (Figure 2). Notice that the overall shape of the tree is not greatly changed by this kind of mutation, especially if lower nodes are preferentially chosen as mutation targets.

Permutation is the third operator used in genetic programming and the most conservative of the three. During permutation, the arguments of a randomly chosen function are randomly permuted (Figure 3). In this case the overall shape of the tree remains unchanged.

In summary, in genetic programming the operators resemble more of a conscious mathematician than the blind way of nature. But in adaptive systems the blind way of nature is much more efficient and systems such as GP are highly constrained. For instance, the implementation of other operators in genetic programming such as the simple yet high-performing point mutation (Ferreira, 2002c) is unproductive, as most mutations result in syntactically incorrect structures (Figure 4). Obviously, the implementation of other operators such as transposition or inversion raises similar difficulties and the search space in GP remains vastly unexplored.

Although Koza described these three operators as the basic GP operators, crossover is practically the only genetic operator used in most genetic programming applications (Koza, 1992). Consequently, no new material is introduced in the genetic pool of GP populations. Not surprisingly, huge populations of parse trees must be used with the aim of creating all the necessary building blocks with the inception of the initial population in order to guarantee the discovery of a good solution only by moving the initial building blocks around.

Finally, due to the dual function of the parse trees (genotype and phenotype), genetic programming is incapable of a simple, rudimentary expression: in all cases, the entire parse tree is the solution.

Gene Expression Programming

Gene expression programming was invented by the author in 1999 (Ferreira, 2001), and incorporates both the simple, linear chromosomes of fixed length similar to the ones used in genetic algorithms and the ramified structures of different sizes and shapes similar to the parse trees of genetic programming. This is equivalent to say that in gene expression programming the genotype and phenotype are finally separated and the system can now benefit from all the advantages this brings about.

Thus, the phenotype of GEP consists of the same kind of ramified structure used in genetic programming. But the ramified structures created by GEP (expression trees) are the expression of a totally autonomous genome. Therefore, with gene expression programming, the second evolutionary threshold — the phenotype threshold — is crossed (Dawkins, 1995). This means that, during reproduction, only the genome (slightly modified) is passed on to the next generation and we no longer need to replicate and mutate rather cumbersome structures: All the modifications take place in a simple linear structure which only later will grow into an expression tree.

The fundamental steps of gene expression programming are schematically represented in Figure 5. The process begins with the random generation of the chromosomes of a certain number of individuals (the initial population). Then these chromosomes are expressed and the fitness of each individual is evaluated against a set of fitness cases (also called selection environment). The individuals are then selected according to their fitness (their performance in that particular environment) to reproduce with modification, leaving progeny with new traits. These new individuals are, in their turn, subjected to the same developmental process: expression of the genomes, confrontation of the selection environment, selection, and reproduction with modification. The process is repeated for a certain number of generations or until a good solution has been found.

The pivotal insight of gene expression programming consisted of the invention of chromosomes capable of representing any parse tree. For that purpose a new language — *Karva* language — was created in order to read and express the information encoded in the chromosomes. The details of this new language are given in the next section.

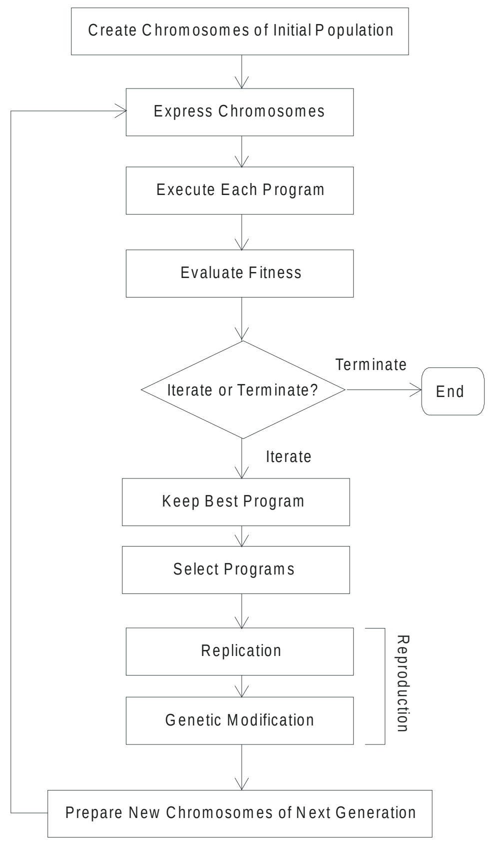
Furthermore, the structure of the chromosomes was designed to allow the creation of multiple genes, each coding for a smaller program or sub-expression tree. It is worth emphasizing that gene expression programming is the only genetic algorithm with multiple genes. Indeed, the creation of more complex individuals composed of multiple genes is extremely simplified in truly functional genotype/phenotype systems. In fact, after their inception, these systems seem to catapult themselves into higher levels of complexity such as multicellular systems, where different cells put together different consortiums of genes (Ferreira, 2002a).

The basis for all this novelty resides on the revolutionary structure of GEP genes. The simple but plastic structure of these genes not only allows the encoding of any conceivable program but also allows their efficient evolution. Due to this versatile structural organization, a very powerful set of genetic operators can be easily implemented and used to search very efficiently the solution space. As in nature, the search operators of gene expression programming always produce valid structures and therefore are remarkably suited to creating genetic diversity.

THE ARCHITECTURE OF GEP INDIVIDUALS

We know already that the main players in gene expression programming are the chromosomes and the expression trees (ETs), the latter being

Figure 5. Flowchart of gene expression programming



the expression of the genetic information encoded in the former. As in nature, the process of information decoding is called translation. And this translation implies obviously a kind of code and a set of rules. The genetic code is very simple: a one-to-one relationship between the symbols of the chromosome and the nodes they represent in the trees. The rules are also very simple: they determine the spatial organization of nodes in the expression trees and the type of interaction between sub-ETs. Therefore, there are two languages in GEP: the language of the genes and the language of expression trees and, thanks to the simple rules that determine the structure of ETs and their interactions, we will see that it is possible to infer immediately the phenotype given the sequence of a gene, and vice versa. This means that we can choose to have a very complex program represented by its compact genome without losing meaning. This unequivocal bilingual notation is called *Karva* language. Its details are explained in the remainder of this section.

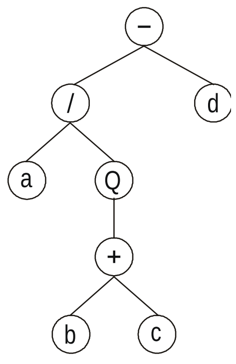
Open Reading Frames and Genes

The structural organization of GEP genes is better understood in terms of open reading frames (ORFs). In biology, an ORF or coding sequence of a gene begins with the start codon, continues with the amino acid codons, and ends at a termination codon. However, a gene is more than the respective ORF, with sequences upstream of the start codon and sequences downstream of the stop codon. Although in GEP the start site is always the first position of a gene, the termination point does not always coincide with the last position of a gene. Consequently, it is common for GEP genes to have non-coding regions downstream of the termination point. (For now we will not consider these non-coding regions, as they do not interfere with expression.)

Consider, for example, the algebraic expression:

$$\frac{a}{\sqrt{b+c}}-d \qquad \textbf{(1)}$$

It can also be represented as a diagram or ET:



where "Q" represents the square root function.

This kind of diagram representation is in fact the phenotype of GEP chromosomes. And the genotype can be easily inferred from the phenotype as follows:

```
01234567
-/daQ+bc
```

(2)

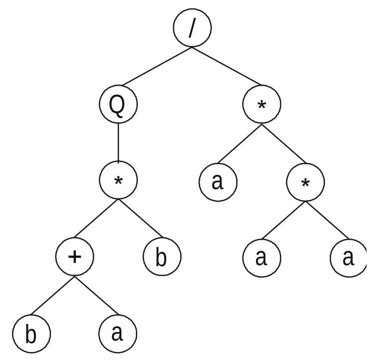
which is the straightforward reading of the ET from left to right and from top to bottom (exactly as we read a page of text). The expression (2) is an open reading frame, starting at "-" (position 0) and terminating at "c" (position 7). These ORFs were named *K-expressions* from Karva language.

Consider another open reading frame, the following K-expression:

```
012345678901
/Q**a*+baaba
```

(3)

Its expression as an ET is also very simple and straightforward. In order to express the ORF correctly, we must follow the rules governing the spatial distribution of functions and terminals. First, the start of a gene corresponds to the root of the expression tree, which is placed in the topmost line. Second, in the next line, below each function, are placed as many branch nodes as there are arguments to that function. Third, from left to right, the nodes are filled consecutively with the next elements of the K-expression. Fourth, the process is repeated until a line containing only terminals is formed. In this case, the following expression tree is formed:



which mathematically corresponds to

$$\frac{\sqrt{(b+a)b}}{a^3}.$$

Looking at the structure of GEP ORFs only, it is difficult or even impossible to see the advantages of such a representation, except perhaps for its simplicity and elegance. However, when open reading frames are analyzed in the context of a gene, the advantages of this representation become obvious. As previously stated, GEP chromosomes have fixed length, and they are composed of one or more genes of equal length. Consequently, the length of a gene is also fixed. Thus, in gene expression programming, what varies is not the length of genes, which is constant, but the length of the ORFs. Indeed, the length of an open reading frame may be equal to or less than the length of the gene. In the first case, the termination point coincides with the end of the gene, and in the latter, the termination point is somewhere upstream of the end of the gene.

What is the function of these non-coding regions of GEP genes? We will see that they are the essence of gene expression programming and evolvability, for they allow the modification of the genome using several genetic operators without restrictions, always producing syntactically correct programs. Thus, in gene expression programming, the fundamental property of genotype/phenotype systems — syntactic closure — is intrinsic, allowing the totally unconstrained restructuring of the genotype and, consequently, an efficient evolution.

In the next section we are going to analyze the structural organization of GEP genes in order to understand how they invariably code for syntactically correct programs and why they allow an unconstrained application of virtually any genetic operator.

Structural Organization of Genes

The genes of gene expression programming are composed of a head and a tail. The head contains symbols that represent both functions and terminals, whereas the tail contains only terminals. For each problem, the length of the head h is chosen, whereas the length of the tail t is a function of h and the number of arguments n of the function with more arguments (also called maximum arity) and is evaluated by the equation:

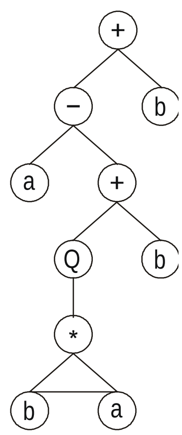
$$t = h\,(n-1) + 1 \qquad \textbf{(4)}$$

Consider a gene for which the set of functions F = {Q, *, /, -, +} and the set of terminals T = {a, b}. In this case $n = 2$; if we chose an $h = 11$, then $t = 11\,(2 - 1) + 1 = 12$; thus, the length of the gene g is 11 + 12 = 23. One such gene is shown below (the tail is shown in bold):

```
0123456789012
+-ba+Qb*ba/abaaaabbaabb
```

(5)

It codes for the following expression tree:



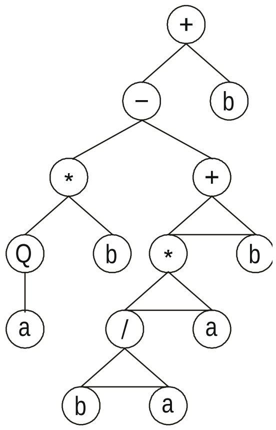
or the equivalent mathematical expression (*a*-). In this case, the open reading frame ends at position 9, whereas the gene ends at position 22.

Suppose now a mutation occurred at position 3, changing the “a” into “*”. Then the following gene is obtained:

```
01234567890123456789012
+-b*+Qb*ba/abaaaabbaabb
```

(6)

And its expression gives:

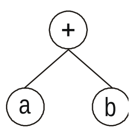


which mathematically corresponds to $b(\sqrt{a}\text{-}1)$. In this case, the termination point shifts four positions to the right (position 13), enlarging and changing significantly the daughter tree.

Obviously the opposite also might happen, and the daughter tree might shrink. For example, consider again gene (5), and suppose a mutation occurred at position 1, changing the "-" into "a":

```
01234567890123456789012
+aba+Qb*ba/abaaaabbaabb
```
(7)

Its expression results in the following ET:



In this case, the ORF ends at position 2, shortening the original ET in seven nodes.

So, despite their fixed length, each gene has the potential to code for expression trees of different sizes and shapes, where the simplest is composed of only one node (when the first element of a gene is a terminal) and the largest is composed of as many nodes as the length of the gene (when all the elements of the head are functions with maximum arity).

It is evident from the examples above that any modification made in the genome, no matter how profound, always results in a structurally correct program. Obviously, the structural organization of genes must be preserved, always maintaining the boundaries between head and tail. We will be able to fully appreciate the plasticity of GEP chromosomes in the section "Genetic Operators and Evolution," where the mechanisms and effects of different genetic operators will be thoroughly analyzed.

Multigenic Chromosomes

The chromosomes of gene expression programming are usually composed of more than one gene of equal length. For each problem or run, the number of genes, as well as the length of the head, are chosen *a priori*. Each gene codes for a sub-ET and the sub-ETs interact with one another, forming a more complex multi-subunit expression tree.

Consider, for example, the following chromosome with length 39, composed of three genes, each with length 13 (the tails are shown in bold):

```
0123456789012012345678901201234567
89012
*Qb+*/bbbabab-a+Qbabbababa/ba-
/*bbaaaaa
```
(8)

It has three open reading frames, and each ORF codes for a sub-ET (Figure 6). The start of each ORF is always given by position 0; the end of each ORF, though, is only evident upon construction of the corresponding sub-ET. As shown in Figure 6, the first open reading frame ends at position 9; the second ORF ends at position 5; and the last ORF ends at position 2. Thus, GEP chromosomes contain several ORFs of different sizes, each ORF coding for a structurally and functionally unique sub-ET. Depending on the problem at hand, these sub-ETs may be selected individually depending on their respective outputs, or they may form a more complex, multi-subunit expression tree and be selected as a whole. In these multi-subunit structures, individual sub-ETs interact with one another by a particular kind of posttranslational interaction or linking. For instance, algebraic sub-ETs can be linked by addition or multiplication whereas Boolean sub-ETs can be linked by OR, AND or IF.

The linking of three sub-ETs by addition is illustrated in Figure 6 c. Note that the final ET could be linearly encoded as the following K-expression:

```
012345678901234567890
++/*-baQba++Qb*/abbba
```

(9)

However, the use of multigenic chromosomes is more appropriate to evolve solutions to complex problems, for they permit the modular construction of complex, hierarchical structures, where each gene codes for a smaller and simpler building block. These smaller building blocks are separated from each other, and thus can evolve independently. Not surprisingly, these multigenic systems are much more efficient than unigenic ones (Ferreira 2001, 2002a).

GENETIC OPERATORS AND EVOLUTION

Genetic operators are the core of all evolutionary algorithms, and two of them are common to all evolutionary systems: selection and replication. Indeed, all artificial systems use a scheme to select individuals more or less according to fitness. Some schemes are totally deterministic, whereas others include a touch of unpredictability. Gene expression programming uses one of the latter, namely, a fitness proportionate roulette-wheel scheme (see, e.g., Goldberg, 1989) coupled with the cloning of the best individual (simple elitism), as it mimics nature very faithfully and produces very good results.

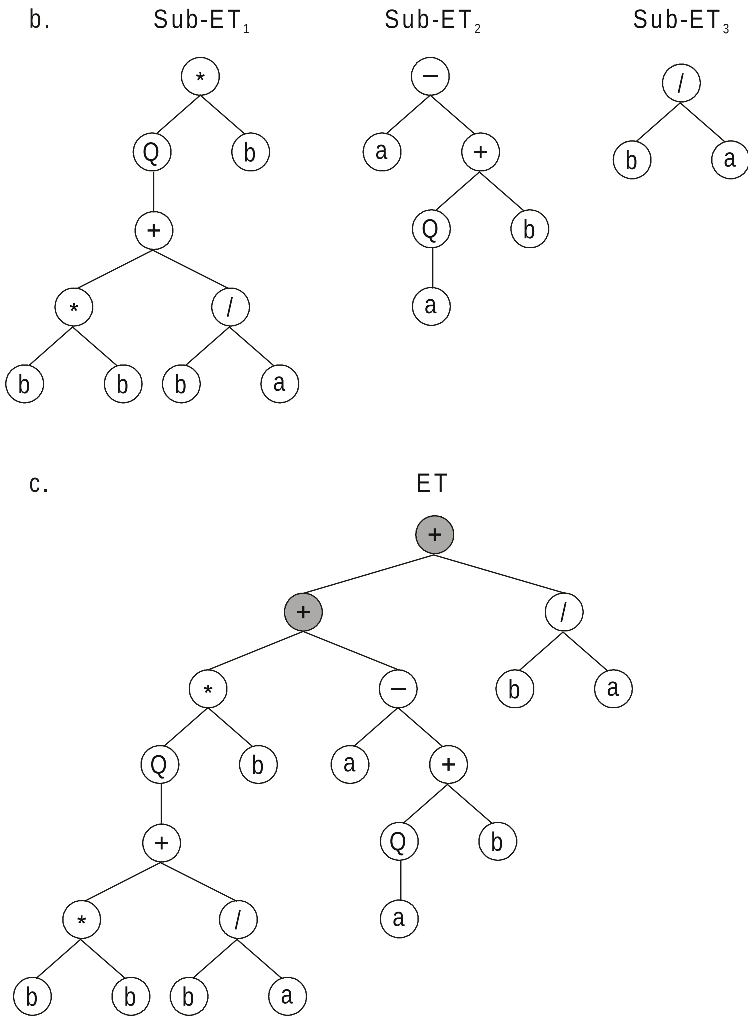
Thus, according to fitness and the luck of the draw, individuals are selected to be replicated. Although crucial, replication is the most uninteresting operator. During replication, chromosomes are dully copied and passed on to the next generation. The fitter the individual, the higher the probability of passing on its genes to the next generation. So, during replication, the genomes of the selected individuals are copied every time the roulette picks them up. And the roulette is spun as many times as there are individuals in the population so that the same population size is maintained from generation to generation.

Although the center of the storm, by themselves, selection and replication do nothing in terms of adaptation. In fact, by themselves they can only cause genetic drift, making populations less and less diverse with time until all the individuals are exactly the same. So, the corner stone of all evolutionary systems is genetic modification. And different algorithms create this modification differently. For instance, genetic algorithms normally use mutation and recombination; genetic programming uses almost exclusively tree recombination; and gene expression programming uses mutation, inversion, transposition, and recombination.

With the exception of GP, which is severely constrained in terms of tools of genetic modification, in both GAs and GEP it is possible to implement easily a vast set of search operators because the search operators act on simple linear chromosomes. In fact, a varied set of search operators was implemented in gene expression programming in order to shed some light on the dynamics of evolutionary systems, but what is important is to provide for the necessary degree of genetic diversification in order to allow an efficient evolution. Nevertheless, mutation (by far the most efficient operator) by itself is capable

Figure 6: Expression of GEP genes as sub-ETs — (a) A three-genic chromosome with the tails in bold; Position zero marks the start of each gene; (b) Sub-ETs codified by each gene, which correspond respectively to $b\sqrt{b^2+b/a}$, *a-(*$\sqrt{a}$*+b), and b/a; (c) The result of posttranslational linking with addition, which obviously corresponds to* $b\sqrt{b^2+b/a} + a - \sqrt{a} - b + b/a$; *the linking functions are shown in gray*

a. `012345678901201234567890120123456789012`
`*Qb+*/`**`bbbabab`**`-a+Qba`**`bbababa`**`/ba-/*`**`bbaaaaa`**



of wonders. However, the interplay of mutation with other operators not only allows an efficient evolution but also allows the duplication of genes and their subsequent differentiation; the creation of small repetitive sequences; and so forth, making things really interesting.

In the remainder of this section we will see how the search operators work and how their implementation in gene expression programming is a child's play due to the simple fact that the genome is completely autonomous and consequently is not tied up in the structural complexities of the computer programs encoded within.

Mutation

In gene expression programming, mutations can occur anywhere in the chromosome. However, the structural organization of chromosomes must remain intact; that is, in the heads any symbol can change into another (function or terminal), whereas in the tails terminals can only change into terminals. This way, the structural organization of chromosomes is preserved, and all the new individuals produced by mutation are structurally correct programs.

Consider the following three-genic chromosome:

```
01234567890120 1 2 3 4 56789012
0123456789 0 1 2
/ b Q a * * b b b b a b a - - + * Q -
abbbabaQ*a+**baabbba
```

Suppose a mutation changed the "*" at position 5 in gene 1 to "a"; the "-" at position 1 in gene 2 to "Q"; and the "a" at position 2 in gene 3 to "*". In this case the following chromosome is obtained:

```
01234 5 67890120 1 2 3 4567890
12012 3 4 56789012
/ b Q a * a b b b b a b a - Q + * Q -
abbbabaQ**+**baabbba
```

Note that if a function is mutated into a terminal or vice versa, or a function of one argument is mutated into a function of two arguments or vice versa, the expression tree is usually modified drastically. Note also that the mutation on gene 1 is an example of a neutral mutation, as it occurred in the non-coding region of the gene. It is worth emphasizing that the non-coding regions of GEP chromosomes are ideal places for the accumulation of neutral mutations, which are known to play an important role in evolution (Ferreira, 2002b; Kimura, 1983). In summary, in gene expression programming there are no constraints both in the kind of mutation and the number of mutations in a chromosome as, in all cases, the newly created individuals are syntactically correct programs.

Inversion

We know already that the modifications bound to make a big impact occur usually in the heads of genes. Therefore, the inversion operator was restricted to these regions. Here any sequence might be randomly selected and inverted.

In gene expression programming, the inversion operator randomly chooses the chromosome, the gene to be modified, and the start and termination points of the sequence to be inverted. It is worth pointing out that this is the first time the inversion operator is described in gene expression programming.

Consider, for instance, the following three-genic chromosome:

```
01 2 3 4 5 6 789012012 3 4
5 67890120123456789012
/+aQ*aaabaaab/aa/baaababab-
Q++aQababaab
```

Suppose that the sequence "aQ*" in gene 1 (positions 2-4) was picked up to be inverted. Then the following chromosome is formed:

```
012 3 4 5 6 7 8 90120123456789
012012 3 4 56789012
/+*Qaaaabaaab/aa/baaababab-
Q++aQababaab
```

It is worth pointing out that, since the inversion operator was restricted to the heads of genes, there is no danger of a function ending up in the tails and, consequently, all the new individuals created by inversion are syntactically correct programs.

Transposition and Insertion Sequence Elements

The transposable elements (also called transposons) of gene expression programming are fragments of the genome that can be activated and then jump to another place in the chromosome. In GEP there are three kinds of transposable elements: (1) short fragments with a function or terminal in the first position that transpose to the head of genes except the root (insertion sequence elements or IS elements); (2) short fragments with a function in the first position that transpose to the start position of genes (root IS elements or RIS elements); (3) and entire genes that transpose to the beginning of chromosomes.

IS Transposition

Any sequence in the genome might become an IS element and, therefore, these elements are randomly selected throughout the chromosome. A copy of the transposon is made and inserted at any position in the head of a gene, except the first position. The transposition operator randomly chooses the chromosome, the start and termination points of the IS element, and the target site. It is worth pointing out that the implementation of this operator as described here slightly differs from the original implementation (Ferreira, 2001), where the length of the IS elements was chosen *a priori*.

Consider the following chromosome composed of three genes, each with a head size of six:

```
01234567890120123456789012012345678
9012
+*+-Q/baaaabbQ+aa*abaaaaba*+-a/-
aabbbba
```

Suppose that the sequence "a/-" in gene 3 (positions 3-5) was picked up as an IS element to be then inserted between positions 1-2 in gene 2, obtaining:

```
01234567890120123456789012012345678
9012
+*+-Q/baaaabbQ+a/-abaaaaba*+-a/-
aabbbba
```

Note that, in this case, a perfect copy of the transposon appears at the site of insertion. Note also that a sequence with as many symbols as the IS element is deleted at the end of the head (in this case, the sequence "a*a" was deleted). Thus, despite this insertion, the structural organization of chromosomes is maintained and, therefore, all the new individuals created by IS transposition are syntactically correct programs.

Root Transposition

All root IS elements start with a function, and therefore must be chosen among the sequences of the heads. For that, a point is randomly chosen in the head and the gene is scanned downstream until a function is found. This function becomes the start position of the RIS element. If no functions are found, the operator does nothing.

The RIS transposition operator randomly chooses the chromosome, the gene to be modified, and the start and termination points of the RIS element. It is worth noticing that this operator is slightly different from the original RIS transposition (Ferreira, 2001), as the length of the transposon is randomly chosen by this simpler RIS transposition.

Consider the following chromosome composed of three genes, each with a head size of six:

```
01234567890120123456789012012345678 9012
01234567890120123456789012012345678 9012
/+b*Q/babababaQ*aQ*QaaababaQa*/
+abbbaaab
```

Note that during transposition, the whole head shifts to accommodate the RIS element, losing, at the same time, the last symbols of the head (as many as there are in the transposon). In this case, the sequence "+b*" was deleted and the transposon became only partially duplicated. As with IS transposition, the tail of the gene subjected to RIS transposition and all nearby genes remain unchanged. Note, again, that all the programs newly created by this operator are syntactically correct, as it also preserves the structural organization of the chromosome.

Gene Transposition

In gene transposition an entire gene works as a transposon and transposes itself to the beginning of the chromosome. In contrast to the other forms of transposition, in gene transposition, the transposon (the gene) is deleted at the place of origin.

The gene transposition operator randomly chooses the chromosome to be modified and then randomly chooses one of its genes (except the first, obviously) to transpose. Consider the following chromosome composed of three genes:

```
01234567890120123456789012012345678 9012
-ab+a-babaaaaQ+bab/babbbba*-*Q*-
abbabab
```

Suppose gene 3 was chosen to undergo gene transposition. In this case the following chromosome is obtained:

```
012345678901201234567890120123456
7 8 9 0 1 2
*-*Q*-abbabab-ab+a-babaaaaQ+bab/
babbbba
```

Apparently, gene transposition is only capable of shuffling genes and, for sub-ETs linked by commutative functions, this contributes nothing to adaptation in the short run. Note, however, that when the sub-ETs are linked by a non-commutative function, the order of the genes matters and, in this case, gene transposition becomes a macromutator. However, gene transposition becomes particularly interesting when it is used in conjunction with recombination, for it allows not only the duplication of genes but also a more generalized shuffling of genes or smaller building blocks.

Recombination

In gene expression programming there are three kinds of recombination: one-point recombination, two-point recombination, and gene recombination. In all types of recombination, two chromosomes are randomly chosen and paired to exchange some material between them, creating two new daughter chromosomes.

One-Point Recombination

In one-point recombination the parent chromosomes are paired and split up at exactly the same point. The material downstream of the recombination point is afterwards exchanged between the two chromosomes.

Consider the following parent chromosomes, each composed of three genes:

```
0123456 7 8 9 0 1 201234 5 6
7 8 90120123456 7 8 9 012
*b-Qb /
a b a a bQ* * Q + * bbaaabb*Q-
- Q Q a ab b bbb
```

```
-/bQa+aabbbba/Q*b/aababaaa-/a/a/abaaabb
```

Suppose bond 4 in gene 2 (between positions 3 and 4) was randomly chosen as the crossover point. Then, the paired chromosomes are both cut at this bond, and exchange between them the material downstream of the crossover point, forming the offspring below:

```
012345678901201234567890120 1 2 3 4 56789012
*b-Qb/aaabaabQ**Q/aababaaa-/a/a/abaaabb
-/bQa+aabbbba/Q*b+*bbaaabb*Q--QQa-abbbbb
```

It is worth emphasizing that GEP chromosomes can cross over any point in the genome, continually disrupting old building blocks and continually forming new ones. Furthermore, due to both the multigenic nature of GEP chromosomes and the existence of non-coding regions in most genes, entire genes and intact open reading frames can be swapped between parent chromosomes. Thus, the disruptive tendencies of one-point recombination (splitting of building blocks) coexist side by side with its more conservative tendencies (swapping of genes and ORFs), making one-point recombination (and of course two-point recombination too) a very well balanced genetic operator. Furthermore, like all the other recombinational operators, when one-point recombination is used together with gene transposition, it is also capable of duplicating genes.

Two-Point Recombination

In two-point recombination two parent chromosomes are paired and two points are randomly chosen as crossover points. The material between the recombination points is afterwards exchanged between the parent chromosomes, forming two new daughter chromosomes.

Consider the following pair of recombining chromosomes:

```
01234 5 6 7 8 9 0 1 20 1 2 3 45678 9 0 1 2 012345 6 7 8 9 012
bb * a a b a a a aQ*a/ b + b b b a a a b Q + / a a + b abaabb
+-Qa/Qaabbaba+Q-+/+abbbaaa//+-/+bababab
```

Suppose bond 7 in gene 1 (between positions 6 and 7) and bond 4 in gene 3 (between positions 3 and 4) were chosen as crossover points. Then, the following daughter chromosomes are created:

```
012345 6 7 8 9012012 3 4 5 67 890120123456789012
/bQbb*aabbaba+Q-+/+abbbaaa//+-a+babaabb
+-Qa/QaabaaaaQ*a/b+bbbaaabQ+/a/+bababab
```

It is worth emphasizing that two-point recombination is more disruptive than one-point recombination in the sense that it recombines the genetic material more thoroughly, constantly destroying old building blocks and creating new ones. But like one-point recombination, two-point recombination has also a conservative side and it is good at swapping entire genes and open reading frames. And, as observed for one-point recombination, two-point recombination can also give rise to duplicated genes if it were used together with gene transposition.

Notwithstanding, if the goal is to evolve good solutions, one-point or two-point recombination should never be used as the only source of genetic variation, as they tend to homogenize populations (Ferreira, 2002c). However, together with mutation, inversion and transposition, these operators are an excellent source of genetic variation and are more than sufficient to evolve good solutions to virtually all problems.

Gene Recombination

In the third kind of GEP recombination, entire genes are exchanged between two parent chromosomes, forming two daughter chromosomes containing genes from both parents. The exchanged genes are randomly chosen and occupy exactly the same position in the parent chromosomes. Consider the following parent chromosomes:

```
012345 6 7 8 9 0 1 20123456
7 8 9 0120 1 2 3 456789012
/+*--b b a a a b a b*+b-
a a b Q **+*b a b a bbab
Q//b-baababaa/ab/QQbaababaQ*+a++bbaaaaa
```

Suppose gene 2 was chosen to be exchanged. In this case the following offspring is formed:

```
0123456 7 8 9 012012345678901201
23456789012
/ + * - - b b a a a b a b / a b /
QQbaababaQ**+*bababbab
Q//b-baababaa*+b--aabaaaabQ*+a++bbaaaaa
```

Note that, with this kind of recombination, similar genes can be exchanged but, most of the times, the exchanged genes are very different and new material is introduced in the population.

It is worth emphasizing that this operator is unable to create new genes: the individuals created by gene recombination are different arrangements of existing genes. Obviously, if gene recombination were used as the unique source of genetic variation, more complex problems could only be solved using very large initial populations in order to provide for the necessary diversity of genes. However, GEP evolvability is based not only in the shuffling of genes (achieved by gene recombination and gene transposition), but also in the constant creation of new genetic material, which is carried out essentially by mutation, inversion and transposition (both IS and RIS transposition) and, to a lesser extent, by recombination (both one-point and two-point recombination).

EVOLVING COMPUTER PROGRAMS FOR DIAGNOSING BREAST CANCER

In this section we are going to use gene expression programming to design a computer program that can be used to diagnose breast cancer. The data sets used both for training and testing were obtained from PROBEN1 — a set of neural network benchmark problems and benchmarking rules (Prechelt, 1994). Both the technical report and the data sets are available through anonymous FTP from Neural Bench archive at Carnegie Mellon University (machine *ftp.cs.cmu.edu,* directory */afs/cs/project/connect/bench/contrib/prechelt*) and from the machine *ftp.ira.uka.de* in directory */pub/neuron*. The file name in both cases is *proben1.tar.gz*.

In this diagnosis task the goal is to classify a tumor as either benign (0) or malignant (1) based on nine different cell analyses (input attributes or terminals).

The model presented here was obtained using the *cancer1* data set of PROBEN1, where the binary 1-of-*m* encoding in which each bit represents one of *m*-possible output classes was replaced by a 1-bit encoding ("0" for benign and "1" for malignant). The first 350 samples were used for training and the last 174 were used to test the performance of the model in real use. This means that absolutely no information from the test set samples or the test set performance are available during the adaptive process. Thus, both the classification accuracy and classification error on the test set can be used to evaluate the generalization performance of the evolved models.

For this problem a very simple function set was chosen, composed only of the four arithmetic operators, that is, F = {+, -, *, /}, where each function was weighted five times; the set of terminals consisted of the nine attributes used in this problem and were represented by T = {d0, ..., d8} which correspond, respectively, to clump thickness, uniformity of cell size, uniformity of cell shape, marginal adhesion, single epithelial cell size, bare nuclei, bland chromatin, normal nucleoli, and mitoses.

In classification problems where the output is often binary, it is important to set criteria to convert real-valued numbers into 0 or 1. This is the 0/1 rounding threshold R that converts the output of a chromosome into "1" if the output is equal to or greater than R, or into "0" otherwise. For this problem we are going to use $R = 0.1$.

The fitness function used to evaluate the performance of each candidate model is very simple and is based on the number of samples correctly classified. Thus, the fitness f_i of an individual program i corresponds to the number of hits and is evaluated by the formula:

$$\text{if } n > C, \text{ then } f_i = n; \text{ else } f_i = 0 \quad \textbf{(10)}$$

where n is the number of sample cases correctly evaluated, and C is the number of samples in the class with more members (predominant class).

As it is customary in genetic programming (Koza, 1992) and gene expression programming (Ferreira, 2001), the parameters used per run are summarized in a table (Table 1). Note that, in this case, a small population of 50 individuals and chromosomes composed of three genes with an $h = 8$ and sub-ETs linked by addition were used. The program below was discovered after 423 generations (genes are shown separately and a dot is used to separate each element):

```
*.+.d0.*.*.*.+.*.d7.d0.d8.d3.d5.d4.d3.d5.d6
*.+.*.d0.*.*.*.-.d5.d4.d1.d5.d1.d0.d2.d1.d1
*.d5.*.+.d6.*.+.d5.d2.d2.d1.d1.d7.d0.d7.d4.d0
```
(11a)

It has a fitness of 340 evaluated against the training set of 350 fitness cases and maximum fitness on the test set of 174 examples. This means that this model is very good indeed, with a classification accuracy of 100% and a classification error of 0% in the test set. In the training set a classification accuracy of 97.14% and a classification error of 2.86% were obtained.

Note that for the expression of chromosome (11a) to be complete the sub-ETs must be linked by addition and the 0/1 rounding threshold must be taken into account. With the software APS 3.0 by *Gepsoft*, the model (11a) above can be automatically converted into a fully expressed computer program or function, such as the C++ function below:

```
int apsModel(double d[])
{
    const double ROUNDING_THRESHOLD = 0.1;
    double dblTemp = 0;
    dblTemp = ((((d[0]*d[8])*(d[3]+d[5]))+((d[4]*d[3])*d[7]))*d[0]);
    dblTemp += ((d[0]+((d[0]-d[2])*d[5]))*((d[4]*d[1])*(d[5]*d[1])));
    dblTemp += (d[5]*(((d[5]*d[2])+(d[2]+d[1]))*d[6]));
    return (dblTemp >= ROUNDING_THRESHOLD ? 1:0);
}
```
(11b)

Similarly, all models evolved by gene expression programming can be immediately converted into virtually any programming language through the use of grammars, including the universal representation of parse trees (Figure 7). These trees can then be used to grasp immediately the mathematical intricacies of the evolved models and therefore are ideal for extracting knowledge from data. As can be clearly seen in Figure 7, all the cell analyses seem to be relevant to an accurate diagnosis of breast cancer. This is, indeed, one of the great advantages of gene expression programming: the possibility of extracting knowledge almost instantaneously, as the models evolved

Table 1. Settings used in the breast cancer problem

Number of generations	500
Population size	50
Number of training samples	350
Number of testing samples	174
Function set	(+-*/)5
Terminal set d	0 - d9
Rounding threshold	0 .1
Head length	8
Number of genes	3
Linking function	+
Chromosome length	51
Mutation rate	0.044
Inversion rate	0 .1
IS transposition rate	0.1
RIS transposition rate	0.1
One-point recombination rate	0.3
Two-point recombination rate	0.3
Gene recombination rate	0.1
Gene transposition rate	0.1

by GEP can be represented in any conceivable language, including the universal diagram representation of expression trees.

CONCLUSION

In this chapter the details of implementation of gene expression programming were thoroughly explained, giving other researchers the possibility of implementing it themselves. Furthermore, this new algorithm was summarily compared to genetic algorithms and genetic programming in order to bring into focus the fundamental differences between the three techniques and, consequently, enable readers to appreciate the advantages a full-fledged genotype/phenotype system brings into evolutionary computation. In addition, the classification task solved in this work clearly demonstrates the modeling prowess of this new technique: The compact computer programs evolved by gene expression programming in its native Karva code can be immediately used to generate highly sophisticated computer programs in virtually any programming language through the use of grammars as is already done in commercially available software.

Chapter 7.23
Checking Female Foeticide in the Information Age

Chetan Sharma
Datamation Foundation Charitable Trust, India

Divya Jain
Datamation Foundation Charitable Trust, India

INTRODUCTION

In India, the practice of sex-selective abortion or female foeticide (in which an unborn baby is aborted or killed before birth simply because it is not a boy) is only the latest manifestation of a long history of gender bias, evident in the historically low and declining population ratio of women to men. Moreover, the medical fraternity in India has been quick to see entrepreneurial opportunities in catering to insatiable demands for a male child. Until recently, the technology was prohibitively expensive. The three chief pre-natal diagnostic tests being used to determine the sex of a foetus (sexing) are amniocentesis, chronic villi biopsy (CVB) and ultrasonography. Amniocentesis is meant to be used in high-risk pregnancies, in women older than 35 years. CVB is meant to diagnose inherited diseases like thalassaemia, cystic fibrosis and muscular dystrophy. Ultrasonography is the most commonly used technique. It is non-invasive and can identify up to 50% of abnormalities related to the central nervous system of the foetus. But sexing has become its preferred application. A ban on the government departments at the center and in the states, making use of pre-natal sex determination for the purpose of abortion a penal offence, led to the commercialization of the technology; private clinics providing sex determination tests through amniocentesis multiplied rapidly and widely. These tests are made available in areas that do not even have potable water, with marginal farmers willing to take loans at 25% interest to have the test. Advertisements appear blatantly encouraging people to abort their female foetuses to save the future cost of dowry. The portable ultrasound machine has allowed doctors to go from house to house in towns and villages. In a democracy, it is difficult to restrict rights to business and livelihood if the usual parameters are fulfilled. An argument by Rathee (2001) brings to light the fact that the recent technological developments in medical practice combined with a vigorous pursuit of growth of the private health sector have led to the mushrooming of a variety of sex-selective services. This has happened not only in urban areas, but deep within rural countryside, also—areas where the other dimensions of healthcare and development are yet to penetrate. Indeed, the indications are that given these lethal combinations, the phenomenon of sex-selective abortions is growing nationwide. Furthermore, these discriminatory services are being provided and projected in the name of "democratic choice" as a measure of "upliftment" of women, since they are being saved from dowry deaths, burning and other forms of torture and violence they would have undergone once they were born. This pure greed for money is also equated by a large section of doctors to "people's demand."

BACKGROUND

In an age when females have left no stones unturned in almost every field, there are people who still accord a lower status to women. "What's wrong with a girl child? In this era of gender equality, why this sexual discrimination?" In some of our Indian societies, while a childless woman is perceived as incomplete, one who has given birth to daughters is partially complete. Only the one who has produced a son enjoys a status of sorts. The problem is intimately related to the institution

Figure 1.

of dowry. "If it's a girl child, we will have to spend first on her education and then on her marriage and dowry ... It doesn't stop there. We will also have to meet some of her expenses after marriage. How I wish I get a son!" The bias against females is also related to the fact that sons are looked at as a type of insurance. Even our religions have been prejudiced against women. According to Manu (2000 BC-2000 AD), a woman has to be reborn as a man to attain moksha (redemption). A man cannot attain moksha unless he has a son to light his pyre. Also, it says a woman who gives birth to only daughters may be left in the 11^{th} year of marriage. This obviously shows the gender bias in our male-dominated, patriarchal society.

FEMALE FOETICIDE AND LAW

There has been an inability to discuss the issue of foeticide without the larger debate on abortion, which is legally allowed and has been seen as a triumph of the women's rights movement in the country. India has allowed abortion on broad medical and social grounds since the Medical Termination of Pregnancy (MTP) Act was passed in 1971, further trivializing the issue of foeticide. The Pre-Conception and Pre-Natal Diagnostic Techniques (Prohibition of Sex Selection) Act and Rules 1994 (as amended up to 2002) (the PCPNDT Act), a result of determined action by NGOs against grossly unethical medical terminations of healthy pregnancies, mandates that sex selection by any person, by any means, before or after conception, is prohibited. But while the Act seeks to regulate and prevent misuse of pre-natal diagnostic techniques, it rightly cannot deny them, either. The PCPNDT Act allows pre-natal diagnosis only for chromosomal abnormalities, genetic metabolic disorders and congenital abnormalities. The law, however, permits ultrasound clinics, clinics for medical termination of pregnancies and assisted reproductive facilities as a routine matter and legitimate business. Then there is the legally binding Code of Medical Ethics, constituted by the Indian Parliament in the Medical Council Act (1956) that many doctors conveniently ignore. Doctors are legally bound to report medical malpractice. The PCPNDT Act mandates that any person conducting ultrasonography or any other pre-natal diagnostic technique must maintain proper records. The Act requires use of a written form, duly signed by the expectant mother, as to why she has sought diagnosis. Violations are punishable by imprisonment and a fine. The law also permits abortions for failure of contraception. It is a huge challenge for the government to detect violations of the PNDT Act, since it is a crime of collusion and by consensus.

The Ground Reality

Female foeticede is now more widespread in the country than ever before. The practice that was restricted to a few states a few years ago has now spread all over the country. Not only the poor, but even the middle classes and the rich in India are biased against the girl child and women. The provisional figures of Census[1] 2001, which have frightened even the Health Department, show that the Child Sex Ratio (CSR, the number of girls in the age group of 0 to 6 years per 1,000 boys of the same age group) has declined sharply from 945 females per 1000 males in 1991 to 927 females. Furthermore, the CSR is actually worse than the national average in Himachal Pradesh, Punjab, Chandigarh, Uttaranchal, Haryana, Delhi, Rajasthan, UP, Gujarat, Maharashtra and Daman and Diu. The Overall Sex Ratio (OSR, which looks at the ratio of all females to males, not just those in the 0-6 age group) is even worse in places like Chandigarh (773:1000), Delhi (821:1000) and Punjab (874:1000). Health experts say these are some of the lowest sex ratios in the world. Here is a paradox. During the final decade of the last millennium, the CSR recorded its highest fall, dropping 18 points from 945 to 927. However, during the same decade, the OSR recorded its highest gain, rising 6 points from 927 to 933. In every census since 1951, the two ratios have gone more or less hand in hand, dropping steadily except in the late 1970s (see Table 1). The sudden fall in the number of girls in the youngest age group is believed to be proof of the increased incidence of sex-selective abortions or female foeticide. Most of these abortions are the result of the misuse of sex determination technologies, such as ultrasound scanning and amniocentesis.

What is a woman's role in all this? Whether in choosing her spouse, contraception methods and the first pregnancy, place of delivery and so forth, does her choice or decision really matter at all? Or is it really possible for a woman to decide about having an abortion, if she has to survive as a daughter-in-law in the family? Let's assume her husband supports the birth of a female child; even then, she will prefer to have a male child to get respect from her in-laws family, in order to save her marriage.

- Mrs. A from Jalandhar district was married in Chandigarh. Both the husband and wife are highly educated (post-graduates). The husband earns a salary of Rs.4,000 per month. At present they live in a joint family consisting of the father-in-law, mother-

> in-law, brother-in-law and his wife. The brother-in-law has a 13-year-old only son. All the members are highly qualified—one of the brothers-in-law and his wife are doctors and live separately. Mrs. A has one daughter. She conceived a second time after keeping a conscious spacing of three years. In the fifth month of pregnancy, she went for amniocentesis and found the foetus to be a female. She did not reveal this to her in-laws, but secretly, with her husband's consent, she underwent an abortion. The researcher was able to contact her before the event, and found Mrs. A to be depressed and pale with fear and the guilt of having conceived a daughter. Sobbing, she said that she was ashamed of having a female foetus. While her husband did not mind having a daughter again, she herself wanted to have only two children, and to earn the respect of the family, she presumed that it is important to have a son. What a dilemma!

If a woman doesn't have any say in this matter, don't you think that this forced female foeticide is an act of violence against women? So where is the cure of this disease? With law? Doctors in India believe 2 million foetuses are killed every year through abortion, simply because they are female. Although it is an illegal practice, with the increasing availability of sex determination tests, it is impossible to keep track of such cases. There is little doubt that in India the PCPNDT Act of 1994 has not been very effective. The facts revealed by the census speak for themselves. We need, rather, to attempt more broad-reaching strategies that will address the economic and cultural roots of the problem. What is required is that the available legislation for prevention of sex determination needs strict implementation, alongside the launching of programs aimed at altering attitudes, including those prevalent in the medical profession. In rural areas, as the number of marriageable women declines, men would tend to marry younger women, leading to a rise in fertility rates and thus a high rate of population growth. The abduction of girls is an associated phenomenon. It was recently reported in *The Hindustan Times* that young girls from Assam and West Bengal are kidnapped and sold into marriage in Haryana. It is only by a combination of monitoring, campaigning and effective legal implementation that the deep-seated attitudes and practices against women and girls can be eroded.

Girls and women not only face inequity and inequality, they are even denied the right to be born if their families do not wish so. In fact, many families do not wish their women folk to deliver baby daughters. Confronted with this situation, it is high time to take preventive measures against female foeticide. Both local leadership and government agencies should plan a concerted long-term program aimed at the educational and socio-economic advancement of the community—for example, by social welfare and poverty alleviation programs—to improve the economic status of women. To wean people away from the traditional practices, voluntary organizations should come forward to promote social education and awareness among the people through cultural programs, public debate and so forth. There is a need for sustained campaigning and active monitoring of the act. State governments should realize the importance and priority of the law and not merely treat it with their usual complacency. Structures for implementation of the 1994 law need to be created at the district level. Volunteers have to be actively mobilized to monitor registration and functioning of sex determination clinics at different districts. Cases have to be filed against the violators and social consciousness has to be raised against the crime. Members of society and religious leaders have a positive role in creating a morally reformed society. The long-term task is to foster a culture of goodness and human dignity that inoculates individuals and institutions against the infection of this despicable human practice.

INTERVENTIONIST ROLE OF INFORMATION AND COMMUNICATION TECHNOLOGIES

Progress of science and technology is mandatory for the progress of a nation, but what matters most is its manifestation and beneficial application. Today, information technology has changed the communication paradigm, making it no longer difficult to reach a large number of people more or less at the same time; and that, too, enables them to respond, interact as well as obtain a copy of the information within a low-cost. information and communication technologies (ICTs), apart from making people aware of this heinous crime, can also play a highly interventionist role by pro-actively pursuing cases against erring doctors, booking them under the law of the land as well as helping people in general change their opinion about a "girl child." An important tool helping the government of India accomplish their cherished goal of altogether stopping female foeticide, set up by Datamation Foundation Charitable Trust, is a Web site solely dedicated to Female Foeticide (www.indiafemalefoeticide.org). This major ICT-based campaign and advocacy program is to help prevent occurrences of sex-selective tests and selective abortions of female foetuses in India. The purpose is to mobilize the population that apparently wants female foeticide, a medical system happy to supply the necessary technology, and a section of feminists arguing that female foeticide is about reproductive rights and choices.

FUTURE TRENDS

Online Attempts to Check Female Foeticide

The India Female Foeticide portal includes some distinctive features. The "Femicide" section provides some rich background information on the prevalence and practice of Female Foeticide, including reasons for the sex-selective tests. The site not only covers the regulatory aspects—PNDT Act of 1994 and the Medical Council of India's code of conduct to crack down sex selection – but also includes a complaint-lodging process in the best tradition of e-governance. The complaint-lodging process is a very critical feature, as it protects the identity of the complainant and yet provides an effective vehicle for booking the doctor, maternity home, ultrasound clinic or radiology clinic. The complaints are retrieved into a database format at Datamation, where they are handed over to the central PNDT Cell (Ministry of Health and Family Welfare) and other respective state and district authorities for re-addressal. To date, the Foundation has received about 580 complaints, and has passed these to respective authorities. The interpretation of the law in form of demographic data is also put on the Web site. Another important platform for the Web site is the "Pledge Support" page, which highlights two features—Pledge Support and Information. Through the "pledge support" feature, one can enter information regarding the type of volunteer service the person or the organization is ready to offer, and the "information" option allows one to enter information about any ultra-sound clinics, doctors, radiologists and so forth to enable database building.

Serving as a knowledge repository on the issue is the "What's New" page. The attempt here is awareness generation and capacity building both among the community and the stakeholders. Through e-mails, to date the Foundation has succeeded in spreading awareness among 8 million people worldwide on this issue. The "Links/Resources "page contains the contact addresses of different NGOs and agencies working for the prevention of female foeticide, and gives data for state-wise, sex ratio and female foeticide and sex selection. To enable awareness generation through sound and visual media, radio and video links have also been added to the Web site. An important feature started under this initiative is the e-Newsletter, through which the Foundation disseminates news, articles, reports and other studies on a weekly basis to make the various segments (students, NGOs, medical community, educationalists, government officials, researchers) of the society aware about issues of gender inequality, female foeticide and sex-selective abortions. "Youth Voices," a newly started section on the portal, is an effort to motivate and encourage youth participation in eradicating this menace and spreading awareness among other groups. To enable communication on this issue among various segments of society, we have started a discussion forum that allows free-flow and exchange of ideas among people.

CONCLUSION

Fully understanding that an evil such as this cannot be addressed in isolation, we are also closely examining related social malaise, such as dowry, women's underemployment and exploitation in society, education standards of the girl child as well as high school dropouts among girls, early marriages and the arranged marriage system. It is our endeavor to develop sustainable development models for each of the above-listed social malaise in India so that these have an impact on improving the ratio of females in the Indian society.

KEY TERMS

Child Sex Ratio (CSR): The number of girls in the age group of 0 to 6 years per 1,000 boys of the same age group.

Dowry: Money or property brought by a woman to her husband at marriage.

Female Foeticide: Practice in which an unborn baby is aborted or killed before birth simply because it is not a boy.

Manu: The primordial father of the human race and sovereign of the earth who first instituted religious ceremonies and devised a code of laws.

Moksha: In Hinduism, liberation and bliss (nirvana) from the cycle of rebirth (samsara); also called *mukti* or *moksha*.

Overall Sex Ratio: The ratio of all females to males, not just those in the 0-6 age group.

ENDNOTE

[1] When we talk of the Indian Census, it is important to understand that our sex ratio is defined as the number of females per 1,000 men, unlike the West, where sex ratio is the complete opposite and defined as the number of males per 1,000 females.

ABSTRACT

Healthcare applications are demanding with respect to their IT needs. Due to their complexity they need strong IT support which must provide enough freedom to their users in the medical domain because of the high degree of flexibility required by them. We have chosen a process based technology, called data logistics, which can cope with these almost conflicting requirements. Data logistics is based on clinical processes. However, when data logistics processes are executed, this happens transparently to the users and provides them a huge degree of freedom in determining the sequence of process execution. In order to cope with these challenging features, the process execution environment for data logistics processes is generated according to our model driven development approach called process driven architecture (PDA). Several clinical studies illustrate

the feasibility, effectiveness, and efficiency of the data logistics approach. This article both exposes the rationale of the data logistics approach and provides a deep inside into the implementation concepts.

INTRODUCTION

General Factors

The medical application domain has been a great challenge for information technology solutions for decades (Anderson, 1997; Berg & Toussaint, 2003; Lenz, Elstner, Siegele, & Kuhn, 2002) and is sometimes even considered as the "killer application" in the field of process support (Dadam, Reichert, & Kuhn, 2000). This estimation is based on the high complexity of the medical domain (Anderson, 1997; Lenz et al., 2002), which results from multiple factors. According to Anderson, J. G. (1997), Berg, (1999), and Kuhn, Giuse, Bakker, Ball and Gel (2001), these factors can be divided into two groups: technical and socio organizational.

Technical Factors

There are several technical factors that lead to high complexity. First, medical processes are by nature not static and thus require high flexibility during execution (Dadam et al., 2000). Depending on the current health condition of a patient, various treatments must be made possible (Dadam et al., 2000). Consequently, the challenge during process execution is "not to restrict the physician or the nurse" (Dadam et al., 2000), but to silently assist and support decisions of the medical staff. Second, the underlying process models need to be quickly adaptable to new requirements, as medical processes change constantly over time (Lenz & Kuhn, 2004). Typical reasons for that are new medical research findings and organizational or juridical amendments. An organically grown heterogeneous process landscape is the third factor; this heterogeneity leads to isolated integration islands. Processes differ in their characteristics like complexity, duration, number of actors, and so forth. Dadam et al. (2000) require either sophisticated or radical integration solutions.

Socio Organizational Factors

The unique combination of several socio-organizational factors is typical for the medical application domain. First, clinical routine is characterized by high workload and continuous high demands on all process participants. This is not surprising, as the medical staff is "responsible for many patients and they have to provide an optimal treatment process for each of them" (Dadam et al., 2000). Second, the process participants differ in their knowledge about the clinical applications. So, "cooperation between organizational units as well as the medical personnel [becomes] a vital task" (Dadam et al., 2000) for the clinical application domain. Third, the complexity of processes is very high, which results from the numerous and sophisticated dependencies within and between processes. This complexity is hard to manage for all process members. Last but not least, IT is often considered critically by the medical staff. According to Anderson (1997), "physicians have been unwilling to change their traditional practice of using the paper medical record." Anderson (1997) also notes that physicians accept information systems that allow for an improved patient treatment process but resist against information system that try to automate medical decisions. By involving process participants in information system development at an early stage, it can be assured that the realization of a medical process complies with their way of organizing work. This early involvement can increase IT acceptance (Anderson, 1997; Berg, 1999; Handler, Feied, Coonan, Vozenilek, Gillam, Peacock et al., 2004; Lenz, Buessecker, Herlofsen, Hinrichs, Zeiler, & Kuhn, 2005). We will now replenish and concretize the above requirements by experiences deduced from our research projects.

Analyzing the Clinical Application Domain

The results of this article have been acquired in two projects founded by the German Research Foundation:

1. Our sub-project C.5 of the Collaborative Research Center ("Sonderforschungsbereich") 539 "Glaucoma Including Pseudo-exfoliation-Syndroms" (SFB 539. (2007) deals with intelligent linking and adaptation of IT systems in order to improve the quality of the treatment of glaucoma patients. The research work is characterized by both clinical routine and clinical research. Consequently, an adequate information system has not only to support patient treatment but also the clinical research work which is split into two scientific goals. The first goal is the support of long running research studies based on quality assured data. The second goal is the development of an integrated semimobile workplace for early diagnosis of the glaucoma disease.
2. Our second project, "Fundamentals of Process Oriented Information Systems for Integrated Healthcare Networks," has been driven by the demand for process-oriented information systems (IS) in healthcare networks. IS have to support the treatment of patients according to clinical pathways (Beyer, Kuhn, Meiler, Jablonski & Lenz, 2004). Independent from their close relationship to IT, clinical pathways provide a concept to optimize the treatment of a group of patients with a similar diagnosis. Pathways are initiated, designed, and consented by a healthcare provider, for example, a hospital, and describe the treatment process considering both evidence-based medical guidelines and the organization of the institution. Clinical pathways need to be supported by medical IS.

In an overall perspective, medical IS have to meet the general requirements discussed in the last section but also have to bring optimal patient treatment and efficient support of clinical research work into a perfect balance. So the daily medical work is covered by three main areas (see Figure 1):

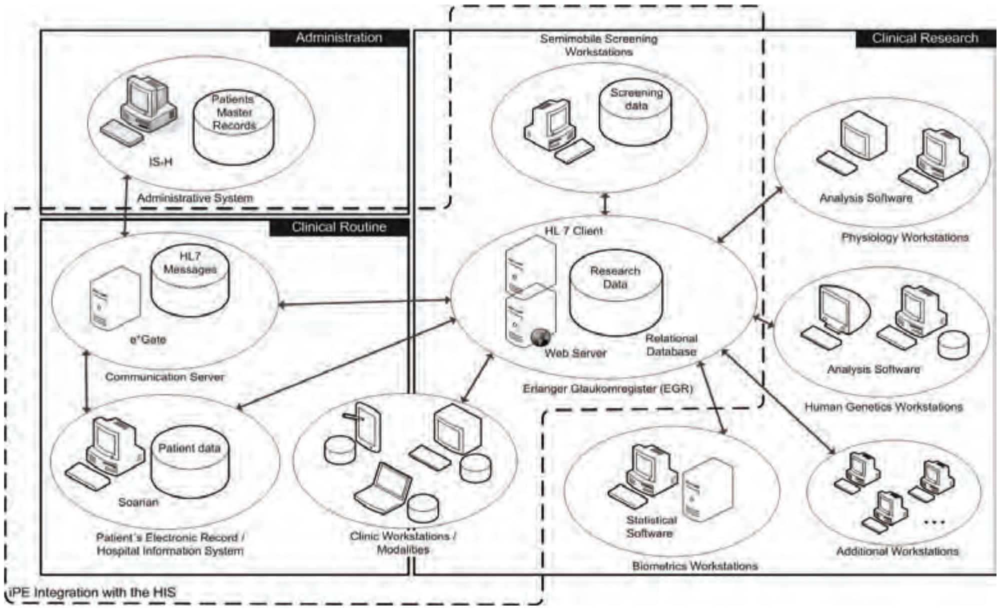
1. **Patient treatment:** Patients must be treated according to newest medical knowledge standardized by medical guidelines and clinical pathways in order to achieve optimal results.
2. **Clinical research:** Medical knowledge must be enhanced by clinical research mostly based on clinical studies.
3. **Administrative tasks:** Medical work is accompanied and supported by many administrative tasks to ensure correct factoring based on the concept of diagnosis related groups (DRGs).

Figure 1 shows a typical scenario based on these three areas as deduced from our research projects. The details shall not be discussed here, as the complexity is obvious.

Formalized Problem Analysis

Having identified concrete problem areas, we will formalize the main IT-related challenges and requirements from a technical point of view. A general problem statement derived from the observations of the two previous subsections boils down to two major issues. On the one hand, the complexity of healthcare applications has to be coped with. We foster a process based solution in this article. On the other hand, the complex healthcare applications are heavily depending on data that have to be shared between them.

Figure 1. Overview of our project setting: Clinical routine, clinical research and administration



Again, we foster a process based solution which is especially tailored to data integration problems. In the following we analyze these problem areas by first starting with the investigation of the data integration problem.

In general there are many different scenarios for data integration. The ideal setting is that all applications access a central data store, preferably a database system. However, not all applications—especially not healthcare applications—can follow this (simplified and naive) model. Figure 2 depicts a typical scenario of a healthcare application, presented in an abstract form. There are a number of so-called modalities (MOD_x), that is, technical equipment like a digital camera for making pictures of the papilla (e.g., KOWA fundus camera) or a laser scanning device (e.g., Heidelberg Retina Tomograph 2 [HRT2]). Typically, data created at a certain modality (e.g., images) are of different quality and structure (format); both are legacy and often not standardized. Also, data are first stored locally at the modalities themselves; these local data stores are here called $DB\text{-}MOD_x$.

Besides modalities, various information systems (IS_y) are deployed in clinical applications, such as a hospital information system (HIS). Also these information systems maintain their proprietary data management facilities; we call them $DB\text{-}IS_y$. Typically, data created at modalities have to be integrated into these information systems. However, data exchange among information systems is also necessary, and data also have to be transferred from information systems to modalities (e.g., patient identifications). Thus, from an abstract perspective, data have to be exchanged between and among modalities and information systems, respectively. Hence, we generalize modalities and information systems to (the term) "healthcare applications" (APPs) since we are going to develop a general data integration mechanism and can therefore abstract from concrete systems.

Data exchange between APPs does not always occur synchronously and at once, that is, when data are entered into the system (e.g., at a particular modality). For example, before such data are passed on to some consuming systems (APPs), the examination results at that modality must first be reviewed. Only if the results are assessed as valid can they be transferred to other APPs. The knowledge what data are when passed on to what consuming APPs can best be drawn from so-called clinical processes.

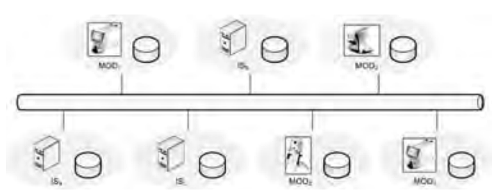
A very promising solution approach for the data integration issue in healthcare application is supported by process technology. Albeit, the usage of conventional process management technology is not practicable. For instance, conventional workflow management systems (as an example of conventional process technology) bear conceptual gaps in the field of adaptability and flexibility which makes their usage in this application scenario inadequate (Jablonski, Heinl, Horn, Neeb, Stein & Teschke, 1999). In order to prepare this discussion and to present our principle solution idea, some highly relevant constraints (Cx) from the healthcare application area have to be identified:

1. **(C1) Data transformation:** The data artifacts created by the different APPs have different formats, use different terminologies, and refer to different ontologies, but they must be synchronized with each other.
2. **(C2) Data identification:** Data produced at the different APPs use different identification schemes.
3. **(C3) Execution flexibility:** Data exchange between the APPs is very cumbersome. This is mostly due to the fact that the clinical personnel are very flexible in using the modalities during examinations. So it can hardly be predicted when an APP will be used; the physicians decide very spontaneously when taking the patients' actual condition into account. Consequently an IT system must not dictate the order of steps within an examination.
4. **(C4) Evidence based:** All examinations have to obey certain clinical and/or medical requirements. These are normally derived from clinical pathways and medical guidelines (Hellmann, 2003).
5. **(C5) Modeling flexibility:** Our application scenario is continuously changing since it is representing a research process. Due to newly discovered facets, the research process is constantly adjusted.
6. **(C6) Ease of use:** Data exchange between the APPs must occur transparently to the clinical personnel, as far as possible. As the personnel already have to handle multiple computer applications, it does not want to be burdened by just another IT system (Berg, 1999; Berg & Toussaint, 2003). Data management is regarded as an "auxiliary" task that should best be done by IT systems autonomously.

An analysis of the above requirements shows that they belong to three categories:

1. **Technical:** To cope with different formats, terminologies, ontologies (C1)), and identification schemes (C2) requires a technical solution. Among other things, mappings between data contribute to this matter.
2. **Application specific:** Clinical application scenarios tend to be spontaneous (C3), but restricted (C4) and dynamic (C5). This can be traced back to the enormous complexity of a patient treatment process.
3. **Usage:** Transparency of data management is a major need since it is regarded as an

Figure 2. Clinical (health care) application scenario



auxiliary, technical task, not as a medically motivated requirement (C6).

Our contribution is a process based data logistics mechanism that—transparently to the clinical users—controls the data exchange between the APPs. It is a process based concept since:

1. processes are regarded as being a suitable means to cope with complex application scenarios (C4),
2. processes can easily be modified and adjusted to changing requirements (C5), and
3. processes deliver a sophisticated structural framework to integrate diverse (technical) tasks of data exchange, that is, terminology, format, and ontology adjustment, and synchronization of identification schemes (C1, C2).

The above list reveals that still constraints C3 (flexible execution) and C6 (transparency of execution) must be dealt with. These constraints will not be met by processes directly, but by our data logistics concept.

In the next section, process management in healthcare application is discussed; especially the data logistics approach is presented. Our multi-staged approach to efficiently generate flexible process execution environments for healthcare processes—the process driven architecture (PDA)—is described in the following section. The implementation of our process management system (iPE) is detailed in the section following process driven architecture.

PROCESS MANAGEMENT IN HEALTHCARE APPLICATIONS

The Data Logistics Approach

Our data logistics method is based on an extended process management concept to cover all requirements identified in Section 1.3 (C1 to C6). The first step of our development method (Section 3) is to model clinical applications as processes (Beyer et al., 2004; Korycan, T. (1995). In order to sustain consistency and adequacy, these process definitions are based on medical guidelines and clinical pathways.

It is well recognized that process modeling is an excellent means to cope with complex and huge applications (Hammer & Champy, 1993; Ireson, 1997).

Especially the interactions between multiple participants and systems can be modeled efficiently such that constraint C4 is met perfectly. It is also well known from literature (Beyer et al., 2004) that process models are quickly and easily adoptable to changes. The graphical representation of processes facilitates change operations effectively and efficiently (constraint C5) even for domain experts such as the medical personnel.

Since we choose a perspective oriented process model, the technical requirements C1 and C2 can also be met without special efforts. In the perspective oriented process model, data constitute a separate perspective (Ireson, 1997).

Terminology, format, and ontology transformations, as well as synchronization of identifications are specific tasks associated with this data perspective.

Still, constraints C3 and C6 have to be addressed. They cannot be directly covered by normal process management. In order to cope with them, process management has to be extended by certain concepts, which we refer to as data logistics. Data logistics assumes the following:

- When the medical staff performs an examination, it is not guarded directly by the clinical processes defined in the first step of our method. Instead, it can use an application (APP) as spontaneous as if the data logistics have not been installed (C3), that is, the APPs could be used spontaneously. However, there must be some mechanism that controls the medically correct order of examinations. We will discuss this in Section 2.3.

- When an APP is used, data typically will be produced and stored in the local data stores ($DB\text{-}MOD_x$ and $DB\text{-}IS_y$, respectively). According to the data logistics specifications—which are derived from the defined clinical processes—these data are transformed and transported to specific sinks. This happens totally transparent to the users (C6).

The content of the second step of our data logistics method is to derive the data logistics processes from clinical processes. We call them data logistics workflows (DL workflows) in order to distinguish them from the "normal" clinical processes defined in the first step of our method. DL workflows run permanently and take care that data exchange between APPs is performed at the right time between the right APPs. One of the main features of DL workflows is their adjacency to clinical processes, that is, also to medical guidelines and clinical pathways. So, the very technical character of data logistics is directly connected to the clinical application field.

Having introduced the data logistics method, three main issues have to be investigated in the next sections:

- How to specify clinical processes?
- How to derive DL workflows from clinical processes?
- How to execute and implement DL workflows?

Processes

The following discussion about process management mostly concentrates on workflow management. Workflow management is regarded to aim at the execution of processes, which is our major interest. We will not provide a comprehensive introduction into workflow management in this section; instead we refer to Ireson, (1997) for a broad discussion of this topic.

According to the perspective oriented workflow model; a workflow consists of several perspectives which are weaved together. The functional perspective builds the skeleton of a workflow; it describes the tasks a workflow has to accomplish. The organizational perspective identifies the agents (e.g., physicians) responsible to perform a task and the operational aspect specifies applications supporting the execution of a workflow step. The control flow perspective defines the execution order between workflows. Finally the data aspect defines in/out parameters of workflows and how data flow between workflows.

In Figure 3 (left side) a very simple workflow model is depicted. Workflow WF1 is executed before workflow WF2 and WF3 respectively. The solid lines describe the data flow between workflows (WF). For instance, WF1 produces a data item OUT1 that becomes the input IN2 of WF2. In this figure we just use the parameters OUT1 and IN2 for readability; each input and output of a workflow can comprise a whole set of in- and out-parameters (e.g., documents). Additionally a control flow is defined between WF1 and WF2

Figure 3. A sample clinical workflow

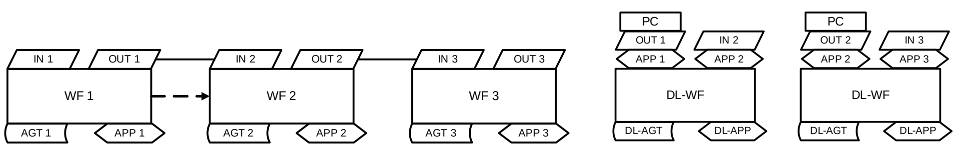


Figure 4. Processing of workflows in a conventional workflow management system (WfMS)

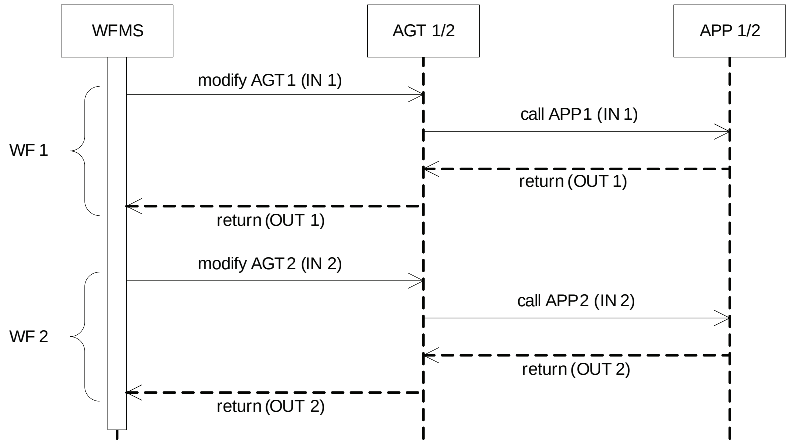


that, for instance, specifies that WF2 may not be executed before a certain time has passed. AGT1 denotes the agents that are responsible to perform WF1 whereas APP1 denotes the applications called by WF1 (e.g., an ophthalmic system). For simplicity we assume in the following that there is just one single agent and application specified for each workflow.

We will now provide arguments why the direct enactment of clinical processes by a workflow management system would not be acceptable for our clinical application scenario. Figure 4 shows as a simplified (unified modeling language [UML]) sequence diagram for workflow processing. The workflow management system (WfMS) selects a workflow that is ready for execution; in our case this is WF1 (see Figure 3). The WfMS notifies the declared agent (AGT) (here: AGT1) to perform the workflow step. The agent calls an application (here: APP1) that has to be executed. Required input data are always provided on the calls.

Figure 4 shows the substantiate duty of the WfMS which is to proactively trigger and initiate work to do. That means the following: If an agent has not been triggered by the WfMS it will not be able to perform its task. This behavior is contrary to what we have experienced in clinical applications and what we have postulated in Section 1.3 (constraint C3). There, we were assuming that the agents (e.g., physicians) are spontaneously selecting ophthalmic modalities for examinations. That means they cannot wait for a WfMS to offer such a modality for use, but they want freely—just piloted by medical requirements—to be able to select a modality. This is an absolute contradiction to the behavior a WfMS induces. As a marginal note, many trials to use WfMS technology in clinical environments were failing due to this discrepancy (Koppel, Metlay, Cohen, Abaluck, Localio, Kimmel et al., 2005).

In order to return to one of the primary goals we have to revisit our application scenario. Originally, data have to be exchanged between applications. This task is not directly fulfilled by the workflow depicted in Figure 3. Workflow management focuses the coordination of tasks, here WF1 and WF2. Indirectly, those tasks are also coordinated and connected through the association of these tasks with agents and application systems.

For the upcoming discussion of data logistics we need a semiformal model for workflow management. Therefore, we define the perspectives of a workflow in the following:

Control flow (CF) is a mapping CF⊆WF×WF which connects individual workflows of the set of all workflows (WF) with each other.

Data flow (DF) is a mapping DF⊆(WF, d_x) ×(WF, d_y). ((WF_x, d_x), (WF_y, d_y)) is element of DF if d_x is an output of WF_x and d_y is an input of WF_y (and both are type compatible, that is, data item d_x can be mapped onto data item d_y). Please note that there might be multiple DF or CF connections between two workflows.

A workflow WF_x∈WF is a structure ($DESC_x$, AGT_x, APP_x) where $DESC_x$ is its description, AGT_x is the agent responsible to execute the workflow, and APP_x is the application called within WF_x. Consequently, WF⊆DESC×AGT×APPP where DESC is the set of all activity descriptions, AGT is the set of all agents, and APPP is the set of all available applications. Without loss of generality, we assume that there are normally just one agent and one application associated with a workflow.

With this simple workflow model at hand we are now able to model clinical workflows. Especially as we use the customizable perspective oriented process (workflow) model of our process modeling tool iPM (ProDatO GmbH. (2006), we are able to model clinical processes appropriate. Meiler (2005) illustrates how the iPM workflow model can be effectively customized to describe clinical processes within a process driven application development methodology like the one we introduce in Section 3. Having accomplished this, the first task formulated at the end of Section 2.1 is fulfilled.

The simple workflow model also facilitates a formal derivation of DL workflows from clinical processes. This was the second open task formulated at the end of Section 2.1. The basic idea is that data exchange requirements between modalities (expressed in a DL workflow) can be derived from clinical processes as the example at the beginning of this section reveals: by combining the workflows WF1 and WF2 as shown in Figure 3 (left side) a data flow between APP1 and APP2 is specified.

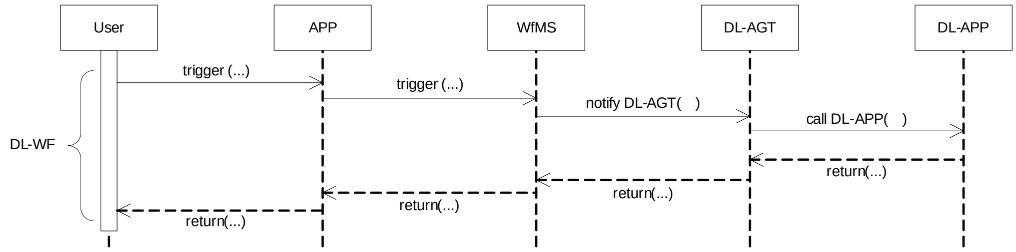
Data Logistics

In this section we present the data logistics approach. We start with an example that illustrates the basic idea (Section 2.3.1). Section 2.3.2 demonstrates the formal transformation of clinical processes into DL workflows.

An Illustrating Example

Data logistics aims at the coordination of data exchange between APPs. What does that mean with respect to the examples of both Figure 3 and Figure 4? When APP1 is executed (under the supervision of WF1) then the output data OUT1 has to flow from APP1 to APP2 (here it becomes the input data IN2). This is equal to the fact that after the use of application APP1, created data are

Figure 5. Processing of data logistics



distributed to APP2. Without loss of generality, our example data flow is just between two applications. It is no conceptual problem to extend this to multiple APPs.

Data logistics focuses on data exchange between APPs. Thus, we now change the perspective. Instead of observing the clinical processes (workflows, respectively) (Figure 3 and Figure 4), we look onto the DL workflows derived from them. A DL workflow needs a couple of special components:

- **DL-APP:** This is a special purpose application that is capable of shipping data from data sources to sinks, that is, to perform a data transport between APPs. In order to function it needs the following parameters: the participating APPs (data source and data sink), the corresponding output and input data, and the process context.
- **DL-AGT:** This is a special purpose agent who is associated with an APP, that is, each APP maintains a specific DL-AGT. The DL-AGT is triggered when the corresponding APP is used. The DL-AGT then initializes the local DL-APP, that is, it initializes data logistics and thus performs the data transport.
- **DL-WF:** This is a DL workflow that is always associated with a DL-APP and a DL-AGT.

The above components are sufficient to describe DL workflows. Figure 3 (right side) exposes the two DL workflows which are derived from the clinical process of Figure 3 (left side). The general rule is to create one DL workflow for each data connection of a clinical process (here: data flow between APP1 and APP2, and between APP2 and APP3). Section 2.3.2 will explain this issue in detail.

In Figure 5 the execution of a DL workflow is illustrated. The following sequence of operations takes place:

- A user is calling an APP, that is, the corresponding wrapper.
- The wrapper of this APP recognizes this and informs the WfMS about the usage.
- The WfMS notifies the DL-AGT of this APP to be prepared for initializing data exchange; this normally happens after the user ceases to use the APP.
- The DL-AGT calls the DL-APP with the corresponding parameters (see above) to initiate data exchange.

There are a couple of observations that must be discussed here in detail:

- There is only one DL workflow to be performed, namely DL-WF. Depending on the provided parameters, it is controlling data exchange between corresponding APPs. Similar, there is only one specific agent (DL-AGT) and one specific application (DL-APP) required. We will later go into details of this discussion.
- Since there is just a “normal” workflow, a “normal” agent, and a “normal” application involved, a conventional WfMS is suitable as execution platform.
- Although Figure 5 is simplifying the processing it nicely demonstrates that now the initializing actor is the user of an APP. This well corresponds to requirement C3. Besides, the data exchange takes place transparently such that constraint C6 is also fulfilled.

Aside from implementation details which are explained later, the demonstrated DL workflow is fulfilling all the requirements identified in Section 1.3. It is derived from clinical processes (C4, C5), it allows spontaneous user interaction (C3), and it organizes data exchange transparently (C6). The remaining two technical requirements C1 and C2 will be explained in Section 2.3.2.

Formal Derivation of DL Workflows

One of the most important advantages of our data logistics approach is that it has both a robust content related origin (the clinical processes) and a unique formal foundation.

The transformation from clinical processes to DL workflows focuses on data flows between process steps of a clinical process. Thus, for any two workflows WF_i and WF_j connected by a data flow (from WF_i to WF_j) the following DL workflow DL-WF can be derived: DL-WF = ($DESC_{DL-WF}$, DL-AGT, DL-APP)

$DESC_{DL-WF}$ is the description of the data logistic workflow, DL-AGT is the general data logistics agent, and DL-APP is the general data logistics application. These three components of the DL workflow will be the same for all clinical processes. Nevertheless the input and output parameters of a DL-WF are more interesting than the above aspects. For WF_i and WF_j with input data IN_i, IN_j, output data OUT_i, OUT_j, and applications APP_i, APP_j, the input data for the DL-WF are `PC`, OUT_i, APP_i. The output data for the DL-WF are `PC`, IN_j, APP_j.

The parameter PC indicates the process context (PC) in which a data logistics workflow is performed. Through this context information the two workflows WF_i and WF_j are determined. This context information is necessary, since the APPs can be reused in various clinical processes for different purposes. So the data logistics system must recognize not only the usage of a certain APP, but also the context (i.e., clinical process) this APP is used in. This determines where to transmit the data created at the APP.

Executing DL Workflows

Unfortunately, simply transporting data from APP1 to APP2 is by far not enough in a real world application scenario like we encountered. In fact many different data structures are used by the participating applications, modalities, and information systems. A closer investigation of the relevant data reveals that the data in general differ in three respects: format, (applied) ontology, and terminology. As a consequence the DL workflows not only have to consider data transport but also data transformation; the latter deals with the differences between formats, ontologies, and terminologies of different APPs.

There are two principal approaches to cope with the challenge of a set of heterogeneous data structures. The simple, but laborious strategy would be to implement a specialized transformer for every pair of applications that exchange data. This approach is in principle feasible, as the use of the process context (PC [Section 2.3.2]) allows us to mostly automatically select what transformer to use during the execution of the DL workflow. Yet, in an application scenario that involves more than a hand full of data flows, the number of required transformers rises according to the following formula, where *n* is the number of participating data structures:

$$\frac{n*(n-1)}{2}$$

It is obvious, that this approach is cumbersome and error prone in a real world setting. This problem is well known in the medical domain and several standards like health level 7 (HL7) (Health Level Seven Inc., 2006) and the clinical document architecture (CDA) (Dolin, Alschuler, Beebe, Biron, Boyer, Essin et al., 2001) try to solve it. Thus we decided to use the same strategy and offered a generic data structure that serves as application independent data container. This significantly reduces the number of needed transformers, as every application needs only a single transformer to convert its data structure to the common data structure and vice-versa. In our projects we mainly use the Erlanger Glaukomregister (Figure 1) and its generic relational database schema as common data structure. In Section 4.3 we outline an example where we further standardized our glaucoma research data structure by using CDA to be able to link our research database to the HIS "Soarian" and to an electronic patient record.

After this comprehensive discussion of the basic concepts of our data logistics approach, the next section gives a brief introduction to our holistic development approach for process oriented applications.

PROCESS DRIVEN ARCHITECTURE (PDA)

We developed a comprehensive methodology to efficiently support the semiautomatic generation of process oriented applications, called process driven architecture (PDA). It is used to provide a modeling and execution environment for DL workflows.

Foundations of the Process Driven Architecture

Our approach is inspired by several concepts derived from the area of model driven software development and especially the Object Management Group's (OMG) model driven architecture (MDA) (Kleppe, Warmer, & Bast, 2003). The MDA is a highly structured general purpose approach to facilitate the semiautomatic generation of software, based on the OMG's unified modeling language (UML) (2007). It allows for the specification of software based on customized UML models. The models are built upon the terminology of the application domain, generally referred to as the domain specific language (DSL). The MDA promotes an iterative development cycle based on three, increasingly system specific model levels: the computation independent model (CIM), the platform independent model (PIM), and the platform specific model (PSM).

The most abstract, but at the same time most domain specific model level is the CIM, which may be modeled using any kind of domain specific description (e.g., narrative use cases). This fuzzy method to describe a software system on a very high semantic abstraction level might be regarded as advantage, as it offers much flexibility, otherwise it might be regarded as disadvantage, as it avoids efficient tool support to specify and transform the CIM to the next model level. In fact, using the MDA often results in a semantic gap between the CIM and the PIM, as it in general involves multiple human interpretations of the imprecisely described CIM.

The PIM is specified using an individually customized version of UML, mostly based on UML stereotypes and UML profiles. Consequently, it is the first machine interpretable description of the software system and thus it can be automatically transformed to the next model level. Nevertheless, it still is not connected with a certain system platform (e.g., the .NET platform). Finally the PSM is generated directly by transforming and enriching the PIM by platform specific details, that is, an UML model of the software system is produced.

As mentioned above, the MDA inspired the development of the PDA. Unfortunately, it turned out during our two projects (Section 1) that a simple domain specific adoption of the MDA and UML would not fulfill the characteristic requirements of process oriented software development. The goals of the MDA are very generically to support the generation of any kind of software using the UML. However the UML is not perfectly suitable to describe complex and highly flexible medical processes, like the ones we encountered at the clinical application domain (Section 1.2). Several facts account for that. First, the UML currently does not directly support the design of an arbitrary graphical modeling notation. Second, a comparative analysis of several process modeling methodologies and languages revealed that the UML offers no concepts that are expressive enough to model processes precisely on a high abstraction level. Especially the UML 2.0 activity diagram currently does not provide satisfactory modeling constructs for our modeling needs. A project specific comparison of several process modeling methodologies and languages can be found in Müller, S. (2007) work. Third, the MDA's CIM is too imprecise to allow for a semiautomatic and thus effective and efficient transformation into the PIM.

As a result, we decided to develop a generic development method for process oriented applications based on the perspective oriented process modeling paradigm used for our PDL approach (Section 2). This allows us to build a perfectly integrated approach to efficiently derive an executable process oriented software system from a domain specific process description understandable for domain experts, such as the medical personnel.

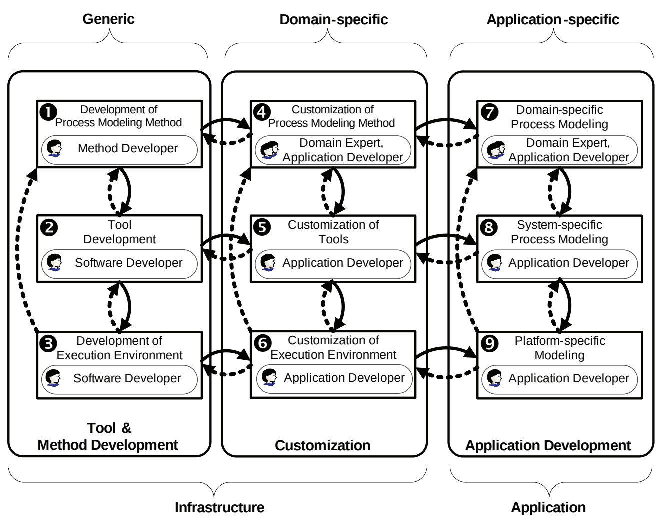
The PDA Approach

The PDA promotes a comprehensive approach for the development of process oriented software systems, which covers not only the application development, but also the prior development of adequate tools, methodologies, and their necessary customizations (Müller, 2007). The overall PDA development process is divided into three stages (Figure 6): tool and method development, customizing, and application development.

During the first stage the basic process modeling methodology, for example, the perspective oriented process modeling method, and associated tools are developed. This is done in three steps. First, a method developer, typically embodied by an industrial consortium (e.g., the OMG) or a researcher, designs a process modeling method (Figure 6, ❶). Second, software developers create specialized tools to be able to efficiently perform modeling tasks using the new process modeling method (Figure 6, ❷). Finally, an execution environment is developed that can implement processes modeled using the newly designed method (Figure 6, ❸). The tool and method development stage is generic by nature, as it is independent from any application domain and the results, that is, the methodology and the tools, can be used very widely. At the first sight, it seems to be plausible that the tool and method development stage is executed sequentially.

The second stage of the PDA approach adopts the results of the first stage to a certain application domain, for example, the clinical field of application. Yet, it is still independent of a con-

Figure 6. The multi layered PDA approach



crete application process and thus belongs to the infrastructure development. The customization stage is split into three steps as well. In the first step, the process modeling method is customized to the application domain (Figure 6, ❹). Typically this involves the cooperative design of modeling constructs that adhere to the terminology of the application domain. For example, the application independent modeling construct "organizational unit" may be specialized as physician, assistant medical technician, patient, and so forth. Actually, a new idiom of the modeling language, called the domain specific language (DSL) (van Deursen, Klingt, & Visser, 2000), is created that serves as communication basis between the domain experts and the application developers (Sections 1.1 and 2.1). This step is critical to many model driven software development approaches (Stahl & Völter, 2005) and thus has to be performed in close cooperation between experienced domain experts and application developers. The newly introduced modeling constructs and all other modifications of the modeling methodology subsequently have to be reflected in the modeling tools, which is done in the next step (Figure 6, ❺). The application developer is responsible to configure the used tools accordingly, that is, the tools have to be highly adaptable. The process execution environment has to be customized to fit into the application domain as well (Figure 6, ❻). The necessary actions at this step range from the installation of basic infrastructure, such as a Web server, to the provision of network access to required information systems, such as a HIS. Again, the customization steps are in practice interdependent and executed iteratively, if necessary. At the end of the customization stage, all tools and the modeling methodology are fitted to the intended application domain, that is, the development infrastructure is ready to be used for the "production" of process oriented applications.

For every process that is to be supported by our PDA approach, only the application development stage has to be passed. Three steps constitute the PDA application development. At first, a domain specific model ("clinical pathway") of the process to support is drafted cooperatively by the domain experts, for example, the medical personnel, and the application developers (Figure 6, ❼). This step is of utmost importance for the quality of the resulting process support application and has to be done very carefully. This ability to generate an application that is ready to run directly results from the comprehensive efforts during the customization stage. Directly after the domain specific process modeling is finished, the application developer takes care of system specific adoptions and enrichments of the process model by simply wiring the previously configured and prepared tools with the elements in the process model (Figure 6, ❽). All actions that have to be taken after this step may be automated and do not need any further human interaction if prepared well during the customization stage. The last application development step comprises the generation, compilation, and deployment of the application (Figure 6, ❾). What steps are exactly necessary depends on what kind of process execution environment was selected, that is, the generation of software is treated differently than the deployment of a workflow in a WfMS. Respectively, the degree of manual intervention strongly depends on the specific situation, especially if a well organized test and release cycle follows. The application development stage results in an executable process oriented application.

The next section gives a brief insight on how we applied our PDA approach within our two projects.

The Adaptation of the PDA

The PDA provides the structural framework for the development of process oriented application systems. In the following, we illustrate two of our major design decisions and briefly introduce the tools we used. As mentioned in Section 3.2, our first important decision regarding the tool and method development was to use the perspective oriented process modeling methodology for our projects. As a consequence, we chose the sole existing process modeling tool for perspective oriented process modeling, the integrated process modeler (i>PM) provided by ProDatO GmbH (ProDatO GmbH. (2006). This tool offers a convenient graphical editor and is easily adoptable to a new application domain mostly by configuration. When we started our project, i>PM offered the default graphical notation for perspective oriented modeling and several specialized notations (i.e., DSLs) for the automotive segment of industry. After the domain specific customization of the process modeling method, we added our DSL for the medical domain, called i>PM4Med, to i>PM and iteratively extended it. Thus we are able to perfectly support the system and domain specific modeling steps during the application development phase.

The second important strategic decision was to develop our own process execution environment. During the last years we pursued and compared two completely different approaches to support process execution in the sense of data logistics (Section 2.1). The first approach was a monolithic execution environment that is capable of interpreting XML-based process type definitions from i>PM4Med directly (Jablonski, Lay, Müller, Meiler, Faerber, Derhartunian et al., 2005). For this kind of application it is characteristic that new features have to be added to the central process interpretation and execution engine. Obviously this central process interpretation and execution engine is complex and it can easily become the bottleneck during process execution. Although we never experienced any serious problems with this kind of execution environment, we decided to try to develop a generative approach as alternative implementation. Thanks to the structured PDA development approach, we were able to introduce the new implementation step by step using clearly defined interfaces between the PDA stages and steps. Especially the users and the domain experts were nearly not affected by this transition.

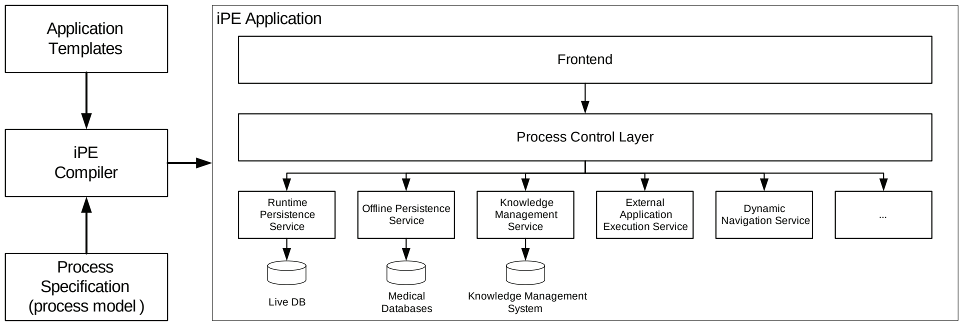
IPE: ARCHITECTURE AND IMPLEMENTATION

Modeling processes using a DSL helps to understand the procedures occurring within a medical institution. Beside this, processes can also practically support people; this is the application field of iPE, our solution for the execution of process models. The core component of iPE is the iPE compiler which we have developed for transforming process models into applications which can be interactively executed by a computer.

Function and Architecture of the iPE Compiler

The iPE compiler has been implemented with the concepts of the perspective oriented process modeling in mind. This means that the compiler can deal with arbitrary perspectives in such a way that their translation into executable code can be defined from the outside. The compiler itself reads a given process model and transforms it into a representation that is independent of the modeling language used for describing one process. After this conversion the model is passed on to single subprograms—called generators—which are responsible for producing the single components of the final application. It is the responsibility of each generator to decide which perspectives are interpreted and which are left out. Furthermore, the code the generator is producing out of the process model only depends on the generator and not on the compiler. This allows us to develop sets of generators which result – when used together – in one type of application (e.g., a Web application). With this in mind we also refer to the generators as templates for the mapping of a process to an application. Looking at the result

Figure 7. The iPE compiler generates the iPE application



of the compilation, an application has been built which is specific to the application domain and the process.

Figure 7 shows the use of the iPE compiler. The iPE compiler uses templates to transform the process model first into a modeling language neutral representation and then into an executable application. The architecture of the generated applications only depends on the templates and not on the compiler. Adding a new perspective to a process model means to provide in iPE a template for the compiler for code generation and changing the existing template for the language mapping into the neutral representation.

Architecture of an iPE Application

We have written a set of templates which generates a Web application for a given process. The architecture of these applications follows the classical model-view-controller (MVC) (Gamma, Helm, Johnson, & Vlissides, 1995) design pattern. The application has been split into three layers. The first layer is the front-end which is only used for the interaction of a process with its users if no other application for the execution of a process step is given. The second layer is the process control layer (PCL) which manages the interactions of the front-end and the third layer, the data layer. The front-end corresponds with the *view*, the PCL with the *controller*, and the data layer with the *model* in the MVC pattern. The data layer is again divided into separate services which add functionality to the iPE application being generated. In Figure 7 the following components are shown:

- **Runtime persistence service (RPS):** The RPS stores all the data gathered during the execution of a process.
- **Offline persistence service (OPS):** The OPS only considers data which is of special interest (e.g., patient records). At specific points during the execution, the OPS writes or reads data to/from medical databases.
- **Knowledge management service (KMS):** The KMS supports the user of a process by displaying links to additional background information, for example, about a special treatment or disease. Also during the execution new knowledge is created which can be written to a knowledge database through this service.
- **External application execution service (EAES):** This service is responsible for the interaction with external programs and/or hardware (e.g., a word processor for filling out special forms).

- **Dynamic navigation service (DNS):** The DNS decides for the next process in the line of execution depending on the users inputs.

These services can then be mapped onto the perspectives of the perspective oriented process modeling approach. The RPS and OPS together make up the data and data flow perspective, the KMS corresponds to a knowledge perspective (if introduced at all); the EAES is the direct counterpart of the operational perspective. The functional perspective is not directly visible. In an iPE application every process which did not specify the operational perspective is mapped onto a "default application" which is in our case simply a Web page displaying the incoming and outgoing data providing some functionality to manipulate it. The DNS implements more than one perspective. It considers causal dependencies in between processes (e.g., given through the functional perspective) as well as dependencies given through the data and data flow perspective respectively (a process can only be executed in case the data needed as input is available). Last but not least the organizational perspective is not shown; it is also implemented as a service attached to the PCL.

The PCL is the link in between the front-end and the data layer. It creates commands out of the inputs which manipulate data (RPS and OPS), determine the new process to be executed (DNS), and start the actual execution (EAES). Feedback is provided for the user through the front-end.

Integrating Data Logistics into a Clinical Application

An important issue with all clinical support systems is how they store data persistently. As described in the architecture section iPE implements a two staged persistence layer consisting of the runtime persistence layer (RPS) and the off-line persistence layer (OPS). The RPS has to store all data that are generated during a session. However the RPS only has to ensure that data are kept during process execution. After completing the process all medical data are committed to the OPS and removed from the RPS system.

After the execution of a path, the OPS has to make all medical data of the corresponding instance persistent. Two persistent storage systems are used: The HIS "Soarian" stores data used in the clinical routine, whereas the Erlanger Glaukomregister serves as central research database (Figure 1) for the SFB 539 (Section 1). Data are submitted to Soarian using HL7 messages containing glaucoma related data encoded in a newly developed CDA/SCIPHOX (Heitmann, Schweiger, & Dudeck, 2002) compliant document structure (Gerdsen, Müller, Jablonski, & Prokosch, 2006).

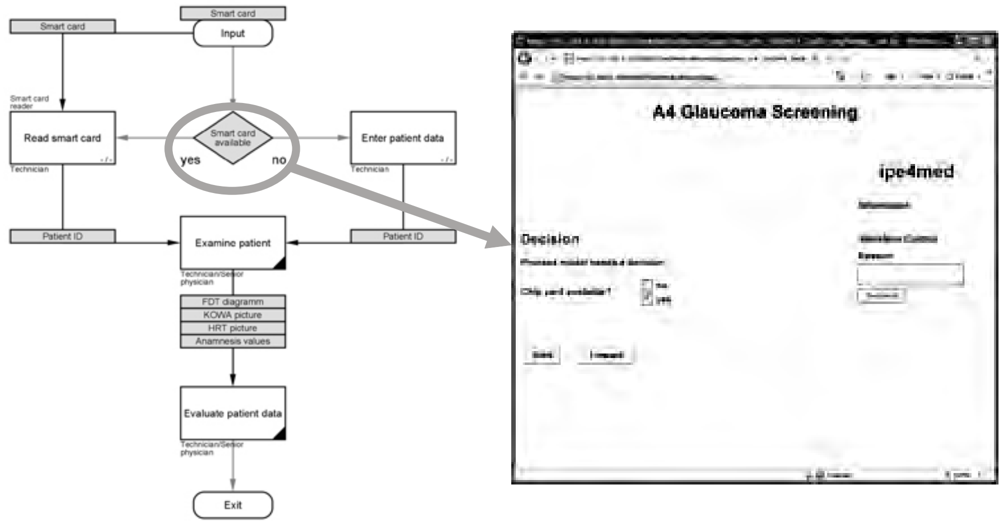
Execution Semantics and Application Example

The iPE engine is the central component as it generates the Web application which is our interface to the users. When processes are executed, three major concerns have to be reflected by the execution environment:

1. Be as restrictive as necessary so that no important steps in the process are left out.
2. Be as flexible as possible so that physicians and medical assistants have a high degree of freedom.
3. Provide all information that helps to fulfill the given task.

In the following section we explain how the execution of DL workflows is going to take place and how the three identified concerns are implemented. As example, we use a glaucoma screening process that is used at the Ophthalmic Department of the University of Erlangen for the early detection of the glaucoma disease. The process shows the following global structure.

Figure 8. Decision support during process execution



At first a patient ID has to be selected and the patient's master record has to be created. Then the patient is examined and the medical findings are transferred into the database. Finally a physician has to evaluate the patient data and a medical findings letter is printed.

It is quite common during the execution of a process that the user comes to some decisions. Figure 8 displays a situation at the beginning of the process where the patient's master record has to be entered into the system. In the German health system this record is stored on the smart card provided by the health insurance and can usually be read electronically by a smart card reader. However, this process is also used in a research environment where users do not have to provide insurance data obligatorily. Since the system cannot determine whether a smart card is available, iPE creates a Web page where a medical technician can provide information about the availability of the smart card (Figure 8).

In Figure 9 the execution of the process step "Review Patient Data" is depicted. First of all, an HRT2 picture of the right eye is presented to the physician; this data and further data to assess the state of the patient's eye are shown in the GUI (not all of them are visible in Figure 9). Below each section of the GUI (i.e., HRT picture or the patient's anamnesis) a physician can enter medical findings. As these findings are standardized and coded by numbers, a physician can select an appropriate entry out of a list; this feature increases the consistency of data entry, since only eligible data are offered. Later in the process these number codes are automatically transformed into readable text and printed in a findings letter.

In the information section of the GUI (right side) additional background information is provided that supports the user during his daily work. Here, links to Web pages in the clinic's intranet, operating instructions, or best practices, as well as hints can be given. Also the integration with knowledge management systems is possible and a first prototype exists that demonstrates the integration.

After each step of the process the DNS decides for the next process in the line of execution. As

Figure 9. Reviewing the patient’s data

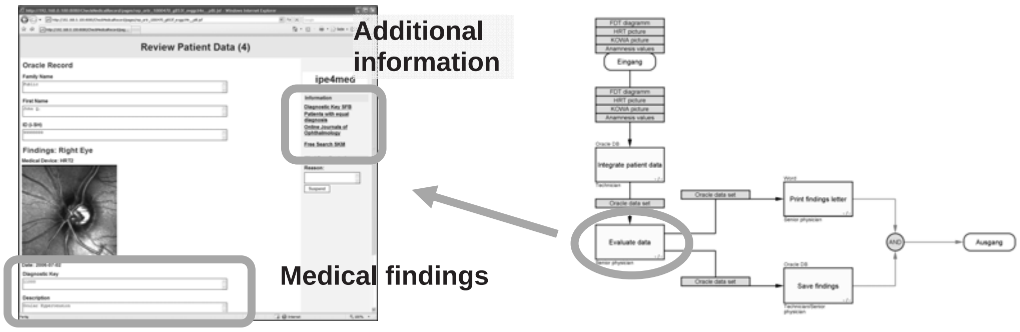


Figure 10. Dynamic navigation during process execution

described in Section 4.1, causal, organizational, and data flow dependencies are analyzed as well as the steps that already have been completed to determine which steps can be executed. The list of executable process steps is then displayed in the “Dynamic Navigation” section in the Web page (see Figure 10). Before a user can complete a certain process step, the user has to select which step has to be executed next. This way the control flow of the application can be determined by the user, whereby the boundaries of the process definition have to be regarded (control and data flow). The DNS is the central component in implementing our requirement for medical process execution engines to be as restrictive as necessary, but also to be as flexible as possible.

Even though this simple scenario only gives a glimpse on the functionality iPE offers, it demonstrates how flexible processes can be executed by iPE. Through the template based architecture of iPE, the generated applications can be tailored to the specific requirements of an application domain.

CONCLUSION

This contribution presents an integrated approach for process and data integration in healthcare applications. We provide a process based solution for data and process integration of healthcare applications. Long term studies in real clinical applications—some parts of them are discussed in this article—prove the feasibility of the approach.

One of the major contributions of our approach is the integration of multiple concepts and techniques from IT into a powerful process and data integration mechanism. Starting with process management, incorporating data management concepts, and completing the approach with the PDA, a powerful and comprehensive modeling, development, and execution environment for healthcare applications is constituted.

Currently we are working at the incorporation of a knowledge management component during the process execution. It should be used to capture knowledge about DL workflow execution to be later offered to new clinical personnel in order to better and faster made familiar with the clinical processes. We expect that this will further leverage the supportive effects of our data logistics approach for the medical personnel.

Chapter 7.25
Approximate Processing for Medical Record Linking and Multidatabase Analysis

Qing Zhang

David Hansen
CSIRO ICT Centre, Australia

ABSTRACT

In this article we investigate how approximate query processing (AQP) can be used in medical multidatabase systems. We identify two areas where this estimation technique will be of use. First, approximate query processing can be used to preprocess medical record linking in the multidatabase. Second, approximate answers can be given for aggregate queries. In the case of multidatabase systems used to link health and health related data sources, preprocessing can be used to find records related to the same patient. This may be the first step in the linking strategy. If the aim is to gather aggregate statistics, then the approximate answers may be enough to provide the required answers. At least they may provide initial answers to encourage further investigation. This estimation may also be used for general query planning and optimization, important in multidatabase systems. In this article we propose two techniques for the estimation. These techniques enable synopses of component local databases to be precalculated and then used for obtaining approximate results for linking records and for aggregate queries. The synopses are constructed with restrictions on the storage space. We report on experiments which show that good approximate

results can be obtained in a much shorter time than performing the exact query.

INTRODUCTION

There is an increasing amount of data being captured in health systems. The data are generally spread among many different data systems. Primarily the data are used for patient treatment; however secondary use of this data is important for improving the health service and medical treatments. These data might be used by the health service to ensure that there is adequate service provision. The medical community may use these data for gathering important information on diagnosis, treatment, and outcome for evidence based practice and future research. With the data spread between so many data repositories, multidatabase systems (Stead, Miller et al., 2000) provide one way to access the data. However, performing queries across large distributed data sets can be expensive, both in time and computing resources.

A typical multidatabase query is to validate patient records across separate local databases which refer to the same person. This can be difficult when, as is often the case, there is no global identifier to provide a single key. For example, suppose one database records the diagnosis information of patients who have been diagnosed with a particular cancer and another database records the information of patients who have received chemotherapy. If no unique patient identifier exists for these two databases, identifying information must be compared from the two databases to identify records which refer to the same patient. Based on the linking results, other analytic queries can then be issued to analyze diagnosis and treatment details.

The linking result can be represented as a *link table* that lists all matched records along with some measure of accuracy of the match. The number of records in the link table is known as the *selectivity* of the link table. The global query optimizer of a multidatabase system uses this selectivity to decide proper strategies on dissecting global query, transferring data among local databases, and so forth. However, a naïve selectivity estimation requires linking two local databases first, which may be very time consuming and even unaffordable due to the large amount of medical data or network failure possibilities. This provides a first motivation for developing an effective selectivity estimation method in a health multidatabase.

Our second motivation comes from the exploratory nature of some queries. In cases, such as decision support systems, users may not be particularly interested in the exact result (Chakrabarti, Garofalakis et al., 2000). An example of this situation may be the case of investigating the relationships between two diseases. Users may first wish to know that the number of patients linked in the two disease databases is big enough to do any further analysis. A large amount of time can be saved if the system can provide an approximate result early. Users then decide if a fuller investigation is warranted.

Motivated by these, we have developed a method for link table selectivity estimation based on constructing database synopses of large and complicate health databases. Since the size of the synopses is strictly limited to the storage requirements of the system, the main challenge in our method is to construct a "good" synopsis which can provide a close estimation to the exact result. We test our approximation methods on various synthetic databases. Experiments show that our techniques can provide close approximation in a much quicker response time than getting the exact result through the naïve query-and-count way.

The rest of the article is organized as follows. The following section presents the background of the selectivity estimation and the structure of our selectivity estimation module. The third section presents our estimation method based on wavelet transformation. The next section presents the estimation method based on histogram synopses. The following section evaluates our selectivity estimation techniques with various experiments. The sixth section demonstrates how to use our method for more complex multidatabase aggregate queries. The next to last section lists related works and the last section remarks our work and states possible future research issues.

BACKGROUND

In this section, we briefly review two traditional selectivity estimation techniques used in relational databases, the histogram and wavelet. Selectivity estimation is the use of precomputed synopses of the original data to estimate the number of records satisfying the selection criteria. Since such synopses usually occupy a small space compared with the original data, the quick response of the approximate answer would be naturally expected. However, constructing an efficient synopsis is a trade-off between space and accuracy. Moreover, in an environment where original data keep changing dynamically, updating the constructed synopses accordingly is an important issue. In this article, we assume that the original data are relatively static and hence the synopses can be updated by a periodically reconstructing procedure.

Formally, given a relation **R** and an attribute **X** of **R**, the domain **D** of **X** is the set of all possible values of **X**, and a finite set **V** ($\subseteq$ **D**) denotes the distinct values of **X** in an instance *r* of **R**. Let **V** be ordered increasingly. An instance *r* of **R** can be denoted by **T,** known as r's *data distribution:* **T** = $\{(v_1, f_1), ..., (v_n, f_n)\}$. In **T**, every (v_i, f_i) is called the value-frequency pair. Each v_i is unique and is called a *value* of **T**. The f_i of the pair is the occurrence of v_i in **T** and is called the *frequency* v_i. Selectivity of values between v_a and v_b is to count the number of tuples in **R** that satisfy $v_i \leq$ **R.X** $\leq v_b$. In other words, it is to calculate the summation of the frequencies of values between v_a and v_b. A synopsis **S** of the instance *r* is a compression of **T** and its size is much less than that of **T**. Many techniques have been proposed to compute **S** from **T** in literature. We focus on two of them in the followings: the histogram synopses and the wavelet synopses.

Constructing Histogram Synopses

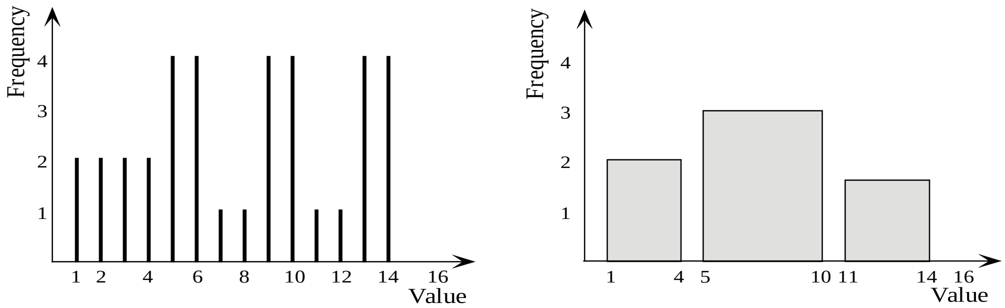
Histogram techniques have been used for selectivity estimation in commercial database management systems for few decades. Although estimation through histogram is fairly straightforward, it is not easy to construct a good histogram due to various data and query distributions.

We now provide a data distribution **T** as a running example. **T** and one of its histogram synopses are depicted in Figure 1.

The techniques for building the histogram synopses focus on *inner bucket estimation* and *bucket partition*. The common goal is to minimize the difference between the original and the approximate data. The inner bucket estimation is to approximate the distribution of value-frequency pairs that fall in one bucket. A generally adopted approximation is to assume the uniform value distribution and average frequency representation. That is values in one bucket are assumed to be spaced evenly. The frequencies in one bucket are represented uniformly by their average.

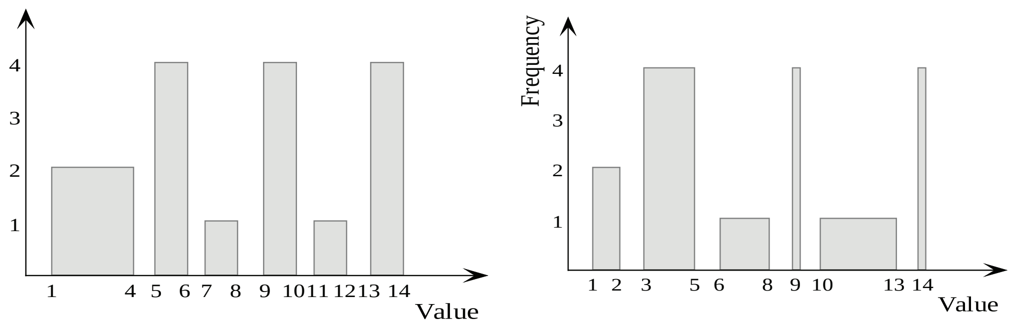
The bucket partition studies how to effectively partition the original data distribution, with a given bucket number. Traditional partition methods, including equiwidth and equidepth, have been widely used in commercial database environments (Kooi, 1980; Piatetsky-Shapiro & Connell, 1984). Other partition techniques, such as max-diff and v-optimal have been developed during recent years (Ioannidis, 1993; Jagadish, Jin et al., 2001). Techniques for constructing a nontrivial multidimensional histogram, that is, a histogram against multiple related attributes, have

Figure 1. Data distribution and histogram



a. Data disribution *b. Histogram with 3 buckets*

Figure 2. Various histograms



a. A perfect 6 buckest histogram *b. another 6 buckets histogram*

also appeared in literature since 1997 (Poosala & Ioannidis, 1997; Acharya, Poosala et al., 1999; Lee, Kim et al., 1999).

More buckets generally lead to less approximation error. As in Figure 2(a), the histogram with six buckets is considered a perfect one as it can accurately represent **T**. Under a fixed bucket number, different partition strategies also have great impacts on the histogram's performance. As in Figure 2(b), although the histogram also has six buckets, it is obviously much worse compared to the one in Figure 2(a).

Constructing Wavelet Synopses

Wavelet techniques have been used successfully in signal and image processing (Graps, 1995; Hubbard, 1996). Wavelet analysis combines the advantages of the Fourier transformation and windowed Fourier transformation. It adopts a wavelet prototype function, called a *mother wavelet*, to compress the original data to a synopsis. The simplest mother wavelet is the Haar wavelet which was proposed in 1909 by Alfred Haar. It has been used for selectivity estimation since 1998 and has been greatly developed thereafter.

We still employ the data distribution **T** in our last example to show details of constructing Haar wavelet synopses. First, we apply Haar wavelet transformation on the frequency distribution of **T,** [2, 2, 2, 2, 4, 4, 1, 1, 4, 4, 1, 1, 4, 4, 0, 0]. Note that we add several 0 frequencies to make the number of **T** to be the power of 2. This original distribution will be considered having resolution level 4 (Figure 3). Note that the resolution represents the approximation of the original data. Data at higher resolution level preserve more original data information compared to data at lower level. The Haar wavelet transforms **A** by averaging the values of each pair, starting from the first two values of **A**, to get new *low-resolution* representations. It also records the difference of the pairs as coefficients on the same resolution level. By applying the transformation recursively, we reach the average value at resolution 0 with all the coefficient values are computed on the fly. Figure 3 shows details of the Haar wavelet transformation on **A**.

Thus the Haar wavelet transformation converts **A** to $\mathbf{W_A}$, [2.25, 0, −0.25, 0.25, 0, 1.5, 1.5, 2, 0, 0, 0, 0, 0, 0, 0, 0]. Each entry in $\mathbf{W_A}$ is called a *wavelet coefficient*. Second, we approximate $\mathbf{W_A}$ by keeping only those most significant coefficients to fit the space limitation of the synopses, and treat other coefficients as 0. For instance, to compress $\mathbf{W_A}$ with four coefficients space limit, we record a synopsis **S** as **S** = [(2.25, 1), (1.5, 6), (1.5, 7), (2, 8)]. The second number of the pairs in **S** indicates the non-zero coefficient's position. Applying inverse Haar wavelet transformation, we can get the approximation of the original frequency distribution **A**.

LINKING ESTIMATION THROUGH WAVELET

In this section, we introduce a record linking estimation method based on wavelet techniques. We start with a naïve approximation method. Then we propose our wavelet linking estimation technique.

A Naïve Approximation

This method is motivated by the folklore *blocking technique* used in the record matching. The basic idea is to subdivide records to be linked into a set of mutually exclusive subsets under same criteria that guarantees no matches occurring across blocks. The possible linking can therefore only happen between corresponding blocks. Given two such blocks, b_α and b_β, to link. Let $S(b_\alpha)$ and $S(b_\beta)$ represent the number of records. If there are no duplicate patient records in each block, we simply estimate the selectivity of the possible linked records with $\min(S(b_\alpha), S(b_\beta))$. If however there exists duplicate records, we estimate the linking selectivity with $\max(S(b_\alpha), S(b_\beta))$. For simplicity reason, we assume no record duplication in this article.

The blocking estimation method can be further tuned when we partition the records into more detail buckets. We show this in the following example.

Example 1. *Two blocks b_α and b_β with $S(b_\alpha) = 400$ and $S(b_\beta) = 500$. Suppose the exact linked records between b_α and b_β is 200. A rough selectivity estimation of linking is 400 as shown in Figure 4(a). After partitioning each table into two blocks according to patient's gender, as shown in Figure 4(b), we can improve our estimation to 300. Figure 4(c) shows further partitions make a closer 250 selectivity estimation.*

From the above observation, we conclude the following property.

Property 1: *Given two patient records to link. More partitions on the record guarantees a monotonic approach to the exact linking result.*

Based on this property, we develop the naïve approximation method. Formally, to estimate the linking between two patient records R_α and R_β, we partition them using a hash function *H*, which guarantees that no records will be linked across different hash bucket. Let $B_H(R_\alpha)$ and $B_H(R_\beta)$ represent the partitioned buckets. Then for each corresponding bucket pair, $B_H(R_\alpha)$ and $B_H(R_\beta)$, we choose the one with the smaller size as the selectivity estimation. Details are presented in Algorithm 1. Suppose the bucket number of the partition is *N*. The naïve method's time complexity is *O(N).*

Algorithm 1 Naïve Estimation
Input:
Records R_α, R_β and hash function H
Output:
Selectivity estimation of linked records
Description:
1: $B_H(R_\alpha)$:= Partition R_α by H; $B_H(R_\beta)$:= Partition R_β by H;
2: **for** each bucket $b_\alpha \in B_H(R_\alpha)$ **do**
3: find the bucket $b_\beta \in B_H(R_\beta)$, which has same hash key as b_α;
4: estimation + = $\min(S(b_\alpha), S(b_\beta))$;
5: **end for**
6: Output estimation

Applying the naïve method, we can partition the patient records of the local databases beforehand and store those partitions as data synopses for future linking estimation. It is obvious from Property 1 that the accuracy of the naïve method largely depends on the number of buckets. However, more buckets require more storage space, which is strictly limited by the available space in the global multidatabase server. We normally can not afford enough space for the nave method. This motivates us to develop the following wavelet method. For simplicity reason, we will use the bucket number to represent the size of available storage space hereafter.

Constructing Wavelet Synopses

To construct the wavelet synopses with a given bucket number B, we first partition the patient records **T** with the hash function *H*, as in the naïve method. Counting the number of records falling in each bucket, we organize them into a one-dimensional array $A(T)$. Transferring this one-dimensional array using the Haar wavelet, we get the coefficient array. For each coefficient *i*, suppose its resolution is *j*, we normalize the coefficient by . Then we choose the largest number of B/2 coefficients, in absolute normalize value, as well as their positions to store as the data synopses. In fact this is provably optimal with respect to minimizing the overall root-mean-squared error (i.e., L^2-norm average error) in data compression (Stollnitz, DeRose et al., 1996).

The procedure of wavelet estimation is quite similar to that of the naïve method. Details are presented in Algorithm 2. Note that we omit the procedures of constructing the wavelet synopses and reconstructing the original data from the synopses as they are covered in the background section.

Algorithm 2 Wavelet Estimation
Input:
Wavelet synopses W_α of records R_α and W_β of records R_β
Output:
Selectivity estimation of linked records
Description:
1: $B_H(R_\alpha)$:= Compute approximate original buckets of R_α from W_α;
2: $B_H(R_\beta)$:= Compute approximate original buckets of R_β from W_β;
3: **for** each bucket $b_\alpha \in B_H(R_\alpha)$ **do**
4: find the bucket $b_\beta \in B_H(R_\beta)$, which has same hash key as b_α;
5: estimation += min($S(b_\alpha)$, $S(b_\beta)$);
6: **end for**
7: Output estimation

Given a naïve hash partition with N buckets and a wavelet synopsis with B buckets. The time complexity on approximating the number of records of any hash bucket from the wavelet synopses is log *B*. Thus the time complexity of Algorithm 2 is $O(N \log B)$, where $N \gg B$.

The wavelet estimation can still be very time consuming while *N* is very large. This can be prohibitive in some online query processing situation. Thus in the next section, we propose our histogram estimation which always guarantees a fixed estimation time.

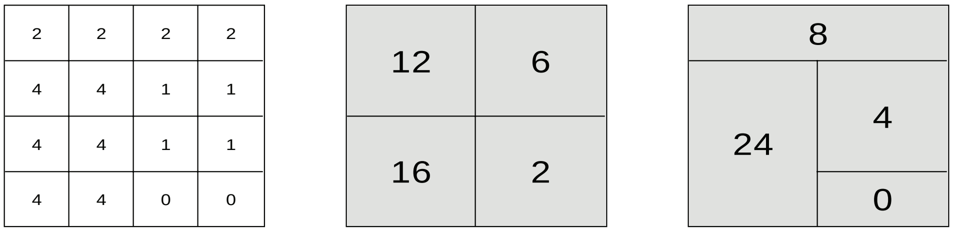
LINKING ESTIMATION THROUGH HISTOGRAM

In this section, we propose our linking estimation method based on the multidimensional histogram techniques. We first introduce constructing the histogram from the original patient records. Then we present how to estimate the selectivity of the linking records from the histogram.

A Multidimensional Histogram

Similar to the partition-and-linking idea, we construct the histogram through partitioning the original patient records first. However, instead of using only one hash function to partition the records into many buckets, we use several hash functions to partition the records into a multidimensional grids. That is, we partition the records such that no linking happens across grids. Examples of these hash functions can be the date of birth, the gender, and so forth. Counting the number of records falling in each grid, we get a multidimensional array. Due to the multidatabase server's space limitation, we can not store the whole array as our data synopses.

Figure 5. The 4 buckets histograms



(a) Original grid *(b) One 4 bucket histogram* *(c) Another 4 bucket histogram*

Instead we approximate the array through a B buckets histogram. In each histogram bucket, we adopt the uniform distribution assumption. That is, the number of records of each grid that belongs to the bucket will be represented by the average number of records in the bucket. Figure 5(a) is an example of patients records partitioned into 16 grids. The numeric number represents the number of records in that grid. Suppose we want to construct a four buckets histogram. Figure 5(b) is one possible histogram. Figure 5(c) is another possible histogram. Note that the number in each bucket represents the total number of records in that bucket.

Since we use the uniform distribution assumption, the more uniform intra-bucket distribution, the better estimation from the histogram. We formalize the problem as follows. Given a B buckets histogram, considering a bucket b_i, $1 \leq i \leq B$, suppose b_i includes n grids and the numbers in those grids are defined as $g_1,..., g_n$. The skew of bucket b_i is defined as: , here is the average of all g_j, $(1 \leq j \leq n)$. The skew of the histogram is the summation of each bucket's skew: . To acquire an accurate estimation, the goal is to find a histogram which has minimal skew, under a given number of buckets. For example, the histogram in Figure 5(c) is the best four buckets histogram since its skew is 0.

Unfortunately, constructing such a minimal skew histogram is a difficult problem that is provably NP-hard for even simple instances (Muthukrishnan, Poosala et al., 1999). Many approximate approaches have been proposed. In this article, we adopt a binary space partition techniques, the *min-skew* partition (Acharya et al., 1999). It is a heuristic partition method. At each step, it partitions one of the existing buckets into two sub-buckets. This partition is guided by minimizing the current total histogram skew. We demonstrate the min-skew partition through constructing a four bucket histogram on former example. Initially, consider the histogram has only one big bucket that holds all those grids. Its skew is $sk_1 = 35$ as shown in Figure 6(a). To divide it into two buckets, we have all together six choices: three different horizontal partition and three different vertical partitions, as pointed by the arrows in Figure 6(a). After calculating, we choose the one that can reach maximal skew decrease as shown in Figure 6(b). Continuing with similar steps, we reach the final four buckets histogram. The histogram partitioned by min-skew has a total skew 2, which is greater than the optimal partition in Figure 5(c).

After partition, we store the bucket information to form the histogram synopses. For each bucket, we only store its range, that is, the two coordinate values on each dimension, and the number of records in that bucket.

Estimation Through Histogram

The selectivity estimation through histogram synopses is much quicker compared with wavelet synopses. As mentioned before, we assume the average distribution in each histogram bucket. To estimate the number of possibly linked records of two buckets, we only need to multiply the space of the overlapping area with the smaller density of the two buckets. That is, given two buckets, b_α whose range is v_α with n_α number of records, and b_β whose range is v_β with n_β number of records. The number of linked records of these two buckets is estimated as . The algorithm of linking selectivity estimation through histogram synopses is as follows.

Algorithm 3 Histogram Estimation
Input:
Histogram H_α of records R_α and H_β of records R_β
Output:
Selectivity estimation of linked records
Description:
1: **for** each bucket $b_\alpha \in H_\alpha$ **do**
2: **for** each bucket $b_\beta \in H_\beta$ **do**
3: **if** b_α overlaps with b_β **then**
4: estimation +=
5: **end if**
6: **end for**
7: Output estimation

It is easy to see that, given B buckets histogram, the estimation's time complexity is $O(B^2)$. This means that the estimation through histogram synopses can always guarantee a quick response no matter how large the original record size is.

EXPERIMENTS

In this section, we study the performance of our methods on linking selectivity estimation of generic and health data. We implement our two types of synopses, wavelet and histogram, respectively. The wavelet synopsis is a one-dimension synopsis. The histogram synopsis is a multidimension synopsis. We first evaluate these two synopses against the generic data. Then we compare them against the health data. All algorithms are implemented through GCC 4.0.2. The experiments are performed on a Pentium IV 3.2 Ghz CPU with 1 GB memory computer.

The data used in our experiment is synthetic data. Specifically, we generate two sets of data. One includes generic person record tables with the person's name, date of birth (DOB), and gender. The other is the lung cancer patient records which includes patients' details as well as the treatments received.

Experiment Results on Generic Data

In this experiment, we generate two classes of tables to link, A and B. Each class includes three tables with different distribution on a person's

Figure 6. The MinSkew partition

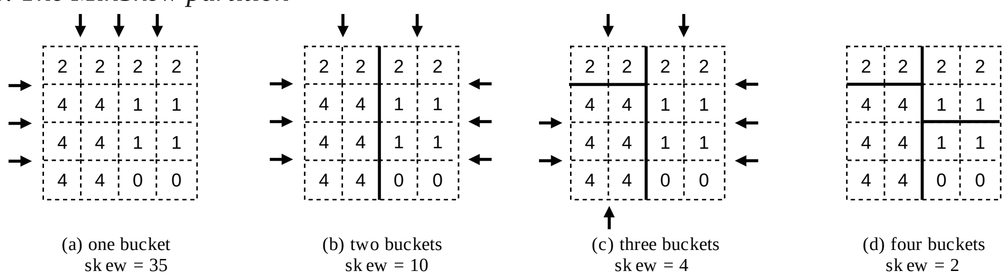


Figure 7. Linking estimation on generic data

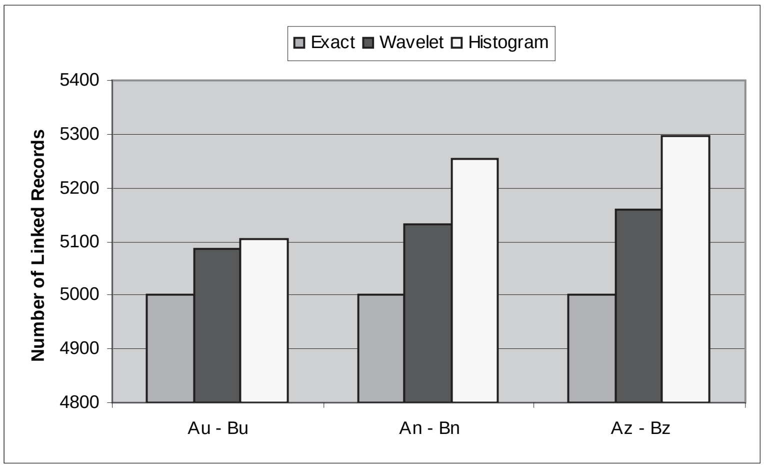

Figure 8. Linking estimation time used by various synopses

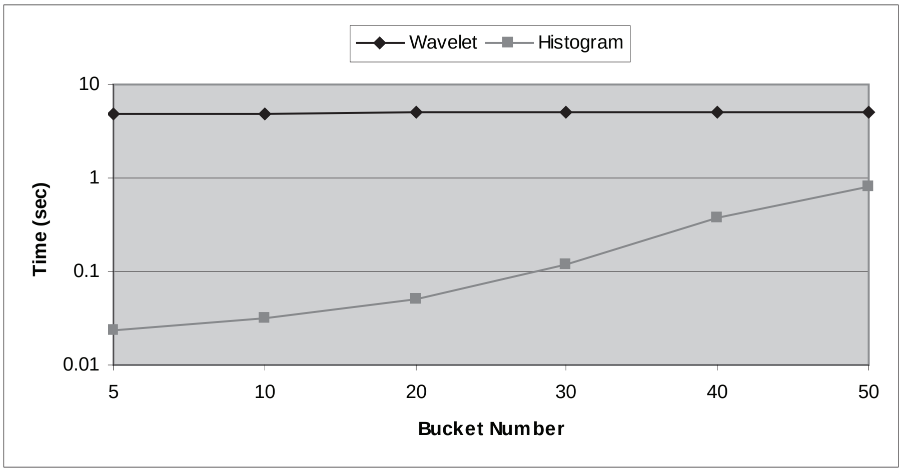

Figure 9. Linking estimation for various bucket numbers

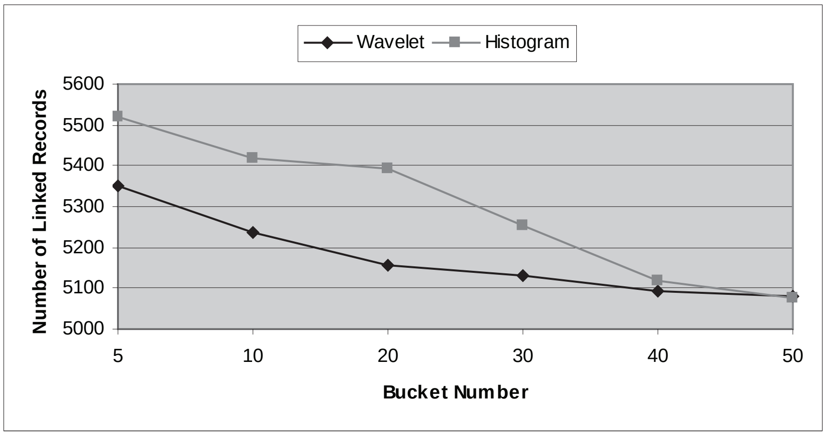

DOB ranging from 1900-1-1 to 1999-12-31. We use A_u to represent the table in class A with uniform DOB distribution. A_n represents the table with standard normal DOB distribution. A_z represents the table with zipf DOB distribution. Here we set the zipf parameter $z = 1$, which means a medium skew distribution. For tables in class B, we also generate three similar tables and adopt the same naming convention as in class A. Each table has 10,000 tuples, which represents 10,000 different people recorded in that table. To compare our methods, we assign a uniform storage space to both the wavelet and histogram synopses. We use the bucket number B of the histogram synopses to measure the assigned space. Since we construct a four-dimensional histogram, we need to store nine numbers in each bucket of our histogram synopses which includes every two extents on each dimension and the number of records in that bucket. Note that in the wavelet synopses, we keep both the value and the position if storing a coefficient. Thus when we mention the synopses size B in our experiment, we mean constructing a B buckets four-dimensional histogram synopses or a wavelet synopses with coefficients.

Linking the six tables from two classes, we get nine linking results under each linking method accordingly. Figure 7 shows selected results of linking three pairs of tables that have same DOB distribution. The synopses size is $B = 30$. Note that we omit the linking results between other tables as those do not indicate significant difference. From the experiment results, the wavelet and histogram synopses both demonstrate good approximate results with reasonably small errors. Of all the three linking between different distribution types depicted in Figure 7, the approximation for linking between uniform distributed data generates the smallest error. This is because that when data have skew distribution, such as normal or zipf distribution, a large estimation error will occur while approximating the selectivity of buckets that has many people's records. We also note that the wavelet synopses normally generate better estimation results compared to the histogram synopses. This is partly due to rough approximation techniques, the uniform assumption, used in estimating the values inside a histogram bucket.

However, as mentioned before, the estimation time based on histogram synopses is much shorter compared to that on wavelet synopses. Figure 8 shows the comparisons between the estimation time on linking tables A_n and B_n. It is obvious that estimation based on histogram synopses is remarkably quicker than that based on wavelet synopses.

Our last experiment on the generic data is to evaluate the influences of synopses size on the estimation accuracy. Again, we test the linking estimation between the tables, A_n and B_n, through various wavelet and histogram synopses whose sizes range from 5 to 50. Figure 9 shows the result. It is interesting to note that the storage space changing has more influences on the estimation accuracy of the histogram synopses.

Experiment Results on Synthetic Health Data

In this part, we generate health data to emulate the real clinic and hospital patients' records. To imitate real situations, we also generate some errors and typographical errors in the person's records of the health data. For example, a patient's DOB may be recorded as 6019-3-82, which should be 1960-3-28. A patient's gender information may be lost. We generate two pairs of such patient databases for linking. The first pair includes database HA and HB, which has 3000 and 667 records individually. This represents the situation when a large number of linked records exists in the databases. The second pair includes tables HC and HD, which has 32 and 24 records individually. This represents the situation when a small number of linked records exists in the databases. To acquire the exact linking results, we use our health data integrator as introduced by Hansen, Pang et al. (2005). We apply 40 buckets to construct our wavelet and histogram synopses. Figure 10 shows the results. It indicates that when the number of actually linked records is large, both wavelet and histogram synopses can provide good estimations. The approximation quality is however decreased when the number of linked records is small.

CASE STUDY

In this section, we demonstrate how the presented link selectivity estimation techniques can facilitate estimate more complex aggregate queries in a health multidatabase system. We start by assuming our two synthetic health databases, HA and HB, as two component databases of a health system. Database HA records the information of patients having cancer A at any of the three stages, from I to III. Database HB records similar information of patients having cancer B at any of the two stages, from I to II. In both databases, information such as patient name, date of birth, gender, diagnosed stage, treatment results, and so forth, is recorded.

An investigation about the potential relationships between cancer A and B naturally leads to queries involving both databases. A typical analysis is to find the number of patients having both cancers at various stage combinations. This incurs a group of link and aggregate queries. Namely we link databases HA and HB first to find patients who are recorded in both databases. Then we issue six aggregate queries to acquire detail numbers. Figure 11 shows the exact query results, that is, the detail distribution of the 647 (refer to Figure 10) linked patients.

There exist many approximate techniques processing complicate aggregate queries across several databases. The unique global ID for each record is a de facto assumption in those

Figure 10. Linking estimation on health data

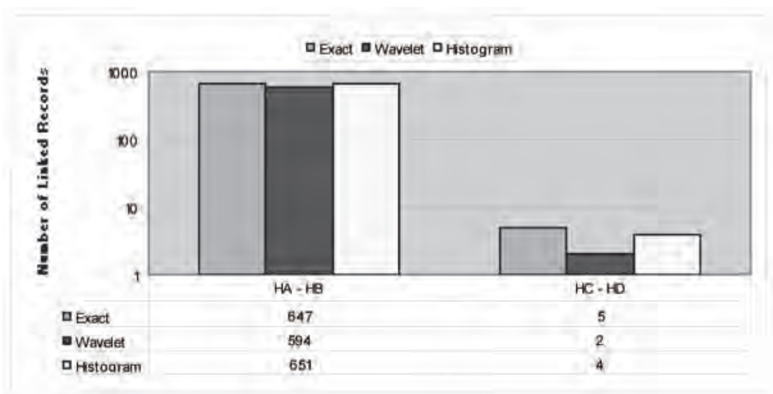

Figure 11. Exact answer for aggregate query

Cancer A / Cancer B	Stage I	Stage II	Stage III
Stage I	225	117	95
Stage II	111	50	49

techniques. However this assumption is usually not held in a multidatabase system, which makes those existing techniques no more applicable. Now combining our selectivity estimation techniques, we can process multidatabase aggregate queries as follows:

- Compute the approximate linking radio δ for each database, which is defined as the number of approximate linked results divided by the number of records, through our link estimation technique.
- Compute the initial approximate results of the aggregate query q_i by assuming unique patient record, through any existing approximate query processing technique.
- Compute the final approximation results q_f, $q_f = \delta_* q_i$.

Figure 12 shows the approximate results of the aggregate query involving database HA and HB.

RELATED WORKS

Medical record linking links patient records across organizations. Current techniques are those for data linkage problems, which are also defined as object identification, data matching, and so forth. Much research has been done for the data linkage problem (Fellegi & Sunter, 1969; Newcombe, 1967; Newcombe, Kennedy et al., 1959; Winkler, 1999). Existing techniques can be classified into two groups (Cochinwala, Dalal et al., 2001):

- *searching techniques* involve searching for potentially linkable pairs of records. Typical techniques include a nested-loop join, band join, blocking, and so forth (DeWitt, Naughton et al., 1991; Newcombe, 1988).
- *matching techniques* involve deciding whether or not a given record pair is correctly matched. Typical models are probabilistic and nonprobabilistic (Dey, Sarkar et al., 1998; Monge & Elkan, 1996; Newcombe, 1967).

CONCLUSION AND FUTURE WORK

In this article, we present two approximate techniques for the estimation in a multidatabase system. We first provide a naïve technique on the selectivity estimation. Based on this, we develop two techniques, namely wavelet and histogram. Given a limited storage space, our method can construct efficient wavelet or histogram data synopses. Experiment results show that our approximation method can quickly provide good estimations. We also conclude from our experiments that although wavelet synopses are generally more accurate than histogram ones, the approximation time used by wavelet synopses is much longer. Thus histogram techniques may be more promising when used in an online environment, where prompt answers are expected.

Currently we assume that original data is in a relatively static environment. Thus whenever change happens, we just reconstruct new data

Stage II	104	55	62

synopses and discard old ones. However, how to efficiently maintain an up-to-date synopsis in a dynamic environment will be one of our future works. Another possible future work is to investigate how to process nonaggregate approximate queries, such as join, in a multidatabase system.

ACKNOWLEDGMENT

We would like to thank Marilla O'Dwyer for providing the real health data and helpful discussions.

Data Mining Medical Information:
Should Artificial Neural Networks be Used to Analyse Trauma Audit Data?

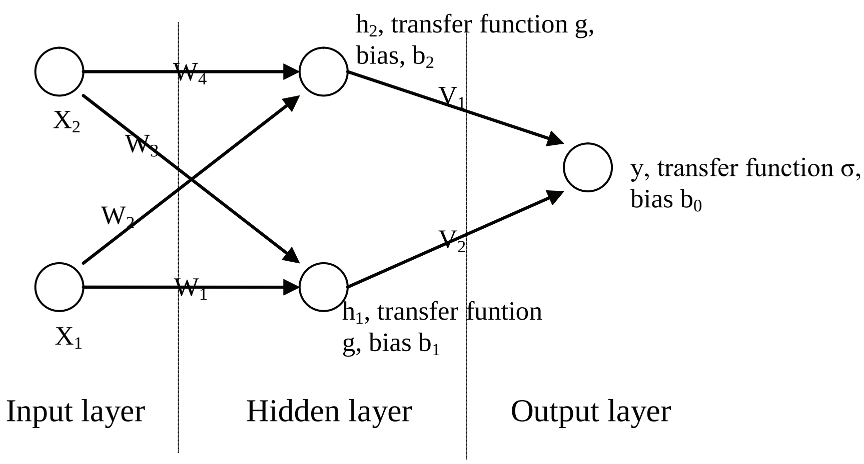
ABSTRACT

Trauma audit is intended to develop effective care for injured patients through process and outcome analysis, and dissemination of results. The system records injury details such as the patient's sex and age, the mechanism of the injury, various measures of the severity of the injury, initial management and subsequent management interventions, and the outcome of the treatment including whether the patient lived or died. Ten years' worth of trauma audit data from one hospital are modelled as an Artificial Neural Network (ANN) in order to compare the results with a more traditional logistic regression analysis. The output was set to be the probability that a patient will die. The ANN models and the logistic regression model achieve roughly the same predictive accuracy, although the ANNs are more difficult to interpret than the logistic regression model, and neither logistic regression nor the ANNs are particularly good at predicting death. For these reasons, ANNs are not seen as an appropriate tool to analyse trauma audit data. Results do suggest, however, the usefulness of using both traditional and non-traditional analysis techniques together and of including as many factors in the analysis as possible.

INTRODUCTION

An Artificial Neural Network (ANN) attempts to model human intelligence using the neurons in a human brain as an analogy. ANNs have been described numerous times (Lee & Park, 2001; Bose & Mahapatra, 2001; Setiono, Thong, & Yap, 1998; Lee, Hung Cheng, & Balakrishnan, 1998), but a brief description is that the network accepts a series of factors as input, which it processes to output a probability that the input belongs to a certain class. For example, in the case of the trauma data analysed in this study, the characteristics of the trauma are the input to the ANN, which then outputs the probability that the patient will die. The processing is done by layers of neurons (called hidden layers) which apply a weight to each input factor according to how important that factor is in calculating the classification probability. The weight is learned by the network during its training. In training, a series of input factors to which the correct classification is known is fed into the ANN. The ANN then adjusts its weights to minimise the error between its predicted classification and the known correct class. A pictorial representation of an ANN is shown in Figure 1.

An ANN has the potential to discriminate accurately between patients who will live and those who will die, and can capture complex relationships between factors that traditional analysis methods may miss. However, there are two potential problems with using ANNs to analyse trauma data. First, they are affected by imbalances in the data (Fu, Wang, Chua, & Chu, 2002). A common characteristic of medical data is its imbalance (Cios & Moore, 2002). What this means is that the attribute of interest to data miners is likely to be present only in a minority of records in the dataset. In the case of the trauma data discussed here, a much higher percentage of patients lived than died. The second disadvantage with neural networks is that it is very difficult to explain and to justify the model. In other words, after train-



Output of h_1, $h_{1out} = g(w_1x_1 + w_3x_2 + b_1)$
Output of h_2, $h_{2out} = g(w_2x_1 + w_4x_2 + b_2)$
Output of node y, the output layer which uses the sigmoid function and is the probability of a certain class, for instance DEATH = 1, given the input vector $\overline{x}$,
$p(DEATH = 1 \mid \overline{x}) = s(v_1(h_{1out}) + v_2(h_{2out}) + b_0)$

ing, it is difficult to explain why one neuron is weighted in a particular way. The ANN often does not have an underlying probabilistic model (Giudici, 2003), and evaluation of the model usually is done by examining its output — its predictive accuracy. In mining medical data, consideration is also usually given to the model's sensitivity and specificity and less frequently to the model's positive and negative predictive value.

Despite this, ANNs frequently have been used in healthcare. For example, Lee and Park (2001) applied neural networks in order to classify and predict the symptomatic status of HIV/AIDS patients; Baxt, Shofer, Sites, and Hollander (2002) used an ANN to aid in the diagnosis of acute myocardial infarction; Lapuerta, Azen, and LaBree (1995) used neural networks to predict the risk of coronary artery disease. DiRusso, Sullivan, Holly, Nealon Cuff, and Savino (2000) used ANNs to predict survival in trauma patients that was similar to the application in the current study. ANNs are just one of a number of techniques that are known collectively as machine learning. Others long have been used in medical applications to improve decision making (Konomenko & Kular, 1995). Lavrac (1999) lists some applications: diagnosis and prognosis in oncology (Bratko & Konomenko, 1987), liver pathology (Lesmo, Saitta, & Torasso, 1982), neuropsychology (Muggleton, 1990) and gynecology (Nunez, 1990). Breault, Goodall, & Foss (2002) used a decision tree to examine a diabetic data warehouse. Imberman, Damask, and Thompson (2002) identified association rules in a head trauma dataset. The aim of this article is to examine how analysing trauma data with an ANN compares with a more traditional logistic regression analysis.

Trauma Audit and Research Network

In 1991, in response to a report from the Royal College of Surgeons of England, the government supported a pilot system for treating trauma patients at the North Staffordshire Hospital (NSH) in Stoke-on-Trent in the UK (Oakley, MacKenzie, Temppleton, Cook, & Kirby, 2004). At the same time, a system for collecting trauma data from a set of core hospitals in England and Wales was established at the University of Manchester. This project, the Major Trauma Outcome Study (UK), grew in size with more hospitals becoming involved. By the late 1990s, one-half of all trauma-receiving hospitals in England and Wales returned data to the now renamed Trauma Audit & Research Network (TARN). NSH served as a core hospital and has contributed trauma audit data to TARN since that time.

Trauma is the most common cause of death in those under 40, and many of these are preventable (TARN, 2004). Trauma audit is intended to develop effective care for injured patients through process and outcome analysis and through dissemination of results. The system records injury details, such as the patient's sex and age, the mechanism of the injury, various measures of the severity of the injury, initial management and subsequent management interventions, and the outcome of the treatment, including whether the patient lived or died. Several analyses that used traditional statistical techniques have been performed on the data and published (Oakley et al., 2004; Templeton et al., 2000). Oakley et al. (2004) analysed six years of NSH trauma audit data from April 1992 through March 1998 in order to identify factors related to mortality and to examine whether there was a longitudinal trend in mortality. Multiple logistic regression analysis evidenced eight factors as determinants of mortality. In order of importance, these were age, head Abbreviated Injury Score (AIS), chest AIS, abdominal AIS, calendar year of admission, external injury AIS, mechanism of injury, and primary receiving hospital. However, the data from NSH never have been modelled as an ANN.

This article continues as follows. The next section describes the method of preparing and analysing the data by ANN and logistic regression. The results are then presented, compared, and discussed.

METHOD

The study concerned trauma audit data from patients treated at the North Staffordshire Hospital from 1993 to 1999 and from 2001 to 2004 (the gap was due to a lack of resources during this period, which affected data collection). The data were limited to those most severely injured patients, since there should be most to learn from such patients. Patients with an Injury Severity Score (ISS) greater than 15 were included. All the injury scores (Abbreviated Injury Scores, ISS, and Glasgow Coma Scores) were assigned, checked, and entered into the database by trauma audit staff under the guidance of three clinicians (three of the authors) as soon as possible after the injury. All were well-trained in the use of the scoring systems. (For an explanation of all of these scoring techniques, see Baker [1974] and Teasdale and Jennett [1974]) Very little data were missing, as the summary in Table 1 shows.

The criteria for inclusion just described left 1,658 records in the data set with which to train and test different ANN models. The factors shown in Table 1 were included as input, with the output being whether the patient lived or died. If the data are well-balanced with approximately equal numbers of patients who lived and died, learning algorithms will have a better chance of finding patterns that distinguish the two groups. As has been explained already, the trauma audit data are very imbalanced — 79% of patients lived, 21% died. Machine learning techniques usually are biased toward the majority class, as these dominate during training (Fu et al., 2002). For example, a classifier could achieve 79% accuracy with this data by always predicting "live." A number of techniques has been examined to deal with this (Guo & Viktor, 2004): undersampling the majority class (Kubat & Matwin, 1997), oversampling the minority class (Ling & Lee, 1998), doing both together (Chawla, Bowyer, Hall, & Kegelmeyer, 2002), and boosting the learning algorithm (Schapire, 2001). The data were balanced by adjusting the proportion of the patients who died by a factor of 3.685. However, it has been suggested that record balancing has no impact on neural network models (Fu et al., 2002).

The data mining package SPSS Clementine 7.0 was used to create the ANNs. This software allows the user to specify any ANN model (the model consists of the number of hidden layers of neurons and the number of neurons in each hidden layer), and the learning rates (alpha and eta, which specify how the weights change during training). All the neurons are fully connected and each is a feed-forward, multi-layer perceptron that uses the sigmoid transfer function (Watkins, 1997). The learning technique used is back propagation. This means that, starting with the given topology, the network is trained, then a sensitivity analysis is performed on the hidden units, and the weakest are removed (Watkins, 1997). This training/removing is repeated for a set length of time. A k-fold cross-validation technique was used to test the ANN models, with k set to five. This is good practice when building neural networks with medical data (Cunningham, Carney, & Jacob, 2000). Using this technique, the data were split into five groups. When splitting the dataset, those patients who lived were selected randomly and independently of those patients who died in order to keep the same proportion of live/die outcomes in each set. Four of the sets were used to train each ANN model; the fifth was used to test it. This then was repeated another four times so that each group was used to test the model once. The overall performance of the model was then the average performance of the five tests. Four different ANN models were tested in this way. To decide which ANN models to test, a range of models was trained with a random sample of two-thirds of the data and tested on the remaining one-third. Again, the split was made to keep the same proportion of live/die

Table 1. NSH trauma audit data (note that high AIS relates to an increase in severity, whereas high GCS relates to a decrease in severity)

Outcomes								
Alive or dead	98.97	344 (21) dead, 1296(79) alive						

outcomes in each set. These models differed on the number of hidden layers, neurons, and learning rates. The four best performing models were selected. Specific guidelines on how to choose these parameters were unavailable, as this was dependent upon the underlying data generating process (Berardi, Patuwo, & Hu, 2004), which is unknown, so experimentation like this is a reasonable approach.

The multiple logistic regression model was created using SPSS 11.0, and the factors shown in Table 1 were considered for inclusion. Such a model normally would not be tested using k-fold cross validation. In this case, the logistic regression model was created using the same random two-thirds of the data from before and tested on the remaining one-third.

In many data mining applications, the evaluation criterion is the percentage of correct classifications made by an algorithm. However, in medical data mining, consideration also must be given to the percentages of false positive and false negative classifications. The evaluation criteria for comparing the algorithms here are sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV). The sensitivity is the proportion of actual deaths that were correctly predicted to die, whereas the specificity is the proportion of actual survivors who were correctly predicted to survive. The positive predictive value (PPV) is the probability that a subject for whom the model predicts as dying actually will be a true death, and the negative predictive value (NPV) is the probability that a subject predicted as surviving actually will survive.

RESULTS

The number of hidden layers, the number of neurons in each layer, and the learning rates of the four ANN models are shown in Table 2. The results of the k-fold cross validations are shown in Table 3. Also shown in Table 3 are the results of the logistic regression analysis. The logistic regression model itself is shown in Table 4. This model shows that the mechanism group, age group, GCS-motor, Head AIS, Abdomen AIS, and External AIS all are associated independently with survival during a hospital stay. Those patients who have suffered a fall or assault have decreased odds of death compared to those involved in a motor vehicle crash. Those suffering a fall greater than two meters in height compared to those involved in a motor vehicle crash have much decreased odds of death (odds ratio = 0.27; 95% confidence interval is 0.13 to 0.53). A less severe GCS motor score is associated with decreased odds of death compared to a more severe injury. Those suffering abdominal or external injuries have increased

Table 2. Model characteristics

	ANN1	ANN2	ANN3	ANN4
Number of hidden layers	2	1	3	3
Number of neurons in layer 1	30	30	30	30
Number of neurons in layer 2	20	N/A	20	20
Number of neurons in layer 3	N/A	N/A	10	10
Alpha	0.5	0.5	0.3	0.4
Initial eta	0.5	0.5	0.5	0.5
High eta	0.9	0.9	0.8	0.8
Low eta	0.01	0.01	0.05	0.05
Eta decay	30	30	20	20

odds of death during a hospital stay. Correcting for the other factors included in the model, those with a head AIS of five or six have an odds ratio of 1.68 of death compared to those with a score of 0; however, those with head AIS scores of 1-4 appear to have decreased odds of death compared to those with a score of 0. Increasing age is associated with increased odds of death, especially for those over 70 years old. A cut-point of 0.2 was used in the logistic regression in order to increase the sensitivity (and thereby decrease the specificity).

All of the ANNs achieved roughly 80% overall predictive accuracy and slightly outperformed the logistic regression model in this respect, although this finding is examined more closely in the next section. There is no one agreed procedure for presenting ANN architectures with their weights, and in this case, it is not possible to show the four neural networks, since each was trained five times, and for each training session, the final weights were different. However, in an attempt to illustrate the ANNs, Table 5 shows the 10 most important factors in each when trained with two-thirds of the data used to create the logistic regression model. Apart from ANN2, these appear very similar.

DISCUSSION AND CONCLUSION

Implications for Practice

Interpreting Table 5 is difficult. While three of the four ANN models show Abdomen AIS to be the most important factor in determining whether a patient lives or dies, it should be remembered that it is a network of factors that calculates the output, and Abdomen AIS can be used only to make a prediction in conjunction with all the other factors. As the following demonstrates, the ANN is not designed to analyse individual factors in the way that logistic regression can. Apart from ANN2, the models show reasonable agreement in the most important factors. ANN2, however, suggests that time, day, and month of admission are important determinants of death. This appears counter-intuitive, although when these factors are removed as inputs and then the ANNs are retrained, the predictive accuracy of each drops to around 73%. Clearly, therefore, these factors do have an impact on building the classifier. It is possible to suggest ideas about why this might be (staff will be affected by tiredness at difference times of the day, staff and patients may be affected by the seasons, and staff turnover may have an impact

Table 3. K-fold cross validation results (note that for the analysis, death was considered the positive outcome)

	ANN1	ANN2	ANN3	ANN4	LR
True positives	44	41	41	44	84
True negatives	219	219	221	219	286
False positives	38	38	37	39	86
False negatives	26	30	29	26	23
Sensitivity	63	57	58	62	79
Specificity	87	85	86	85	77
Predictive accuracy	80	79	80	80	77
Positive predictive value	54	53	53	55	49
Negative predictive value	89	88	88	89	92

Table 4. Logistic regression model (note that high AIS relates to a increase in severity, whereas high GCS relates to a decrease in severity, and odd ratios refer to odds of death as opposed to survival)

Factor	No. of Patients	Odds Ratio (95% CI)	p-value
Mechanism

10	Referred from another hospital	Day of admission	Penetrating injury	Face AIS

from year to year). It seems far-fetched to suggest that these have a real impact on mortality, and in fact, when chi-squared tests were performed to examine the relationship between these factors and death, no significant association was found. So, it is known that these factors have some influence, but it is not clear what that influence is. Perhaps there are complex cross-correlations between these factors and others that can be modelled by the ANN but not explained. Discussions on how to deal with peculiarities like this are scarce in the ANN literature. One way of trying to examine these cross-correlations is to list the meaningful factors with which day, month, and year could be correlated. In this instance, there do not appear to be any. This goes back to one of the two big disadvantages of using ANNs: it is not possible to show why a neuron is weighted in a certain way after training. Without this, the usefulness of ANNs is severely impaired, and, in the case of trauma audit data, illustrates the limitations of an ANN as an analysis tool.

While ANNs may not be suitable alone for analysing trauma audit data, they may have a place alongside more traditional techniques. The results demonstrate the value of recording as much data about the trauma as possible and including it in an exploratory analysis. An analysis by ANN may be valuable for identifying factors that previously have not or normally would not be identified as having an impact on outcomes, such as time of day, which was identified in this study by an ANN but not by logistic regression. These factors then can be investigated by traditional techniques in order to examine their impact.

The implication of this is that the goal of using ANNs in analysing trauma data can only ever be one of prediction. The ANN cannot be used to analyse the individual factors that are important in making this prediction. If the goal is to analyse these factors, then logistic regression is more suitable. If an ANN is used for survival prediction, this will have implications for treatment (e.g., if carers believe a patient will die, their care changes from one of treatment to one of making the patient's last moments as comfortable as possible). Such systems already exist and are currently in use. For instance APACHE is used to predict an intensive care patient's risk of dying, although its advocates claim that it is used only to help carers consider the issue of whether their treatment is making a difference (http://www.

openclinical.org/aisp_apache.html, retrieved October 17, 2005) rather than deciding on what treatment to give.

Comparison with Logistic Regression

The ANN models appear to support the findings of Oakley et al. (2004) and the current logistic regression model about which factors have an impact on mortality, but they also demonstrate that outcomes are dependent on a complex interplay among a large number of factors and cannot be predicted easily or very accurately. While the ANN overall predictive accuracy is better than that of the logistic regression model, the logistic regression model is better at predicting death than all four ANN models; the sensitivity is 79% for the logistic model and ranges between 57% and 63% for the ANN models. Although the logistic regression model outperforms all the ANNs in sensitivity, it has a lower specificity (this is probably due to the cut-point being moved from the default of 0.5 to 0.2). The positive predictive value of the logistic regression model is slightly lower than the ANNs, showing that fewer than half of those predicted to die actually did die during their hospital stay. The results of analysing the trauma audit data show that the ANN is a relatively poor predictor of death and is of limited use in examining the determinants of death.

Concluding Remarks

The management of multiple-injured patients remains difficult with input from a number of surgical and medical specialities. Trauma scoring systems are a useful research tool, permitting comparison of multiple-injured patients in different centres around the world. Mortality remains a favoured outcome to study in trauma data mining, but others may be considered. Length of stay in hospital is one, although this really measures the process of care rather than anything specific about the injury. Disability as a result of the injury is another worthwhile outcome to study, but it is difficult to measure, especially when comparing different injury patterns. Future research should be directed at producing a scoring method to measure disability, similar to the AIS. Research to follow up patients after discharge from a hospital also would be useful in order to measure their outcome in terms of both continuing morbidity and quality of life. Trauma audit systems such as TARN take time to evolve; the data grow at a slower rate than some other medical databases, which means that improvements in patient care cannot be expected immediately. The University Hospital of North Staffordshire is starting to see a reduction in deaths; hopefully, studies such as the present one will help to continue this trend.

ABSTRACT

Recent research shows that ontology as background knowledge can improve document clustering quality with its concept hierarchy knowledge. Previous studies take term semantic similarity as an important measure to incorporate domain knowledge into clustering process such as clustering initialization and term re-weighting. However, not many studies have been focused on how different types of term similarity measures affect the clustering performance for a certain domain. In this article, we conduct a comparative study on how different term semantic similarity measures including path-based, information-content-based and feature-based similarity measure affect document clustering. Term re-weighting of document vector is an important method to integrate domain ontology to clustering process. In detail, the weight of a term is augmented by the weights of its co-occurred concepts. Spherical k-means are used for evaluate document vector re-weighting on two real-world datasets: Disease10 and OHSUMED23. Experimental results on nine different semantic measures have shown that: (1) there is no certain type of similarity measures that significantly outperforms the others; (2) Several similarity measures have rather more stable performance than the others; (3) term re-weighting has positive effects on medical document clustering, but might not be significant when documents are short of terms.

INTRODUCTION

Recent research has been focused on how to integrate domain ontology as background knowledge to document clustering process and shows that ontology can improve document clustering performance with its concept hierarchy knowledge (Hotho et. al., 2003; Jing et. al., 2006; Yoo et. al., 2006). Hotho, Staab and Stumme (2003) employed WordNet synsets to augment document vector and achieves better results than that of "bag of words" model on public domain. Yoo, Hu, and Song (2006) applied MeSH domain ontology to clustering initialization and achieved promising cluttering results. Terms are first clustered by calculating semantic similarity using MeSH ontology (http://www.nlm.nih.gov/mesh/) on PubMed document sets. Then the documents are mapped to the corresponding term cluster. Last, mutual reinforcement strategy is applied. Varelas et al. (2005) integrated domain ontology using term re-weighting for information retrieval application. Terms are assigned more weight if they are semantically similar with each other. Jing et al. (2006) adopted similar technique on document clustering.

Although existing approaches rely on term semantic similarity, not many studies have been done on evaluating the effects of different similarity measures on document clustering for a specific domain. Yoo, Hu, and Song (2006) employed one similarity measure that calculates the number of shared ancestor concepts and the number of co-occurred documents. Jing et al. (2006) compared two ontology-based term similarity measure. Even though these approaches heavily relied on term similarity information and all these similarity measures are domain independent, however, to date, relatively little work has been done on evaluating measures of term similarity for biomedical domain (where there are a growing number of ontologies that organize medical concepts into hierarchies such as MeSH ontology) on document clustering. In our pervious study (Zhang et al., 2007), a comparative study is conducted on a selected PubMed document set. However, the conclusion on one dataset may not be very general. Moreover, the similarity score threshold applied in previous study brings unfairness to term re-weighting since the distribution of similarity scores are different in terms of different similarity measure. Therefore, for a fair comparison, we use the minimum path length between two documents as the threshold.

Clustering initialization and term re-weighting are two techniques adopted for integrating domain knowledge. In this article, term re-weighting is chosen because: (1) a document is often full of class-independent "general" terms, how to discount the effect of general terms is a central task. Term re-weighting is more possible to help discount the effects of class-independent general terms and thus aggravates the effects of class-specific "core" terms; (2) hierarchically clustering terms (Yoo, Hu, & Song, 2006) for clustering initialization is more computational, expensive and more lack of scalability than that of term re-weighting approach.

As a result, we evaluate the effects of different term semantic similarity measures on document clustering using term re-weighting, an important measure for integration domain knowledge. We examine four path-based similarity measures, three information content- based similarity measures, and two feature-based similarity measures for document clustering on two biomedical literature sets: Disease10 and OHSUMED23. The rest of the article is organized as follows: the "Term Semantic Similarity Measures" section describes term semantic similarity measures; the "Methodology" section shows document representation and defines the term re-weighting scheme. The "Datasets" section lists two biomedical data sets. In the "Experimental Results And Analysis" section, we present and discuss experiment results. The last section briefly concludes the article.

TERM SEMANTIC SIMILARITY MEASURES

Ontology-based similarity measure has some advantages over other measures. First, ontology is manually created by human beings for a domain and thus more precise; second, compared to other methods such as latent semantic indexing, it is much more computational efficient; Third, it helps integrate domain knowledge into the data mining process. Comparing two terms in a document using ontology information usually exploits the fact that their corresponding concepts within ontology usually have properties in the form of attributes, level of generality or specificity, and their relationships with other concepts (Pedersen et al., 2007). It is worth noting that there are many other term semantic similarity measures such as latent semantic indexing, but this is out of scope of this study and our focus is on term semantic similarity measure using ontology information. In the subsequent subsections, we classify the ontology-based semantic measures into the following three categories.

Path-Based Similarity Measure

Path-based similarity measure usually utilizes the information of the shortest path between two concepts, of the generality or specificity of both concepts in ontology hierarchy, and of their relationships with other concepts.

Wu and Palmer (1994) developed a similarity measure finding the most specific common concept that subsumes both of the concepts being measured. The path length from most specific shared concept is scaled by the sum of IS-A links from it to the compared two concepts.

$$S_{W\&P}(C_1,C_2)=\frac{2H}{N_1+N_2+2H} \qquad (1)$$

In the Equation 1, N_1 and N_2 is the number of IS-A links from C_1, C_2 respectively to the most specific common concept C, and H is the number of IS-A links from C to the root of ontology. The similarity score is between 1(for similar concepts) and 0. In practice, we set H to 1 when the parent of the most specific common concept C is the root node.

Li et al. (2003) combines the shortest path and the depth of ontology information in a non-linear function:

$$S_{Li}(C_1,C_2)=e^{-\alpha L}\frac{e^{\beta H}-e^{-\beta H}}{e^{\beta H}+e^{-\beta H}} \qquad (2)$$

where L stands for the shortest path between two concepts, α and β are parameters scaling the contribution of shortest path length and depth, respectively. The value is between 1(for similar concepts) and 0. In our experiment, we set α and β to 0.2 and 0.6, respectively for the best performance.

Leacock and Chodorow (1994) defined a similarity measure based on the shortest path $d(C_1, C_2)$ between two concepts and scaling that value by twice the maximum depth of the hierarchy, and then taking the logarithm to smooth the resulting score:

$$S_{L\&C}(C_1,C_2)=-\log\left(d(C_1,C_2)/2D\right) \qquad (3)$$

where D is the maximum depth of the ontology and similarity value. In practice, we add 1 to both $d(C_1, C_2)$ and $2D$ to avoid log (0) when the shortest path length is 0.

Mao and Chu (2002) presented a similarity measure using both shortest path information and number of descendents of compared concepts.

$$S_{Mao}(C_1,C_2)=\frac{\delta}{d(C_1,C_2)\log_2(1+d(C_1)+d(C_2))} \qquad (4)$$

where $d(C_1, C_2)$ is the number of edges between C_1 and C_2, $d(C_1)$ is the number of C_1's descendants, which represents the generality of the concept. Here, the constant δ refers to a boundary case where C_1 is the only direct hypernym of C_2, C_2 is the only direct hyponym of C_1 and C_2 has no hyponym. In this case, because the concepts C_1 and C_2 are very close, δ should be chosen close to 1. In practice, we set it to 0.9.

Information Content-Based Measure

Information content-based measure associates probabilities with concepts in the ontology. The probability is defined in Equation 5, where *freq(C)* is the frequency of concept C, and *freq(Root)* is the frequency of root concept of the ontology (Pedersen et al., 2007). In this study, the frequency count assigned to a concept is the sum of the frequency counts of all the terms that map to the concept. Additionally, the frequency counts of every concept includes the frequency counts of subsumed concepts in an IS-A hierarchy.

$$IC(C) = -\log\left(\frac{freq(C)}{freq(Root)}\right) \quad (5)$$

As there may be multiple parents for each concept, two concepts can share parents by multiple paths. We may take the minimum $IC(C)$ when there is more than one shared parents, and then we call concept C the most informative subsumer— $IC_{mis}(C_1, C_2)$. In another word, $IC_{mis}(C_1, C_2)$ has the least probability among all shared subsumer between two concepts.

$$S_{Resnik}(C_1, C_2) = -\log IC_{mis}(C_1, C_2) \quad (6)$$

$$S_{Jiang}(C_1, C_2) = -\log IC(C_1) - \log IC(C_2) + 2\log IC_{mis}(C_1, C_2) \quad (7)$$

Resnik (1999) defined a similarity measure that signifies that the more information two terms share in common, the more similar they are, and the information shared by two terms is indicated by the information content of the term that subsume them in the ontology. The measure reveals information about the usage within corpus of the part of the ontology queried. Jiang and Conrath (1998) included not only the shared information content between two terms, but also the information content each term contains.

Lin utilized both the information needed to state the commonality of two terms and the information needed to fully describe these two terms. Since $IC_{mis}(C_1, C_2) >= \log IC(C_1), \log IC(C_2)$ the similarity value varies between 1 (for similar concepts) and 0.

$$S_{Lin}(C_1, C_2) = \frac{2\log IC_{mis}(C_1, C_2)}{\log IC(C_1) + \log IC(C_2)} \quad (8)$$

Feature-Based Measure

Feature-based measure assumes that each term is described by a set of terms indicating its properties or features. Then, the more common characteristics two terms have and the less non-common characteristics they have, the more similar the terms are (Varelas et al., 2005). As there is no describing feature set for MeSH descriptor concepts, in our experimental study, we take all the ancestor nodes of each compared concept as their feature sets. The following measure is defined based on the discussion in Knappe et al. (2006) and Lin (1003):

$$S_{BasicFeature}(C_1, C_2) = \frac{|Ans(C_1) \cap Ans(C_2)|}{|Ans(C_1) \cup Ans(C_2)|} \quad (9)$$

where $Ans(C_1)$ and $Ans(C_2)$ correspond to description sets (the ancestor nodes) of terms C_1 and C_2 respectively, $C_1 \cap C_2$ is the join of two parent node sets and $C_1 \cup C_2$ is the union of two parent node sets.

Knappe et al. (2006) developed a similarity measure, as seen below, using the information of generalization and specification of two compared concepts:

$$S_{Knappe}(C_1,C_2) = p \times \frac{|Ans(C_1) \cap Ans(C_2)|}{|Ans(C_1)|} + (1-p) \times \frac{|Ans(C_1) \cap Ans(C_2)|}{|Ans(C_2)|} \quad (10)$$

where p's range is [0, 1] that defines the relative importance of generalization versus specialization. This measure falls between 1 (for similar concepts) and 0. In our experiment, p is set to 0.5.

METHODOLOGY

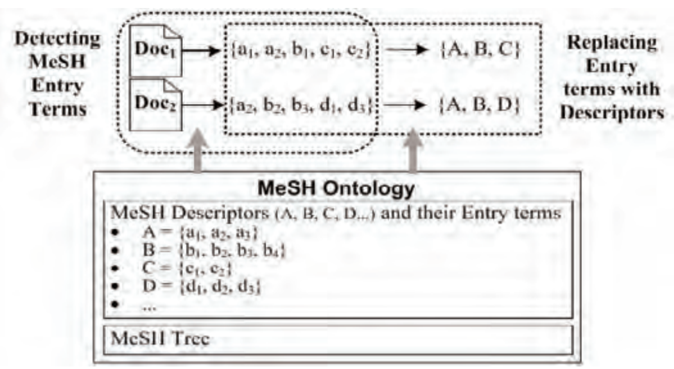
Given a document set, our clustering method is composed of the following steps: (1) apply ontology to index whole document set; each document is thus represented as a vector of terms; (2) each term's weight is re-calculated by the proposed term re-weighting method; (3) Spherical K-means is run the on the dataset.

MeSH Ontology

Ontology is very important to biomedical documents clustering. First, biomedical literature is usually composed of many complicated biomedical concepts with name variations containing usually more than one word. Second, bag-of-words model suffers from "the curse of dimension" and lacks interpretation power to clustering results. Therefore, MeSH ontology is applied to index biomedical literature in this article.

Medical Subject Headings (MeSH) [www.nlm.nih.gov./mesh] mainly consists of the controlled vocabulary and a MeSH Tree. The controlled vocabulary contains several different types of terms, such as Descriptor, Qualifiers, Publication Types, Geographics, and Entry terms. Descriptor terms are main concepts or main headings. Entry terms are the synonyms or the related terms to descriptors. For example, "Neoplasms" as a descriptor has the following entry terms {"Cancer," "Cancers," "Neoplasm," "Tumors", "Tumor", "Benign Neoplasm," "Neoplasm, Benign"}. As a result, descriptors terms are used in this research. MeSH descriptors are organized in a MeSH Tree, which can be seen as the *MeSH Concept Hierarchy*. In the MeSH Tree, there are 15 categories (e.g., category A for anatomic terms), and each category is further divided into subcategories. For each subcategory, corresponding descriptors are hierarchically arranged from most general to most specific. In addition to its ontology role, MeSH descriptors have been used to index PubMed articles. For this purpose, about 10 to 20 MeSH terms are manually assigned to each article (after reading full papers). On the assignment of MeSH terms to articles, about three to five MeSH terms are set as "MajorTopic" that primarily represent the article. This indicates that submitting Major

Figure 1. PubMed document indexing



Topic MeSH term query to PubMeD usually retrieves dataset with ground truth.

MeSH Concept Indexing

Terms in each document are mapped to the entry terms in MeSH and then maps the selected Entry terms into MeSH Descriptors to remove synonyms.

In detail, our indexing system matches the terms in each document to the entry terms in MeSH and then maps the selected entry terms into MeSH Descriptors. Instead of searching all entry terms in the MeSH against each document, we select 1- to 5-gram words as the candidates of MeSH Entry terms. Then, only those candidate terms are chosen that match with MeSH entry terms. We then replace those semantically similar entry terms with the Descriptor term to remove synonyms. Next, some MeSH Descriptors are filtered out that are too common or have nothing do with the contents of PubMed articles (e.g., ENGLISH ABSTRACT or Government supported); A stop term list is generated for this purpose by analyzing 10 years of PubMed documents (1995-2004). At the time of this writing, there are about 23,833 unique MeSH descriptor terms, 44,978 MeSH ontology nodes (one descriptor term might belong to more than one ontology nodes) and 593,626 MeSH entry terms.

MeSH entry term sets are detected from documents "Doc_1" and "Doc_2" using the MeSH ontology, and then the Entry terms are replaced with Descriptors based on the MeSH ontology. Both MeSH descriptors and entry terms are multi-grams.

Term Re-Weighting

A document is often full of class-independent "general" words and short of class-specific "core" words, which leads to the difficulty of document clustering. Steinbach et al. (2000) examined on the data that each class has a "core" vocabulary of words and remaining "general" words may have similar distributions on different classes. To solve this problem, we should "discount" general words and "emphasize" more importance on core words in a vector. Jiang and Conrath (1998) and Varelas et al. (2005) define the term re-weighting scheme as below:

$$\tilde{x}_{ji1} = x_{ji1} + \sum_{\substack{i_2=1 \\ i_2 \neq i_1}}^{m} S\left(x_{ji1}, x_{ji2}\right) \cdot x_{ji2} \qquad (11)$$

where x stands for term weight, m stands for the number of co-occurred terms, and $S(x_{ji1}, x_{ji2})$ stands for the similarity score between two concepts. Through this re-weighting scheme, the weights of semantically similar terms will be co-augmented. Since we are only interested in re-weighting those terms that are more semantically similar with each other, it is necessary to set up a threshold value—the minimum similarity score or the minimum path length between compared concepts. In practice, document is first represented according to certain scheme such as TF-IDF. Then, each term's weight is augmented by Equation 11.

Table 1. The document sets and their sizes

	Document Sets	No. of Docs
1	Gout	642
2	Chickenpox	1,083
3	Raynaud Disease	1,153
4	Jaundice	1,486
5	Hepatitis B	1,815
6	Hay Fever	2,632
7	Kidney Calculi	3,071
8	Age-related Macular Degeneration	3,277
9	Migraine	4,174
10	Otitis	5,233

DATASETS

Disease10

Disease10 dataset is collected from PubMed (a Web interface of Medline documents) by submitting queries using "MajorTopic" tag along with the corresponding MeSH term of the disease name. For example, if the disease name's corresponding MeSH term is "Gout," then the query will become "Gout [Major Topic]." Table 1 shows the ten classes of document sets and their document numbers (24,566 documents). The document class name is the query name. The average document length for MeSH descriptor is 13 (as shown in Table 2). Compared to the average document length—81—when using bag of words representation, the dimension of clustering space is dramatically reduced. A general stop term list is applied to bag of words scheme.

OHSUMED23

OHSUMED consists of scientific abstracts collected from Medline, an online medical information database. The selected OHSUMED corpus contains 13,929 Medline abstract of the year 1991, each of which was assigned with one or multiple labels out of 23 cardiovascular diseases categories. Excluding abstracts with multiple labels, we indexed the rest 7,400 abstracts belonging to 23 classes.

EXPERIMENTAL RESULTS AND ANALYSIS

Evaluation Methodology

Cluster quality is evaluated by four extrinsic measures, *entropy* (Steinbach, Karypis & Kumar, 2000), *F-measure* (Larsen & Aone, 1999), *purity* (Zhao & Karypis, 2001), and *normalized mutual information (NMI)* (Banerjee & Ghosh, 2002). NMI is defined as the mutual information between the cluster assignments and a pre-existing labeling of the dataset normalized by the arithmetic mean of the maximum possible entropies of the empirical marginal, that is:

$$NMI(X,Y) = \frac{I(X;Y)}{(\log k + \log c)/2} \quad (12)$$

where X is a random variable for cluster assignments, Y is a random variable for the pre-existing labels on the same data, k is the number of clusters, and c is the number of pre-existing classes. NMI ranges from 0 to 1. The bigger the NMI is the higher quality the clustering is. NMI is better than other common extrinsic measures such as purity and entropy in the sense that it does not necessarily increase when the number of clusters increases. Purity can be interpreted as the classification rate under the assumption that all samples of a cluster are predicted to be members of the actual dominant class for that cluster. Entropy is a more comprehensive measure than purity since rather than just considering the number of objects "in" and "not in" the most frequent class, it considers the entire distribution. F-score combines the

Table 2. Document indexing schemes

Indexing Scheme	No. of term indexed	Avg. doc length
MeSH descriptor term	8829	13
Word	41,208	81

information of precision and recall which is the extensively applied in information retrieval, with values falling in [0, 1] and the larger is the value, the better is the cluster quality.

Experiment Settings

To improve the efficiency of the calculation of term-term similarity, a 44,978 term-term similarity matrix (including all MeSH descriptors) is constructed for each similarity measure before the document vector re-weighting.

The similarity score is disregarded between two terms of which minimal path length is larger than 3, since we are only interested in augmenting the weights of terms that are similar enough. This is better than setting a similarity score threshold and very important to evaluate different semantic similarity measures in a fair manner. The distributions of the similarity scores between documents are usually various in terms of different similarity measures. Setting one threshold to all similarity measures can make the results easily biased toward several measures and need time consuming tuning (Zhang et al., 2007). Therefore, we apply minimum length threshold instead of similarity score threshold. The minimum path length is defined as:

$$MinLen(C_1, C_2) = Dep(C_1) + Dep(C_2) - 2 \cdot Dep(C_1, C_2) \qquad (13)$$

where $Dep(C_1)$ indicates the depth of concept C_1 within the ontology and $Dep(C_1, C_2)$ is the depth of the nearest co-parent of concept C_1, C_2.

Apparently, the similarity score range of $S_{L\&C}$, S_{Resnik} and S_{Jiang} is not within [0, 1]. For a fair comparison, their similarity matrices are normalized before they are applied to re-weighting document vector. In detail, each similarity score is denominated by the row sum. In this study, each document is represented as TF-IDF vector since this scheme achieves much better performance than normalized term frequency and term frequency (Zhang, Zhou, & Hu, 2006). Each document vector is re-weighted using equation the equation by Pedersen, Pakhomov, Patwardhan, and Chute (2007) and the ontology term-term similarity matrix. Spherical K-means is used for documents clustering, for it is a well-known vector-based clustering algorithm. Documents are also indexed using unigram words for a more comprehensive comparison. Documents are not considered in our experiments if they contain fewer than five terms. The whole process is implemented using dragon toolkit (Zhou, Zhang, & Hu, 2006).

Table 3. Clustering results of Disease10

Type of Measure	Measure Name	Entropy	F-Score	Purity	NMI
Path-based	Wu & Palmer	0.348	0.858	0.874	0.779
	Li et al.	0.304	0.834	0.901	0.799
	Leacock	0.276	0.853	**0.923**	**0.811**
	Mao et al.	0.342	0.830	0.875	0.782
Information-Content-based	Resink	0.295	0.856	0.906	0.802
	Jiang	0.300	0.848	0.905	0.800
	Lin	0.342	0.845	0.882	0.782
Feature-based	Basic Feature	0.358	0.818	0.872	0.775
	Knappe	0.350	0.834	0.876	0.778
MeSH descriptor		0.341	0.772	0.867	0.776
Word		0.245	0.755	0.908	0.820

Result Analysis

Table 3 and 4 show the experimental results of document clustering on Disease10 and OHSUMED23 datasets, respectively. The nine ontology-based similarity measures are divided by their corresponding types including: path-based, information-content-based and feature-based. "MeSH descriptor" and "Word" indicate the type of document representation and they do not use term re-weighting scheme.

Comparison Between"Re-Weighting" and "None Re-Weighting"

The performance between re-weighting and none re-weighting varies in terms of the corresponding datasets. For Disease10 dataset, most similarity measures slightly outperform none re-weighting, that is, MeSH descriptor. For OHSUMED23 dataset, the results of different schemes are very close. Three measures including Li, Zuhair and McLean (2003), Leacock and Chodorow (1994) and Resnik (1999) have slightly better performances than none re-weighting scheme. These results show that the re-weighting scheme can slightly improve document clustering, but it is not very significant. They also show that term re-weighting as a method of integrating domain ontology to clustering might not be a very effective approach when the documents are short of terms (Table 2), because when all these terms are very important core terms for the documents, ignoring the effects of some of them by re-weighting can cause serious information loss. This is on the contrary to the experiment results (Jing et al., 2006) in general domain where document length is relatively longer.

Comparison Between Different Similarity Measures

Experimental results on two datasets show that, among the three types of term similarity measures, there is no certain type of measure that significantly outperforms others. Interestingly, information-content-based measures, with the support of corpus statistics, have very similar performances with the other two types of measure. This may indicate that the corpus statistics is fit with ontology structure of MeSH and thus does not have better performance than path-based measures. Two path-based measures including Leacock and Chodorow (1994) and Li, Zuhair, and

Table 4. Clustering results of OHSUMED23

Type of Measure	Measure Name	Entropy	F-Score	Purity	NMI
Path-based	Wu & Palmer	2.209	0.244	0.347	0.165
	Li et al.	**2.181**	**0.253**	**0.356**	**0.174**
	Leacock	2.199	0.241	0.351	0.168
	Mao et al.	2.183	0.255	0.354	0.173
Information- Content-based	Resnik	2.194	0.252	0.352	0.170
	Jiang	2.199	0.251	0.351	0.168
	Lin	2.234	0.239	0.341	0.158
Feature-based	Basic Feature	2.219	0.241	0.344	0.162
	Knappe	2.226	0.239	0.340	0.160
MeSH descriptor		2.193	0.248	0.353	0.170
Word		2.321	0.200	0.302	0.130

McLean (2003) achieve the best performance on both datasets, respectively. Both measures consider not only the shortest path and depth of two concepts. Judging from the overall performance on the two datasets, Li, Zuhair, and McLean (2003), Leacock and Chodorow (1994), Mao and Chu (2002), Resink (1999) and Jiang and Conrath (1998) have rather more stable performances than that of the other measures. Feature-based measures always have the worst performance. This shows that using parent concepts as features may have negative impact on term re-weighting.

Comparison Between Ontology-Based and Word-Based Document Representation

The performance of word scheme is significantly different on the two datasets. For Disease10 dataset, word scheme is slightly better than ontology-based scheme, but this is not significant. On OHSUMED23 dataset, word scheme performs significantly worse than the other schemes. The results show both advantage of ontology and the limitation of ontology. First, while keeping competitive or significantly better clustering results, not only the dimension of clustering space but also the computational cost are dramatically reduced especially when handling large datasets. Second, existing ontologies are under growing, they are still not enough for many text mining applications. For example, there are only about 44,000 unique MeSH descriptor terms for the time of writing. Third, there is also limitation of term extraction. So far, existing approaches usually use "exact match" to map abstract terms to entry terms. This will cause serious information loss. For example, when representing document as MeSH descriptor terms, the average document length is only 13 for Disease10, while the length of the corresponding word representation is 81. Finally, if taking advantage of both medical concept representation and informative word representation, the results of text mining application can be more convincing.

CONCLUSION AND FUTURE WORK

In this article, we evaluate the effects of nine semantic similarity measures with a term re-weighting method on document clustering of PubMed document sets. The spherical k-means clustering experiment shows that term re-weighting has some positive effects on medical document clustering, but might not be very significant. In detail, we obtain following meaningful findings by comparing nine semantic similarity measures three types: path-based, information-content-based and feature-based measure with two indexing schemes—MeSH descriptor and Word: (1) term re-weighting achieves very similar clustering results with none term re-weighting. Some of them outperform none re-weighting, some of them do not and neither of them is very significant, which indicates that term re-weighting can be effective in a very limited degree when documents are short of terms because when most of these terms are distinguishable core terms for a document, ignoring some of them by re-weighting will cause information loss; more developed ontology and advanced term extraction technique may help term re-weighting achieve better results; (2) There is no certain type of measure that is significantly better than others; the best performance are achieved by two path-based measures including Leacock and Chodorow (1994) and Li, Zuhair, and McLean (2003) that consider both the closeness and the depth of the compared concepts; feature-based measures have the worst overall performance, which shows that using parent concepts as feature set is not effective for this application; although information- content-based measures consider both ontology and corpus statistics, they do not achieve better results than the other measure types; (3) the performance of MeSH scheme is much better than that of word scheme on OHSUMED23 dataset and slightly worse than word scheme on Disease10 dataset, which demonstrates both the advantage and limitation of domain ontology; while keeping competitive or significantly better results, indexing using MeSH ontology dramatically reduces the dimension of clustering space and computational complexity; however, the limitation of ontology such as limited concepts and rough term extraction techniques can cause information loss easily and thus hurt the clustering performance. Furthermore, this finding indicates that there should be an approach taking advantage of both medical concept representation and informative word representation.

In our future work, we may consider other biomedical ontology such as Medical Language System (UMLS) and also expand this comparative study to some public domain.

Chapter 7.28
Ontology-Based Spelling Correction for Searching Medical Information

Jane Moon
Monash University, Australia

Frada Burstein
Monash University, Australia

ABSTRACT

There has been a paradigm shift in medical practice. More and more consumers are using the Internet as a source for medical information even before seeing a doctor. The well known fact is that medical terms are often hard to spell. Despite advances in technology, the Internet is still producing futile searches when the search terms are misspelled. Often consumers are frustrated with irrelevant information they retrieve as a result of misspelling. An ontology-based search is one way of assisting users in correcting their spelling errors when searching for medical information. This chapter reviews the types of spelling errors that adults make and identifies current technology available to overcome the problem.

INTRODUCTION

Medical terminology includes many words which nonprofessionals find difficult to spell. For novice computer users it can be extremely frustrating when, as a result of misspelling, they cannot find relevant information. The medical implications of errors arising as a result of misspelling a word is well documented in the literature (Lambert, 1997; Lilley, 1995). Reports show that there is a significant error rate observed in patient records—in particular, in discharge letters (Blaser et al., 2004). An intelligent system could provide the users with some suggestions in order to assist in using correct words when dealing with medical information. However; it seems we are still far from reaching this goal.

A word processing program such as Microsoft Word, auto corrects typos and provides advice on whether a word is correctly spelt through a process of "verification and offers users to spell correctly via a process of 'correction'" (Berghel & Andreu, 1998). However, word correction is based on text spelling alone and can cause more problems at the correction stage. For example, Microsoft Word does not distinguish homophones such as *heroin* or *heroine* (Jones & Martin, 1997). The approach it takes in correcting spelling is not context based (Fallman, 2002) or ontology based (Khan, McLeod, & Hovy, 2004; Patel, Supekar, Lee, & Park, 2003; Tijerino & Reza, 2005), it does not recognize blank space which wastes a lot of space (Nix, 1981) and does not exhibit much intelligence. Popular search engines such as Yahoo and Google do provide some spelling correction by prompting a list of words based on keywords. In most cases search method is based on simple word searches and frequency distributions and these do not capture the meaning behind the words. Mauldin (1991) calls this phenomenon *keyword barrier*. Breaking through the keyword barrier will require a system that understands the texts they process.

There have been many attempts to produce spelling correction programs. They focus on various approaches including word concatenation (Berghel & Andreu, 1998), spelling correctors such as *Talisman* (Berghel, 1998), and correcting misspellings that contain a single error form (Pollock & Zamora, 1984). Some of these systems are domain specific and operate in chemistry, such as ChemSpell (Mitton, 1996; Zamora, 1978, 1980).

With the recent explosion of portals and ever expanding health information searching via medical/health portals, the question of the effectiveness of these health portals remains to be answered. Despite major advances and efforts to make portals user friendly, the research shows (Moon, 2005; Moon & Burstein, 2005) that most portals still lack essential functions for assisting users with information retrieval and hence losing potential users from existing portals. Even though the medical portals analyzed had the answers to users' queries, the major problem lay in the portal's inability to handle misspelling, thereby lacking an essential provision for assisting users (Moon & Fisher, 2005).

Another issue is that some major search engines provide a list of words that are not, however, always relevant to the user's query. This is demonstrated in Figures 2-4. Recent advances in ontology-based search is suggested to be overcoming the shortcomings of keyword search (Khan et al., 2004). At least it eliminates lists of words that are not domain specific. It is highly domain specific and context based, thereby eliminating unnecessary retrieval of information. It is an efficient, time-saving method.

In this research we explored the basic patterns of adult spelling errors and researched the spelling error corrector to see what technique has been used. In addition, we present an evaluation of some existing medical spell correctors to test if they meet users' needs. We describe an ontology-based, spell checker architecture that would assist users with medical information retrieval.

Review of Spell Check Approaches

The literature on misspelling is diverse and much of it is based on studies of children. However, very little has been studied on adults. Review of papers show that spelling mistakes in adults are predictable (Yannakoudakis & Fawthrop, 1983). This section describes the types of spelling errors and the existing approaches to their correction.

General Pattern of Spelling Errors

A natural language such as English is not static. The English language is one of the most difficult languages to learn as it has the following properties:

- It is not a phonetic language; there are many words that are not spelled the way they sound.

- It has many borrowed words that are not of English origin.
- It has many suffixes and prefixes that serve the same or similar purposes.

It is natural to make spelling errors in a language as complicated as English. General spelling errors can occur for many reasons, two of which are most common, typographical errors and orthographic errors. These can be described as follows (Peterson, 1980).

Typographic error. The first one occurs when the user knows the correct spelling but enters wrong typing because of fatigue, memory lapse, distraction, carelessness, or inadvertent mistake. This type of error is not consistent but is predictable since it relates to the position of keys on the keyboard and is probably related to finger movements.

There are many different reasons for making typographic spelling errors. One can make mistakes due to keyboard dualities. For example, one may use a keyboard for more than one language where key settings vary; for example, the keyboard can be used for English as well as Spanish and could lead to some sort of confusion. Another reason can be forgetting to use shift key characters or forgetting to undo the capital locks. Phonetic similarities such as "ka" and "ga," which are similar in Japanese could lead to confusion. Visual similarity could also lead to mistakes. For instance if two letters are similar then one may mistype the character without realizing it.

Cognitive/Orthographic errors. This relates to the writer's knowledge, and to the difference between how a word sounds and how it should be spelled. The words with different forms, for example, verbs or nouns can be confusing depending on what context they are used, for example, *effect* and *affect.*

Consistent human spelling error is related to a systematic break of rule rather than exception. Examination of performance errors in spelling seems to indicate the spelling errors are random, but closer study of individual performers invariably reveals a pattern. Across individual spelling, errors are often idiosyncratic, but often there is a substantial degree of intra-individual consistency in the types of errors being made. Most of the spelling errors occur because of some type of systematic errors due to "logical" though incorrect reasoning.

Most spelling errors can be generated from correct spelling by a few simple rules. Damerau (1964) indicates that 80% of all spelling errors are the result of:

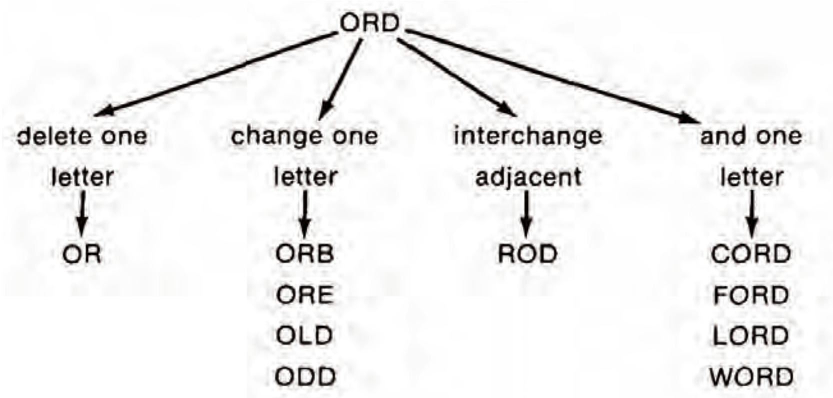
- transposition of two letters,
- insertion of a letter,
- missing a letter, or
- one wrong letter.

Yannakoudakis and Fawthrop (1983) confirmed that there are patterns in spelling errors; and continued Damerau's (1964) study and found that:

- many errors are made in the use of vowels;
- many errors are made in the use of the letters "H," "W," and "Y;"
- doubling and singling of any letters is common;
- few errors are made in the first character of a word;
- transposition of any two adjacent characters is common;
- missing or adding a character is common; and
- certain consonants are more frequently interchanged than others.

Based on Damerau's (1964) simple method, a SPELL check program can be written as in Figure 1.

Figure 1. Show Damerau's simple "arithmetic at" system based on deletion, insertion, transposition, and addition using ORD as example (Damerau, 1964)



Spelling Correctors

There are two types of spelling programs: *spell checkers* and *spell correctors.* Spell checkers simply look at the entered words and check whether they are correctly spelled. Spell correctors detect misspelled words and try to correct them. A spell corrector uses elements of pattern matching, appropriate algorithms, and coding theory.

Much work has been done on spelling correction algorithms, some based on phonetics, others are algorithms, clustering, and measuring distances which will be described in the following paragraphs.

Error Detection

The two most widely used error detection methods are n-gram analysis (Morris & Cherry, 1975; Zamora, Pollock, & Zamora, 1981) and dictionary look up (Aho and Corasick, 1975; Knuth, 1973; Peterson, 1980). These two approaches can be summarized as follows:

Trigram analysis is a method used to correct spelling by analyzing parts of words in three-letter sequences. It identifies three possible candidates for representing meaningful words. N-gram is used to perform trigram analysis:

- An *n-gram* is an n-letter sequence, extracted from a word, where *n* is usually 1, 2, or 3. In general, n-gram analysis techniques check each n-gram in an input string against a precompiled table of n-gram statistics to determine whether the n-gram can occur in a word. If it does, its frequency of occurrence in the words of the language is computed. Strings containing n-grams that do not occur in words or occur very infrequently are considered to be possible misspellings. For instance, the word HEPATITIS contains the trigrams: -HE, HEP, EPA, PAT, ATI, TIT, TIS, IS- where hyphen (-) represents the word boundary (Yannakoudakis & Fawthrop, 1983).
- *Dictionary lookup techniques* check whether an input string appears in a dictionary. It can be regarded as a special case of n-gram analysis where variable length n-grams delimited by blanks or punctuations are used (Zamora et al., 1981). Response time may become a problem as the size of the dictionary grows. To save the search time, most often the suffix is stripped before analysis. This could also present a problem, as meaning could sometimes be changed or lost without a suffix.

Error Correction

There has been much advance in the last decade on spelling error correction. Calculating the distance between strings has been a widely used method for error correction with a degree of success. Some of the error correction methods based on *distance between strings* are the *minimum edit distance*, *Hamming distance*, and *Levenshtein distance*. Another method of error correction that are based on learning from user's errors and improving and adapting from user's mistakes is called the *neural net technique*. The following paragraph describes approaches to error correction in detail.

Calculating distance between strings has been a commonly used option for modern spell checkers and seems to work well at least in English. In English spell correction word boundary problems such as in the word *forgot* (forgot – for got), run-ons such as in *form – inform*, or short words such as prepositions (to, or, at) are difficult. N-gram is used to correct context-independent problems. However, Asian languages such as Japanese and Chinese consist of run-on words, which are context dependent.

The latest word processor programs are capable of suggesting a replacement for a mistyped word. Spell checkers "know" how to evaluate distance between a misspelled word and the words in its files. Words whose evaluated distance is the smallest are suggested as candidates for replacement.

The minimum edit distance technique was first developed by Damerau (1964), to compute the minimum number of editing operations (such as insertion, deletion, transposition, and substitution) that are required to fix misspelled strings.

Hamming distance (H) is defined only for strings of the same length. Hamming distance is named after Richard Hamming; it is an algorithm that measures the number of *substitutions* required to change one string to the other. For strings s and t, H(s, t) is the number of places in which the two strings differ, have different characters.

For example (http://en.wikipedia.org/wiki/Hamming_distance):

- The Hamming distance between **1011101** and **1001001** is 2.
- The Hamming distance between **2143896** and **2233796** is 3.
- The Hamming distance between "***toned***" and "**roses**" is 3.

Hamming distance is used in telecommunications, signal distance, and cryptography. For more sophisticated systems where addition, subtraction are required, Levenshtein distance is more appropriate.

Levenshtein distance (or edit distance) is more sophisticated. It is defined for strings of arbitrary length. It counts the differences between two strings, where we would count a difference not only when strings have different characters but when one has a character and the other does not. It is the smallest number of insertions, deletions, and substitutions required to change one string or tree into another. An H(m x n) algorithm computes the distance between strings, where m and n are the lengths of the strings (http://www.nist.gov/dads/HTML/levenshtein.html).

The *simple correlation matrix technique* is a correlation technique. Each misspelled word is represented by an n-dimensional feature where Hamming distance of strongly correlated matches the most probably correct word (Cherkassky, Vassilas, Brodt, Wagner, & Fischer, 1974).

The *singular value decomposition* (SVD): Correlation Matrix Technique to apply matrix transformation techniques to simple correlation matrices in an effort to improve spelling correction accuracy (Deerwester, Dumais, Furnas, Landauer, & Harshman, 1990). The goal of SVD is to find the most relevant similarity in lexical space.

The correction of words rests on the basis of three common phenomena: nonword error detection, isolated word error correction, and context-dependent word correction (Kukich, 1992).

The *neural net technique* has the potential to adapt to specific error patterns of their user community, thus maximizing their correction accuracy for that population. This can have a user—adaptable chip that continuously monitors and learns from specific users or groups of users to improve spelling errors (Kukich, 1988).

Kukich did experiments to compare the effectiveness of spelling of the available three techniques to see the effects for different size word lexicons.

As can be seen from Table 1, slight improvements were noted with the neural network of approximately 15%. There was very little difference in performance regardless of numbers of words in the dictionaries.

In the past two decades there has been a lot of exploration of new techniques in word spelling errors (Nagata, 1996; Jones & Martin, 1997; Yannakoudakis & Fawthrop, 1983). There have also been many spelling corrector programs produced based on various algorithms. Table 2 lists some of such products and gives an overview of the strategies and characteristics of those products.

Impact of Spelling Errors on Medical Information Seeking

Medical terms are usually very hard to spell. Typing incorrectly or spelling phonetically can yield to inappropriate or irrelevant results, which causes a waste of time, resources or, at times, can give a false alarm if the users are not aware of the error. Blaster et al. (2004) found that spelling errors caused significant errors in patient discharge letters. Through earlier usability testing on Australian medical portals we found that the users did not want to come back to the sites that did not have spelling error correction facilities to assist their search (Moon & Burstein, 2005). In many instances the users could not find the information they were looking for from such portals. We have concluded then that spelling correction facility is one of the essential characteristics of an intelligent portal.

Most of the spelling correction techniques mentioned previously are developed for general English language. However, most of these techniques can be applied in a medical context too. In this chapter we investigate how a generic technique, such as Damerau (1964) method, can be suitably applied to medical settings to improve the system, to make a system more “intelligent” in assisting users in seeking information. Before looking at the generic architecture we analyze the functionality of two popular existing commercial medical spell checkers. The problem with using commercial products is high cost and lack of flexibility, which can be achieved with customized development.

ANALYSIS OF MEDICAL SPELL CHECKERS

We studied medical spell checkers to see how useful they were in dealing with correcting spell-

Table 1. Comparison of three spelling correction methods (Adopted from Kukich, 1992)

Techniques	521-Word Lexicon	1,142-Word Lexicon	1,872-Word Lexicon
Minimum Edit Distance	64%	62%	60%
Simple Correlation Matrix (Hamming Distance)	69%	68%	67%
Neural Network	75%	75%	?

ing errors in medical portals. The following two commercial products are available in assisting users with difficult medical terminology and names of medications. Spellex (www.spellex.com) and MediSpell (www.medispell.com) were identified as the most popular and comprehensive packages. Spellex searches for medical words of 670,000 words while MediSpell searches 170,000 words.

We compared the two products against the misspelling of medical terms to see what help the users would get. The words tested were chosen from the usability testing done in an earlier study of the effectiveness of Australian government medical portals (Moon & Burstein, 2005; Moon & Fisher, 2005). Heuristic usability terms were chosen as they are closer to natural language processing, that is, the users are dynamic and unpredictable

Table 2. Some spelling correction programs

Name of the product	Strategies	Advantages	Disadvantage	Reference
Spell	Based on addition, deletion, insertion and transposition. The list is matched against the dictionary	Short words correct well.	High percentage errors on long strings. Many orthographical errors fall outside of the scope of SPELL	Peterson, 1980
Speecop	Strings are converted to similarity keys. These similarity keys are blurred to mimic original words. The keys found within certain target keys are considered possible corrections.	Frequent problem of doubling, undoubling and transposition are all seen as original words.	Dependence on first few consonants. This causes problems especially on omission of words. Good with frequent typological errors.	Pollock & Zamora, 1984
Talisman	Designed for typing and knowledge errors.	In built to the system i.e. Microsoft.	Logic based (programmed to system) not semantic based.	Berghel & Andreu, 1988
Trigram Analysis	Use of trigrams to correct misspelling.	Works well on long words. Error position is not important.	Single error may disturb all or virtually all trigrams in a short word. Transposition disturb trigrams and thus difficult to correct.	Van Berkel and De Smedt, 1988
Spell Therapist	Linguistic method for correction of orthographical errors. Combines phonological code and checks dictionary for phonemic words.	Works well for words that are homophonous spellings.	Not suitable for typological errors and does not work for hard phonological differences, i.e., ‘managable’, ‘recommand’ doesn’t correct.	Van Berkel and De Smedt, 1988
The Penguin	Grammar and Spell Checking	Takes into account of idioms, colloquialism, names, and slang expressions. Dynamic, rather than prescriptive such as Microsoft Word.	Not contextual.	Fallman, 2002

in the way they spell the words especially when the word is long and difficult.

We have chosen words such as *schizophrenia*, *methotrexate*, and *Tamoxifen*. Schizophrenia is a common mental disease, Methotrexate is a common drug for sufferers of rheumatoid arthritis, and Tamoxifen is a common drug for breast cancer. These terms were chosen because of their wide usage in the community as found from usability testing (Moon & Fisher, 2005).

Both products give a list of synonyms as a pop-up box as seen in Figures 2-4.

A search for the query on skizophrenia produced the following lists:

- Sacciformis
- Schizophrenic ←
- Schizophrenics
- Shakespeareans

As can be seen, there were four words prompted and they were matched according to the sounds. The word *Shakespeareans* seems rather inappropriate in this list.

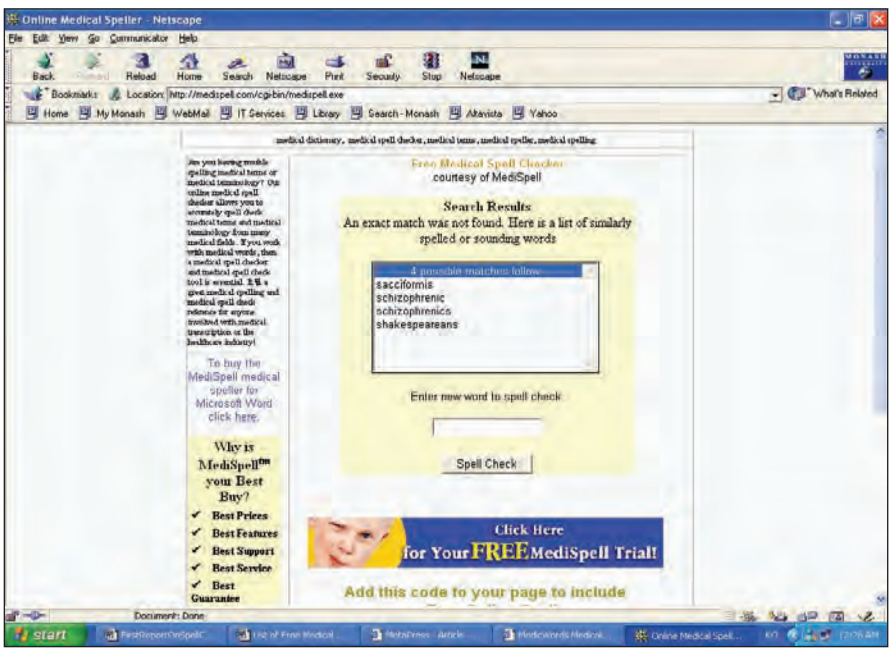
It would also be useful if those hits offered a description of what each word meant. For instance, what is sacciformis? Upon looking it up in a medical dictionary without suffix, *sacciform* is "bag-shaped" or "like a sac" (Davis, 1981), which is also useless in medical context.

Typing a common drug for breast cancer "Tamoxifen" spelled as "Tomoxifen" gave out the following options:

- Tensopin
- timespan
- TinCoBen
- Tamoxifen ←
- Temazepan

An intelligent guess is required to select Tamoxifen as the correct word, as there is no description of definition of any of the options offered. Tensopin is a drug for hypertension, TinCoBen

Figure 2. MediSpell search on "schizophrenia"



is a skin protectant for skin disease, temazepan is a cannabis. Timespan is an unreasonable list of words for selection.

In another search, typing Methotrexate, a common drug for arthritis, misspelt as "Metatrexate" gave the following options (www.spellex.com/cgi-bin/spellex.exe):

As the result the following list of drug names was produced:

- MEDdirect
- Matricide
- Matruchoti
- Maturest
- Methotrexate ←
- Metrizoate
- metrocyte

From the previous list, one could choose more than one selection as there is a lot of similarity with keywords Methotrexate:

- Matricide is a term used for killing a mother
- Matruchoti a type of species of Bacteria represented as *Bacterionema matruchoti*
- Maturest is an English word being a mature
- Metrizoate is a diagnostic radiopaque that usually occurs as the sodium slat
- Metrocyte refers to a neuron.

As can be seen from the list of words offered as alternatives for Methotrexate they have a completely different meaning for the users to choose. Offering words spelled on the basis of phonology as an alternative choice can be risky and at times dangerous, especially when dealing with large ethnic backgrounds. For instance, in Vietnamese the ending letter "t" is often not pronounced. If the user spells phonetically the user could easily type Methotrexate as Methotrax or Mesotrax.

As can be seen from Figures 2, 3, and 4 of screen dumps, phonetically based spelling alone is not very useful and can be extremely time consuming for the users to select individual choices and check on the Internet for their meaning. However, if the descriptions of words are provided to the users so they could select what they need rather than checking individually. Equally, if the list of words is domain specific, that is, for Rheumatoid Arthritis the hit list returns drugs pertaining to

Figure 3. Spellex search on "Tamoxifen"

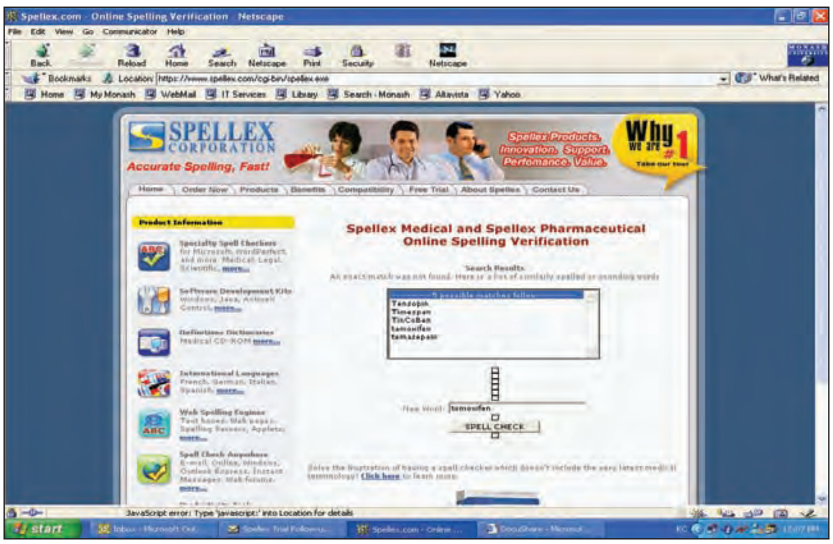


Figure 4. Spellex search on "Methotrexate"

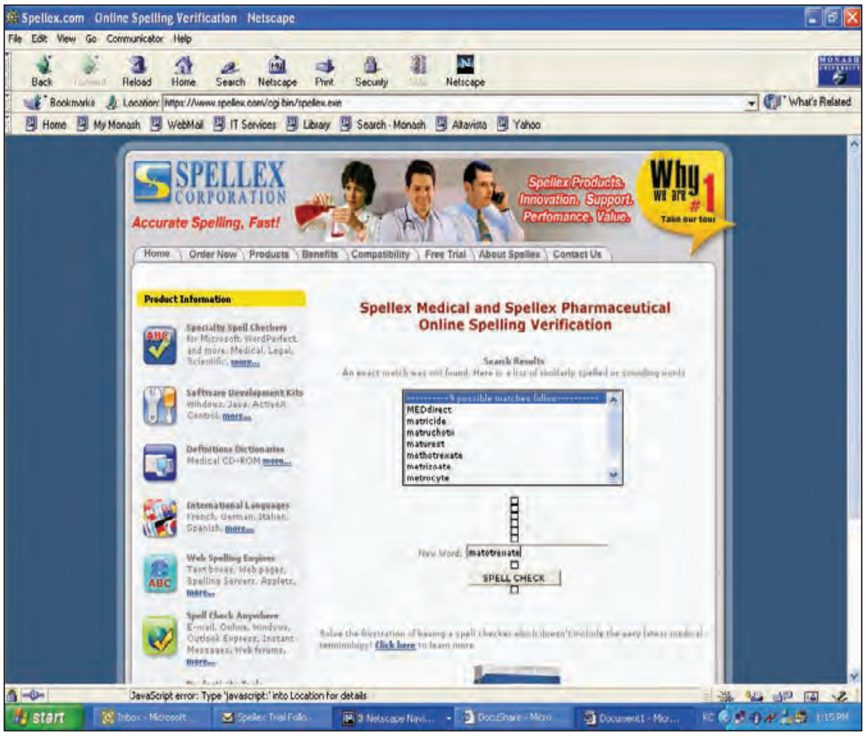


the field would be helpful. The ontology-based search is aiming to solve this problem.

The following section describes steps that can be taken to improve current medical portals in particular correcting spelling mistakes and giving the users hit lists that are relevant to their field of search thereby reducing the time spent for searching, improving the user satisfaction by proving the choice for their selection, and helping them to find the relevant information.

Spelling Correction for Medical Information Retrieval

Generic spelling error detecting tools have been described in the earlier section of this article and their advantages and disadvantages described (Table 2). A few different types of error detection techniques, such as string-string edit distances, statistical packages such as SVD, Hamming distance, and the Levenshtein method have been described. These as well as statistic-based algorithms, where the search is based on probability cannot recognize the search domain. What is lacking in these spell checkers is that the searches are not context based. Spelling error correction based on phonetics combines with context-specific retrieval would eliminate the unnecessary list of words that are offered but not relevant to the user. In addition, ontology-based search can be utilized for searching words specific to the domain thus eliminating words that are not within the specific domain. In this section we consider a few approaches for dealing with phonetic errors in medical contexts, which have proven to be the most frequently encountered misspellings identified from our prior usability study of medical portals. We propose a system architecture, which is based on these approaches. The main advantage of this system is the ability to recognize terms relevant to the users' context as well as provide definitions for these terms.

The following section describes the phonetic and semantic-based search for such a system.

Damerau's Simple Detection Method

By using Damerau's (1964) simple method we can see that 80% of all spelling errors are the results of the following four methods. Damerau's method was developed for English but it can be applied in medical terms as in the following example. The word for liver disease *cirrhosis* can be wrongly written as follows:

1. insertion of a letter: cirrhossis;
2. deletion of a letter; cirhosis;
3. replacement of a letter by another one: cirrhocis; or
4. transposition of two adjacent letters: cirhrocis

In order for a medical portal to recognize these terms as related to the same word, the following methods can be used. These methods combine phonetic and context-based search to achieve more efficient information retrieval.

Phonetic-Based Spell Correction and Aspell

Lawrence Philips' *Metaphone Algorithm* is an algorithm which returns a rough approximation of how an English word sounds (http://aspell.net/metaphone). The original metaphone method was developed in 1990 for the C language, with more later upgrades to 4GI and for Perl, Java, and now Visual C++ and PHP. This method is used widely by Linux as an open source and matches English words phonetically rather than contextually (Jones & Martin, 1997). Lawrence Philips' methods superceded Soundex (developed by Robert Russell and Margaret Odell and was patented in 1918 and 1922) (http://patft.uspto.gov/netacgi/nph-Parser?patentnumber=1,262,167). Lawrence Philip's Metaphone combines the metaphone algorithm based on phonology and Aspell's open source. Aspell's open source spell checker is an advanced version of Ispell's which uses the basic strategy of inserting a space or hyphen, one letter deletion, one letter addition, and interchanging two adjacent letters when used for a correct term. It is an open source and it is free requiring only a little effort to download it.

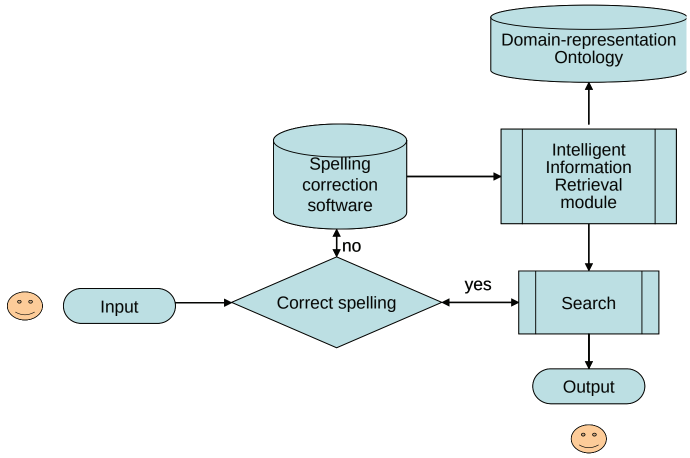
Semantic-Based Search

Kukich (1992) mentioned, in her much quoted review of technologies for automatic word correction, that research on context-based search was still in its infancy and that the task of fixing context-dependent text was an elusive one. She mentioned that 40-45% of spellings are contextual errors (Kukich, 1992a, 1992b). Natural language is complex and according to Zipf's law, "most events occur rarely and a few very common events occur most of the time" (Pedersen, 1996, p. 1). Indeed there has been much progress in parsing technology and grammar checking in English (Bernth, 1997). One example of analysis that incorporate semantic search is *latent semantic analysis (LSA)*.

The LSA proposed by Jones and Martin (1997) promises to be a step further from traditional spelling methods. In traditional spelling methods, the emphasis has been correcting the spelling rather than providing words that are relevant to contexts. Since many words are polysemous (have many meanings) and have many synonyms (words with similar meanings), trying to find the right word that matches the context has not been easy. LSA, with its use of a SVD matrix, has to some extent be able to correct the spelling errors in confusion sets (words such as *principle* and *principal*). However, it does not work yet on unedited texts (Jones & Martin, 1997).

Part of speech (POS). (Ruch, 2002) POS is about an experiment combining string-to-string

Figure 5. Ontology-based spelling correction architecture



distance, POS word + word language and found that POS word + word language improved search. Also spelling corrections using both left and right context outperformed the use of the left context.

Ontology-based query expansion using Unified Medical Language System (UMLS). UMLS is a full set of knowledge sources for the medical domain and is hierarchy based. The research shows that users often use the users use scenario-specific queries for information retrieval. The search terms are not keywords such as *hepatitis* or *cancer* but scenario-based search terms such as *lung, cancer treatment,* and *lung excision.* This is different to query expansion, which sought to search keywords in various documents and tried to link the words with documents. However, ontology-based query would look for keywords as well as the words in context. For instance, *lung excision* not only looks for *lung cancer* but also searches for *smoking, cigarette,* and *lymph node* (Liu & Chu, 2005).

SYSTEM DESIGN

In the system we propose that the user-entered term is first analyzed using phonetic approach as part of a spelling correction software. The terms that this process identifies as possible options are then compared with the domain ontology model. As a result of such comparison those not relevant to the user are excluded, the remaining terms are defined clearly using the definitions stored as part of the ontology. Such search procedure not only increases the relevance of the final results but improves the level of user satisfaction.

FUTURE TRENDS

In general, medical terminology is very challenging. Understanding the general spelling error patterns of adults and thus creating a system that understands the general algorithm of adult spellers could improve the system. For years scientists have worked on improving systems for information retrieval. Clearly a better system is required if users' needs are to be satisfied. Agent theory, use of artificial intelligence via fuzzy logic, artificial neutral networks, and Semantic Web-based systems are all being researched and refined. Ontology-based search has potential in that the listed hits are relevant to specific domain, thereby reducing the retrieval of irrelevant word lists.

CONCLUSION

Natural language processing is complicated, and English is a challenging language when it comes to spelling. Adult spelling errors are either typological or orthographical, and many different types of error detection and error correction methods have been developed. Although these studies have been done on English generally, the same techniques can be applied specifically to medical information retrieval. However, the challenge is that medical terminology or jargon often involves difficult, non-English words. From the usability study it was seen that users often spell phonetically and often use a scenario-based search rather than a keyword search.

Current spelling aid systems which are built on a phonetic basis might have high recall but are low in precision. Combinations of phonetic-based systems with a knowledge-based search are seen to improve searches by 5-10% (Liu & Chu, 2005). What is more, Liu and Chu suggest that user queries are often scenario-based rather than keyword based. Ontology-based searches using a medical corpus such as UMLS narrows the search to the medical context thereby reducing irrelevant information, that is, nonmedical information. With the use of query expansion it could prove to be more efficient.

KEY TERMS

Dictionary Lookup Techniques. Dictionary lookup techniques check whether an input string appears in a dictionary. Response time may become a problem as the size of the dictionary grows. To save the search time most often suffixes are stripped, and this can cause some problems.

Hamming Distance H. H is defined only for strings of the same length. For strings s and t, H(s,t) is the number of places in which the two string differ, or have different characters.

Levenshtein (or edit) Distance. Levenshtein distance is more sophisticated. It is defined for strings of arbitrary length. It counts the differences between two strings, where we would count a difference not only when strings have different characters but when one has a character whereas the other does not. The smallest number of insertions, deletions, and substitutions required to change one string or tree into another. A H(m x n) algorithm to compute the distance between strings, where m and n are the lengths of the strings (http://www.nist.gov/dads/HTML/levenshtein.html).

Minimum Edit Distance. Minimum edit distance is based on calculating the distance between a misspelled word and eh words in its files. Words whose evaluated distance is the smallest are offered as candidates for replacement.

N-Gram is an n-letter subsequence of a string, where *n* is usually 1,2, or 3. In general, n-gram analysis techniques check each n-gram in an input string against a precompiled table of n-gram statistics to determine whether the n-gram can occur in a word. If it does, its frequency of occurrence in the words of the language is computed. Strings containing n-grams that do not occur in words or occur very infrequently are considered to be possible misspellings.

Phoneme. Phoneme is the smallest unit of sound in a language which can distinguish two words, that is, *pan* and *ban* differ in that *pan* begins with /p/ and *ban* begins with /b/.

Simple Correlation Matrix Technique. Simple coorelation matrix technique is a correlation technique. Each misspelled word is represented by an n-dimensional feature where Hamming distance of strongly correlated matches the most probably correct word (Cherkassky et al., 1974).

Trigram Analysis. Trigram analysis is a method used to correct spelling. It simply means three possible candidates for representing words where n-gram is used to apply the analysis.

ABSTRACT

With the advent of new sequencing technology for biological data, the number of sequenced proteins stored in public databases has become an explosion. The structural, functional, and phylogenetic analyses of proteins would benefit from exploring databases by using data mining techniques. Clustering algorithms can assign proteins into clusters such that proteins in the same cluster are more similar in homology than those in different clusters. This procedure not only simplifies the analysis task but also enhances the accuracy of the results. Most of the existing protein-clustering algorithms compute the similarity between proteins based on one-to-one pairwise sequence alignment instead of multiple sequences alignment; the latter is prohibited due to expensive computation. Hence the accuracy of the clustering result is deteriorated. Further, the traditional clustering methods are ad-hoc and the resulting clustering often converges to local optima. This chapter presents a Bayesian framework for improving clustering accuracy of protein sequences based on association rules. The experimental results manifest that the proposed framework can significantly improve the performance of traditional clustering methods.

INTRODUCTION

One of the central problems of bioinformatics is to predict structural, functional, and phylogenetic features of proteins. A protein can be viewed as a sequence of amino acids with 20 letters (which is called the primary structure). The explosive growth of protein databases has made it possible to cluster proteins with similar properties into a family in order to understand their structural, functional, and phylogenetic relationships. For example, there are 181,821 protein sequences in the Swiss-Prot database (release 47.1) and 1,748,002 sequences in its supplement TrEMBL database (release 30.1) up to May 24, 2005. According to the secondary structural content and organization, proteins were originally classified into four classes: α, β, α+β, and α/β (Levitt & Chothia, 1976). Several others (including multi-domain, membrane and cell surface, and small proteins) have been added in the SCOP database (Lo Conte, Brenner, Hubbard, Chothia, & Murzin, 2002). Family is a group of proteins that share more than 50% identities when aligned, the SCOP database (release 1.67) reports 2630 families.

Pairwise comparisons between sequences provide good predictions of the biological similarity for related sequences. Alignment algorithms such as the Smith-Waterman algorithm and the Needleman-Wunsch algorithm and their variants are proved to be useful. Substitution matrices like PAMs and BLOSUMs are designed so that one can detect the similarity even between distant sequences. However, the statistical tests for distant homologous sequences are not usually significant (Hubbard, Lesk, & Tramontano, 1996). Pairwise alignment fails to represent shared similarities among three or more sequences because it leaves the problem of how to represent the similarities between the first and the third sequences after the first two sequences have been aligned. It is suggested in many literatures that multiple sequence alignment should be a better choice. While this sounds reasonable, it causes some problems we address here. The most critical issue is the time efficiency. The natural extension of the dynamic programming algorithm from the pairwise alignment to the multiple alignment requires exponential time (Carrillo & Lipman, 1988), and many problems related to finding the multiple alignment are known to be NP-hard (Wang & Jiang, 1994). The second issue is that calculating a distance matrix by pairwise-alignment algorithm is fundamental. ClustalW (Thompson, Higgins, & Gibson, 1994) is one of the most popular softwares for multiple-alignment problems. It implements the so-called progressive method, a heuristic that combines the sub-alignments into a big one under the guidance of a phylogenetic tree. In fact, the tree is built from a pre-computed distance matrix using pairwise alignment.

Many protein clustering techniques exist for sorting the proteins but the resulting clustering could be of low accuracy due to two reasons. First, these clustering techniques are conducted according to homology similarity, thus a preprocessing of sequence alignment should be applied to construct a homology proximity matrix (or similarity matrix). As we have mentioned, applying multiple sequence alignment among all proteins in a large data set is prohibited because of expensive computation. Instead, an all-against-all pairwise alignment is adopted for saving computation time but it may cause deterioration in accuracy. Second, most of the traditional clustering techniques, such as hierarchical merging, iterative partitioning, and graph-based clustering, often converge to local optima and are not established on statistical inference basis (Jain, Murty, & Flynn, 1999).

This chapter proposes a Bayesian framework for improving clustering accuracy of protein sequences based on association rules. With the initial clustering result obtained by using a traditional method based on the distance matrix, the strong association rules of protein subsequences for each cluster can be generated. These rules satisfying both minimum support and minimum confidence can serve as features to assign proteins to new clusters. We call the process to extract features from clusters the alignment-less alignment. Instead of merely comparing similarity from two protein sequences, these features capture important characteristics for a whole class from the majority, but ignore minor exceptions. These exceptions exist due to two reasons: the feature itself or the sequence itself. For the first reason, the feature being selected could be inappropriate and thus causes exceptions. Or, there does not exist a perfect feature that coincides for the whole class. The second reason is more important. The sequence causing the exception may be pre-classified into a wrong cluster; therefore, it should be re-assigned to the correct one. The Bayes classifier can provide optimal protein classifications by using the *a priori* feature information through statistical inference. As such, the accuracy of the protein clustering is improved.

The rest of this chapter is organized as follows. The background reviews existing methods relevant to protein clustering and the motivations of this chapter. The third section presents the ideas and the theory of the proposed method. The fourth section gives the experimental results with a dataset of protein sequences. The final section concludes this chapter.

BACKGROUND

Related Works

Many clustering techniques for protein sequences have been proposed. Among them, three main kinds of approaches exist, namely the hierarchical merging, iterative partitioning, and graph-based clustering. All of these methods use a pre-computed similarity matrix obtained by performing pairwise alignments on every pair of proteins. In the following we briefly review these approaches.

- **Hierarchical Merging:** The hierarchical merging clustering (Yona, Linial, & Linial, 1999, 2000; Sasson, Linial, & Linial, 2002) starts with a partition that takes each protein as a separate cluster, and then iteratively merges the two clusters that have the highest similarity from all pairs of current clusters. The similarity between two clusters is derived from the average similarity between the corresponding members. Thus, the hierarchical merging procedure forms a sequence of nested clusterings in which the number of clusters decreases as the number of iterations increases. A clustering result can be obtained by specifying an appropriate cutting-off threshold, in other words, the iterative merging procedure progresses until the maximal similarity score between any two clusters is less than the cutting-off threshold. The algorithm for hierarchical merging clustering is summarized in Figure 1.
- **Iterative Partitioning:** The iterative partitioning method (Jain & Dubes, 1988; Guralnik & Karypis, 2001; Sugiyama & Kotani, 2002) starts with an initial partition of *k* clusters. The initial partition can be obtained by arbitrarily specifying *k* proteins as cluster centers then assigning each protein to the closest cluster whose center has the most similarity with this protein. The next partition is obtained by computing the average similarity between each protein and all members of each cluster. The partitioning process is iterated until no protein changes its assignment between successive iterations. Although the iterative partitioning method has some variants like ISODATA (Ball & Hall, 1964) and *K-means* (McQueen, 1967), their general principles can be described as shown in Figure 2. A post-processing stage can be added to refine the clusters obtained from the iterative partitioning by splitting or merging the clusters based on intra-cluster

and inter-cluster similarity scores (Wise, 2002).

- **Graph-based Clustering:** These methods (Tatusov, Koonin, & Lipman, 1997; Enright & Ouzounis, 2000; Bolten, Schliep, Schneckener, Schomburg, & Schrader, 2001) represent each protein sequence as a graph vertex, and every pair of these vertices are connected by an edge with a label on it. The label denotes the similarity score between the two proteins represented by the vertices connecting to the corresponding edge. A partition of the graph can be generated by cutting off the edges whose labels are less than a specified similarity threshold, and each connected component of vertices corresponds to a cluster of proteins since the similarity scores between proteins from the same component are higher than those between proteins from different components. The general idea of the graph-based clustering is outlined in Figure 3. A post-refining process can be conducted by using the graph-based clustering result as the input to a cluster-merging algorithm which iteratively merges the nearest neighboring clusters if the relative entropy decreases with the merging of the clusters (Abascal & Valencia, 2002).

Motivations

The protein clustering result obtained by using the above mentioned approaches could be of low accuracy. This is partly due to the reason that these clustering methods use only pairwise sequence alignment information and partly because these clustering techniques often converge to local optima. Since it is computationally prohibitive to derive multiple sequence alignment information, an alternative is to calculate the statistics from the sequences directly by using data mining techniques. More precisely, the *association rules* between the amino acids in the protein sequences are mined within each cluster. Then the rules satisfying minimum confidence can serve as salient features to identify each cluster. Moreover, matching each protein sequence with the association rule provides a good estimate of the *a priori* probability that the protein satisfies the rule. The statistical inference can compensate the accuracy inadequacy of the clustering result due to the pairwise alignment and the local clustering technique. Therefore, we propose to improve the clustering accuracy by using the Bayes classifier with the conditional probabilities of association rules with each cluster and the alignment scores between protein sequences and these rules.

Figure 1. Summary of hierarchical merging clustering

```
        create.cluster(p);
Repeat
        Find clusters x, y such that similarity(x, y) is maximal;
        If similarity(x, y)>cutting_off_threshold then merge.cluster(x, y);
        Otherwise, terminate;
```

Select *k* proteins as initial cluster centers
Repeat
    Compute the average similarity between each protein and each cluster;
    Generate a new partition by assigning each protein to its closest cluster;
Until no proteins change assignment between successive iterations

Figure 3. Summary of graph-based clustering

Represent each input sequence as a vertex, and every pair of vertices are connected by an edge.
Label each edge with the similarity score between the two connected vertices.
Create a partition of the graph by cutting off the edges whose similarity scores are less than a specified threshold.

METHODS

With the assistance of association rule mining and Bayes classifier, our system improves the clustering accuracy of traditional protein-clustering methods. The system overview is shown in Figure 4. First, a traditional protein-clustering approach (either one of the hierarchical merging, iterative partitioning, or graph-based clustering methods) is performed to obtain an initial clustering result of the input protein sequences. In general, the traditional protein-clustering approach consists of three steps as shown in the upper grey box: (1) perform the local alignment (such as BLAST with scoring matrix of BLOSUM 62) between each pair of protein sequences, (2) construct a distance matrix from the raw distance scores (such as the E-values produced by BLAST) of the local alignment, and (3) apply the clustering method with the distance matrix to get the clustering result.

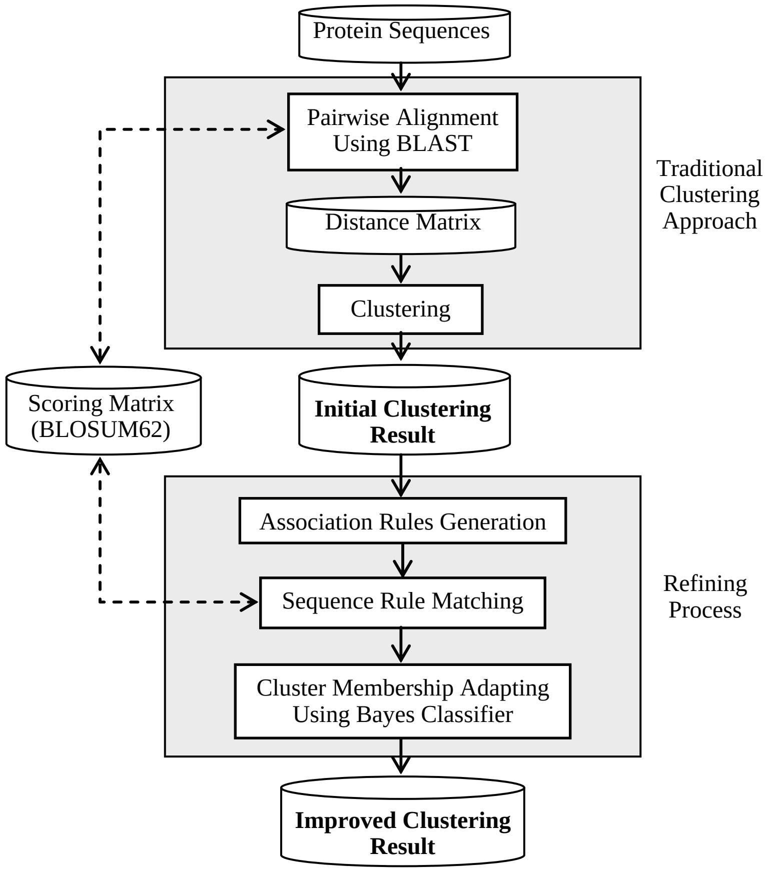
Second, the refining process (as shown in the lower grey box) is performed such that the clustering result is improved. The refining process also consists of three steps: (1) generate strong association rules which satisfy minimum confidence for each cluster, (2) perform sequence rule matching between each protein sequence and each association rule based on local alignment, and (3) adapt cluster membership of each protein sequence by using Bayes classifier and its matching score. The proposed refining process improves the clustering result based on statistical inference. The association rules used are statistically confident and the reassignment of protein sequences using Bayes classifier satisfies the maximum *a posteriori* criterion.

We now present the refining process in details.

Sequence Association Rule Generation

Association rule mining has been intensively used for finding correlation relationships among a large set of items and has delivered many successful

Figure 4. System overview



applications, such as catalog design, cross marketing, and loss-leader analysis (Han & Kamber, 2001). Association rule mining finds significant associations or correlation relationships among a large repository of data items. These relationships, represented as rules, can assist the users to make their decisions. Traditionally, association rule mining works with unordered itemset, that is, the order of the items appearing in the itemset does not matter (Agrawal, Imielinski, & Swami, 1993). However, the order of the amino acids appearing in a protein sequence reserves important phylogeny information among homologies and should be taken into account. The *sequence Apriori algorithm* (Agrawal & Srikant, 1994, 1995) which adapts the classical association rule mining algorithm for sets of sequences can be used for this purpose.

Given a cluster C of protein sequences, the algorithm finds sets of sequences that have support above a given *minimum support*. The *support* of a sequence X with respect to C, denoted by $\text{support}_C(X)$, is the number of sequences in C that contain X as subsequence. A sequence is called *frequent* if its support is greater than the given *minimum support*. To expedite the search for all frequent sequences, the algorithm enforces an iterative procedure based on the a priori property

Figure 5. An illustrative example of sequence association rule matching: (a) A substitution matrix, (b) Two possible alignments between the sequence and the association rule

	a	b	c	d	
a	2	-1 2	0		
b	-1 3	-	2	1	
c	2	-2 2	-	1	
d	0	1	-1 4		

(a)

Sequence:	*adabdacd*	Score
Association rule:	*dadd*	4+2+1+4=11
Association rule:	*dadd*	4+2 -1+4= 9

(b)

which states that any subsequence of a frequent sequence must be also frequent. It starts with the set of frequent 1-sequences which are the frequent sequences of length 1 and uses this set to find the set of frequent 2-sequences, then the set of frequent 2-sequences is used to find the set of frequent 3-sequences, and so on, until no more longer frequent sequences can be found. As the number of frequent sequences can be extremely large for a cluster of protein sequences having length of hundreds of amino acids, we retain the frequent sequences that are not contained in longer ones and restrict the search for frequent sequences of length 5 to 10. The reduced set of frequent sequences is sufficient for deriving similarity statistics in homology since longer frequent sequences of length more than 10 usually have lower support and a number of short frequent sequences within the specified range of lengths that the longer ones contain as subsequences can still be reserved.

With the set of found frequent sequences, we generate sequence association rules as follows. For a given frequent sequence *X*, it can be divided into two disjoint subsequences *A* and *B* with their position information attached. For example, let *X* be '*abcde*', one of the possible divisions could be *A* = '*a_c_e*' and *B* = '*_b_d_*'. A sequence association rule is of the form $A \Rightarrow B$ where both *A* and *B* contain at least one amino acid. *A* is called the rule *antecedent* and *B* is called the rule *consequent*. A sequence association rule is *strong* if it has a confidence value above a given *minimum confidence*. The confidence of a rule $A \Rightarrow B$ with respect to protein cluster *C*, denoted by $\text{confidence}_C(A \Rightarrow B)$, is defined as:

$$\text{confidence}_C(A \Rightarrow B) = \frac{\text{support}_C(A \cup B)}{\text{support}_C(A)} \quad (1)$$

where denotes the supersequence that is properly divided into *A* and *B*. We generate all strong sequence association rules for each cluster of protein sequences.

Sequence Association Rule Matching

In order to determine the cluster membership of each protein, we need to propose a measure which estimates the possibility that the evolution of a protein follows a particular association rule. Here we propose a rule matching scheme which is analogous to local sequence alignment without gaps. Given a sequence *t* and a strong association rule *r*, we compute the alignment score between *t* and *r* according to a substitution matrix with the constraint that no gap is allowed and the rule *antecedent* cannot be substituted in order to detect most similarities. For example, suppose we use the substitution matrix as shown in Figure 5 (a). Let the sequence be *'adabdacd'* and the association rule be '*da_d'* ⇒ '_ _*d_*', there are two possible alignments as illustrated in Figure 5 (b) and the best alignment score without gaps is 11.

Assume that we obtain a set of strong association rules $\Re = \{r_1, r_2, \ldots, r_n\}$ from the procedure of sequence association rule generation, the probability that the evolution of a protein *t* follows a particular association rule r_i can be estimated by:

$$p(r_i \mid t) = \frac{w(r_i, t)}{\sum_{h=1}^{n} w(r_h, t)} \qquad (2)$$

where $w(r_i, t)$ is the alignment score between r_i and *t*. As such, we can use the probabilities:

$$\left(p(r_1 \mid t),\ p(r_2 \mid t), \ldots,\ p(r_n \mid t)\right)$$

as the feature values of protein *t*, and determine its cluster membership by using the Bayes classifier.

Cluster Membership Adapting by Using Bayes Classifier

The Bayes classifier is one of the most important techniques used in data mining for classification. It predicts the cluster membership probabilities based on statistical inference. Studies have shown that the Bayes classifier is comparable in performance with decision tree and neural network classifiers (Han & Kamber, 2001). Herein we propose to predict the cluster membership of each protein by using the Bayes classifier with association rules.

Let the initial clustering result consists of *k* clusters, denoted by $\Im = \{C_1, C_2, \ldots, C_k\}$, from which a set of *n* strong association rules is derived. The *a priori* probability $p(C_i)$ that a protein belongs to cluster C_i can be calculated by counting the ratio of C_i in size to the whole set of proteins. The condition probability $p(r_i \mid C_j)$ that a protein satisfies association rule r_i given that this protein is initially assigned to cluster C_j is estimated by the average probability $p(r_i \mid t)$ for any $t \in C_j$. The conditional probability $p(r_i \mid t)$ that the evolution of protein *t* follows association rule r_i is estimated by using Equation (2). We then use the naïve Bayes classifier to assign protein *t* to the most probable cluster C_{Bayes} given by:

$$C_{Bayes} = \arg\max_{C_j \in \Im} \left\{ \prod_{i=1}^{n} \left(p(r_i \mid C_j)\, p(r_i \mid t) \right) p(C_j) \right\} \qquad (3)$$

In theory, the naïve Bayes classifier makes classification with the minimum error rate.

EXPERIMENTAL RESULTS

We validate our method by using protein sequences selected from SCOP database (release 1.50, Murzin, Brenner, Hubbard, & Chothia, 1995; Lo Conte et al., 2002) which is a protein classification created manually. SCOP provides a hierarchy of known protein folds and their detailed structure information. We randomly select 1189 protein sequences from SCOP and these sequences compose 388 protein clusters according to manual annotations on structure domains. The mean length of these protein sequences is 188 amino acids. Our method is implemented in C++ programming language and the experiments are conducted on a personal computer with a 1.8 GHz CPU and 512 MB RAM.

Accuracy Measures

To define the accuracy measures of protein classification, some notations are first introduced. For every pair of protein sequences, the predicted classification and the annotated classification have four possible combinations. *TP* (true positive) is the number of pairs predicted in the same domain given that they are in the same SCOP domain, *TN* (true negative) is the number of pairs predicted with different domains given that they are in different SCOP domains, *FP* (false positive) is the number of different SCOP-domain pairs that are predicted in the same domain, and *FN* (false negative) is the number of SCOP-domain pairs that are predicted in different domains. Two accuracy measures, namely *sensitivity* (S_n) and *specificity* (S_p), are defined as follows:

$$S_n = \frac{TP}{TP + FN} \tag{4}$$

and

$$S_p = \frac{TP}{TP + FP} \tag{5}$$

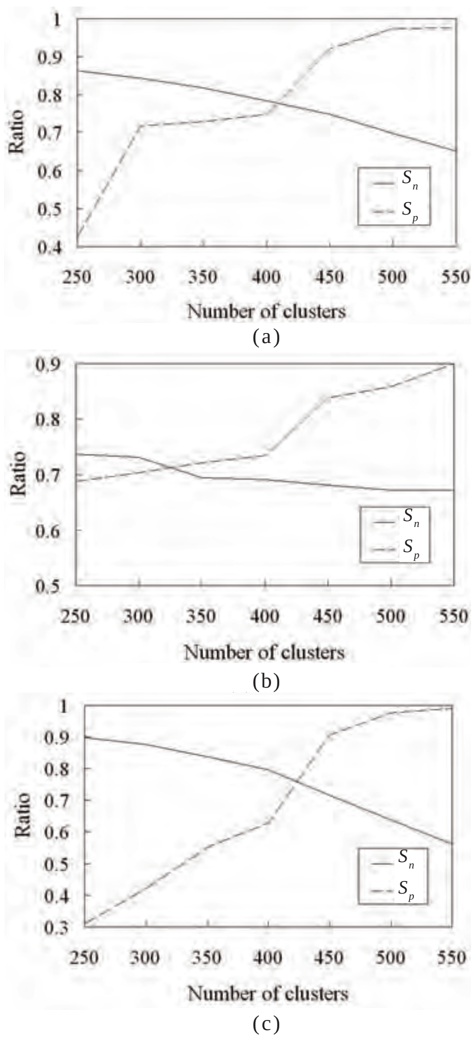
Sensitivity is the proportion of SCOP-domain pairs that have been correctly identified, and specificity is the proportion of pairs predicted in the same domain that are actually SCOP-domain pairs. Sensitivity and specificity cannot be used alone since perfect sensitivity can be obtained if all the pairs are predicted in the same domain, and specificity is not defined if all the pairs are predicted in different domains. To compare the performance between two competing methods, a sensitivity vs. specificity curve is usually used for evaluation. Or alternatively, the mean of sensitivity and specificity values can be used as a unified measure.

Performance Evaluation

We first evaluate the clustering performance using the traditional methods, in particular, we have implemented the hierarchical merging method (Sasson et al., 2002), the K-means algorithm (modified from Guralnik & Karypis, 2001, by changing the feature space to pair-wise E-value), and the graph-based clustering (Bolten et al., 2001). Various clustering thresholds are specified to obtain the performances at different specified numbers of clusters. Figures 6 (a) - 6 (c) show the variations of sensitivity and specificity as the number of clusters increases for hierarchical merging, K-means, and graph-based clustering, respectively. These curves are intuitive since the mean size of clusters is smaller if the partition with more clusters is obtained and, in general, the smaller the cluster-mean size is, the lower the sensitivity is, but the higher the specificity is. If we take the accuracy values obtained when the number of clusters is equal to the true number (388), the hierarchical merging method with S_n = 0.79 and S_p = 0.73 is superior to the K-means algorithm which produces S_n = 0.69 and S_p = 0.72, while the graph-based clustering has medium performance (S_n = 0.80 and S_p = 0.63).

Next we evaluate the improvement for clustering accuracy due to our Bayesian framework. From the clustering results obtained by traditional clustering methods, we apply the sequence association rule mining to generate strong association rules. Each protein sequence is matched with these rules and updates its cluster membership by using the Bayes classifier in order to improve the accuracy. Because the sensitivity values obtained by hierarchical merging, K-means, and graph-based clusterings with the true cluster number (388) are 0.79, 0.69, and 0.80, respectively, we compute the specificity improvement for these methods within a range of sensitivity close to these values. Figures 7 (a) - 7 (c) show the sensitivity vs. specificity curve for illustrating the improvement achieved. It is observed that the proposed refining process

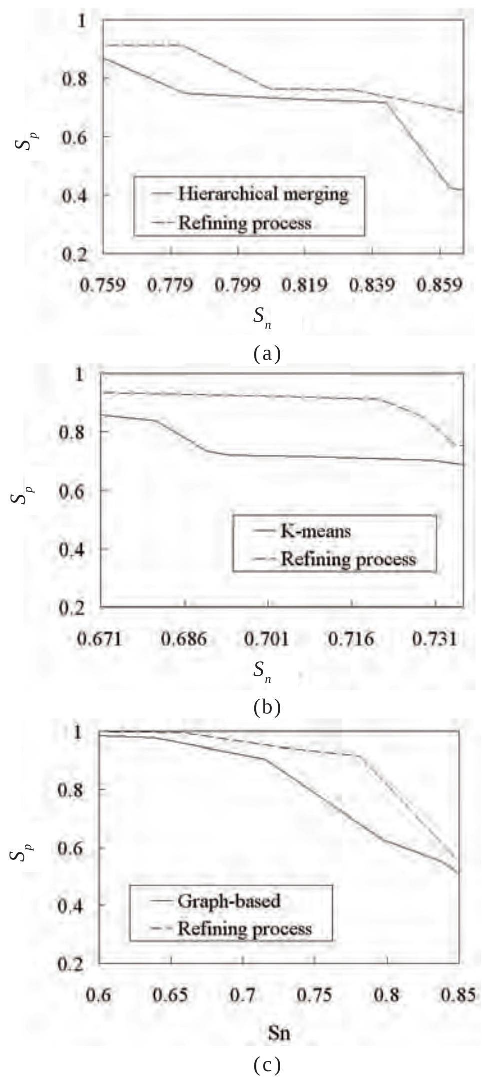
Figure 6. Performances of traditional clustering methods, (a) hierarchical merging clustering, (b) K-means clustering, (c) graph-based clustering



can significantly improve the specificity of the traditional methods. The average improvements in Sp are 0.09, 0.11, and 0.06 for hierarchical merging, K-means, and graph-based clustering, respectively. We also compute the accuracy improvement by using the unified measure of $(S_n + S_p)/2$ as shown in Figs. 8 (a) - 8 (c). The average improvements over various specified numbers of clusters are 0.03, 0.04, and 0.03 for hierarchical merging, K-means, and graph-based clustering, manifesting the robustness of the proposed framework.

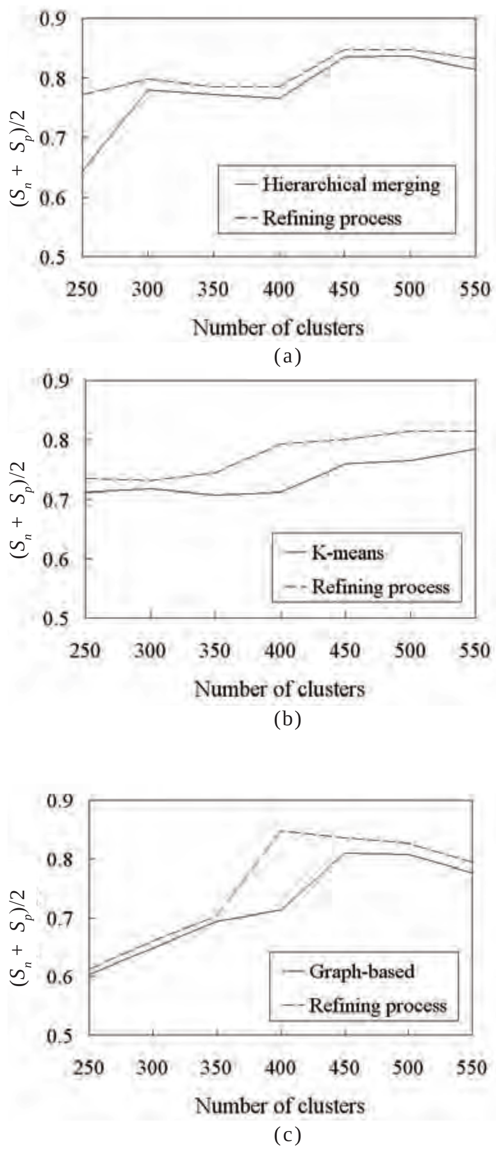
Table 1 shows the incurred computation time (in seconds) by each component of the proposed framework and the corresponding percentage to the whole for our collective database. We observe that the distance matrix computation using pairwise sequence alignment and the association rules generation using sequence Apriori algorithm are the most time-consuming components, and they

Figure 7. Performance improvement for specificity vs. sensitivity, (a) hierarchical merging clustering, (b) K-means clustering, (c) graph-based clustering



consume 35% and 33% of the total computation time, respectively. Further, the computation time for the refining process involving the last two components of Table 1 is about half of the whole time needed. That is, for our collective database, the proposed framework provides a considerable amount of accuracy improvement (as shown in Figures 7-8) for the traditional protein-clustering algorithms by doubling the computation time. In general cases, the time proportion for the refining process diminishes when the number of sequences in the database increases. Suppose there are m sequences in the database, and for simplicity, assume that their average length is r. The time complexity for calculating a distance matrix is $\Theta(m^2 r^2)$, for performing traditional clustering is $\Omega(m^2)$, and for generating the association rules of fixed length is $\Theta(mr)$. Rule matching and Bayesian classification depends on two factors: the number of features extracted and the number

Figure 8. Performance improvement for the unified measure, (a) hierarchical merging clustering, (b) K-means clustering, (c) graph-based clustering



of clusters classified (and remember that each rule is within a fixed length). The former can be regarded as a constant once the lengths of rules and the alphabet (which is 20 for amino acids) are fixed to constants. Therefore a rough calculation asserts that it takes $\Theta(mrc)$ where c is the number of clusters. As a summary, the time complexity for each component is $\Theta(m^2 r^2)$, $\Omega(m^2)$, $\Theta(mr)$, and $\Theta(mrc)$, respectively. Parameter r, the average length of peptide sequences, is around 300 and can be regarded as a constant. Parameter c grows mildly as the number of sequences increases. As a result, when the number of sequences in a database grows larger, the percentage of the computing time on the refining process becomes smaller.

Table 1. The computation time used by each component of the proposed method

	CPU Time (second)	Percentage
Distance Matrix Computation	162	35%
Traditional Clustering	6 4	14%
Association Rules Generation	157	33%
Rule Matching and Bayesian Classification	8 7	18%

SUMMARY

Protein sequence clustering is useful for structural, functional, and phylogenetic analyses. As the rapid growth in the number of sequenced proteins prohibits the analysis using multiple sequences alignment, most of the traditional protein-clustering methods derive the similarity among sequences from pairwise sequence alignment. In this chapter, we have proposed a Bayesian framework based on association rule mining for improving the clustering accuracy using existing methods. A selective dataset from SCOP has been experimented and the result manifests that the proposed framework is feasible. The main features of the proposed framework include:

- The proposed framework improves the accuracy of a given initial clustering result which can be provided by any clustering methods. Therefore, the user is still able to choose a particular clustering method which is suited to his/her own analysis of the final result.
- From the initial clustering result, the sequence association rules among amino acids are mined. These rules represent important relationships for the sequences belonging to the same cluster.
- The association rules serve as features for classification of proteins. Using Bayes classifier, the classification error can be minimized based on statistical inference.

Future research is encouraged in expediting the computation for distance matrix and association rule generation in order to extend the application of the proposed framework to large protein databases such as SWISSPROT.

Chapter 7.30
Retrieving Medical Records Using Bayesian Networks

Luis M. de Campos

INTRODUCTION

Bayesian networks (Jensen, 2001) are powerful tools for dealing with uncertainty. They have been successfully applied in a wide range of domains where this property is an important feature, as in the case of information retrieval (IR) (Turtle & Croft, 1991). This field (Baeza-Yates & Ribeiro-Neto, 1999) is concerned with the representation, storage, organization, and accessing of information items (the textual representation of any kind of object). Uncertainty is also present in this field, and, consequently, several approaches based on these probabilistic graphical models have been designed in an attempt to represent documents and their contents (expressed by means of indexed terms), and the relationships between them, so as to retrieve as many relevant documents as possible, given a query submitted by a user.

Classic IR has evolved from flat documents (i.e., texts that do not have any kind of structure relating their contents) with all the indexing terms directly assigned to the document itself toward structured information retrieval (SIR) (Chiaramella, 2001), where the structure or the hierarchy of contents of a document is taken into account. For instance, a book can be divided into chapters, each chapter into sections, each section into paragraphs, and so on. Terms could be assigned to any of the parts where they occur. New standards, such as SGML or XML, have been developed to represent this type of document. Bayesian network models also have been extended to deal with this new kind of document.

In this article, a structured information retrieval application in the domain of a pathological anatomy service is presented. All the medical records that this service stores are represented in XML, and our contribution involves retrieving records that are relevant for a given query that could be formulated by a Boolean expression on some fields, as well as using a text-free query on other different fields. The search engine that answers this second type of query is based on Bayesian networks.

BACKGROUND

Probabilistic retrieval models (Crestani et al., 1998) were designed in the early stages of this discipline to retrieve those documents relevant to a given query, computing the probability of relevance. The development of Bayesian networks and their successful application to real problems has caused several researchers in the field of IR to focus their attention on them as an evolution of probabilistic models. They realized that this kind of network model could be suitable for use in IR, specially designed to perform extremely well in environments where uncertainty is a very important feature, as is the case of IR, and also because they can properly represent the relationships between variables.

Bayesian networks are graphical models that are capable of representing and efficiently manipulating n-dimensional probability distributions. They use two components to codify qualitative and quantitative knowledge, respectively: first, a directed acyclic graph (DAG), G=(V,E), where the nodes in V represent the random variables from the problem we want to solve, and set E contains the arcs that join the nodes. The topology of the graph (the arcs in E) encodes conditional (in)dependence relationships between the variables (by means of the presence or absence of direct connections between pairs of variables); and second, a set of conditional distributions drawn from the graph structure. For each variable $X_i \in V$, we therefore have a family of conditional probability distributions $P(X_i \mid pa(X_i))$, where $pa(X_i)$ represents any combination of the values of the variables in $Pa(X_i)$, and $Pa(X_i)$ is the parent set of X_i in G. From these conditional distributions, we can recover the joint distribution over V.

This decomposition of the joint distribution gives rise to important savings in storage requirements. In many cases, it also enables probabilistic inference (propagation) to be performed efficiently (i.e., to compute the posterior probability for any variable, given some evidence about the values of other variables in the graph).

$$P(X_1, X_2, \ldots, X_n) = \prod_{i=1}^{n} P(X_i \mid pa(X_i))$$

The first complete IR model based on Bayesian networks was the Inference Network Model (Turtle & Croft, 1991). Subsequently, two new models were developed: the Belief Network Model (Calado et al., 2001; Reis, 2000) and the Bayesian Network Retrieval Model (de Campos et al., 2003, 2003b, 2003c, 2003d). Of course, not only have complete models been developed in the IR context, but also solutions to specific problems (Dumais, et al., 1998; Tsikrika & Lalmas, 2002; Wong & Butz, 2000).

Structural document representation requires IR to design and implement new models and tools to index, retrieve, and present documents according to the given document structure. Models such as the previously mentioned Bayesian Network Retrieval Model have been adapted to cope with this new context (Crestani et al., 2003, 2003b), and others have been developed from scratch (Graves & Lalmas, 2002; Ludovic & Gallinari, 2003; Myaeng et al., 1998).

MAIN THRUST

The main purpose of this article is to present the guidelines for construction and use of a Bayesian-network-based information retrieval system. The source document collection is a set of medical records about patients and their medical tests stored in an XML database from a pathological anatomy service. By using XML tags, the information can be organized around a well-defined structure. Our hypothesis is that by using this structure, we will obtain retrieval results that better match the physicians' needs. Focusing on the structure of the documents, data are distributed between two different types of tags: on the one hand, we could consider fixed domain tags (i.e., those attributes from the medical record with a set of well-defined values, such as sex, birthdate, address, etc.); and on the other hand, free text passages are used by the physicians to write comments and descriptions about their particular perceptions of the tests that have been performed on the patients, as well as any conclusions that can be drawn from the results. In this case, there is no restriction on the information that can be stored. Three different free-text passages are considered, representing a description of the microscopic analysis, the macroscopic analysis, and the final diagnostic, respectively.

Physicians must be able to use queries that combine both fixed and free-text elements. For example, they might be interested in all documents concerning males who are suspected of having a malignant tumor. In order to tackle this problem, we propose a two-step process. First, a Boolean retrieval task is carried out in order to identify those records in the dataset, mapping the requirements of the fixed domain elements. The query is formulated by means of the XPath language. These records are then the inputs of a Bayesian retrieval process in the second stage, where they are sorted in decreasing order of their posterior probability of relevance to the query as the final output of the process.

The Bayesian Network Model

Since, for those attributes related to fixed domains, it is sufficient to consider a Boolean retrieval, the Bayesian model will be used to represent both the structural and the content information related to free-text passages. In order to specify the topology of the model (a directed acyclic graph, representing dependence relationships), we need to determine which information components (variables) will be considered as relevant. In our case, we can distinguish between two different types of variables: the set that contains those terms used to index the free-text passages, $T = \{T_1,\ldots,T_M\}$, with M being the total number of index terms used; and set D, representing the documents (medical records) in the collection. In this case, we consider as relevant variables the whole document D_k and also the three subordinate documents that comprise it: macroscopic description, D_{mk}; microscopic description, $D_{\mu k}$; and final diagnostic, D_{fk} (generically, any of these will be represented by $D_{\bullet k}$). Therefore,

$$D = \{D_1, D_{m1}, D_{\mu 1}, D_{f1},\ldots,D_N, D_{mN}, D_{\mu N}, D_{fN}\},$$

with N being the number of documents that comprise the collection[1].

Each term variable, T_i, is a binary random variable taking values in the set $\{\bar{t}_i, t_i\}$, where $\bar{t}_i$ stands for the term T_i is not relevant, and t_i represents the term T_i is relevant. The domain of each document variable, D_j, is the set $\{\bar{d}_j, d_j\}$, where, in this case, $\bar{d}_j$ and d_j mean the document D_j is not relevant for a given query, and the document D_j is relevant for the given query, respectively. A similar reasoning can be stated for any subordinate document, $D_{\bullet j}$.

In order to specify completely the model topology, we need to include those links representing the dependence relationships between variables. We can distinguish two types of nodes. The first type links between each term node $T_i \in T$ and each subordinate document node $D_{\bullet j} \in D$, whenever T_i belongs to $D_{\bullet j}$. These links reflect the dependence between the (ir)relevance values of this document and the terms used to index it and will be directed from terms to documents. Therefore, the parent set of a document node $D_{\bullet j}$ is the set of term nodes that belong $D_{\bullet j}$ to (i.e., $Pa(D_{\bullet j}) = \{T_i \in T \mid T_i \in D_{\bullet j}\}$).

The second type links by connecting each subordinate document $D_{\bullet j}$ with the node document D_j to which it belongs, reflecting the fact that the relevance of a document to a query will depend only on the relevance values of its subordinate documents. These links will be directed from subordinate to document nodes.

It should be noted that we do not use links between terms and documents, because we consider these to be independent, given that we know the relevance value of the subordinate documents. Consequently, we have designed a layered topology for our model that also represents the structural information of the medical records. Figure 1 displays the graph associated with the Bayesian network model.

Probability Distributions

The following step to complete the design of the model is the estimation of the quantitative components of the Bayesian network (i.e., the probability distributions stored in each node). For term nodes, and taking into account that all terms are root nodes, marginal distributions need to be stored. The following estimator is used for every term T_i: $p(t_i) = (1/M)$ and $p(\bar{t}_i) = (M-1)/M$. Therefore, the prior probability of relevance of any term is very small and inversely proportional to the size of the index.

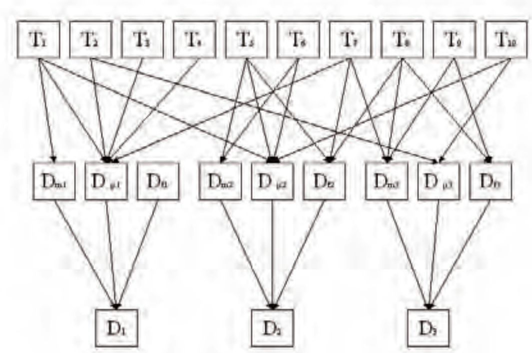
Considering now document and subordinate document nodes, it is necessary to assess a set of conditional probability distributions, the size of which grows exponentially with the number of parents. We therefore propose using a canonical model that represents the particular influence of each parent in the relevance of the node. In particular, given a variable X_j (representing a document or a subordinate document node), the probability of relevance given a particular configuration of the parent set $pa(X_j)$ is computed by means of

$$p(x_j \mid pa(X_j)) = \sum_{i \in pa(X_j)} w_{ij},$$

where the expression $i \in pa(X_j)$ means that only those weights where the value assigned to the ith parent of X_j in the configuration $pa(X_j)$ is relevant will be included in the sum. Therefore, the greater the number of relevant variables in $pa(X_j)$, the greater the probability of relevance of X_j.

The particular values of the weights w_{ij} are first, for a subordinate document, $D_{\bullet j}$, $w_{ij} = (tf_{ij} idf_i^2)/(\sum_{T_k \in Pa(D_{\bullet j})} tf_{kj} idf_k^2)$, with tf_{ij} being the frequency of the term ith in the subordinate document and idf_i the inverse document frequency of the term T_i in the whole collection; and second, for a document node, D_j, we use three factors $\alpha = w_{mj,j}$, $\beta = w_{\mu j,j}$ and $\delta = w_{fj,j}$, representing the influence of the macroscopic description, microscopic

Figure 1. Topology of the Bayesian information retrieval model



description, and final diagnosis, respectively. These values can be assigned by the physicians with the restriction that the sum $\alpha + \beta + \delta$ must be 1. This means, for example, that we can choose $\alpha = \beta = \delta = 1/3$, so we decide that every subordinate document has the same influence when calculating the probability of relevance for a document in general. Another example is to choose $\alpha = \beta = 1/4$ and $\delta = 1/2$, if we want the final diagnosis to obtain a higher influence by the calculation of the probability of relevance for a document in general.

Inference and Retrieval

Given a query Q submitted to our system, the retrieval process starts by placing the evidences in the term *subnetwork*—the state of each term T_{iQ} belonging to Q is fixed to t_{iQ} (relevant). The inference process is then run, obtaining, for each document D_j, its probability of relevance, given that the terms in the query are also relevant, $p(d_j \mid Q)$. Finally, documents are sorted in decreasing order of probability and returned to the user.

We should mention the fact that the Bayesian network contains thousand of nodes, many of which have a great number of parents. In addition, although the network topology is relatively simple, it contains cycles. Therefore, general-purpose propagation algorithms cannot be applied for reasons of efficiency. We therefore propose the use of a specific inference process (de Campos et al., 2003), which is designed to take advantage of both the topology of the network and the kind of probability function used at document nodes, but ensuring that the results are the same as those obtained using exact propagation in the entire network. The final probability of relevance for a document, therefore, is computed using the following equations:

$$p(d_k \mid Q) = \alpha \cdot p(d_{mk} \mid Q) + \beta \cdot p(d_{\mu k} \mid Q) + \delta \cdot p(d_{fk} \mid Q)$$

where $p(d_{\bullet k} \mid Q)$ can be computed as follows:

$$p(d_{\bullet j} \mid Q) = \sum_{T_i \in D_{\bullet j} \cap Q} w_{ij} + (1/M) \sum_{T_i \in D_{\bullet j} \setminus Q} w_{ij} = (1/\mathrm{M}) \sum_{T_i \in D_{\bullet j}} w_{ij} + (M-1)/M \sum_{T_i \in D_{\bullet j} \cap Q} w_{ij}$$

FUTURE TRENDS

Because of the excellent features offered by Bayesian networks for representing relationships between variables and their strengths, as well as their efficient inference mechanisms, these probabilistic models will be used in many different areas of IR.

Following the subject of this article (i.e., dealing with structured documents), one interesting line of research would be the introduction of decisions in the inference process. Instead of returning a ranking of documents, it might be very useful to give the user only those parts of the document that might be relevant, instead of the whole document. A first attempt has been made by de Campos, et al. (2004) using influence diagrams. This field is relatively new and is an open and promising research line. On the grounds of the basic methodology proposed in this article, an intuitive step in this line of work would be to open the field of research to the area of recommendation systems, where Bayesian networks also can perform well.

The Web is also a challenging context. As well as the large number of existing Web pages, we must consider the hyperlinks between these. A good treatment of these links by means of a suitable representation through arcs in a Bayesian network and by means of the conditioned probability distributions, which should include the positive or negative influences regarding the relevance of the Web page that is pointed to, should help improve retrieval effectiveness. Finally, another interesting point would be not to consider index terms independent among them, but to take into account relationships, captured by means of data mining techniques with Bayesian networks.

CONCLUSION

In this article, we have presented a retrieval model to deal with medical records from a pathological anatomy service represented in XML. The retrieval model operates in two stages, given a query: the first one employs an XPath query to retrieve XML documents, and the second, using Bayesian networks, computes a probability of relevance using IR techniques on the free text tags from records obtained in the previous step. This model ensures not only an accurate representation of the structure of the record collection, but also a fast mechanism to retrieve relevant records given a query.

KEY TERMS

Bayesian Network: A directed acyclic graph where the nodes represent random variables and arcs represent the relationships between them. Their strength is represented by means of conditional probability distributions stored in the nodes.

Information Retrieval: A research field that deals with the representation, storage, organization, and accessing of information items.

Probability Distribution: A function that assigns a probability to each value that a random variable can take, fulfilling the Kolmogorov's axioms.

Recommendation System: Software that, given preferences expresses by a user, select those choices, from a range of them, that better satisfy these user's preferences.

Structured Document: A textual representation of any object, whose content could be organized around a well-defined structure.

XML: Acronym for Extensible Markup Language. A meta-language directly derived from SGML but designed for Web documents. It allows the structuring of information and transmission between applications and between organizations.

XPath: A language designed to access the different elements of an XML document.

ENDNOTE

[1] The notation T_i (D_j, respectively) refers to both the term (document, respectively) and its associated variable and node.

Chapter 7.31
Bayesian Network Approach to Estimate Gene Networks

Seiya Imoto
University of Tokyo, Japan

Satoru Miyano
University of Tokyo, Japan

ABSTRACT

In cells, genes interact with each other and this system can be viewed as directed graphs. A gene network is a graphical representation of transcriptional relations between genes and the problem of estimation of gene networks from genome-wide data, such as DNA microarray gene expression data, is one of the important issues in bioinformatics and systems biology. Here, we present a statistical method based on Bayesian networks to estimate gene networks from microarray data and other biological data. Because microarray data are measured as continuous variables and the relationship between genes are usually nonlinear, we combine Bayesian networks and nonparametric regression to handle continuous variables and nonlinear relations. Most parts of gene networks are still unknown, and we need to estimate them from observational data. This problem is equivalent to the structural learning of Bayesian networks, and we solve it from a Bayes approach. The main difficulty of gene network estimation is due to the number of genes involved in the network. Therefore, it leads to model overfitting to the observational data like microarray data. Hence, a combination of various kinds of biological data is a key technique to estimate accurate gene networks. We show a general framework to combine microarray data and other biological information to estimate gene networks.

INTRODUCTION

The microarray technology has produced a huge amount of gene expression data under various conditions such as gene knock-down, overexpression, experimental stressors, transformation, exposure to a chemical compound, and so forth. Along with this new data production, there have been considerable attempts to infer gene networks from such gene expression profile data, and several computational methods have been proposed together with gene network models such as Boolean networks, differential equation models, and Bayesian networks.

A Bayesian network is an effective method in modeling phenomena through the joint distribution of a large number of random variables. In recent years, some interesting works have been established in constructing gene networks from microarray gene expression data by using Bayesian networks. Friedman and Goldszmidt (1998) discretized the expression values and assumed multinomial distributions as the candidate statistical models. Pe'er, Regev, Elidan, and Friedman (2001) investigated the threshold value for discretizing. On the other hand, Friedman, Linial, Nachman, and Pe'er (2000) pointed out that the discretizing probably loses information of the data. In addition, the number of discretizing values and the thresholds are unknown parameters, which have to be estimated from the data. The resulted network strongly depends on their values. Then Friedman et al. (2000) considered fitting linear regression models, which analyze the data in the continuous variables (see also Heckerman & Geiger, 1995). However, the assumption that the parent genes depend linearly on the objective gene is not always guaranteed. Imoto et al. (2002) proposed the use of nonparametric additive regression models (see also Green & Silvermn, 1994; Hastie & Tibshirani, 1990) for capturing not only linear dependencies but also nonlinear structures between genes. In this chapter, we introduce a method for constructing the gene network by using Bayesian networks and the nonparametric regression, which is more suitable for estimating gene networks from microarray gene expression data than discrete type Bayesian networks.

Once we set the graph, we have to evaluate its goodness or closeness to the true graph, which is usually unknown. Hence, the construction of a suitable criterion becomes the center of attention of statistical genetic network modeling. Friedman and Goldszmidt (1998), used the BDe criterion, which was originally derived by Cooper and Herskovits (1992) for choosing a graph (see also Heckerman, Geiger, & Chickering, 1995). The BDe criterion only evaluates the Bayesian network model based on the multinomial distributions and Dirichlet priors. However, Friedman and Goldszmidt (1998) kept the unknown hyperparameters in Dirichlet priors and we only set up the values experimentally. We investigate the graph selection problem as a statistical model selection or evaluation problem and theoretically derive a new criterion for choosing a graph using the Bayes approach (see Berger, 1985). The proposed criterion automatically optimizes all parameters in the model and gives the optimal graph when we can score all candidate graphs.

The problem of finding an optimal Bayesian network is known to be NP-hard. The brute force method employing all computing resources in the world would even require time exceeding the lifetime of the solar system for finding an optimal Bayesian network of 30 genes from 100 microarray datasets. Our approach has made it possible to find optimal and near optimal Bayesian networks with respect to the score of the network in a reasonable time and has provided an evidence of the biological rationality in this computational approach (Ott & Miyano, 2003; Ott, Imoto, & Miyano, 2004; Ott, Hansen, Kim, & Miyano, 2005). For larger networks, we carefully employ the greedy hill-climbing algorithm for finding better gene networks.

The main drawback for the gene network construction from microarray data is that, while the gene network contains a large number of genes, the information contained in gene expression data is limited by the number of microarrays, their quality, the experimental design, noise, and measurement errors. Therefore, estimated gene networks contain some incorrect gene regulations, which cannot be evaluated from a biological viewpoint. In particular, it is difficult to determine the direction of gene regulation using gene expression data only. Hence, the use of biological knowledge, including protein-protein and protein-DNA interactions (Bader, Donaldson, Wolting, Ouellette, Pawson, & Hogue, 2001; Ideker, Ozier, Schwikowski, & Siegel, 2002; Ito, Chiba, Ozawa, Yoshida, Hattori, & Sakaki, 2001) sequences of the binding site of the genes controlled by transcription regulators (Lee, Rinaldi, Robert, Odom, Bar-Joseph, Gerber et al., 2002), literature, and so forth, are considered to be a key for microarray data analysis. The use of biological knowledge has previously received considerable attention for extracting more information from microarray data (Bannai, Inenaga, Shinohara, Takeda, & Miyano, 2002; Bussemaker, Li, & Siggia, 2001; Hartemink, Gifford, Jaakkola, & Young, 2002; Masys, 2001; Ong, Glasner, & Page, 2002; Pilpel, Sudarsanam, & Church, 2001; Segal, Barash, Simon, Friedman, & Koller, 2002; Segal et al., 2003a, Segal et al., 2003b). In this chapter, we also provide a general framework for combining microarray data and biological knowledge aimed at estimating a gene network by using a Bayesian network model.

We show the effectiveness of our approach by the analysis of *Saccharomyces cerevisiae* gene expression data obtained by singly disrupting 100 genes, which are almost all transcription factors together with binding site information. We also apply the method to the estimation of human endothelial cell gene networks by using 270 novel gene knock-downs and time-course of gene expression following treatment with the drug fenofibrate.

MODELING OF GENE NETWORKS

In gene network estimation, we regard a gene as a random variable representing the abundance of a specific RNA species, shown as a node in a graph, and the interaction between genes is represented by the direct edge between nodes. In this section, we show our basic model for constructing gene networks from microarray gene expression data. More precisely, we introduce a combination of Bayesian network and nonparametric regression to model gene networks.

Bayesian Networks with Continuous Variables

Suppose that $\{X_1, ..., X_p\}$ is the set of p random variables, and that the dependency among these p random variables is shown as a directed graph G. When the random variables X_j take discrete values, we can decompose the joint probability of $\{X_1, ..., X_p\}$ into the product of conditional probabilities as:

$$\Pr(X_1, ..., X_p) = \prod_{j=1}^{p} \Pr(X_j \mid Pa(X_j)) \qquad (1)$$

where $Pa(X_j)$ is the set of random variables corresponding to the direct parents of X_j in G. Because gene expression data take continuous variables, some discretization methods are required for using the Bayesian networks based on the discrete random variables described above. However, the discretization lead to information loss, and the number of categories and the threshold values are parameters to be optimized. To avoid the discretization, we rewrite the decomposition of joint probability given in (1) by using densities.

Suppose that we have the observational data $\boldsymbol{X} = (\boldsymbol{x}_1, ..., \boldsymbol{x}_n)'$ of the set of p random variables $\{X_1, ..., X_p\}$, where $\boldsymbol{x}_i = (x_{i1}, ..., x_{ip})'$ and x_{ij} is the gene expression value of jth gene from ith microarray. That is, we measure p genes' expression values by n microarrays. We then rewrite the decomposition (1) by:

$$f(\boldsymbol{X} \mid \boldsymbol{\Theta}, G) = \prod_{i=1}^{n}\prod_{j=1}^{p} f_j(x_{ij} \mid \boldsymbol{pa}_{ij}, \boldsymbol{\theta}_j) \qquad (2)$$

where $\boldsymbol{\Theta} = (\boldsymbol{\theta}'_1, ..., \boldsymbol{\theta}'_p)'$ is a parameter vector, and $\boldsymbol{pa}_{ij}$ is the expression value vector of $Pa(X_j)$ measured by ith microarray. Hence, the construction of the graph G is equivalent to model the conditional probabilities f_j ($j = 1, ..., p$), that is essentially the same as the regression problem. A possible and simple solution of the construction of conditional density is given by using the linear regression as:

$$x_{ij} = \beta_0 + \beta_1 p_{i,1}^{(j)} + \cdots + \beta_{q_j} p_{i,q_j}^{(j)} + \varepsilon_{ij}$$

where β_j (j=1, ..., q_j) are parameters, ε_{ij} (i = 1, ..., n) are independently and normally distributed with mean 0 and variance σ^2_j, and $\boldsymbol{pa}_{ij} = (p_{i,1}^{(j)}, ..., p_{i,q_j}^{(j)})'$ with $q_j = |Pa(X_j)|$. This model assumes the relationships between genes are linear, and it is unsuitable to extract effective information from the data with complex structure. Also, the assumption that the parent genes depend linearly on the objective gene is not always guaranteed. To capture even nonlinear dependencies, (Imoto, Goto, & Miyano, 2002) proposed the use of the nonparametric additive regression model (Hastie & Tibshirani, 1990) of the form:

$$x_{ij} = m_{j1}(p_{i,1}^{(j)}) + \cdots + m_{jq_j}(p_{i,q_j}^{(j)}) + \varepsilon_{ij} \qquad (3)$$

where m_{jk} $(\cdot)$(k = 1, ..., q_j) are smooth functions from $\Re$ to $\Re$. We construct m_{jk} $(\cdot)$ by the basis function expansion method with B-splines (De Boor, 1978; Imoto et al., 2003):

$$m_{jk}(p) = \sum_{s=1}^{M_{jk}} \gamma_{sk}^{(j)} b_{sk}^{(j)}(p)$$

where $\gamma_{sk}^{(j)}$ (s = 1, ..., M_{jk}) are parameters, $\{b_{1k}^{(j)}(\cdot), ..., b_{M_{jk}k}^{(j)}(\cdot)\}$ is the prescribed set of B-splines, and M_{jk} is the number of B-splines. We then have the Bayesian network and nonparametric regression model:

$$f_j(x_{ij} \mid \boldsymbol{pa}_{ij}, \boldsymbol{\theta}_j) = \frac{1}{\sqrt{2\pi\sigma_j^2}} \exp\left[-\frac{\{x_{ij} - \sum_k \sum_s \gamma_{sk}^{(j)} b_{sk}^{(j)}(p_{ik}^{(j)})\}^2}{2\sigma_j^2}\right]$$

Note that the Bayesian network model based on the linear regression is included in this model as a special case. To extend from the additive regression model to a general regression, (Imoto, Higuchi, Kim, Jeong, & Miyano, 2005) proposed a Bayesian network with moving boxcel median filtering to capture such interactions.

Information Criterion for Structural Learning

Once we set a graph, the statistical model based on the Bayesian network and nonparametric regression can be constructed and estimated by a suitable procedure. However, the problem that still remains to be solved is how we can choose the optimal graph which gives a best approximation of the system underlying the data. Notice that we cannot use the likelihood function as a model selection criterion, because the value of likelihood becomes large in a more complicated model. Hence, we need to consider the statistical approach based on the generalized or predictive error, Kullback-Leibler information, Bayes approach, and so forth (see e.g., Akaike, 1973; Burnham & Anderson 1998; Konishi, 1996; Konishi & Kitagawa, 1996, for the statistical model selection problem). In this section, we construct a criterion for evaluating a graph based on our model from Bayes approach.

The posterior probability of the graph $p(G \mid \boldsymbol{X})$ is given by:

$$p(G|\boldsymbol{X}) = \frac{p(G)\,p(\boldsymbol{X}|G)}{p(\boldsymbol{X})} \propto p(G)\,p(\boldsymbol{X}|G)$$

where $p(G)$ is the prior probability of the graph, $p(\boldsymbol{X} \mid G)$ is the likelihood of the data $\boldsymbol{X}$ conditional on G, and $p(\boldsymbol{X})$ is the normalizing constant and does not depend on the selection of G. The likelihood $p(\boldsymbol{X} \mid G)$ is computed by the marginization:

$$p(\boldsymbol{X} \mid G) = \int f(\boldsymbol{X} \mid \boldsymbol{\Theta}, G)\, p(\boldsymbol{\Theta} \mid \boldsymbol{\lambda}, G)\, d\boldsymbol{\Theta} \qquad (4)$$

where $p(\boldsymbol{\Theta} \mid \boldsymbol{\lambda}, G)$ is the prior distribution on the parameter $\boldsymbol{\Theta}$ specified by the hyperparameter $\boldsymbol{\lambda}$. We now suppose the decomposition:

$$p(\boldsymbol{\Theta} \mid \boldsymbol{\lambda}, G) \prod_{j=1}^{p} p_j(\boldsymbol{\theta}_j \mid \boldsymbol{\lambda}_j)$$

We also assume that the prior distribution on the parameter vector $\boldsymbol{\theta}_j$ is decomposed as:

$$p_j(\boldsymbol{\theta}_j \mid \boldsymbol{\lambda}_j) = \prod_{k=1}^{q_j} p_{jk}\,(\boldsymbol{\gamma}_{jk} \mid \lambda_{jk})$$

with $\boldsymbol{\gamma}_{jk} = (\gamma^{(j)}_{1k}, ..., \gamma^{(j)}_{M_{jk}k})'$. Each prior distribution $p_{jk}\,(\boldsymbol{\gamma}_{jk} \mid \lambda_{jk})$ is a singular M_{jk} variate normal distribution given by:

$$p_{jk}(\boldsymbol{\gamma}_{jk} | \lambda_{jk}) = \left(\frac{2\pi}{n\lambda_{jk}}\right)^{-(M_{jk}-2)/2} \left|K_{jk}\right|_+^{1/2} \exp\left(-\frac{n\lambda_{jk}}{2}\,\boldsymbol{\gamma}'_{jk} K_{jk}\,\boldsymbol{\gamma}_{jk}\right) \qquad (5)$$

where λ_{jk} is a hyper parameter, K_{jk} is an $M_{jk} \times M_{jk}$ matrix that holds:

$$\boldsymbol{\gamma}'_{jk} \boldsymbol{K}_{jk}\, \boldsymbol{\gamma}_{jk} = \sum_{l=3}^{M_{jk}} (\gamma^{(j)}_{lk} - 2\gamma^{(j)}_{l-1k} + 2\gamma^{(j)}_{l-2k})^2$$

and $|K_{jk}|_+$ is the product of $M_{jk} - 2$ nonzero eigenvalues of K_{jk}. Under the decomposition of the prior of parameters $p(\boldsymbol{\Theta} \mid \boldsymbol{\lambda}, G)$ and the decomposition of the joint density by the Bayesian network given in (2), the marginal likelihood (4) can be rewritten as:

$$p(\boldsymbol{X} \mid G) = \int f\,(\boldsymbol{X} \mid \boldsymbol{\Theta}, G)\,p(\boldsymbol{\Theta} \mid \boldsymbol{\lambda}, G)\,d\boldsymbol{\Theta} = \prod_{j=1}^{p}\left\{\prod_{i=1}^{n} f_j(x_{ij} \mid \boldsymbol{pa}_{ij}, \boldsymbol{\theta}_j)\, p_j(\boldsymbol{\theta}_j \mid \boldsymbol{\lambda}_j)\,d\boldsymbol{\theta}_j\right\}$$

$$\equiv \prod_{j=1}^{p} p_j(\text{sub}.G_j \mid \boldsymbol{X}),$$

where sub.G_j is a subgraph of G consisting of jth gene and its direct parents as the node and edges from these parents to jth gene.

The high-dimensional integral in $p_j(\text{sub}.G_j \mid \boldsymbol{X})$ can be asymptotically approximated with an analytical form by the Laplace approximation:

$$p_j(\text{sub.G}_j \mid \boldsymbol{X}) = \int \exp\{n l_\lambda\,(\boldsymbol{\theta}_j \mid \boldsymbol{X})\}\,d\boldsymbol{\theta}_j$$
$$= \frac{(2\pi/n)^{r_j/2}}{\left|J_\lambda(\hat{\boldsymbol{\theta}}_j)\right|^{1/2}} \exp\{n l_\lambda(\hat{\boldsymbol{\theta}}_j | X)\}\{1 + O_p(n^{-1})\} \qquad (6)$$

where r_j is the dimension of $\boldsymbol{\theta}_j$,

$$l_\lambda(\boldsymbol{\theta}_j \mid \boldsymbol{X}) = \frac{1}{n}\sum_{i=1}^{n} \log f_j(x_{ij} \mid \boldsymbol{pa}_{ij}, \boldsymbol{\theta}_j) + \frac{1}{n}\log p_j(\boldsymbol{\theta}_j \mid \boldsymbol{\lambda}_j),$$

$$J_\lambda(\boldsymbol{\theta}_j) = -\frac{\partial l_\lambda(\boldsymbol{\theta}_j | \boldsymbol{X})}{\partial \boldsymbol{\theta}_j\,\partial \boldsymbol{\theta}'_j}$$

and $\hat{\theta}_j$ is the mode of $l_\lambda(\boldsymbol{\theta}_j | \boldsymbol{X})$. We also decompose the prior probability of the graph $p(G)$ as $\prod_j p(\text{sub}.G_j)$. By taking minus twice logarithm of $p(\text{sub}.G_j) \times (6)$, we then define:

$$\textbf{BNRC}_j = -2\log p(\text{sub}.G_j) - r_j \log(2\pi/n) + \log|J_\lambda(\hat{\theta}_j)| - 2n l_\lambda(\hat{\theta}_j \mid \boldsymbol{X})$$
$$= 2(q_j - 1) - \left(\sum_{k=1}^{q_j} M_{jk} + 1\right)\log\left(\frac{2\pi}{n}\right) + n\log(2\pi\hat{\sigma}_j^2) + n$$
$$+ \sum_{k=1}^{q_j}\{\log|\boldsymbol{\Lambda}_{jk}| - M_{jk}\log(n\hat{\sigma}_j^2)\} - \log(2\hat{\sigma}_j^2)$$
$$+ \sum_{k=1}^{q_j}\left\{(M_{jk} - 2)\log\left(\frac{2\pi\hat{\sigma}_j^2}{n\beta_{jk}}\right) - \log|K_{jk}| + \frac{n\beta_{jk}}{\hat{\sigma}_j^2}\hat{\boldsymbol{\gamma}}'_{jk} K_{jk}\hat{\boldsymbol{\gamma}}_{jk}\right\}$$

with

$$\boldsymbol{\Lambda}_{jk} = \boldsymbol{B}'_{jk}\boldsymbol{B}_{jk} + n\beta_{jk}\boldsymbol{K}_{jk}, \quad \beta_{jk} = \hat{\sigma}_j^2\lambda_{jk},$$
$$\boldsymbol{B}_{jk} = (\boldsymbol{b}_{jk}(p^{(j)}_{1k}), ..., \boldsymbol{b}_{jk}(p^{(j)}_{nk}))',$$
$$\boldsymbol{b}_{jk}(p^{(j)}_{ik}) = (b^{(j)}_{1k}(p^{(j)}_{ik}), ..., b^{(j)}_{M_{jk}k}(p^{(j)}_{ik}))',$$
$$\hat{\sigma}_j^2 = \frac{1}{n}\sum_{i=1}^{n}\left\{x_{ij} - \sum_{k=1}^{q_j}\hat{\boldsymbol{\gamma}}'_{jk}\,\boldsymbol{b}_{jk}(p^{(j)}_{ik})\right\}.$$

Here we approximate the Hessian matrix by:

$$l_\lambda(\boldsymbol{\theta}_j | \boldsymbol{X}) = \frac{1}{n}\sum_{i=1}^{n}\log f_j(x_{ij} | \boldsymbol{pa}_{ij}, \boldsymbol{\theta}_j) + \frac{1}{n}\log p_j(\boldsymbol{\theta}_j | \boldsymbol{\lambda}_j),$$

$$\log\left|J_\lambda(\hat{\boldsymbol{\theta}}_j)\right| \approx \sum_{k=1}^{q_j}\log\left|-\frac{\partial^2 l_\lambda(\hat{\boldsymbol{\theta}}_j | \boldsymbol{X})}{\partial\boldsymbol{\gamma}_{jk}\partial\boldsymbol{\gamma}'_{jk}}\right| + \log\left|-\frac{\partial^2 l_\lambda(\hat{\boldsymbol{\theta}}_j | \boldsymbol{X})}{\partial(\sigma_j^2)^2}\right|$$

Then, we define an information criterion, named BNRC, for the Bayesian network and nonparametric regression model in order to select a graph structure:

$$\mathrm{BNRC}(G) = \sum_{j=1}^{p} \mathrm{BNRC}_j$$

The optimal graph is chosen such that the criterion BNRC is minimal.

Algorithms

Learning Parameters

Consider the nonparametric regression model defined in (3). The estimate $\hat{\boldsymbol{\theta}}_j$ is a mode of $l_\lambda(\boldsymbol{\theta}_j \mid \boldsymbol{X})$ and depends on the hyperparameters. In fact, the hyperparameter plays an essential role in estimating the smoothed curve.

In our model, we construct the nonparametric regression model by 20 *B*-splines. We confirmed that the differences of the smoothed estimates against the various number of the basis functions cannot be found visually. Because when we use a somewhat large number of the basis functions, the hyperparameters control the smoothness of the fitted curves. The algorithm for obtaining $\hat{\boldsymbol{\theta}}_j$ and selection of β_{jk} is summarized as follows:

Step 1: Set j and initialize: $\boldsymbol{\gamma}_{jk} = \boldsymbol{0}(k = 1, ..., q_j)$.

Step 2: Set k and find the optimal β_{jk} by repeating the following steps:

A. Compute:

$$\boldsymbol{\gamma}_{jk} = (\boldsymbol{B}'_{jk} \boldsymbol{B}_{jk} + n\beta_{jk} \boldsymbol{K}_{jk})^{-1} \boldsymbol{B}'_{jk}(\boldsymbol{x}_{(j)} - \sum_{k'\neq k} \boldsymbol{B}_{jk'} \boldsymbol{\gamma}_{jk'}),$$

for fixed β_{jk}. Here $\boldsymbol{x}_{(j)} = (x_{1j}, ..., x_{nj})'$

B. Evaluate: Repeat Step 2-A against the candidate value of β_{jk}, and choose the optimal value of β_{jk}, which minimizes the BNRC_j.

Step 3: Convergence: Repeat Step 2 for $k = 1, ..., q_j, 1, ..., q_j, 1,...$ until a suitable convergence criterion is satisfied.

The mode $\hat{\sigma}_j^2$ is given by:

$$\hat{\sigma}_j^2 = \frac{1}{n}\left\| \boldsymbol{x}_{(j)} - \sum_{k=1}^{q_j} \boldsymbol{B}_{jk}\hat{\gamma}_{jk} \right\|^2$$

Learning Graph Structure

Finding optimal Bayesian networks is computationally hard. Potentially, we need to search the space of directed acyclic graphs of p vertices whose size c_p is approximately:

$$c_p = \frac{p! \times 2^{p(p-1)/2}}{r \times z^p}$$

where $r \sim 0.57436$ and $z \sim 1.17881$ (Robinson, 1973). From this formula we can see that there are roughly 2.34×10^{72} networks with 20 vertices and 2.71×10^{158} for 30 vertices. This complexity does not allow us any brute force approach even with a supercomputer system. Furthermore, without obtaining the optimal Bayesian networks, we cannot have any right insight that the Bayesian network model can really extract biologically meaningful regulatory information from microarray gene expression data. Thus, we are faced with two issues. The first issue is how to cope with this complexity and the second is the search for optimal Bayesian networks and their biological evaluation.

Greedy Heuristics for Searching Bayesian Networks

Some heuristic approaches have been employed for this search problem, for example, greedy algorithms (Friedman et al., 2000; Heckerman et al., 1995; Imoto et al., 2002), simulated annealing (Hartemink et al., 2002), and genetic algorithms (Somereren et al., 2002).

The greedy hill-climbing algorithm due to Heckerman et al. (1995) is shown below as a typical example, where n is the number of repeats. The greedy hill-climbing algorithm assumes a score function for solutions. It starts from some initial solution and successively improves the solution by selecting the modification from the space of possible modifications which yields the best score. When no improvement is found, then the algorithm terminates with the currently best solution. Some ideas should be employed for the choice of the initial solution and for the choice of the space of possible modifications. Biologically reasonable locally optimal Bayesian networks of several hundred genes are reported (Imoto et al., 2002; Imoto et al., 2003; Nariai, Kim, Imoto, & Miyano, 2004; Tamada, Kim, Bannai, Imoto, Tashiro, Kuhara, & Miyano, 2003). The following algorithm is a greedy hill-climbing algorithm provided by Heckerman et al. (1995):

Step 1: Initialize the network as the empty network.
Step 2: Randomly select a permutation π: $\{1, ..., |X|\} \rightarrow X$, where X is the set of vertices.
Step 3: For all $i = 1, ..., p$ do the following two steps:
- **A.** Compute the changes of the score when adding a new parent for $\pi(i)$ or removing or reversing the edge of a parent gene of $\pi(i)$.
- **B.** Select the modification among the modifications which improve the score most without violating the acyclicity condition.

Step 4: Repeat Step 3 until their score does not improve.
Step 5: Repeat Steps 1 through Step 4 for T times and return the best solution found in these iterations.

Search Algorithm for Optimal Bayesian Networks

BNRC score can be decomposed to an additive form $\mathrm{BNRC}(G) = \sum_{j=1}^{p} \mathrm{BNRC}_j$ as shown in Section 2.2. We will formulate this optimization problem in an abstract way: For a finite set X (of genes), we call a function s: $X \times 2^X \rightarrow R$ a score function for X. Then for a DAG $G = (X, E)$ we define the score of X by $\mathrm{score}(G) = \Sigma_{g \in X}\, s(g, Pa(g))$. The problem is to find the best network $G = (X, E)$ which attains the optimal score. In the case of the BNRC score, the problem is defined as a minimization problem. Furthermore, it is noted in Ott et al. (2004) that the case for the MDL score (Friedman & Goldszmidt, 1998) is also formulated as a minimization problem while the case for the BDe score (Cooper & Herskovits, 1992; Friedman & Goldszmidt, 1998; Heckerman et al., 1995) is defined as a maximization problem.

Ott et al. (2004), have devised an algorithm which can find optimal Bayesian networks of size up to 35 if a supercomputer such as SUN FIRE 15K with 96CPUs 900MHz each is used. The algorithm decomposes the search space into subspaces and employs the dynamic programming technique for finding the right subspace as well as for determining the optimal solution in the subspace. In order to describe the algorithm, several notations shall be introduced as follows: For a gene g in X and a subset $A \subseteq X$:

$$F(g, A) = \min_{B \subseteq A} s(g, B)$$

gives the optimal choice of parents for g if the parents are selected from A. An order on a subset $A \subseteq X$ is given as a permutation π: $\{1, ..., |A|\} \rightarrow A$. We denote by Π^A the set of all permutations on A. We denote the subnetwork of $G = (X,E)$, restricted to A by $G(A) = (A, E(A))$. For a permutation $\pi \in \Pi^A$, we say that G is *π-linear* if $\pi^{-1}(g) < \pi^{-1}(h)$ holds for all $(g, h) \in E(A)$. The idea of the algorithm is to decompose the set of all DAGs on A into subsets of π-linear DAGs for all $\pi \in \Pi^A$. Then, we divide the problem into (i) to find the subspace of the search space that contains the optimal network and (ii) to find the optimal network within the selected subspace. We denote:

$$Q^A(\pi) = \sum_{g \in A} F(g, \{h \in A \mid \pi^{-1}(h) < \pi^{-1}(g)\})$$

Then we find the best π-linear network for any given permutation by F and Q. The optimal network can be found by finding the optimal permutation which yields the global minimum, which is given by:

$$M(A) = \arg\max_{\pi \in \Pi^A} Q^A(\pi)$$

Then, the whole algorithm derived in Ott et al. (2004) is described as follows:

Step 1: Compute $F(g, \phi) = s(g, \phi)$ for all $g \in X$.
Step 2: For all $g \in X$ and all $A \subseteq X - \{g\}$ with $A \neq \phi$, compute $F(g, A)$ as

$$\min\{s(g, A), \min_{a \in A} F(g, A - \{a\})\}$$

Step 3: Set $M(\phi) = \phi$.
Step 4: For all $A \subseteq X$ with $A \neq \phi$, execute the following steps:
A. Compute

$$g^* = \arg\max_{g \in A}\{F(g, A - \{g\}) + Q^{A-\{g\}}(M(A - \{g\}))\}$$

B. For all $1 \leq i \leq |A|$, set $M(A)(i) \equiv M(A - \{g^*\})(i)$ and $M(A)(|A|) \equiv g^*$.
Step 5: Return $Q^G(M(G))$.

Here we have the following theorem:

Theorem (Ott et al., 2004)

Optimal Bayesian networks can be found using $(|X| / 2 + 1) \times 2^{|X|}$ *dynamic programming steps, where X is a set of genes.*

A rigorous proof is required to show the correctness of this algorithm that can be found in Ott et al. (2004). Furthermore, with some biologically reasonable constraints on the networks, we can obtain a much faster algorithm (Ott & Miyano, 2003). By computing optimal Bayesian networks of small size and evaluating them, it is reported that optimal Bayesian networks are not necessarily biologically optimal. However, by combining optimal to near optimal Bayesian networks thoroughly, we can extract biologically more accurate information from microarray gene expression data (Ott & Miyano, 2003; Ott et al., 2004; Ott et al., 2005).

Combining Biological Knowledge with Microarray Data

Discrete Information

The criterion BNRC(G), introduced in Section 2.2, contains two quantities: the prior probability $p(G)$ of the network, and the marginal likelihood of the data. The marginal likelihood shows the fitness of the model to the microarray data. The biological knowledge can then be added into the prior probability of the network $p(G)$. Let U_{ij} be the interaction energy of the edge from $gene_i$ to $gene_j$ and let U_{ij} be categorized into I values, H_1, ..., H_I, based on biological knowledge. For example, if we know a priori that $gene_i$ regulates $gene_j$, we set $U_{ij} = H_1$. However, if we do not know whether $gene_k$ regulates $gene_l$ or not, we set $U_{kl} = H_2$. We treat the prior information of each edge independently. Note that in $0 < H_1 < H_2$, it is more natural to choose the network with a large number of H_1 edges rather than H_2 edges in the sense of prior information. Our setting, $H_1 < H_2$, gives a higher prior probability to the graph with a lot of H_1 edges than to the graph with a lot of H_2 edges.

The total energy of the network G can then be defined as:

$$E(G) = \sum_{\{i,j\} \in G} U_{ij}$$

where the sum is taken over the existing edges in the network G. Under the Bayesian network framework, the total energy can be decomposed into the sum of the local energies:

$$E(G) = \sum_{j=1}^{p} \sum_{i \in L_j} U_{ij} = \sum_{j=1}^{p} E_j \tag{7}$$

where L_j is the index set of parents of gene$_j$ and $E_j = \Sigma_{i \in L_j} U_{ij}$ is the local energy defined by gene$_j$ and its parents.

The probability of a network G, $p(G)$, is modeled by the Gibbs distribution (Geman & Geman, 1984):

$$p(G) = Z^{-1}\exp\{-\zeta E(G)\}, \tag{8}$$

where ζ (> 0) is a hyperparameter and Z is a normalizing constant called the partition function

$$Z = \sum_{G} \exp\{-\zeta\, E(G)\}$$

Here the sum is taken over the set of possible networks. By replacing ζH_1, ..., ζH_I with ζ_1, ..., ζ_I, respectively, the normalizing constant Z is a function of ζ_1, ..., ζ_I. We call ζ_j an inverse normalized temperature. By substituting (7) into (8), we have:

$$p(G) = Z^{-1} \exp\{-\zeta\, E_j\} = Z^{-1} \prod_{j=1}^{p} \prod_{i \in L_j} \exp\{-\zeta_{\alpha(i,j)}\}$$

with α $(i, j) = k$ for $U_{ij} = H_k$. Hence, by adding biological knowledge into the prior probability of the network, BNRC can be rewritten as:

$$\mathrm{BNRC}(G, \zeta_1, ..., \zeta_I) = 2\log Z + \sum_{j=1}^{p} \left\{ 2 \sum_{i \in Lj} \zeta_{\alpha(i,j)} + \mathrm{BNRC}_j \right\} \tag{9}$$

We can choose an optimal network under the given ζ_1, ..., ζ_I. Also the optimal values of ζ_1, ..., ζ_I are obtained as the minimizer of (9). Therefore, we can represent an algorithm for estimating a gene network from microarray data and biological knowledge as follows:

Step 1: Set the values ζ_1, ..., ζ_I.

Step 2: Estimate a gene network by minimizing BNRC(G) under the given ζ_1, ..., ζ_I.

Step 3: Repeat Step 1 and Step 2 against the candidate values of ζ_1, ..., ζ_I.

Step 4: An optimal gene network is obtained from the candidate networks obtained in Step 3.

In Step 2, we use the greedy hill-climbing algorithm for learning networks.

The computation of normalizing constant, Z, is intractable even for moderately sized gene networks. To avoid this problem, we compute upper and lower bounds of the partial function and use them to choose the optimal value of inverse normalized temperature. An upper bound is obtained by directed graphs that are allowed to contain cyclic graphs. The number of graphs that has b_1, b_2, ..., b_I edges of ζ_1, ζ_2, ..., ζ_I out of a_1, a_2, ..., a_I edges, respectively, is obtained by:

$$S(b_1, ..., b_I) = \prod_{i=1}^{I} \frac{a_i\,!}{b_i\,!(a_i - b_i)!}$$

The upper bound of Z is then:

$$\sum_{b_1, ..., b_I} S(b_1, ..., b_I) \exp\left(-\sum_{i=I}^{I} b_i \zeta_i \right)$$

Thus, the true value of the partition function is not greater than the upper bound. A lower bound is computed by multilevel directed graphs with following assumptions: (A1) There is one top gene and (A2) Genes at the same level have a common direct parent gene. We also consider joined graphs of some multilevel directed graphs satisfying (A1) and (A2). Because the number of possible graphs is much larger than those included in the computation, the true value of the partition function should be greater than the lower bound. Because the optimization of the network structure for fixed ζ_1, ..., ζ_I does not depend on the value of the partition function, our method works well in practice. Of course, when the number of genes is small, we can perform an exhaustive search and compute the partition function completely. However, we think that the development of an effective algorithm to enumerate all possible networks or approximate the partition function is an important problem.

As a related work, Segal et al. (2003a) proposed an interesting method for combining protein-protein interaction data with microarray gene expression data. They modeled protein-protein interaction data based on Markov networks (Kindeman & Snell, 1980) and considered the joint probability of microarray data and protein-protein data for estimating molecular pathways. Although our model is different from their model, their model contains a hyperparameter, denoted by α, that plays a quite similar role of ζ_1 and ζ_2. Similar to our criterion, their joint probability contains the normalizing constant, which is a function of the hyperparameter, α. While we optimize the hyperparameters by our criterion, they did not compute the normalizing constant and chose the value of α heuristically.

Discrete and Continuous Information

Imoto, Higuchi, Goto, Tashiro, Kuhara, and Miyano (2004), proposed a general framework for combining biological knowledge with expression data aimed at estimating more accurate gene networks. In Imoto et al. (2004), the biological knowledge is represented as the binary values, for example, known or unknown, and is used for constructing $p(G)$. In reality, there are, however, various confidence in biological knowledge in practice. Bernard and Hartemink (2005) constructed $p(G)$ using the binding location data (Lee et al., 2002) that is a collection of p-values (continuous information). In this section, we construct $p(G)$ by using multisource information including continuous and discrete prior information.

Let $\boldsymbol{Z}_k$ be the matrix representation of k-th prior information, where (i, j)-th element $z_{ij}^{(k)}$ represents the information of $\text{gene}_i \rightarrow \text{gene}_j$. For example, (1) If we use a prior network G_{prior} for $\boldsymbol{Z}_k$, $z_{ij}^{(k)}$ takes 1 if $e(i, j) \in G_{\text{prior}}$ or 0 for otherwise. Here $e(i, j)$ denotes the direct edge from gene_i to gene_j. (2) By using the gene knock-down data for $\boldsymbol{Z}_k$, $z_{ij}^{(k)}$ represents the value that indicates how gene_j changes by knocking down gene_i. We can use the absolute value of the log-ratio of gene_j for gene_i knock-down data as $z_{ij}^{(k)}$. Using the adjacent matrix $E = (e_{ij})_{1 \le i, j \le p}$ of G, where $e_{ij} = 1$ for $e(i, j) \in G$ or 0 for otherwise, we assume the Bernoulli distribution on e_{ij} having probabilistic function:

$$p(e_{ij}) = \pi_{ij}^{e_{ij}}(1-\pi_{ij})^{e_{ij}}$$

where $\pi_{ij} = \Pr(e_{ij} = 1)$ For constructing π_{ij}, we use the logistic model with linear predictor

$$\eta_{ij} = \sum_{k=1}^{K} w_k (z_{ij}^{(k)} - c_k)$$

as $\pi_{ij} = \{1 + \exp(-\eta_{ij})\}^{-1}$, where w_k and c_k $(k = 1, ..., K)$ are weight and baseline parameters, respectively. We then define a prior probability of the graph based on prior information $\mathbf{Z}_k (k = 1, ..., K)$ by:

$$p(G) = \prod_i \prod_j p(e_{ij})$$

This prior probability of the graph assumes that edges $e(i, j)(i, j = 1, ..., p)$ are independent of each other. In reality, there are several dependencies among e_{ij}'s such as $p(e_{ij} = 1) < p(e_{ij} = 1 \mid e_{ki} = 1)$, and so forth, and we consider that adding such information into $p(G)$ is premature by the quality of such information.

COMPUTATIONAL EXPERIMENTS

Monte Carlo Simulations

Before analyzing real gene expression data, we perform Monte Carlo simulations to examine the properties of the proposed method. We assume an artificial network with 20 nodes shown in Figure 1 (a). The functional relationships between nodes are listed in Figure 1 (b). The data were generated from the artificial network of Figure 1 (a) with the functional structures between nodes shown in Figure 1 (b). Then, the observations of the child variable are generated after transforming the observations of the parent variables to mean 0 and variance 1. A network was rebuilt from simulated data consisting of 50 or 100 observations, which corresponds to 50 or 100 microarrays, because, recently more microarray data have become available and it is often the case that we can use more than 100 microarrays. While at the starting point of the analysis, we have over 6000 genes for yeast, after some pretreatments of the data or using some prior knowledge, the number of target genes is typically less than 50 or so. We consider such a case in this simulation. As for the biological knowledge, we tried the following situations: (**Case 1**) we know some gene regulations (100%, 75%, 50%, or 25% out of 19 edges shown in Figure 1 (a)) and (**Case 2**) we know some gene regulations, but some (1, 2, or 3) incorrect edges are kept in the database. We set {0.5, 1.0} and $\{\zeta_1$, 2.5, 5.0, 7.5, 10.0} as the candidate values of ζ_1 and ζ_2, respectively.

$$g_{12} = \begin{cases} -1 + \varepsilon_{12}\ (g_6 < -.5) \\ g_6 + \varepsilon_{12}\ (|g_6| \le .5) \\ 1 + \varepsilon_{12}\ (|g_6| > .5) \end{cases} \qquad \begin{array}{l} g_{16} = .8g_8 + \varepsilon_{16} \\ g_{19} = 1/\{1 + \exp(-4g_{10})\} + \varepsilon_{19} \\ g_{20} = 1.1g_{10} + \varepsilon_{20} \end{array}$$

$$g_{17} = \begin{cases} .2g_8 - 1 + \varepsilon_{17}\ (g_8 \le .2) \\ 1.4g_8 + \varepsilon_{17}\ (g_8 > .2) \end{cases} \qquad g_{18} = \begin{cases} .4g_8 + 1\ (|g_8| > .3 \\ (g_8 + 1)^{1.2}\ (g_8 \le .3) \end{cases}$$

(b)

Figure 2 shows two estimated networks: One is estimated by 100 observations (microarrays) alone. We use $\zeta_1 = \zeta_2 = 0.5$, that is, we did not use any prior knowledge (we denote this network by N_0 for convenience). The other is estimated by 100 observations and prior information of 75% gene regulations, that is, we know 14 correct relations out of the all 19 correct edges (we denote this network by N_1). Edges appearing in both networks are colored green, while edges appearing in N_0 or N_1 only are colored blue and red, respectively. By adding prior knowledge, it is clear that we succeeded in reducing the number of false positives. We also find four additional correct relationships. Figure 3 shows the behavior of BNRC, when $\zeta_1 = 0.5$. We find that the optimal value of ζ_2 is 5.0. From the Monte Carlo simulations, we observed that ζ_2 can be selected by using middle values (depicted by a blue line) of upper and lower bounds or upper bounds in practice. For the selection of ζ_1, we use the middle value of the upper and lower bounds of the score of our criterion.

Figure 4 shows the boxplots of the average squared errors (ASEs) that are defined by:

$$ASE = \sum_{i=1}^{100} \sum_{j=1}^{20} (x^*_{ij} - \hat{x}_{ij})^2$$

where x^*_{ij} is the true value of x_{ij}, that is, x^*_{i2} is given by $0.7x_{i1}$, and $\hat{x}_{ij}$ is the estimate of x_{ij} based on the estimated network. Because we repeated the Monte Carlo simulation 1000 times, each boxplot is obtained from 1000 ASEs. Smaller ASE means a more accurate estimated network. From Figure 4, it is clear that by adding prior information we succeeded in reducing the ASE. The distributions of the number of true positives and false positives of the estimate networks are shown in Figure 5. While the estimated networks without prior information contain many correct

Figure 2. An example of resulting networks based on 100 samples. We used $\zeta_1 = 0.5$ *and* $\zeta_2 = 5.0$ *that are selected by our criterion (see Figure 3).*

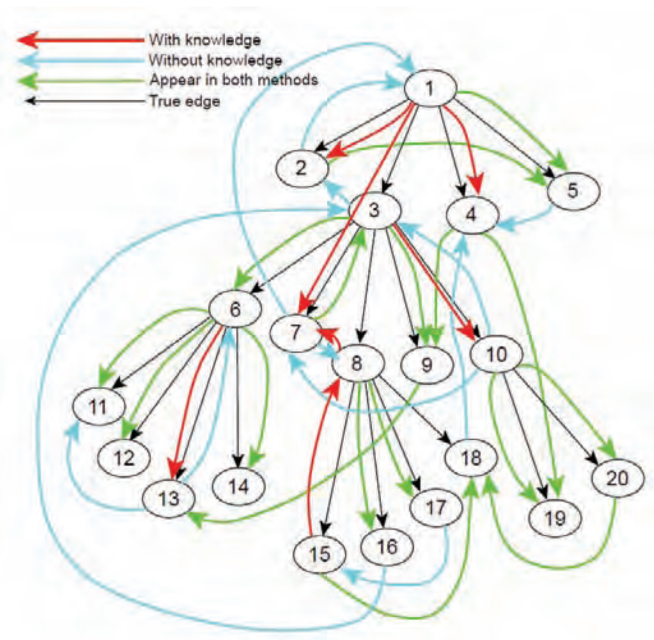

Figure 3. The behavior of BNRC when $\zeta_1 = 0.5$*. We can find out the optimal inverse normalized temperature* ζ_2 *is 5.0.*

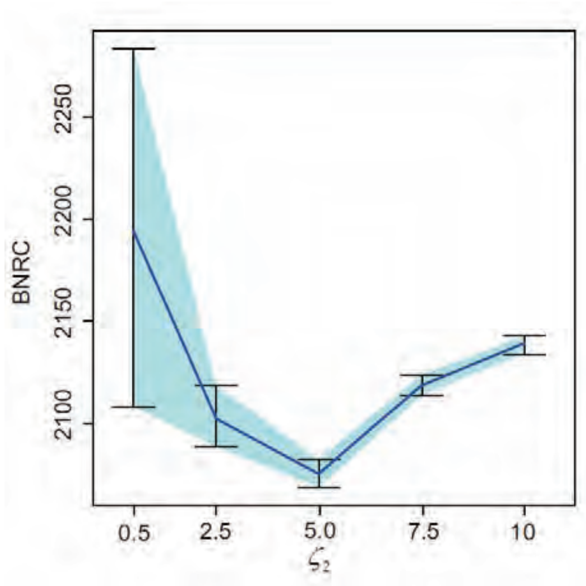

Figure 4. Boxplots of the average squared errors

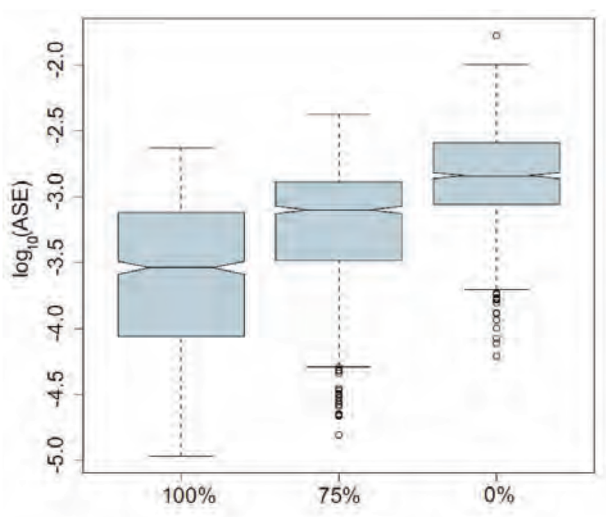
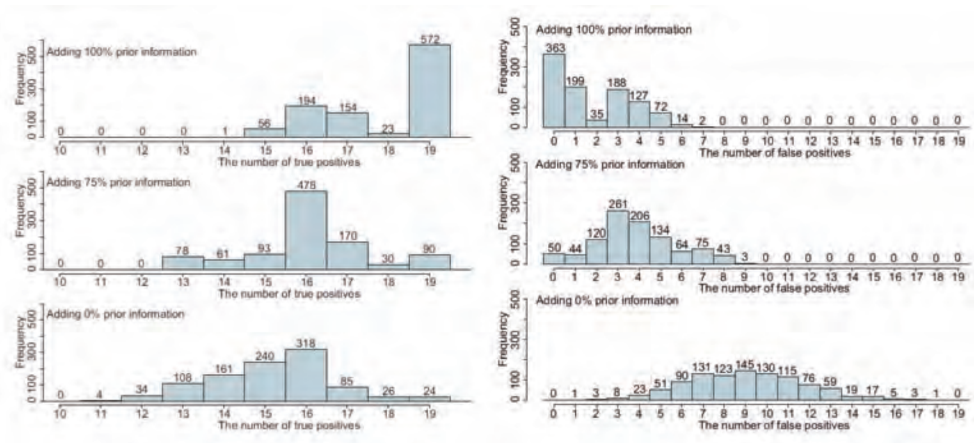


edges, we observe that the proposed method could reduce the number of false positives even if we added only a part of the true relations.

The results of the Monte Carlo simulations are summarized as follows:

Figure 5. Distribution of the number of true positives and false positives of the estimated networks. The left three figures show the number of true positives when we use 100%, 75%, and 0% prior information, respectively. The right three figures show the number of false positives with respect to 100%, 75%, and 0%. Note that because there are 19 edges in the true network, the maximum number of true positives is 19.



In (**Case 1**), we obtained networks more accurately as long as we add correct knowledge. We observed that the number of false positives decreased drastically. We presume the reason is the nature of directed acyclic graphs. Because a Bayesian network model is a directed acyclic graph, one incorrect estimate may affect the relations in its neighborhood. However, by adding some correct knowledge, we can restrict the search space of the Bayesian network model learning effectively.

In (**Case 2**), the results depend on the type of incorrect knowledge:

1. If we use misdirected relations, for example, $gene_8 \rightarrow gene_3$, as prior knowledge, serious problems occur. Because microarray data to some degree support the misdirected relations, they tend to receive a better criterion score.
2. If we add indirect relations such as $gene_1 \rightarrow gene_8$, we observed that our method controlled the balance between this prior information and microarray data and could decide whether the prior relation is true.
3. If irrelevant relations such as $gene_{20} \rightarrow gene_5$ are added as prior information, our method could reject these prior information because the microarray data do not support these relations.

Example Using Experimental Data of Yeast

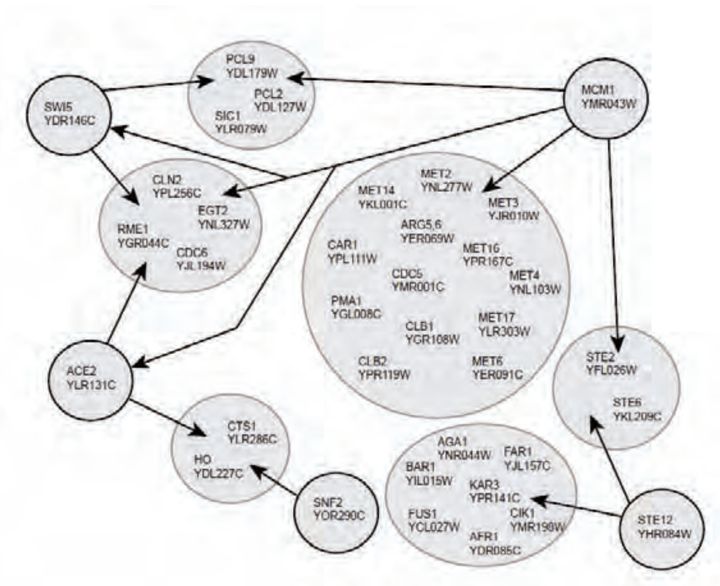
In this section, we demonstrate our method by analyzing *Saccharomyces cerevisiae* gene expression data obtained by disrupting 100 genes, which are almost all transcription factors. We used the BY4741 (*MATa, HIS3D1, LEU2D0, MET15D0, URA3D0*) as the wild type strain and purchased

Table 1. Five transcription factors and their regulating genes

MCM1 :	transcription factor of the MADS box family
	MET14, CDC6, MET2, CDC5, MET6, SIC1, STE6, CLN2, PCL2, STE2, ACE2, MET16,MET3, MET4, CAR1, SWI5, PCL9, CLB1, MET17, EGT2, ARG5,6, PMA1, RME1, CLB2
SWI5 :	transcription factor
	CDC6, SIC1, CLN2, PCL2, PCL9, EGT2, RME1, CTS1, HO
ACE2 :	metallothionein expression activator
	CLN2, EGT2, HO, CTS1, RME1
SNF2 :	component of SWI/SNF global transcription activator complex
	CTS1, HO
STE12 :	transcriptional activator
	STE6, FAR1, KAR3, SST2, FUS1, STE2, BAR1, AGA1, AFR1, CIK1

gene disruptions from Research Genetics, Inc. We focus on five genes, *MCM1*, *SWI5*, *ACE2*, *SNF2*, and *STE12* (see Table 1) and extract genes that are regulated by these 5 genes from the Yeast proteome database. Thus, we construct a prior network, shown in Figure 6, based on the database information. We include the prior network in our Bayesian network estimation method. That is, the purpose of this analysis is to estimate the gene network containing above 36 genes from microarray data together with the prior network. For constructing a Bayesian network with prior

Figure 6. Prior knowledge network. The genes that are in each shadowed circle are regulated by the parent genes.



knowledge, the simplest way is to fix the prior edges and learn the other parts of the network based on the observed data. However, we observed that the score of our criterion, BNRC, of the estimated network learned with fixed prior edges cannot decrease compared with the optimal one. Figure 7 shows the estimated gene network using microarray data only. There are many non-prior edges and many of them are probably false positives. In addition, we find three misdirected relations: "*SWI5* → *MCM1*," "*HO* → *ACE2*," and "*STE6* → *STE12*." By adding the prior network, we obtain the gene network shown in Figure 9. As for the inverse normalized temperatures ζ_1 and ζ_2, we set $\zeta_1 = 0.5$ and choose the optimal value of ζ_2. We also estimated a gene network based on $\zeta_1 = 1$ and found the results described below to be essentially unchanged.

Figure 8 shows the behavior of BNRC with respect to ζ_2. We find that the optimal value of ζ_2 is 2.5. Figure 9 shows the resulting network based on microarray data and the biological knowledge represented by the prior network in Figure 6. We show the edges that correspond to the prior knowledge in black. The edges between genes that are regulated by the same transcription factor in the prior network are shown in blue. The red edges do not correspond to the prior knowledge. In particular, we find that the relationships around *MCM1* improve drastically. The network based on microarray only shown in Figure 7 indicates that only *SIC1* and *ACE2* are regulated by *MCM1*. Note that the underlined genes correspond to the prior network information. After adding the prior knowledge and optimizing the inverse normalized temperatures, we find that 10 genes out of 24 genes that are listed as coregulated genes of *MCM1* in Table 1 are extracted. Also, the relationships around *STE12* become clearer. Before adding prior knowledge, the estimated network in Figure 7 suggests that *FUS1*, *AFR1*, *KAR3*, *BAR1*, *MET4*, *MET16*, and *MCM1* are

Figure 7. Resulting network based on microarray only

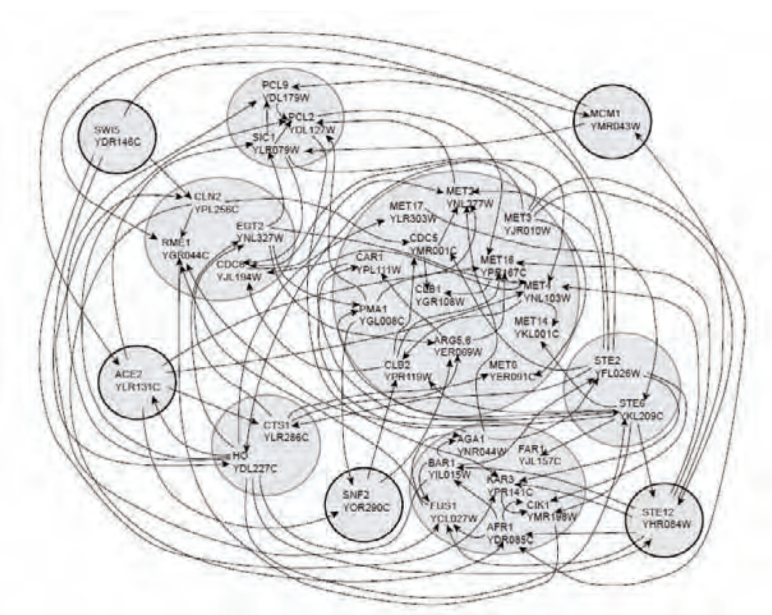


Figure 8. Optimization of ζ_2. We can find out that the optimal value of ζ_2 is 2.5.

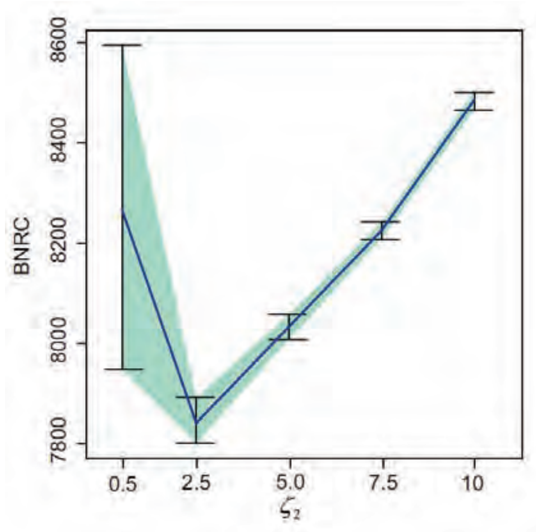

Figure 9. Resulting network based on microarray data and biological knowledge. The inverse normalized temperatures are selected by our criterion (ζ_1 = 0.5, ζ_2 = 2.5).

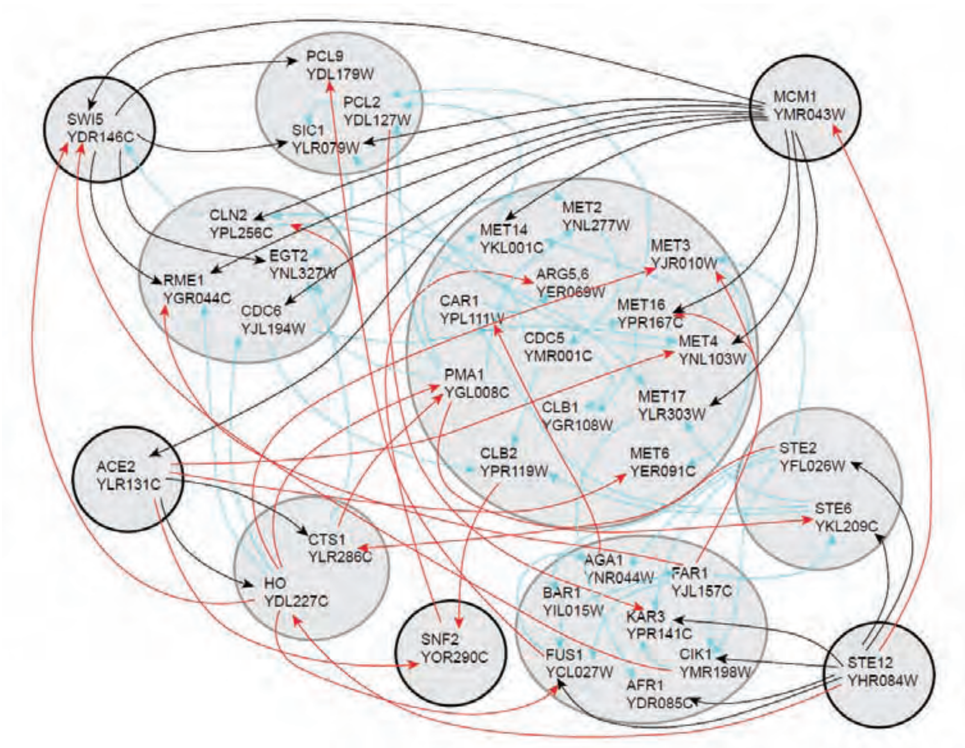

regulated by *STE12*, while *STE12* is controlled by *HO*, *STE6*, and *MET3*. On the other hand, the network in Figure 9 shows that *STE12* regulates *FUS1*, *AFR1*, *KAR3*, *CIK1*, *STE2*, *STE6*, *HO*, and *MCM1*. Note that the three misdirected relations described above are corrected in Figure 9. The difference between the inverse normalized temperatures $\zeta_1 = 0.5$ and $\zeta_2 = 2.5$ is small because the score of the criterion is added as $2\zeta_1$ or $2\zeta_2$, when we add an edge that is listed or not listed in the prior network, respectively. Therefore, microarray data contain this information and we succeeded in extracting this information with the slight help of the prior network.

We optimized the inverse normalized temperature ζ_2 based on the proposed criterion. From the network based on the optimal inverse normalized temperatures, we can find the difference between microarray data and biological knowledge. By comparing Figure 7 with Figure 9, we find that the microarray data reflect the relationship between seven genes (*CLN2*, *RME1*, *CDC6*, *EGT2*, *PCL2*, *PCL9*, and *SIC1*) and two transcription factors (*MCM1* and *SWI5*). On the other hand, we find that there are somewhat large differences between microarray data and the prior network for the relationship between *MCM1* and the 13 genes that are in the biggest circle.

APPLICATION TO HUMAN ENDOTHELIAL CELLS' GENE NETWORK

Fenofibrate Time-Course Data

We measure the time-responses of human endothelial cell genes to 25mM fenofibrate. The expression levels of 20,469 probes are measured by CodeLinkTM Human Uniset I 20K at six time-points (0, 2, 4, 6, 8, and 18 hours). Here, time 0 means the start point of this observation and just before exposure to the fenofibrate. In addition, we measure this time-course data as the duplicated data in order to confirm the quality of experiments.

Because our fenofibrate time-course data are duplicated data and contain six time-points, there are $2^6 = 64$ possible combinations to create a time-course dataset. We should fit the same regression function to a parent-child relationship in the 64 datasets. Under this constrain, we consider fitting nonparametric regression model to the connected data of 64 datasets. That is, if we consider gene i → gene j, we will fit the model $x_j^{(c)}(t) - m_j(x_i^{(c)}(t-1) + e_j^{(c)}(t)$, where $x_j^{(c)}(t)$ is the expression data of gene j at time t in the c-th dataset for $c = 1, ..., 64$. In the Bayesian networks, the reliability of estimated edges can be measured by using the bootstrap method. For time-course data, several modifications of the bootstrap method are proposed, such as block resampling, but it is difficult to apply these methods to the small number of data points generated by short time-courses. However, by using above time-course modeling, we can define a method based on the bootstrap as follows: Let $D = \{D(1), ..., D(64)\}$ be the combinatorial time-course data of all genes. We randomly resample $D(c)$ with replacement and define a bootstrap sample $D^* = \{D^*(1), ..., D^*(64)\}$. We then re-estimate a gene network based on D^*. We repeat 1000 times bootstrap replications and obtain $\hat{G}_T^{*1},...,\hat{G}_T^{*1000}$, where $\hat{G}_T^{*B}$ is the estimated graph based on the B-th bootstrap sample. The estimated reliability of edge can be used as the matrix representation of the first prior information $\boldsymbol{Z}_1$ as:

$$z_{ij}^{(1)} = \#\{B | e(i,j) \in \hat{G}_T^{*B}, B = 1,...,1000\}/1000$$

Gene Knock-Down Data by siRNA

For estimating gene networks, we newly created 270 gene knock-down data by using siRNA. We measure 20,469 probes by CodeLinkTM Human Uniset I 20K for each knock-down microarray after 24 hours of siRNA transfection. The knock-down genes are mainly transcription factors and signaling molecules. Let $\tilde{\boldsymbol{x}}_{D_i} = (\tilde{x}_{1|D_i}, ..., \tilde{x}_{p|D_i})'$ be the raw intensity vector of i-th knock-down microarray. For normalizing expression values of each microarray, we compute the median expression value vector $\boldsymbol{v} = (v_1, ..., v_p)'$ as the control data, where $vj = \text{median}_i(\tilde{x}_{j|D_i})$ We apply the loess normalization method to the MA transformed data and the normalized intensity $x_{j|D_i}$ is obtained by applying the inverse transformation to the normalized $\log(\tilde{x}_{j|D_i}/V_j)$ We refer to the normalized $\log(\tilde{x}_{j|D_i}/V_j)$ as the log-ratio.

In 270 gene knock-down microarray data, we know which gene is knocked-down for each microarray. Thus, when we knock-down gene D_i , genes that significantly change their expression levels can be considered as the direct regulatees of gene D_i. We measure this information by computing corrected log-ratio as follows: The fluctuations of the log-ratios depend on their sum of sample's and control's intensities. From the normalized MA transformed data, we can obtain the conditional variance $s_j = \text{Var}[\log(x_{j|D_i}/v_j) \mid \log(x_{j|D_i} \cdot v_j)]$ and the log-ratios can be corrected $z_{ij}^{(2)} = \log(x_{j|D_i}/v_j) / s_j$, satisfying $\text{Var}(z_{ij}^{(2)}) = 1$.

Results

For estimating fenofibrate-related gene networks from fenofibrate time-course data and 270 gene knock-down data, we first define the set of genes that are possibly related to fenofibrate as follows: First, we extract the set of genes whose variance-corrected log-ratios, $|\log(x_{j|D_i}/v_j)/s_j|$, are greater than 1.5 from each time point. We then find significant clusters of selected genes using GO Term Finder. Table 2 shows the significant clusters of genes at 18 hours. The first column indicates how expression values are changed, that is, right-up-arrow and right-down-arrow mean "overexpressed" and "suppressed," respectively. The GO annotations of clusters with right-down-arrow are mainly related to cell cycle, the genes in these clusters are expressed ubiquitously and this is a common biological function. On the other hand, the GO annotations of clusters with right-up-arrow are

Table 2. Significant GO annotations of selected fenofibrate-related genes from 18 hours microarray

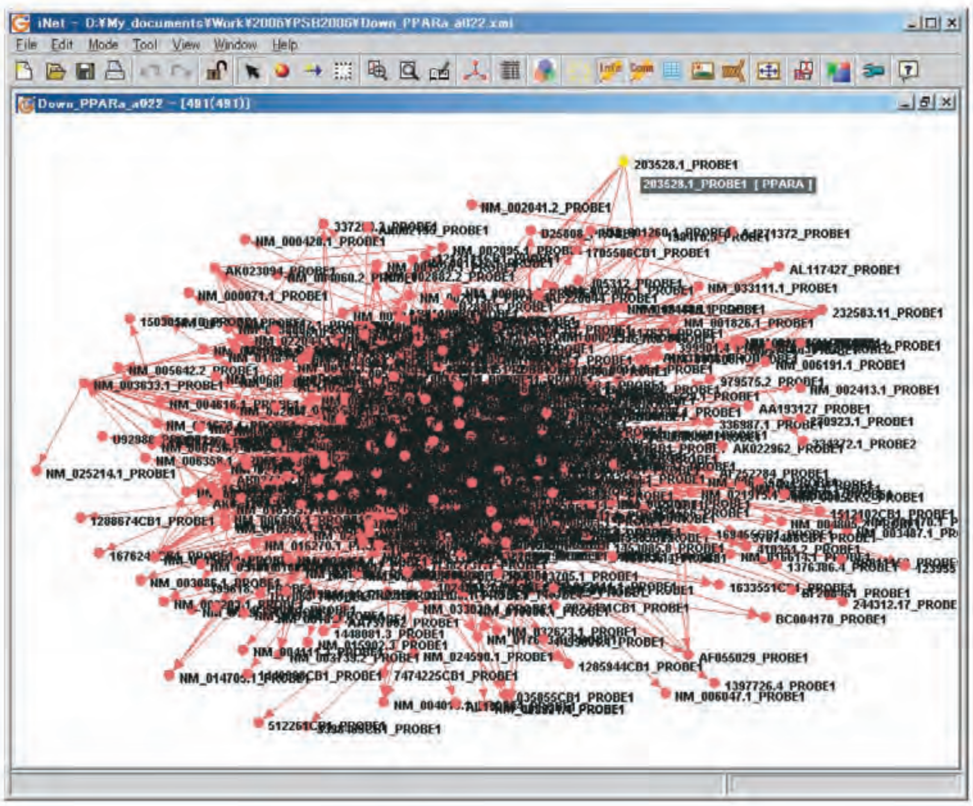
mainly related to lipid metabolism. In biology, it is reported that the fenofibrate acts around 12 hours after exposure (Goya, Sumitani, Xu, Kitamura, Yamamoto, Kurebayashi et al., 2004; Hayashida, Kume, Minami, Inui-Hayashida, Mukai, Toyohara, & Kita, 2004). Our first analysis for gene selection suggests that fenofibrate affects genes related to lipid metabolism, and this is consistent with biological facts. We also focus on the genes from the 8 hour time-point microarray. Unfortunately, no cluster with specific function could be found in the selected genes from the 8 hour time-point microarray However, there also exist some genes related to lipid metabolism. Therefore we use the genes from the 8 and 18 hour time-point microarrays. Finally, we add the 267 knock-down genes (three genes are not spotted on our chips) to the selected genes above, total 1192 genes are defined as possible fenofibrate-related genes and used for the next network analysis.

By converting the estimated dynamic network and knock-down gene information into the matrix representations of the first and second prior information $\boldsymbol{Z}_1$ and $\boldsymbol{Z}_2$, respectively, we estimate the gene network $\hat{G}_k$ based on $\boldsymbol{Z}_1$, $\boldsymbol{Z}_2$ and the knock-down data matrix $\boldsymbol{X}_K$. For extracting biological information from the estimated gene network, we first focus on lipid metabolism-related genes, because the clusters related to this function are significantly changed at 18 hours microarray. In

Figure 10. Down-stream of PPAR-α

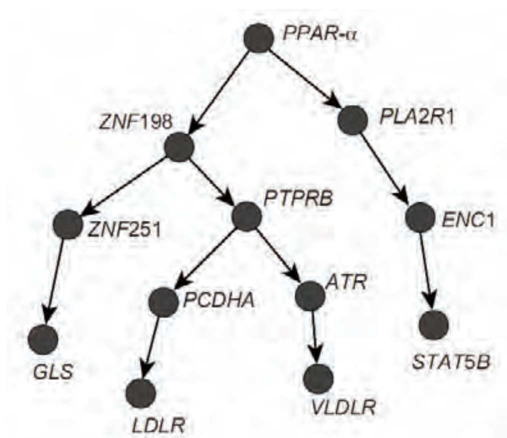


the estimated gene network, there are 42 lipid metabolism-related genes and *PPAR-α* (*Homo sapiens* peroxisome proliferative activated receptor, alpha) is the only transcriptionfactor among them. Actually, *PPAR-α* is a known target of fenofibrate. Therefore, we next focus on the node down-stream of *PPAR-α*. In Figure 10, the node down-stream of *PPAR-α* (491 genes). Here, we consider that genes in the four steps down-stream of *PPAR-α* are candidate regulatees of *PPAR-α*. Among the candidate regulatees of *PPAR-α*, there are 21 lipid metabolism-related genes and 11 molecules previously identified experimentally to be related to *PPAR-α*. Actually, *PPAR-α* is known to be activated by fenofibrate. We show one subnetwork having *PPAR-α* as a root node in Figure 11. One of the drug efficacies of fenofibrate whose target is *PPAR-α* is to reduce LDL cholesterol. LDLR and VLDLR mainly contribute the transporting of cholesterol and they are children of *PPAR-α*, namely candidate regulatees of *PPAR-α*, in our estimated network. As for LDLR, its relationship with *PPAR-α* has been reported (Islam, Knight, Frayn, Patel, & Gibbons, 2005). Moreover, several genes related to cholesterol metabolism are children of *PPAR-α* in our network. We also could extract STAT5B and GLS that are children of *PPAR-α* and have been reported their regulation-relationships with *PPAR-α* (Kersten, Mandard, Escher, Gonzalez, Tafuri, Desvergne, & Wahli, 2001; Shipley & Waxman, 2003). Therefore, it is not surprising that our network shows that many direct and indirect relationships involving known *PPAR-α* regulates are triggered in endothelial cells by fenofibrate treatment. In the node up-stream of *PPAR-α*, *PPAR-α*, and RXR-α, which form a heterodimer, share a parent. We could extract fenofibrate-related gene network and estimate that *PPAR-α* is the one of the key molecules of fenofibrate regulations without previous biological knowledge.

DISCUSSION

In this chapter, we illustrate a statistical method for estimating gene networks from microarray gene expression data. The use of Bayesian networks and nonparametric regression is a key of our method to capture nonlinear relationships

Figure 11. A sub-network related to PPAR-α



between genes. An information criterion we call BNRC, derived from the Bayesian point of view in Section 2, is powerful to evaluate candidate networks and to choose one as the best one. Also, the framework we used to derive BNRC is flexible to combine other biological knowledge. We have conceptually shown the capability of our framework to use protein-protein interaction, binding site information, and other types of information to estimate gene networks. In fact, research has been done using this framework. Tamada, et al. (2003) combined the promoter element detection method with Bayesian networks to find binding sites of transcription factors and to estimate gene networks simultaneously. Nariai et al. (2004) used protein-protein interaction data observed by yeast two hybrid and TAP experiments together with microarray data to estimate gene networks. More recently, Tamada et al. (2005) used protein sequence similarity as evolutionary information of two distinct organisms and estimate gene networks of two organisms, simultaneously. As we described above, combination of multiple types of genomic data is a key to estimate accurate gene networks.

The next step of gene network research is to understand mode-of-action of a chemical compound when we do it to cells by using estimated gene networks. In reality, the affected genes by a chemical compound, or drug, form subgraphs in the whole gene network. Therefore, it is possible to consider estimating subnetworks affected by a drug as a next challenge. This network enables us to know not only genes that are directly affected by the drug (Imoto et al., 2003), but also the drug affected pathways (Tamada et al., 2005). Imoto, Tamada, Araki, Yasuda, Print, Charnock-Jones et al. (2006) provides a concept druggable gene networks to understand mode-of-action of a chemical compound. The druggable gene networks contain known drug target gene and novel drug target candidate genes. They show that several known drug target genes are hubs in the druggable gene network, computationally.

Statistical estimation approach is a way to know gene networks in bioinformatics. This has a background that we do not know or partially know the true gene network and estimate unknown parts by using observational data like microarray gene expression data. However, there is another approach to understand networks in cells. This is based on the known facts and builds a simulation model like Petri net (Matsuno, Tanaka, Aoshima, Doi, Matsui, & Miyano, 2003; Nagasaki, Doi, Matsuno, & Miyano, 2004a, 2004b). We consider that the combination of these two approaches will become a key technology to understanding cellular networks.

Chapter 7.32
Fuzzy Logic in Medicine

Michelle LaBrunda
Cabrini Medical Center, USA

Andrew LaBrunda
University of Guam, USA

ABSTRACT

This article explores the use of fuzzy logic in the medical field. While giving a comparison of classic and fuzzy logic we present the various uses of the applications made possible by fuzzy logic, focusing on diagnosis and treatment. The ever evolving technology making the line between medicine and technology thinner every year, is helping to make the treatment of disease and the mending of injury easier for medical professionals. We also propose several questions that arise from, and may by answered by, fuzzy logic and its applications.

INTRODUCTION

In order to understand the intricacies of fuzzy logic one must build from a thorough understanding of classical logic. A basic component of classic logic is the proposition that a statement can be characterized as either true or false. An example of a proposition is "The country of France contains the Eiffel tower" or "The Eiffel tower is closed on Sundays." In classical logic, propositions are said to be either true or false. Propositions are typically connected using AND, OR, and NOT. On occasion, one might use other connections, but they can all be derived from a combination of these three. The notation used to describe classic logic is called propositional calculus. In most computer programming languages it is common to assign numerical values to the correctness of a proposition where 1 = true and 0 = false. A proposition can either be true or it can be false. It cannot be both at the same time, nor can it simultaneously be neither. Collections of propositions can be transformed to prove truths that might not necessarily be evident on their own. The basic rules of mathematics have been transcribed into propositional calculus and as a result computers are now able to transform a series of propositions into mathematical proofs. Computers are now able to solve proofs in ways never previously conceived.

Fuzzy logic is similar to classical logic in the search for truthfulness of a proposition. Sometimes truth is subjective ill defined. As an example, it is difficult to assign a true or false value to the proposition “Andy is tall” or “Shell is old.” How tall does one have to be before being categorized as “tall”? Likewise, how old does one have to be before being considered “old”? Most would agree that 100 years is old for a person but young for a planet. Like many real-world propositions, the concept of age is relative to its usage. To solve these problems there was a need to develop a more robust system of logic. Rather than assigning a proposition as either 0 or 1 the idea of variable truth was added. The variable is measured over the interval of [0, 1]. Fuzzy logic rose from this concept. One major focus of this discipline is in the development of computational models, which can accurately assign fractional values to the level of truthfulness.

Contrary to the name, the goal of fuzzy logic is to create computer programs that can accept input and provide the user a clear answer. The system is defined as “fuzzy” because it is not always evident, given the input parameters, what logic path the system will take to derive a solution. Fuzzy logic systems are frequently used as expert systems. This type of system attempts to emulate a field expert of a specific discipline. Ideally this software-based expert would be able to accept input, process the information, and output clear concise responses. Unfortunately, in emulating the thought processes of such an expert, the expert system must emulate human thought. Human thought is fuzzy in nature complete with uncertainties, ambiguities, and contradictions. Two experts might not place the same level of importance on the same piece of information. Additionally, they might not look at the same information the same way. Should a glass filled 50% be classified as half full or half empty?

Many techniques have been used to create fuzzy logic programs that function as an expert. The earliest systems used conditional statements with tolerance thresholds using if-then-else rules (Jackson, 1999). This approach, while seemingly simplistic, has been used successfully in a wide variety of medical applications including diagnostics and psychological bias (Shortliffe, 1976). Other less known approaches of fuzzy logic systems are association nets and frames, which have proven difficult to implement with only marginal results. The two most common implementations of fuzzy logic are rule-based and neural networks. Both fuzzy implementations have a diverse range of applications including medicine, avionics, security, and machine learning.

Unlike rule-based fuzzy logic, neural nets do not require thinking patterns to be explicitly specified. Typically two data sets are created to program a neural network. The first data set is the trainer. This set of input is passed into the neural network and processed. The processing phase consists of sorting the input values among an array of memory structures call nodes. Each node retains some information and sorts the remaining information between neighboring nodes. Once all the information has been processed it is evaluated and stored as the template for which all other datasets will be compared.

This technique can loosely be compared to the Japanese game Pachinko, also seen in the game show Price is Right as Plinko. The input values are represented by silver balls that are dropped into an arrangement of pins held by a board. Before the balls reach their final stop at the bottom of the board they make contact with many pins, which change the balls direction and velocity. This makes it almost impossible to predict where a ball will end up when dropped. In the real world, chaos prevents the same input from yielding a consistent output. In a computer model, the same input will always produce the same output. So as the computer receives input, these data are feed into a virtual pachinko machine. The first batch of input is called the trainer input and represents where the balls should be landing under ideal conditions. Once the machine has been trained, new input can be fed into the same virtual pachinko machine. Once processing is complete, the landing spots for the input are compared against a trainer dataset. The greater the discrepancy between the trainer set and the actual set, the greater the error in the system. To complete the analogy, computer scientists put a great deal of effort into determining the optimal location and elasticity of the pins to make sure that good input and bad input produce different results. In the case of expert systems, neural networks do not explicitly extract the rules of an expert. Rather the neural network has learned only to recognize patterns. Therefore, while the results may be good, the neural network will not know why an answer is correct other than to say it looks like other successful inputs. The strength of this approach is that it is not necessary to program each business rule. The weakness of this approach is that substantial training may be required.

Rule-based systems explicitly collect the expert's knowledge. These rules and thinking patterns are then programmed into the system. An important phase of this approach is knowledge acquisition. During this phase a team of programmers develop a rigorous and complete model of the domain rules to be implemented. Rule-based systems do not require a large training set like that of neural network solutions. This is because the domain expert has clearly specified the rules and parameters, whereas a neural network has no knowledge of domain rules, only patterns that seem to have been enforced in past successes. During testing there is usually a tuning phase, where parameters are modified based upon the results of the test data. In addition to smaller datasets, another advantage of a rule-based fuzzy logic system is that it is easier for the system to rationalize its behavior to users. Rule-based fuzzy logic system behavior is determined by rules or parameters and changes to these parameters represent the incentives for the system to take action. This is much more easily communicated to an expert and programmer using rule-based fuzzy logic than a neural network.

FUZZY LOGIC IN THE MEDICAL FIELD

While computer scientists are refining and advancing fuzzy logic, applications within the medical field have already started to emerge. Some of these applications are rudimentary, but with time will prove invaluable. Fuzzy logic has made its way into general medicine, basic science, as well as diagnosis and treatment.

General Medicine

General medicine encompasses an enormous body of knowledge drawing from almost every field imaginable. As technology advances, the lines between medicine and technology are blurring. Fuzzy technology is a relatively new concept in computer science and few articles have been written applying fuzzy logic to medical topics. The application of fuzzy logic in general medicine has been used in addiction modeling, mapping of bruising after being shot while wearing body armor, and in the analysis and evaluation of chronic disease.

The data that are available focus heavily on the mathematics and computer science involved in applying basic fuzzy concepts to medicine. For example, an article by Nieto and Torres (2003) describes a model examining the risk of illicit drug use based on alcohol consumption and smoking habits of adolescents. Instead of labeling people as smokers or non-smokers, the degree of smoking is given a value between 0 (non-smoking) and 1 (smokes like a chimney). The same is true for alcohol consumption. Kosko's hypercube was used and a fuzzy set with a point in a unit hypercube was identified. A hypercube is an "n" dimensional figure analogous to a square. For example, if n=2 the hypercube is a square, if n=3 the hypercube is a cube. They performed a similar successful analysis looking at stroke risk factors. The article largely focuses on the engineering and mathematics behind fuzzy systems. As the utilization of fuzzy systems becomes more intuitive it is likely that articles focusing on the medical application of these systems will become available.

Lee, Kosko, and Anderson (2005) also examine a fuzzy system application to medicine. This article models gunshot bruises in soft body armor with a fuzzy system. When someone wearing soft body armor is shot, the bullet is stopped, but a bruise is produced. Analysis of the bruise and armor deformation can give information on the bullet's mass and momentum. Detailed analysis of information provided from studies such as this may allow engineers to design new types of armor better able to protect the body while minimizing armor weight. While the direct applications to medicine may be somewhat distant, the thought process involved in developing this article further combine medicine and technology bringing the real application closer to existence.

Many facets of general medicine deal with chronic disease. Chronic diseases are illnesses that last for a long time. Examples of chronic disease that will be discussed in this article are chronic kidney disease, cancer, and HIV.

The Diatelic project is a prospective randomized research project designed to test the ability of a fuzzy system to monitor chronic kidney disease patients and alert a physician of disease progression (Jeanpierre & Charpillet, 2004). In this project, patients provided daily Internet updates. These updates were analyzed by a computer using partially observable Markov decision process (POMPD) logic. POMPD is a mathematical framework from which decision-making modeling systems can be made when some of the factors are random and others are controlled. It assumes that the current state of the modeled object cannot be completely known. In the aforementioned study, a nephrologist (kidney specialist) was notified if a patient's condition appeared to be progressing. This system utilizing POMPD requires relatively low computing complexity. As the number of physicians per person continues to decline, systems of this sort will play an important roll in monitoring patient's health, disease progress, and physician alerting as problems develop.

Recent research has been done looking at fuzzy logic in diagnosing breast cancer (Polat, Şahan, Kodaz, & Güneş, 2007). The artificial immune recognition system (AIRS) has been around since 2001. It is a learning algorithm modeled after the functioning of the immune system. Polat et al. applied performance evaluation with fuzzy resource allocation mechanisms to the AIRS creating a new system, Fuzzy-AIRS. Fuzzy-AIRS was used to analyze data from a Wisconsin breast cancer dataset and predicted which samples were most likely to be cancerous. The Fuzzy-AIRS results were compared with histological diagnosis and found to be 99% accurate. Methods such as Fuzzy-AIRS can greatly reduce the time required to analyze samples and allow for more prompt diagnosis and treatment.

HIV is no longer the death sentence it once was. HIV-infected individuals in developed nations are now living nearly normal life spans thanks to advances in medication therapy and diagnosis. Many questions face infectious disease physicians when deciding how to treat HIV. These questions include when to start therapy, what medications to give, and when to change the medications. Medication is generally changed when the HIV mutates and becomes resistant to the medications that the patient is receiving. Recent research by Sloot, Boukhanovsky, Keulen, Tirado-Ramos, and Boucher (2005) utilizes multivariate analyses combined with rule-based fuzzy logic to produces a physician advice system. This system integrates a number of factors affecting the outcome of therapy and suggests a clinical course of action. As the understanding of disease, disease process, and the availability and complexity of medications increases, physicians will become more and more dependent on advice systems such as this in medical decision making. This system would also allow less skilled physicians to provide a basic level of care. This would be of enormous value in developing countries where access to physicians and therapeutic intervention is limited.

Basic Science

Taking a scientific concept and eventually developing a medical application for that concept is a long process. Basic biomedical science is the study of components of biological systems. The goals of this research do not often have direct medical applications but rather provide the building blocks for advanced biomedical diagnostic and therapeutic regimes. All medical advances have their roots in the basic sciences. Basic science includes fields such as biology, microbiology, physics, chemistry, and bioengineering. Fuzzy logic has allowed researchers to make advances that would be difficult and time consuming through other modalities, especially in the arena of modeling complex systems.

One example of the application of fuzzy logic in basic science has been done in the field of gene expression. Almost every cell in the human body contains DNA. DNA is the blueprint directing cellular functions to make each person into a human being and unique individual. On each strand of DNA are regions called genes. Genes can be thought of as the active part of DNA. Each gene contains specific directions on how to make one of the bodies many proteins. Some genes are always active. Others are only active before birth, while others are activated only under special circumstances such as pregnancy or adolescence. Genes that are activated are called expressed genes because their corresponding proteins are produced. The control of gene expression is extremely complex involving numerous chemical messengers that are not completely understood. Disregulation of gene expression has been associated with numerous diseases, most notably cancer.

A study by Du, Gong, Wurtele, and Dickerson (2005) models gene expression utilizing fuzzy logic. Because there are numerous layers of interconnecting factors regulating expression, it is amenable to fuzzy logic modeling. Cluster analysis assumes that genes with similar functions have similar mechanisms of control and produce models based on this assumption. By analyzing these repeated patterns new mechanisms of control have been elucidated.

Another related basic science topic is protein engineering. Proteins are typically built by cellular machinery that is difficult to manipulate. Engineered proteins have applications in the pharmaceutical, agricultural, and synthetic organic chemistry fields, but pure proteins must be produced. The screening of proteins to determine which synthetic proteins have desired traits is a labor intensive and expensive process involving the processing of huge amounts of data. Kato et al. (2005) developed a strategy utilizing a fuzzy neural network to screen proteins constructing a method for more quickly and efficiently screening large sets of proteins.

Diagnosis and Treatment

Once basic science has been well understood, the medical applications of this technology can be explored. Neural network and fuzzy logic have been slowly making their way into medical diagnosis and treatment as well as basic sciences. Fuzzy logic is primarily used as a modeling tool and can help to manage large sets of data while identifying individuals who follow a typical pattern of disease or disease progression. An automated system is much more efficient in processing large amounts from a number of simultaneous sources of data than the manual systems currently employed. Efforts are currently being made to determine optimal modeling systems that will allow data to be processed in an accurate and clinically meaningful manner.

A number of studies are being undertaken evaluating the role of fuzzy logic modeling in medicine. Many diseases have overlapping symptoms and the diagnosis is not always clear. John and Innocent (2005) recently published an article utilizing a fuzzy logic system to differentiate between diseases with similar symptoms. While not yet a perfect model, systems such as this may one day be of great benefit to physicians in trying to distinguish between diseases with similar symptoms. A recent review article by Grossi and Buscema (2006) looks at the application of artificial intelligence and fuzzy systems to outcomes research. As technology advances, fuzzy logic modeling systems may prove invaluable to outcomes research allowing complex data from multiple sources to be integrated into one conclusion that is accessible to patients and their healthcare providers.

Artificial intelligence and fuzzy systems have provided the opportunity to study what has traditionally fallen into the realms of philosophy and psychiatry. Sripada, Jobe, and Helgason (2005) have devised a fuzzy logic model of empathy. The ability to model complex systems may one day suggest treatments for diseases that currently have no therapies.

CONCLUSION

Computer-generated models may be highly accurate, but they will never be perfect. As many questions as answers are generated by high-powered fuzzy modeling systems. How precise must a fuzzy modeling system be before it can be implemented? If a modeling system fails and a patient is not properly diagnosed, who is at fault, the programmer, the physician, or the patient?

With these new modeling systems comes a plethora of ethical questions that will no longer be limited to science fiction films. Will we some day be able to model a person's behavior throughout their life based on their DNA? What would happen if modeling suggests that a baby is likely to become a murderer? If we can model classically human traits such as fear, love, and happiness, where will the limits between human and machine fall? Will we one day select our children based on computer modeling systems predicting their behavior, physical appearance, and aptitudes?

While these questions may seem somewhat premature, they are within the scope of reality. Fuzzy systems and neural networking provide a powerful modeling tool, the breadth of which we are only beginning to comprehend.

Section VIII
Emerging Trends

This section highlights research potential within the field of medical informatics while exploring uncharted areas of study for the advancement of the discipline. Chapters within this section highlight evolutions in evidence-based medicine, the future of e-health, and web portals for medical data. These contributions, which conclude this exhaustive, multi-volume set, provide emerging trends and suggestions for future research within this rapidly expanding discipline.

Chapter 8.1
E-Health Systems:
Their Use and Visions for the Future

Pirkko Nykänen
Tampere University, Finland

ABSTRACT

E-health refers to use of information and communication technologies to improve or enable health and healthcare. E-health broadens the scope of healthcare delivery; citizens are in the center of services and services are offered by information systems often via the Internet. In this chapter e-health systems are classified on the basis of their use and their functionality and the use is discussed from the viewpoints of citizens and health professionals. Citizens are increasingly using Internet and e-health systems to search for medicine or health-related information, and they become better informed and may take more responsibility of their own health. Health professionals are more reluctant to use the Internet and e-health systems in physician-patient communication due to the power and responsibility problems of decisions. In the future the sociotechnical nature of e-health should be considered and future systems developed for real use and user environment with user acceptable technology.

INTRODUCTION

In the information society it is important to develop and apply technologies in such a way that we empower citizens to play a full role. An essential part of the information society, healthcare services are needed by citizens and should be provided efficiently and made accessible to all (Haglund, 2002).

With the information society a new concept, e-health, has been introduced to refer to the use of emerging information technology to improve or enable health and healthcare. Silber (2003) defined e-health as "application of information and communication technologies (ICT) across the whole range of functions that affect health" (p. 3). Eysenbach (2001) gave a broader definition for e-health: An emerging field in the intersection of medical informatics, public health and business, referring to health services and information delivered or enhanced thorough the Internet and related technologies. Alvarez (2002) emphasised the consumer-viewpoint when he defined e-health as a consumer-centered model of healthcare where stakeholders collaborate, utilising ICT and Internet technologies to manage health; arrange, deliver, and account for care; and manage the healthcare system. All these definitions support the conception that e-health means application of information technologies to promote health, and to support healthcare services delivery and use. E-health covers all health strategies: Prevention, treatment, and rehabilitation. It is essential that e-health applications meet the needs of citizens, patients, healthcare professionals, and policy makers. Therefore, evaluation studies are needed to assess the benefits, effects, and impacts of e-health on citizens, professionals, healthcare systems, and healthcare outcomes.

E-health conceptualization broadens the scope of healthcare delivery; citizens are placed at the centre of services, services are in many situations offered to be used through the Internet (e.g., at home) and citizens can have interaction with health professionals who look after their health needs (Silber, 2003; Wilson, Leitner, & Moussalli, 2004). E-health is expected to contribute to development of new ways of delivering health services and to impact on the organisation and structure of the healthcare delivery system. E-health is not only a technological improvement, it is a reengineering of healthcare processes and is of consideration of the sociotechnical aspects of design and development of applications.

E-HEALTH SYSTEMS

E-health applications should make citizens better informed. All citizens should have access to services, use of services should be economically affordable, and citizens should benefit from the use of services. On the other hand, e-health services should improve the quality, availability and effectiveness of healthcare (Grimson et al., 2000; Silber, 2003; Wilson, 2002).

Types of E-Health Systems

Traditionally, three broad categories of e-health applications can be identified: Delivery of care to patients by healthcare professionals, education and dissemination of health-related information and knowledge, and trading health products (Ruotsalainen et al., 2003).

The first category covers systems for *delivery of care to patients by healthcare professionals*, including a wide range of applications from pure administrative to those for care delivery:

- **Hospital systems:** Scheduling systems, logistics systems, management information systems, hospital and patient administration systems, laboratory information systems, radiology information systems, pharmacy systems, nursing systems, and networked services such as electronic messaging between the hospital and other healthcare actors for communication of clinical information and administrative data, including telemedical services such as telepathology and teleconsultation for remote areas.
- **Primary care systems:** Information systems for general practitioners, pharmacists, and dentists for patient management, medical records, electronic prescribing, and information exchange.
- **Home care systems:** Systems that are used to deliver care services via telecommunication or wireless to the patient at home. Examples of such systems are remote vital-signs monitoring systems that enable the patient to receive targeted treatment and medication without the need to visit an outpatient clinic or occupy a hospital bed. These kinds of systems are particularly well developed in diabetes medicine, hypertension management, asthma monitoring, and home dialysis.

The second category covers *systems for education and dissemination of health related information and knowledge* including web-portals and specific health-related Web sites, virtual hospitals, and Internet-based consultation services. These systems may be targeted for:

- **Medical consultation:** Search for the second opinion, search for health-, disease-, or treatment-related information,
- **Medical education and dissemination** of medical publications, preventive materials, and public health related information.

These dissemination systems may help citizens to become informed and empowered through information and knowledge they are able to retrieve and access themselves from the Internet sources. However, the quality and validity of information can be questioned with many Internet information sources (Wilson, 2002). To promote these kinds of Internet information sources and to ensure people that they can confidently and with full understanding of known risks access and use information from the Internet, initiatives like Health on the Net, HI Ethics Program, and Health Online Actions have been established to develop guidelines and quality criteria and to promote codes of ethics for health-related Web sites (Spink et al., 2004; Wilson, 2002).

The third category covers *systems that are developed to trade health related products.* e-commerce or e-trading of medical products, health-related goods, pharmaceuticals, and medical devices is a growing e-health area, and current procedures enable citizens to enter Internet shopping in an easy and secure way.

E-health applications can also be classified according to their functionality and, following this principle, we may currently find the following groups of applications (Ruotsalainen et al., 2003):

- **Regional health information networks** that deploy advanced healthcare services at various levels of healthcare delivery system, including primary care, prehospital health emergency management, and hospital care. These systems are networked and implemented using various technologies. A typical feature for these systems is the integration of existing legacy systems, imaging systems, departmental systems, and administrative systems into one network and development of new, innovative interfaces and applications to provide comprehensive services regionally.
- **Hospital systems, clinical systems, diagnostic systems, hospital management systems** that cover hospital information systems (HIS), various departmental systems like radiology information systems (RIS), pathology information systems, laboratory information systems (LIS), diagnostic systems like decision support, and knowledge-based systems and hospital management systems like accounting, resource management and booking systems.
- **Telemedicine or teleconsultation systems** are used to access an expert opinion, a second opinion, or to monitor remote patient at home or in another healthcare organisation. These systems are especially often planned to support delivery of medical expertise for rural areas.
- **Insurance, cards, or systems that present the payer's view on health services:** These applications are developed to support the use of cards as means to access health services, to get information on the health insurance status, and to register users that are entitled to special services or reimbursements based on their health, age, or employment status.
- **Citizen-centred systems, patient-centred systems and health information portals:** These applications provide health-related

information for patients and health professionals, and additionally they may provide possibilities for consultation services or for buying pharmaceuticals or other health-related products.

- **Home care systems and health-related fitness systems:** Home care systems are meant to monitor chronic diseases at home, to monitor elderly patients, or to teleconsult professionals from home. These systems are often based on wireless technology, such as mobile phones or handheld computers. Home care systems are also used to help in the management of care, in preparing care plans and in coordination of actions and tasks taken by members of care teams. Health-related fitness systems are those meant for healthy people that want to monitor their well-being and fitness.

We see from these typologies that enablers for most e-health systems are the electronic patient records and Internet-based technologies. Electronic patient records make it possible to share medical information between the care providers across the health strategies and medical disciplines and facilitate consultation between care providers on a given patient. The electronic patient records also give possibilities for further networked applications such as electronic prescribing and integrated regional health information networks (Ruotsalainen et al., 2003). However, current electronic patient records still lack a uniform infrastructure for data exchange and systems are heterogeneous and lack agreed and shared vocabularies (Safran & Goldberg, 2000). This restricts sharing of information. Today many e-health systems are building more and more on e-commerce and e-government strategies and experiences on how to use Internet technologies to redesign operation of public services.

E-Health Systems Use by Citizens and Health Professionals

The use of the Internet by citizens and also by health professionals is increasing worldwide (Budtz & Witt, 2002; Fallis & Fricke, 2002; Gruen, 1999; Holliday & Tam, 2004; Rodrigues & Risk 2003; Silber, 2003; Wilson et al., 2004). The Internet is used to access health-related information by people who are ill but also by people who are healthy who look for advice on healthy lifestyles, diets, habits, and health-related products (Jones et al., 2001). Accessing health information is one of the most common reasons for using the Internet: 50% to 75% of Internet users have used it to search for health-related information (Powell & Clarke, 2002). In 2003 approximately 62% of American Internet users searched the Internet for health-related information (Spink et al., 2004). In some cases citizens do not use tailored health-related Web sites but general Internet search engines to access health information. In 2003 40% of Europeans used the Internet to access healthcare services and information (Wilson et al., 2004). Budtz and Witt (2002) showed that of 93 patients in a study, 20% had used the Internet to get health information. In another study, Larner (2002) followed patients for 6 months and found that more than 50% of them had Internet access, and 82% of them were interested in accessing Web sites with relevant medical information. People using the Internet for health information searches reported that they value the convenience, anonymity, and volume of online information (Powell & Clarke, 2002). The patients who search for specific information on their diseases, diagnoses, and treatments report that it is beneficial to have information, advice, and social support from the Internet (Potts & Wyatt, 2002).

In 2002, on average 78% of European general practitioners were online (E-Health, 2004) and 48% of them used electronic patient record systems and, to some extent, other information systems to receive laboratory results and to transfer patient data to other healthcare organisations. Even 36% of general practitioners used telemedicine systems for home monitoring via the Internet or e-mail (Wilson et al., 2004).

When analysing the use of e-health services and health information sources through the Internet, the key findings are that citizens want to have more information and they want better information (Wilson et al., 2004). The use of the Internet for health purposes is rising and citizens would like to have guidance from the health professionals regarding quality Web sites (Silber, 2003). The major reason for the citizens to use Internet information resources is to know more, to be able to ask more precise questions from health professionals, and to understand better health and well-being. Internet health resources support citizens to become better informed and knowledgeable, and through this they also may take more responsibility of their health and well-being.

However, the Internet and other new technologies will interfere with the communication between health professionals and between them and the patient. Impacts of the Internet use do not only come from the communication but from the operational availability of information resources. Holliday and Tam (2004) found that more than 90% of patients had expressed their wish to communicate with their physician via e-mail, but physicians were reluctant to do so. Physicians explained that the physician-patient confidentiality, time concerns, and increased exposure for malpractice were the major reasons for their reluctance. Physicians are somewhat opposing the use of the Internet, especially when it interferes with their decision-making activity (Gerber & Eiser, 2001; Kleiner, Akers, Burke, & Werner, 2002). There seems to be two reasons: A question of power and a question of danger. A question of power implies that physicians want to keep the control on the medical activities, and the question of danger implies that they want to keep control on actions and decisions that are their responsibility. Some physicians even fear that they become technical executors of decisions taken from third parties (e.g., Internet information sources).

Expected Benefits by E-Health Systems

Many studies (Alvarez, 2002; Ruotsalainen et al., 2003; Iliakovidis, Wison, & Healy, 2004) identify the promises of e-health to build on the advances in ICT to support the development of the healthcare infrastructure. Healthcare services are expected to be better accessible and data available any place and any time, independent from where data are stored or created.

Healthcare professionals expect that e-health systems have remarkable impacts on healthcare routines and practices (Eng 2001; Grimson et al., 2000; Ruotsalainen et al., 2003; Wilson et al., 2004). Reliable and accurate information would be available easily and rapidly at the time and place where it would be needed. It would be possible to view information on the prior history of the patient and on diagnostic investigations to avoid redundant testing. Communication between the healthcare providers would be independent of their physical location, and this results in time savings and increased accuracy of diagnosis and effectiveness of care. Health professionals would be able to update their knowledge and expertise though online training sessions and they would be able to consult international colleagues in dealing with particularly complex cases (Ruotsalainen et al., 2003).

Patients and citizens would benefit through better quality health information and services available to them (Ruotsalainen et al., 2003; Silber, 2003; Wilson et al., 2004). The possibility for home monitoring and treatment or follow-up would reduce the need for hospitalisation or travel in order to receive professional care. Patients would regulate with the consent the provision of their data to various healthcare providers. The possibility to control one's own health data would facilitate and increase the mobility of citizens and patients, particularly those suffering of chronic conditions.

E-health systems are expected to harmonise healthcare systems, thus enabling provision of seamless and continuous care (Grimson et al., 2000; Ruotsalainen et al., 2003; Wilson et al., 2004). Interorganisational cooperation would allow sharing of data and information whenever necessary. E-health systems are also expected to result in improved quality and cost-effectiveness of healthcare systems. The fact that healthcare processes would be better documented and thus accountable would provide more possibilities for evaluation and quality assessment, and information could be made available to support decision making and interventions at the public health level.

Eysenbach (2001) listed the 10 *e*'s for e-health systems:

1. Improved *e*fficiency in health care and decrease of costs
2. *E*nhanced quality of care (e.g., by comparisons of care providers)
3. *E*vidence-based in the sense that the effectiveness and efficiency of interventions are proved by scientific evaluations
4. *E*mpowerment of consumers and patients
5. *E*ncouragement of a new relationship between the patient and the physician
6. *E*ducation of physicians through online resources
7. *E*nabling information exchange and communication
8. *E*xtending the scope of health
9. *E*thics as new forms of patient-physician interaction become possible
10. *E*quity to have health care more accessible to all

There is at the same time a threat that those people who do not have money, skills, computers, and Internet connections cannot access e-health services.

Despite of the availability of e-health systems and their potential benefits, e-health systems are not yet widely used in healthcare practices (E-Health, 2004). Iliakovidis et al. (2004) reported some examples of e-health systems which are now entering the European market. However, many promises of e-health research and development have not been fulfilled yet (Ruotsalainen et al., 2003). The major barriers (E-Health, 2004) include lack of commitment by healthcare authorities, missing interoperability of health information systems (which is mostly due to lacking conceptual models), ontologies, and sharable vocabularies. Additionally, the e-health developments by far have been rather technology-oriented and thus the developed systems are not easy to use, technology is expensive and the systems are vulnerable to changes in the environment. Maybe the most important reason for failures is that the socio-technical nature of e-health systems have not been fully considered. Development of e-health systems requires thorough understanding of the health care work practices where systems are to be installed. The needs of the users and the contextual aspects of the systems use should be the starting point for the development (Berg, 1999; Nykänen & Karimaa, 2004).

E-HEALTH VISIONS FOR THE FUTURE

The challenges for e-health are technical, social, economic and political. Eng (2001) pointed out that there is need for strong leadership from health policy makers and need for practical solutions for interoperable systems that are secure, respect confidentiality, and promote the best possible access to health care for all citizens.

In our survey (Ruotsalainen et al., 2003), several of the respondents looked for a comprehensive e-enabled healthcare system, standardised and interoperable, which meets the necessary legal and functional requirements for optimal, seamless, cross-border delivery of services. Implementation of such a system is expected to lead to more equal, accessible, holistic and human-centred healthcare.

In the future we suppose that several Internet-related and other trends will have influence on the design, content, functionality, dissemination, and use of future e-health systems. With globalisation, increasing number of e-health resources will be developed overseas and for global audience (Eng, 2001). Thus, standardisation and cross-cultural factors will become increasingly important.

The digital generation will most likely demand immediate access to information and will rely on online resources to inform health and other decisions (Eng, 2001). Wireless technologies may contribute to the growth of mobile e-health applications for both providers and consumers. Digital television may serve in the future as a cheap and easy platform to offer e-health systems and information for large audiences. Personalisation and tailoring of applications to specific users will put emphasis on privacy and data security issues.

There are many important questions still unanswered with e-health systems: Ethical and legal issues? Who will pay for the use? Who has access to e-health systems? What are the standards, guidelines and good practices for development and use of these systems and technologies?

The basic requirements for the future e-health applications can be derived from the current health informatics and e-health situation. First, e-health applications should serve the users needs, the needs of citizens, patients, healthcare professionals, and healthcare organisations. Second, the applied technology should be user acceptable, cheap and not too cumbersome to use, and vulnerable to changes. Third, e-health applications should be based on the health care information systems infrastructure, they should be integrated with the environment and preferably also be interoperable. Fourth, standards should be applied on design and development. Fifth, security and safety issues have to be solved within the practice and legal frameworks. And finally, all e-health systems and applications should be evaluated to assess the effects and impacts and to find reasons for success or failure.

Chapter 8.2
Healthcare Organizations and the Internet's Virtual Space:
Changes in Action

Stefano Baraldi
Catholic University, Italy

Massimo Memmola
Catholic University, Italy

ABSTRACT

For some years now, the opportunity of innovating business models has basically been linked to continual progress in ICT. Healthcare is no exception; information and communication technologies are generally considered the most effective driver for changing organizations, improving quality, optimizing resources, and so forth, at least in theory. In practice, it is not clear which and how many of these opportunities are really exploited by organizations operating in healthcare. This chapter presents the results of a research project aimed at understanding to what degree and how Italian healthcare organizations make use of the virtual space made available to them by the Internet.

INTRODUCTION

"Who doesn't know the Internet?!"

This is certainly one of the most common answers when hospital patients are asked about their knowledge of the Internet phenomenon.

In fact, it is likely that the word Internet is one of the most common and widely used in Western societies. Whether walking in the streets of New York, Paris, London, or Rome, if passersby are asked the simple question, "What is the Internet?" the answer is always the same: The Internet is something that enables us to communicate, read, learn, play, purchase goods and services, make transactions, and more.

The answer does not vary. Often, in fact, people do not know the technology behind the Internet, but they know what it can be used for. In other words, people know how to use technology even if they do not know how it works (which can be said for many new technologies).

Certainly, new technological developments and their awareness can only increase further thanks to the spread in recent years (or rather in recent months) of mobile communication devices. Equally, it is easy to predict the same happening in developing countries: Because of its low cost, the Internet is often preferred to the telephone for communication with these countries.

The Web, therefore, has changed our lifestyle, our habits, and our way of working, interacting with our acquaintances, and, in few words, dealing with so many aspects of our daily life. We no longer have to physically go to the bank but can transfer money and check our account balances by logging on to our bank's Web site. In the same way, booking our holiday is easier when we can click on the site of a tour operator. The list goes on and on: We can shop online instead of at our local supermarket, or buy books and DVDs from a company abroad.

In the world of healthcare, this revolution has yet to be realized, at least fully. In recent years, literature has often indicated how the digitalization of clinical, organizational, and management processes of health structures brings undeniable benefits both for the efficiency and effectiveness of the company, as well as improving the quality of service offered to patients (Coile, 2002; Goldstein, 2000; Nicholson, 1999). More particularly, the Internet considerably affects the entire process of the creation of the value of a healthcare organization (HCO) if we consider the following:

- It gives the organization a global presence
- It means it can offer more services that are more readily available to more users
- It allows the collection and elaboration of a greater amount of information
- It provides a new channel, the World Wide Web, through which it is possible to transfer information, provide services, make transactions, and create a privileged area of interaction between physicians and patients

The possible applications in a healthcare organization, limited only by the state of the art of technological development, can be schematized according to their functional characteristics.

THE INTERNET AS A TOOL FOR REDUCING GEOGRAPHIC DISTANCES AND AIDING THE DISTRIBUTION OF SERVICES OF A HEALTHCARE ORGANIZATION

The opportunity to provide services in inaccessible areas is one of the aspects of the Internet that has multiple applications for healthcare:

- **Home monitoring:** This service allows the patient to be cared for at home, or in the most convenient place, either through prearranged or automatic transmission of signals and vital parameters, or through the sending of alarms activated by predefined emergency situations. Healthcare personnel can also call back and give instructions to the patient or to semiautomatic equipment.
- **Telemedicine:** This is the provision of a treatment service or remote assistance in the form of tele-consultation, tele-presence, second opinions, Electronic Medical Record, (EMR), and so forth. Generally, these services are offered via the Web and may involve videoconference connection between the patient and the doctor or between medical personnel.

The Internet as a Tool for Sharing Information

The Internet is a special way to exchange information:

- The Internet can be used to share clinical information, both for applications developed to be shared totally or to be shared partially and securely. This can include information contained in clinical records (electronic health records, EHRs) to be shared with healthcare personnel belonging to different organizations who treat or have treated the same patient using secure electronic post services (encoded and authenticated).
- It can be used to research and develop new diagnostic-therapeutic processes or protocols aimed at providing welfare assistance through the use of applications similar to those already developed.
- It can also be used for epidemiologic observation through the development of an information flow for the rapid collection and distribution of epidemiologic information for healthcare companies and organizations.

The Internet as a Support Tool for Management and Training of Human Resources

The technologies of information and communication provide an effective tool the following:

- Running and managing the organization (business intelligence, data warehouse systems, etc.).
- Distance training of operators, providing considerable possible savings in costs and significant benefits for the levels of services offered.
- Managing the organization's information system and integrating, through the Internet, departments and organizational units.

The Internet as a Tool for Reducing Informative Asymmetry

Informative asymmetry is characteristic of any service-providing organization. The transmission of clinical information through the Web allows patients to be guided and informed about their health, and provided with expert advice about illnesses, prevention, and treatments available.

In this way, patients become more aware of the progress of their treatment and the traditional physician-patient relationship is transformed. However, there is still the problem of appointing an authority to guarantee the quality of the information provided.

The Internet as a Tool for Reducing the Cost of Transactions

The most popular service offered is that for making appointments online for diagnostic examinations or specialist treatments through an SBC (single booking centre) set up for a single healthcare organization or for a larger catchment area such as a city or even a region. Other possible applications include the possibility to access the results of diagnostic investigations online, to search for a medical specialist for the treatment of a pathology, to download required documentation for requests and reports, and so forth.

The Internet as a Multipurpose Tool with Virtually Infinite Capacity

The opportunity to provide services through the Internet to several users simultaneously without the physical presence of the doctor has meant that many other operations in the chain of value of a healthcare organization have been revised; this has been shown in many of the solutions described previously (telemedicine, home treatment, online booking, clinical information services, etc.).

In light of this, it is clear that the Internet offers the world of healthcare enormous potential, which can be exploited to improve both efficiency (helping reduce some of a country's highest public costs) and effectiveness (with a consequent improvement in the level of the quality of services offered). There are, however, factors that may limit the spread of Internet solutions or, at worst, lead to the failure of projects under way.

For patients, a highly negative factor is the still-limited access to the Web for many potential users (even in economically advanced countries) and what can be defined as electronic illiteracy, particularly for low-income families. The difference in terms of the needs of those who have access to the Web and those who do not, which is destined to increase, will make it even more difficult for healthcare organizations to decide what to offer. Furthermore, some patients are reluctant to use the Web in so far as they are unable to perceive the qualitative level of the information and services available or simply because they prefer to maintain a more personal relationship with their own physicians.

It is physicians themselves who can be the pioneers of the new technological standards of healthcare when they accept the Internet and ICT solutions in their work and consequently redefine their own competencies. It is not impossible to foresee that in the future the teaching of medicine will involve computers and Web tools for distance learning.

Finally, there are still healthcare organizations and managers who run them who are unable to understand how or why to use available technology, or, more importantly, how to evaluate what the returns for investments could be. In particular, whoever is in charge of an organization (production or healthcare) should be aware that introducing the technology is never an end in itself, but should be regarded as the result of a careful strategic plan through which a thorough evaluation of the real, physical, and virtual consequences of some activities of the chain of value is produced. The benefits, in cost reductions, that may come from the introduction of virtual processes in an organization might, in fact, be cancelled out by the greater costs that other units in the organization accrue.

Moreover, it is also relatively easy to find examples of failure, often caused by a lack of strategic vision or knowledge of how the Internet (and more generally ICT technologies) can change the traditional basic rules of treatment services (Given et al., 2001a; De Luca & Enmark, 2000; Fattah, 2000; Flory, 1999; Glaser, 2002; Minard, 2001, 2002).

On the other hand, several factors (including health demand, medical developments, reduced resources, and increasing competitive pressure) lead us to consider ICT as one of the fundamental means for solving the paradox of doing (ever) better with less. In healthcare, too, the key question seems to be not whether to deploy Internet technologies, but how to deploy them (Given et al., 2000; Porter, 2001).

Starting from this point of view, we carried out a research project (named Health.Net) in order to understand to what extent and how Italian HCOs actually exploit and use the virtual space offered by the Internet.

OBJECTIVES AND RESEARCH METHODOLOGY

In our research, we have tried to focus on the real ability of HCOs to use the Internet to support their organizational, clinical, and management processes (Given et al., 2001b; Alemi, 2000; De Luca & Enmark, 2000; Solovy & Serb, 1999), and to create value (Glaser, 2000) not only for their own users, the patients, but also for all their stakeholders (physicians, staff, students, other HCOs, etc.).

In particular, we tried to shed some light about these issues:

- To what extent and how do Italian HCOs inhabit the Internet?
- What kind of strategy is guiding Italian HCOs in creating their own visibility on the Web?
- What are the results achieved? How much of the opportunities offered by the Internet have been actually exploited?

- What progress is being made by Italian HCOs in the exploitation of Internet potential?
- What are the latest trends and the scope of change?
- Is there any difference or delay in regard to other national healthcare systems?

The project has been carried out in two separate steps: the first in 2002 and the second in 2005. Both in 2002 and in 2005 we tried to accomplish the following:

1. Position the Italian healthcare system in an international context.
2. Analyze the public presence of Italian HCOs on the Internet.

In each year, the first stage of the project (aimed to position the Italian healthcare system in an international context) has been carried out by comparing Italian HCOs with the following:

- A sample of 121 companies in six foreign countries (United States, Canada, United Kingdom, France, Germany, Spain); we paid attention to the biggest structures (i.e., those having over 200 beds) in the capital city or in a similar city in terms of healthcare facilities (Boston, Toronto, London, Paris, Frankfurt, and Milan). HCOs were identified thanks to data displayed on the Internet sites of national ministries.
- Nine HCOs acknowledged as benchmarks in the international literature; benchmarks were identified according to the conclusions drawn in a study carried out in the United States (Goldsmith, 2000). The benchmark Web sites achieved the best performance in terms of contribution to business growth and patients' satisfaction.

During the second stage, we analyzed the presence on the Web of all the Italian HCOs (both public and private) that are officially registered in the database of the Italian Ministry of Health.

In order to give greater significance to the information gathered, it was decided, nevertheless, to consider only autonomous structures as much from a legal point of view as an economic one, in other words, only those organizations that have registered (or can register) a domain with their own name. Thus, for organizations dependent on a local health authority, we considered only the site of the latter; equally, the same approach was used for private structures that are subsidiaries to larger companies.

1,002 organizations were identified in 2002, and 990 in 2005. The reduction in the number of organizations usable for research depended on the following:

- The mergence of some hospital structures by local health authorities decided by some Italian regions.
- The setting up of a process of concentration in large national private healthcare organizations.

Each organization under study was classified as one of five main types: local health unit (LHU, 20%), independent hospital (IH, 10%), scientific institute for research and care (SIRC, 4%), university polyclinic (UP, 1%), and private structure (PS, 65%). The percentage of the total for each type did not change between 2002 and 2005.

For each of these organizations, a preliminary investigation accomplished the following:

a. Identified the HCOs' Web domains by means of the most common (national and international) search engines; in case of broken (no) links, companies were contacted by phone.
b. Took note of Web site status (active, not active, under construction, partially under construction).

At the end of this preliminary phase, 473 sites were identified (47% of the total) in 2002 and 574 sites (58% of the total) in 2005.

In the first year, successive elaborations of the research concerned all the organizations present on the Web. In 2005, we decided to take a sample of 136 sites of the 574 originally identified. The statistical technique used to describe the research sample is that of stratification (Frosini, Montinaro, & Nicolini, 1999).

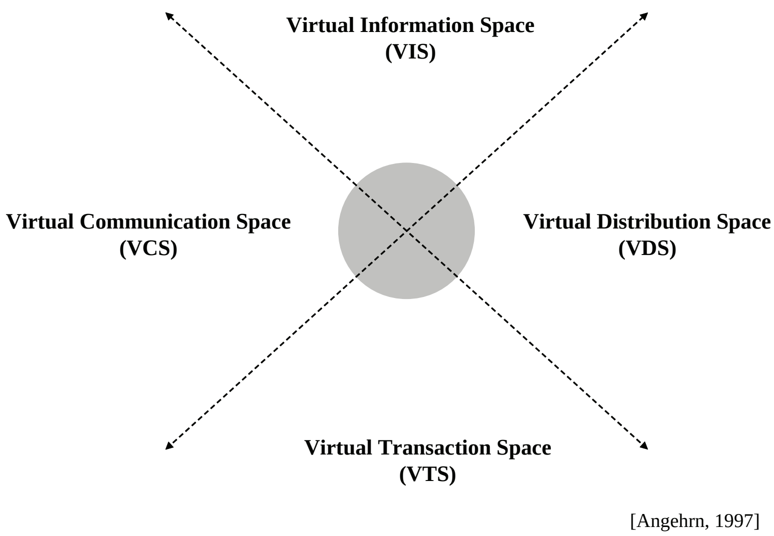
Using this technique, it is possible to obtain an increase in the efficiency of a sampling plan as it reduces the sampling's order of greatness of error without increasing the number of samples.

The population was separated into strata internally as homogeneous and heterogeneous as possible. In other words, the population was divided into *n* underpopulations. From each stratum or underpopulation, a single random sample was taken; there were therefore as many samples as strata. The numerousness of each stratum was decided according to the variance that the stratum presented with reference to the data from the first year, for which a higher number of samples of strata with a greater internal variability were considered. The total number of the samples is obviously equal to the sum of the numbers of each single stratum.

To evaluate not only how many HCOs are on the Web but, above all, the features of their Net presence, we used the ICDT model (Information, Communication, Distribution, Transaction; Angehrn, 1997). Angehrn states that companies should look at the Internet not as a simple communication tool by which information can be exchanged (Nicholson, 1999), but rather as a space in itself, virtual of course, which they can "colonize" in different ways and to different levels, following a strategic vision or not. In this sense, the ICDT framework (Figure 1) effectively works to evaluate which kind of strategic approach is actually guiding HCOs in the conquest of their space on the Web, and, to sum up, how and to what extent, and how successfully, they exploit the opportunities offered by the Internet.

The model takes its name from the segmentation of Internet virtual space into four areas: a virtual information space (VIS), a virtual communication space (VCS), a virtual distribution space (VDS), and a virtual transaction space (VTS). This segmentation emphasizes that the "Internet has extended the traditional market

Figure 1. The ICDT model



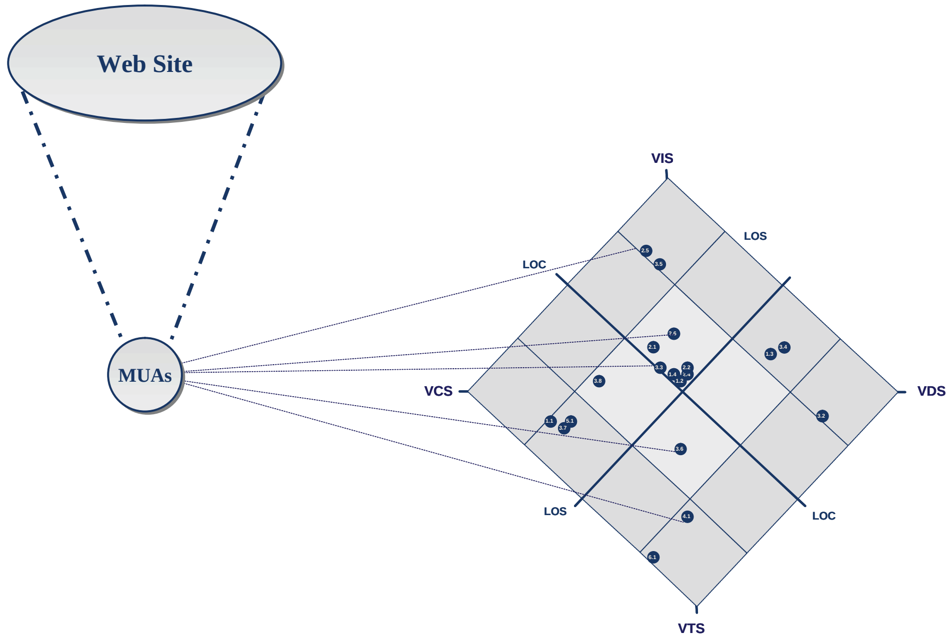
space by providing new spaces in which economic agents can interact by exchanging information, communicating, distributing different types of products and services and initiating formal business transaction" (Angehrn, 1997, p. 362). Some particularities are as follows:

- The VIS consists of the new Internet-based channels through which economic agents can display information about themselves, and the products and service they offer. A hospital can provide patients and any other user with different kinds of information, such as its structure and history, information about how to reach the hospital, available services and clinical specialties, access modes, research projects, and so forth.
- The VTS consists of the new Internet-based channels through which agents can exchange formal business transactions such as orders, invoices, and payments. An HCO can refer a patient to remote transactions such as checkup or hospital-admission online booking, diagnostic-reports consultation, service payments, or medicine purchase.
- The VDS represents a new distribution channel suitable for a variety of products and services. It is a Web space by which companies can provide e-services or e-products. Using such space effectively definitely calls for modifications in the traditional physician-patient relationship as it hosts a wide range of services in telemedicine (teleconsultations, tele-diagnoses, remote access to health-improvement or health-monitoring programs), in prevention, in education, and in information on medicines.
- The VCS is the extension of traditional spaces in which economic agents meet to exchange ideas and experiences, influence opinions, negotiate potential collaboration, and so on. It is an opportunity to create a virtual community in which users can exchange ideas and opinions. Forums, chat lines, and newsgroups can promote debate and discussion among patients and/or between physicians and patients about their own experience, pathologies, and related issues.

We mapped the HCOs' presence on the Web according to their approaches and modes to actually use these different spaces (Figure 2). In particular, we paid attention to the following variables:

- **Complexity**, that is, how far HCOs turn to the Internet to support their institutional activity; an intensive and extensive use of such technology is likely to result in a rich and highly informative Web site that can provide users with corporate information (VIS), services (VDS), interaction and communication (VCS), and transactions (VTS).
- **Typology**, that is, the more or less balanced way in which HCOs exploit the Internet virtual space, achieving a presence in some rather than in all the different kind of spaces (VIS, VTS, VDS, VCS) of the IDCT model.
- **Quality**, measured by considering the level of sophistication (LOS) and the level of customization (LOC) of their Web sites. These two indicators were chosen in order to evaluate the concept of quality objectively and concretely rather than subjectively and vaguely. LOS refers to the technological level (indicating any multimedia elements), while LOC determines the degree of customization of the site content in accordance with the user's specific needs.
- **Effectiveness**, in terms of HCOs' Web site visibility (hits obtained using the most common search engines) and success (number of visitors).

Figure 2. Mapping the Internet presence



Thus, the presence of HCOs on the Internet has been evaluated by the study of the MUAs retrieved from their Web sites (see Table 1). An MUA is a Web site area featuring homogeneity in content and thus embodying a precise territory in the Internet virtual space. Each MUA may spread over more than a single Web page or share the same Web page as other MUAs. Each MUA has been positioned with regard to the following:

- Within its own virtual space of competence (VIS, VDS, VCS, VTS)
- The closer to the margins, the higher the LOS and LOC indexes, which appear on the axes in the graph.

This method has enabled us to evaluate to what degree and how the HCOs that are officially online are really enhancing their presence on the Web. Figure 3 gives as an example the maps relative to the Internet presence of HCOs. Each HCO exhibits one of the following characteristics:

- Although starting with the use of the Internet as a simple, cheap means of communication, it is beginning to expand and significantly improve its presence on the Web, "attacking" other types of virtual space (e.g., X).
- It seems to be interested only in some of the opportunities offered by the Internet in various virtual spaces (e.g., Y).
- Although present on the Internet, it is unable to fully exploit the Web's potential (e.g., Z).

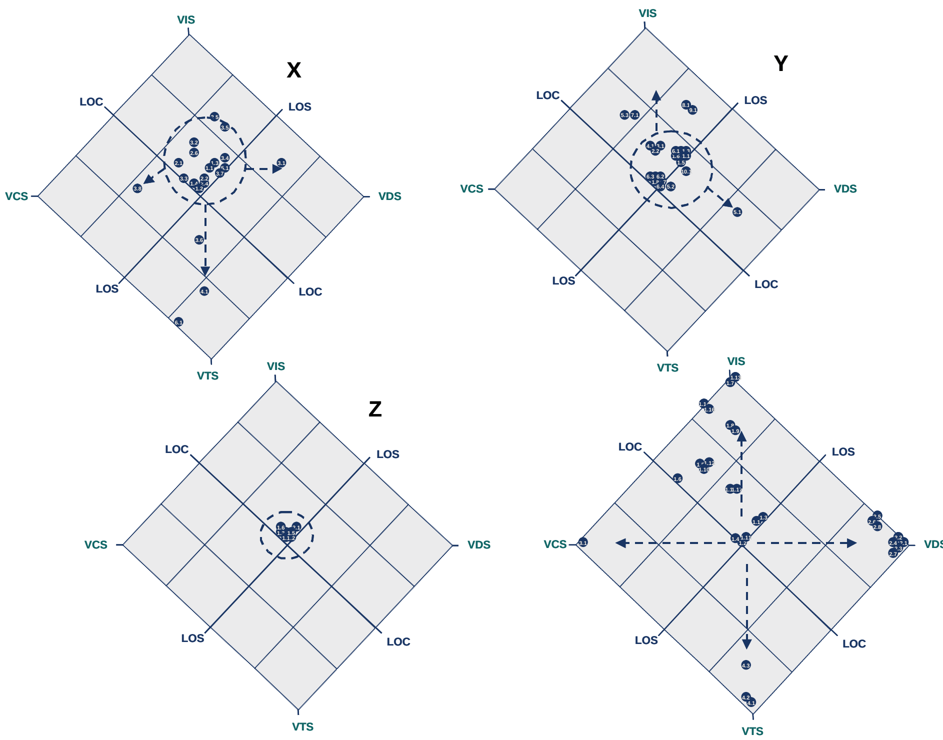
The different types of behavior shown by HCOs in occupying the Internet's virtual space have been grouped into three main clusters:

- The **pioneers**, whose results are better than the national average. These are the HCOs that are more convinced of the potential offered by the Internet and therefore exploit it to a greater extent.
- The **followers**, whose results are in line with the national average. These are the HCOs

Table 1. Methodology for analyzing the Internet presence

Step 1: Preliminary research	• identify Web-site domain by search engine or contacting the HCO by phone • verify Web-site status (active, not active, under construction, partially under construction)
Step 2: Internet presence complexity	• examine Web-site contents and classify them in minimum units of analysis (MUAs) • assess the existence of other structural features (foreign-language version, native-language search engine, Web-site map, extranet)
Step 3: Internet presence typology	• position retrieved MUAs in corresponding virtual space areas (VIS, VDS, VCS, VTS) • verify Web-site use of Internet potential
Step 4: Internet presence quality	• assign the LOS of each MUA • assign the LOC of each MUA
Step 5 : Internet presence effectiveness	• verify Web-site visibility by means of the most common search engines • measure average Web-site traffic

Figure 3. The Internet strategy of an HCO



that, compared with the other members of the sample, are starting to expand and improve their presence on the Web to a greater extent.

- The **latecomers**, whose results are below the national average. These are the companies that, although present on the Web, only exploit its potential to a very limited extent.

MAIN FINDINGS: INTERNATIONAL SURVEY

The Complexity of Internet Presence in the International Sample

There is a considerable distance between the benchmark and the other organizations that make up the international sample. Organizations in the United States and Canada perform best both for the quantity of contents offered on their sites and for the index of complexity. From 2002 to 2005 there was a substantial increase of values assumed from the variables investigated (particularly in the number of MUAs), with a reduction of the gap between European healthcare organizations when compared with those in the United States and Canada.

Through this analysis, we wanted to examine the consistency of the Internet presence of healthcare organizations, not simply according to the number of pages of content on the site, but rather for the value of the content offered in order to achieve the following:

- Give information in the VIS area.
- Deliver services in the VDS area.
- Provide a virtual communication space in the VCS area.
- Accomplish transactions in the VTS area.

Evidence shows that richer content in the different areas is limited to a higher Web site complexity as measured by two indicators: (a) the number of MUAs on the Web site and (b) the structural complexity index (SCI).

The number of retrieved Web site MUAs measures the richness of the content of HCOs' Web sites and ranks their complexity.

SCI is related to a series of structural features intended to improve Web site user friendliness. It is indeed likely that richer content requires greater skill of the user (i.e., patients, physicians, students, or any other stakeholder) in searching for desired information: In such cases, a native-language search engine and a Web site map are, no doubt, helpful. The SCI, then, results from the ratio between actual Web site structural features and research-relevant ones, including the following:

- Native-language search engine
- Web site map
- Foreign-language version of the Web site
- Extranet access

An extranet network can be described as a nonpublic presence on the Internet of an organization. Unlike an intranet, which presupposes a totally private exploitation of the network inside the organization and is reserved for the people who work there, an extranet enables information and content to be offered securely outside the organization. In fact, it can be used to share treatment protocols or, more generally, clinical information between hospitals or physicians, or to provide suppliers with information. Therefore, although not being a tool for improving the readability of a site's contents, an extranet does directly affect the degree of complexity of the Internet presence.

In general, what clearly emerges from examination of the complexity of Internet presence is the considerable distance that separates the group of the benchmark organizations from the others making up the international sample. Moreover, this gap, which is mostly consistent in other areas of research analysis, further increased in 2005.

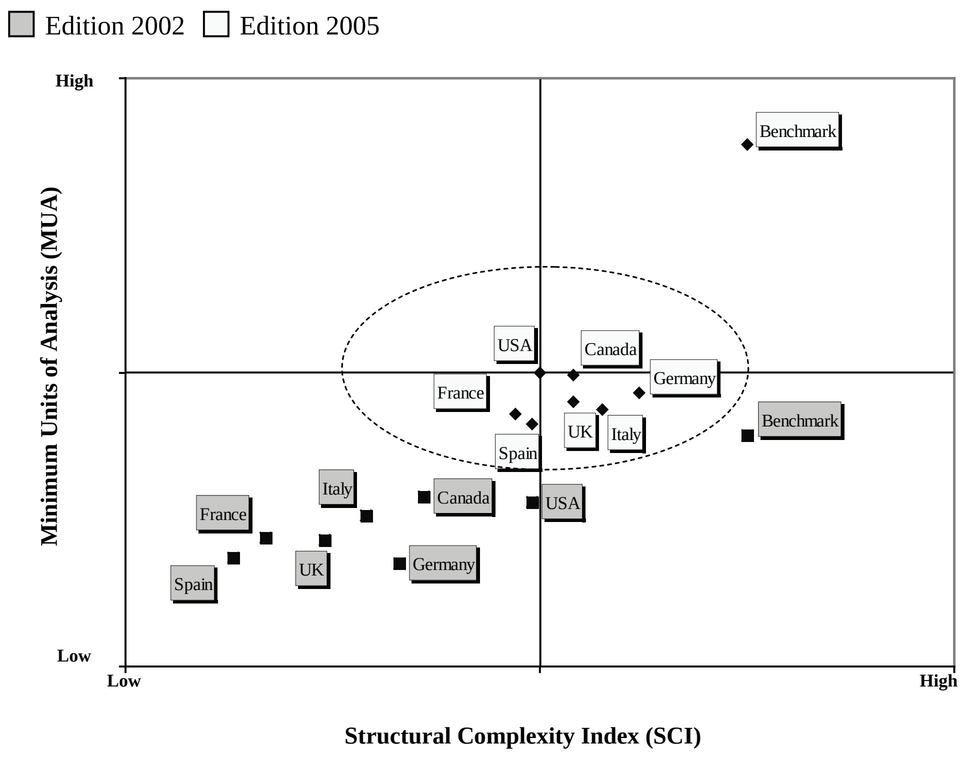
Regarding the quantity of informative contents or services offered by the site, in the year, only the organizations in the United States and Canada performed in any way comparable with those of the benchmark organizations: The average number of MUAs identified was 16.79 for the United States and 17.35 for Canada compared with an average for the benchmark organizations of 23.56. The European average was considerably lower (12.71 MUAs) with the United Kingdom (12.96), Italy (15.47), and Spain (13.2) being more advanced than France (11.17) and Germany (10.75).

Analysis of data from 2005 shows that there was considerable growth in the quantity of content available on sites of healthcare organizations in both Europe and America, but not enough, however, to bridge the gap with respect to the benchmark organizations, which continued their steady growth. Once more, it was the U.S. and Canadian organizations, with an average number of MUAs of around 30 units that were nearer the benchmark 53.22. European organizations, nevertheless, markedly improved their position with an average number of MUAs of 26.32; in contrast to 2002, there was greater homogeneity with no major differences between European countries (Figure 4).

Analysis of the SCI, apart from the theme of the gap between the benchmark and the rest of the international sample (particularly as regards the European organizations), showed for 2002 a particularly high result for U.S. organizations (49%) compared to Europe (23%) and Canada (36%). In Europe, the highest values were in Italy (29%), Germany (33%), and the United Kingdom (24%). Scores for France and Spain were considerably lower at 13% and 17%, respectively.

Here, too, in 2005, there was greater homogeneity of values with an average European figure of 54%, perfectly in line with U.S. organizations at

Figure 4. The complexity of Internet presence of the international sample



50% and those in Canada at 54%; still, however, it is a long way from the benchmark of 75%.

Further interesting points emerge if we examine individual organizational features (foreign-language versions, site maps, internal search engines, access to an extranet).

We now find that the Web sites most likely to have an international slant are those in Italy, Germany, France, and, to a lesser degree, Spain: In these countries, in fact, a foreign-language version of the site is present in 35% of the sites analyzed in 2005. It is also the case that, because of the international importance of the English language (the official Internet language), organizations in the United Kingdom do not much concern themselves with presenting the content of their sites in another language. This factor is probably mitigated in the U.S. and Canadian organizations by the presence of a multiracial society: 29% of U.S. organizations and 15% of those in Canada offer foreign-language versions.

The site map and internal search engine are the two factors that most influence the user friendliness of a site, and nowadays are almost universally present on organizations' Web sites in the international sample; the high number of MUAs activated in sites inevitably creates difficulties in searching for information or services.

The extranet, finally, continues to have a low presence, even at an international level. It is present in little over half of the benchmark organizations (56%), in about a third of those in Canada (33%), a quarter of those in the United States (24%), and a lowly 13% of European ones.

To indicate the complexity of Internet presence, Figure 4 shows three distinct clusters:

- Pioneering organizations that constitute the benchmark and are clearly more advanced than those in the international sample.
- U.S. and Canadian organizations that, despite European organizations making progress, continue to lead, but are still some way behind the benchmark organizations.
- European healthcare organizations, the late arrivals, whose reference values were more homogenous in 2005 and are approaching U.S. and Canadian values.

The Typology of Internet Presence in the International Sample

Only the organizations that make up the benchmark have a widespread and homogenous presence on the Internet, fully exploiting its potential. Despite the progress made in 2005 compared with 2002, the organizations that make up the international sample only partially exploit the Internet, limiting themselves, in the case of European organizations, to a Web strategy with a low to medium profile.

Corporate Web presence enables companies to take advantage of virtual space, whose different areas (VIS, VDS, VCS, VTS) can be variously exploited.

The typology of Internet presence (Step 3) maps HCOs' strategies in colonizing such space in terms of the number of colonized virtual spaces and the actual exploitation of the different kinds of colonized virtual spaces.

The indicators employed in measuring such elements are, respectively, as follows:

- The colonization index, obtained by listing colonized areas (VIS, VCS, VDS, VTS).
- The coverage index, that is, Internet virtual space coverage, both globally and by single area.

The colonization index (how many virtual spaces are actually used by HCOs) is a rather simple, but very useful, indicator for measuring the evolutionary stage reached by an HCO's Internet strategy. However, as areas can be colonized even by a single MUA, this indicator does undoubtedly provide only an approximate value, which has to be completed with the analysis of the coverage index.

While the colonization index measures corporate colonization of single Internet virtual areas, the coverage index ascertains how far companies benefit from it. More specifically, the coverage index by single area is given by the ratio between (a) the number of MUAs in each area of the Web site and (b) the total number of research-retrieved MUAs for each area. The global coverage index is thus the arithmetic average value of all single areas; it measures the overall, though approximate, dimension of how far companies are taking advantage of the Internet's potential.

Regarding the colonization of different sectors of the Internet, it is clear that only the benchmark organizations have a widespread and homogenous presence, fully exploiting the many opportunities that virtual space provides (Figure 5).

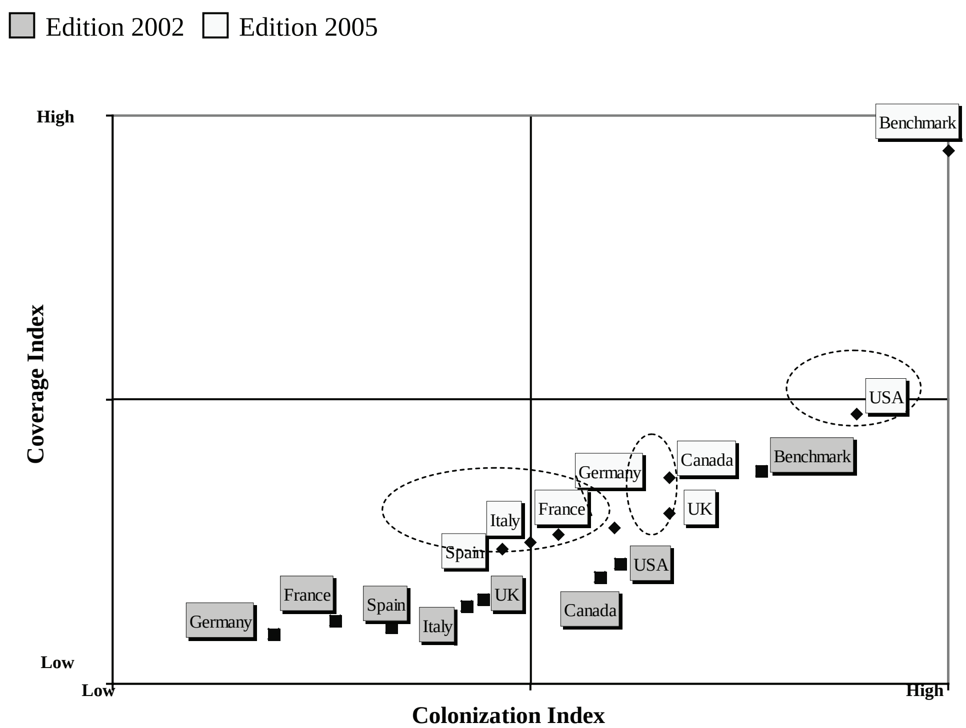
The USA and Canada, as usual, are at a higher level than the European average, in both 2002 and 2005. Organizations in these countries, in fact, occupy three or more of the four areas (VIS, VDS, VCS, VTS) that the Web offers: The average numbers of areas colonized in 2005 were 3.67 and 3.00 respectively. European organizations, on the other hand, adopt a more traditional or low-profile strategy to exploit the Web; the colonization of Internet space remains on average limited to less than three areas (2.66).

Organizations in the United Kingdom (average colonized areas was 3) have a more pervasive Internet presence than the rest of Europe (about 2.5 areas).

Therefore, as often happens, numbers only are not enough to fully describe a phenomenon. Even if, in several cases, development of the presence occurs rather casually depending on contingent circumstances, the logical sequence of colonization of the different spaces, as happens in other sectors, is in this case too, tied to the need to resolve particularly serious organizational crises.

A typical path of development for Internet presence can therefore be outlined as follows:

Figure 5. The typology of Internet presence of international sample



- Entry onto the Internet is by means of the VIS area, which in strategic terms is that which is first attacked by organizations in the initial phase of their presence on the Internet, generally without clear rethinking of their marketing policy, and featuring a traditional approach as regards the media (the traditional "shop window" site); none of the international organizations studied were of this type.
- Later developments involve the VTS area, with the aim of facilitating interaction with patients (online booking of appointments, distance medical reports, complaints and suggestions), suppliers, staff, and so forth; 32% of HCOs have colonized the virtual space made available by the Internet in terms of VIS and VTS.
- Only later, and so far to a limited degree, do HCOs try to provide some of their services through the Internet (VDS area), especially LHUs; 44% of HCOs have managed to increase their presence on the Internet beyond VIS and VTS into a virtual distribution space.
- The VCS area is clearly that which is considered least important, partly because it does not correspond to any of the traditional organizational roles, nor does it provide immediate advantages in terms of optimization of existing organizational processes; 24% of HCOs are currently present in all four types of virtual space provided by the Internet.

The information that emerges from analysis of the coverage index average (Figure 5) shows that, with the exception of the benchmark organizations, the Internet still offers the potential for enormous developments. This is supported by the fact that even with the marked improvements seen in 2005 with respect to 2002 (with percentage variations equal to or over 200% for the United States and Canada, and Europe too), the coverage index remains overall rather low.

There is an abyss between the benchmark organizations and the rest of the world: The ratio of the exploitation of the potential of the Internet is 1:2 for organizations in the United States and Canada (the coverage index in 2005 was 38% and 29% with respect to 75% for the benchmark organizations) and a low 1:3.3 for European organizations (which had an average coverage index of 21%). In Europe, the figures for 2005 were again more homogenous than those for 2002.

An examination of the typology of the Internet presence for organizations in the international sample puts them into three groups (Figure 5):

- The pioneers, comprising the benchmark organizations.
- The chasers, representing organizations in the USA and Canada.
- The latecomers, the other organizations in Europe.

The Quality of Internet Presence in the International Sample

If the benchmark organizations are excluded, once more it is the U.S. and Canadian organizations that perform best for the quality of Internet presence. However, for the user friendliness of informative content and services available on the Web sites, the period of 2002 to 2005 showed a partial closing of the gap by European organizations.

In evaluating the qualitative dimension of Web site content (Step 4), we paid attention to both technical and user-related aspects, such as user-friendliness in information retrieval. Among the several options at hand, research ascertained the quality of Internet presence using the following criteria:

- Level of sophistication.
- Level of customization.

Both are calculated in average terms on Web site-identified MUAs.

The LOS varies according to the technology (in its widest meaning) employed on Web site content editing; its index ranges from 1 to 5 in order to account for intermediate situations between the following:

- MUAs in static Web pages, edited without Internet-specific tools (using, for instance, MS Word, Powerpoint, and similar editors).
- MUAs in highly interactive Web pages, edited using the most recent multimedia tools (such as Flash View animations, audio and video files, pictures, etc.).

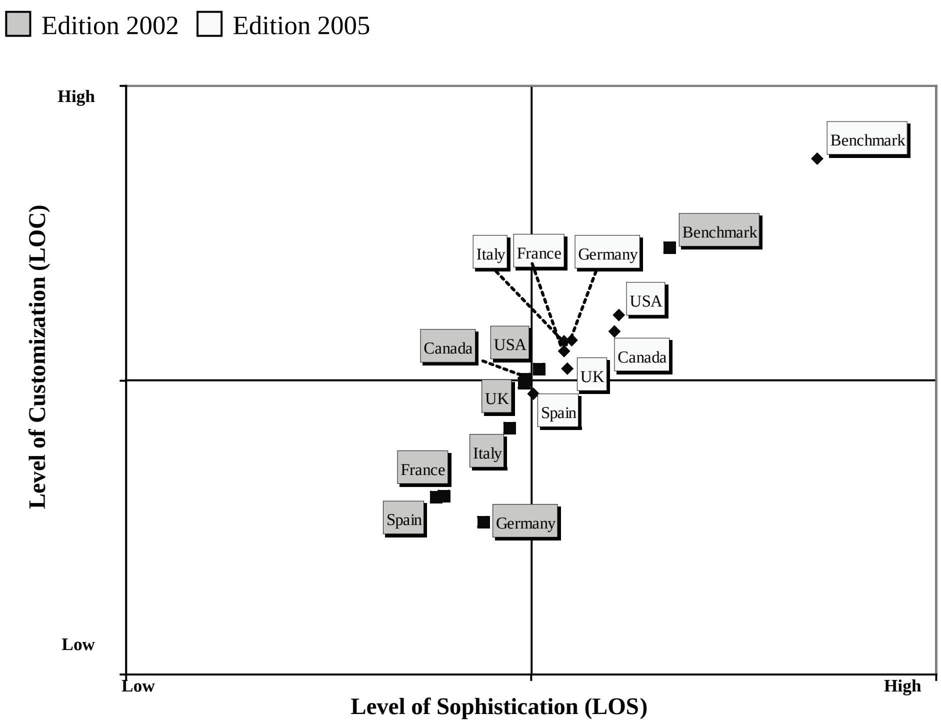
The LOC calculates how far users judge Web site content to fit their needs. In this case, too, the index ranges from 1 to 5 in order to account for intermediate situations between MUAs, as follows:

- MUAs in static Web pages that enable no customization of content and display no additional services.
- MUAs in highly customizable Web pages offering user-profile-related additional services such as e-mail, forums, chat lines, newsgroups, and so forth.

Overall, from the point of view of the level of technological sophistication, there emerges a substantial difference between the organizations that constitute the benchmark and the other healthcare organizations of the international sample, which, as has already been seen in other areas of research, grew further in the period from 2002 to 2005 (Figure 6).

In 2002, in fact, the LOS average for the benchmark organizations was 3.68 against an average value for the United States, Canada, and Europe of 3.04, 2.97, and 2.74 respectively. In Europe, sites of the healthcare organizations in

Figure 6. The quality of Internet presence of international sample



the United Kingdom had values of 2.96, more in line with those of the United States and Canada than with those of the rest of Europe.

In 2005 there was, as usual, a general improvement in values, but it was more consistent for the benchmark organizations (average improvement of 20%) compared with the rest of the sample (average improvement of 15%). More specifically, in the second year of the project, the benchmark organizations had an LOS average of 4.41, which was considerably higher than the average values for the USA (3.43), Canada (3.41), and Europe (3.14). These values indicate that the distance between America and Europe remains largely unchanged. In Europe, the most consistent improvements were in organizations in France (from 2.57 to 3.16), Germany (from 2.76 to 3.20), and Spain (from 2.53 to 3.01).

The same can be said for user friendliness (LOC; Figure 6). Here, from 2002 to 2005 there was greater homogeneity in average values in the USA and Canada compared to Europe. In fact, the average improvement percentage of American and Canadian organizations was 11.5% compared with 30% for Europe. More particularly, the LOC for benchmark organizations rose from 3.90 in 2002 to 4.50 in 2005, for USA organizations from 3.08 to 3.44, for Canadian organizations from 3.01 to 3.33, and for those in Europe from 2.43 to 3.14. Analysis in 2005 did not indicate major differences between European organizations.

Neither were there major variations for the quality of Internet presence (Figure 6):

- Benchmark organizations had an established position.
- Organizations in the United States and Canada were classified as chasers.
- The remainder of organizations in the international sample, mostly European, lags considerably behind the first two groups.

The Effectiveness of Internet Presence in the International Sample

The visibility of the sites of the foreign sample by the main search engines is very high. Generally, the organizations with the best performances for traffic recorded are those that best exploit the potential the Internet offers and consequently their results are higher in all areas of analysis.

HCOs are likely to turn to the implementation of a Web site for basically two main different reasons:

- To maximize their visibility on the Web, that is, rendering themselves available to the highest number of potential users.
- To maximize Web site use by their stakeholders.

As a consequence, their Internet presence effectiveness (and success) depends on reaching such goals. Thus, we decided to measure HCOs Internet effectiveness (Step 5) by jointly considering the following:

- A Web site visibility index, obtained using the most common national and international search engines.
- A Web site traffic ranking as measured by Alexa.com, which offers an international list of sites ranked according to average Web site traffic.

The first indicator measures how simple it is to find Web sites using the most common search engines. All HCOs were searched by name in Italian and international search engines (Virgilio, Lycos, Excite, Iltrovatore, Google, Yahoo, Search.msn, Altavista). Indexes were the ratios between positive responses and search engines' total numbers.

Alexa.com is a site ranking Web sites all over the world according to their traffic. Lists are updated quarterly, measuring both Web site and

Web-page access: The former quantifies Web site visitors per day (displaying its home page), and the latter is calculated considering the number of Web site URLs (uniform resource locators) accessed by the same user. The site hosting the highest Web site and Web-page traffic is ranked first.

It should be pointed out that Alexa.com can only provide an evaluation for the principal domain (e.g., http://www.domain.org or http://www.domain.com). For pages inside the domain (e.g., http://www.domain.org/page.html) or for sub-domains (e.g., http://www.hco.domain.edu), the value given is that of the principal domain. A zero value is given, however, in cases where traffic is so light compared to the average that it is not detectable (usually below position number 6,000,000 in the list).

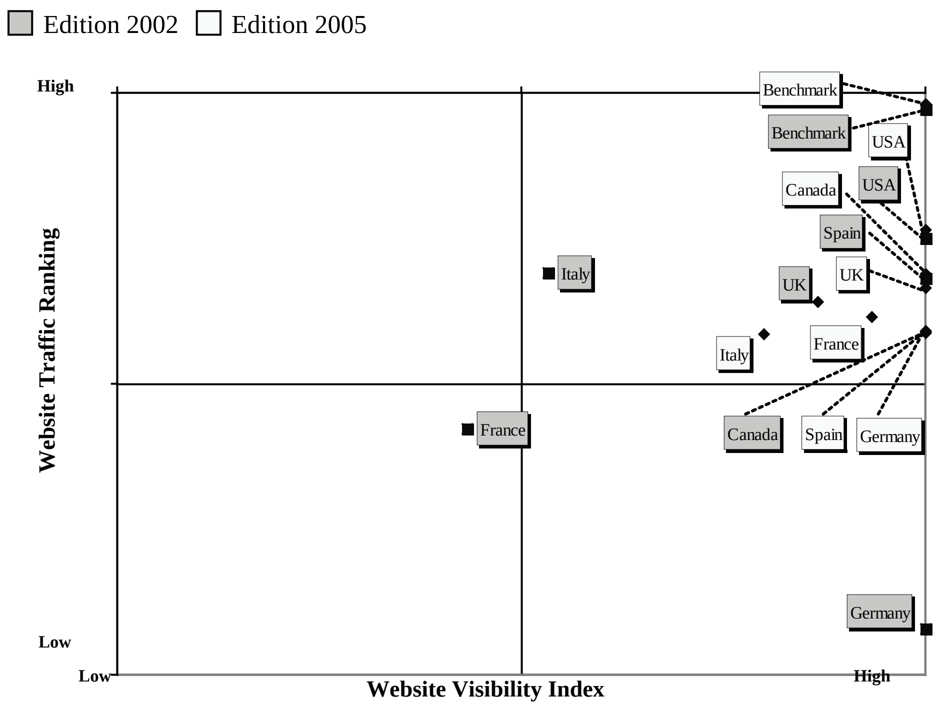
Finally, Alexa.com's evaluation includes all sites on the Web. A process to classify Italian healthcare organizations appropriately has therefore been undertaken.

By evaluating the visibility of organizations in the international sample with the selected search engines, the factor that emerges most clearly is the high traceability both for benchmark organizations and the rest of the sample (Figure 7).

The organizations studied have an almost total visibility in that they are reachable using any of the search engines considered. This, in light of the results of 2005, is the case for the benchmark organizations, for those in the United States and Canada, and almost always for those in Europe. In the latter case, exceptions are Italy and France, although visibility is still high at 94% and 98% respectively.

As regards the ranking of site traffic, generally, those organizations that best interpret the role and potential of the Internet get greater success in return: Figures from Alexa.com for the benchmark organizations are, in fact, considerably higher than for the rest of the organizations in the international sample, both in 2002 and 2005 (Figure 7).

Figure 7. The effectiveness of Internet presence of international sample



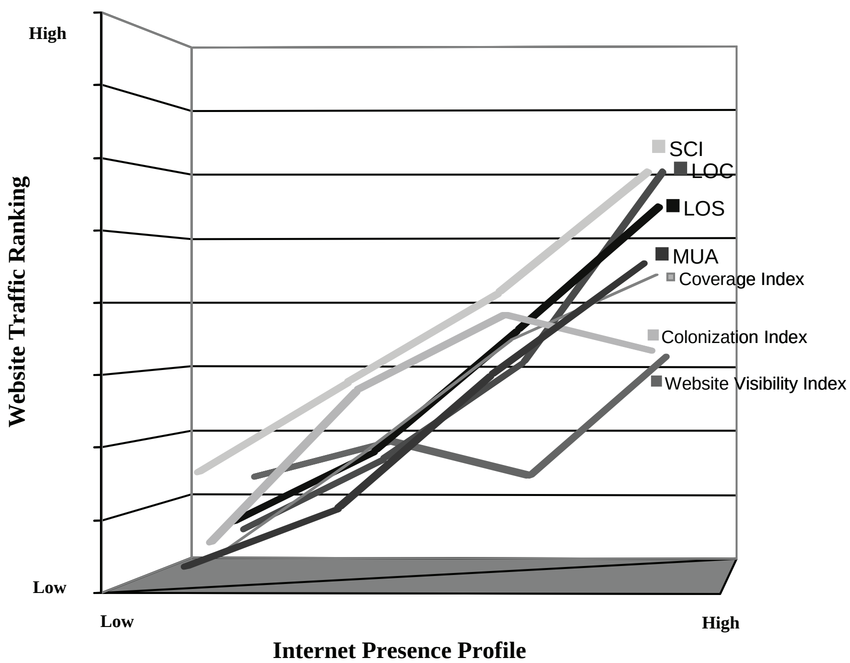
This general trend does not seem to be applicable in results recorded in 2002 for organizations in some countries, as, for example, Canada, Spain, and Italy. Ranking for site traffic, rather low for Canada and on the contrary high for Spain and Italy, are not in line with results obtained in other areas of analysis. In 2002, we attributed this to the following:

- The low population density for Canadian organizations.
- The fact that some sites of Spanish and Italian organizations were guests in the domain of a university or regional organization, and HCO site constituted only a section of the host site; in these cases, Alexa.com's evaluations were influenced by the volume of traffic recorded by the principal domain.

The 2005 research does seem to confirm these suppositions. Unlike in 2002, in fact, sites of organizations in Italy and Spain more often have their own domain that does not affect Alexa.com's evaluations. Recorded performances are therefore substantially in line with those obtained in other areas of analysis with the three types of HCOs:

- The pioneers, or rather the group of benchmark organizations that obtain the best results both in terms of visibility with the search engines and ranking for traffic recorded for their site.
- The chasers, made up of the organizations in the USA and Canada, to which can be added, different from in other areas of research, the organizations of the United Kingdom, which have a markedly better performance for traffic recorded than the average of other European countries.
- A group of latecomers, basically the remainders of the European organizations (France, Germany, Italy, Spain) that are different from the best particularly for traffic recorded for their Web sites rather than for their visibility with search engines.

Figure 8. The ranking variation for Alexa.com vs. the Internet presence profile



Finally, in light of major differences existing between the benchmark organizations and the rest of the foreign sample, it is useful to evaluate whether there is a relationship between the extent to which a site is used and the way in which the organization develops its Internet presence. In this respect, Figure 8 shows the ranking variations for Alexa.com vs. the indicators previously used to evaluate the Internet presence.

As a general, probably predictable, indication, it can be stated that the organizations that best make use of the potential of the Internet are rewarded. This is particularly evident as regards the number of MUAs, the SCI, and the possibility of personalizing the contents of the site.

MAIN FINDINGS: NATIONAL SURVEY

Italian HCOs and their Presence on the Web

The Internet is not yet a phenomenon that is present throughout Italian healthcare: Only 58% of all the organizations have a Web site.

The second part of the project presents a picture that is somehow contradictory. In fact, if the number of structures that are on the Web has not significantly increased (the rise over 3 years was only 11%, from 47% in the first year to 58% in the second), there is now a more homogeneous geographical distribution.

One of the striking facts about the first part of the study was that in the north, 63% of HCOs were on the Web, clearly distancing the centre (43%) and the south (33%). Today, there is still a difference, but the gap has narrowed: The north remains a benchmark with 68% of HCOs online, but the centre (53%) and the south (51%) are catching up.

This kind of heterogeneity between regions is not surprising and is confirmed by other studies concerning the spreading of a managerial culture in Italian HCOs (Anessi Pessina & Cantù, 2003; Baraldi & Monolo, 2004).

This general information has more relevance if analysis is undertaken by company type rather than by geographical area. For public organizations (local healthcare organizations and hospitals), SIRCs, and UPs, the full exploitation of the potential of the Internet is now a reality, regardless of geographical situation (almost everywhere penetration is around 90%); this is not the case for private organizations. These, therefore, seem to hold in much minor consideration the importance of a Web strategy as an essential component of their institutional strategy (the number of organizations online increased from 30% in the first year to 41% in the second).

Probably, public structures have a wider awareness of the potential offered by the Web than private ones because of (a) the recommendations provided by regional healthcare plans, (b) the need to provide information to the general public (e.g., emergency services, waiting lists for specific services), and (c) the attempt to simplify administrative procedures (e.g., booking appointments and giving medical exam results, such as blood tests, online). It should also be borne in mind that the private Italian HCOs are generally small (often with less than 300 beds) and have a limited budget for implementing a high-profile Web strategy.

The Complexity of Internet Presence

There is an increasing depth of presence on the Internet by Italian HCOs: the information available and services activated are increasing as are the tools that allow their content to be best exploited.

If we had to assess the tendency of the phenomenon under discussion based only on this aspect of analysis, we would have to affirm that the Internet is becoming increasingly important for Italian HCOs. The growth of the average amount of information or services offered through the

Internet by Italian HCOs has gone from 10.22 to 17.80, which is a considerable rise of 74%.

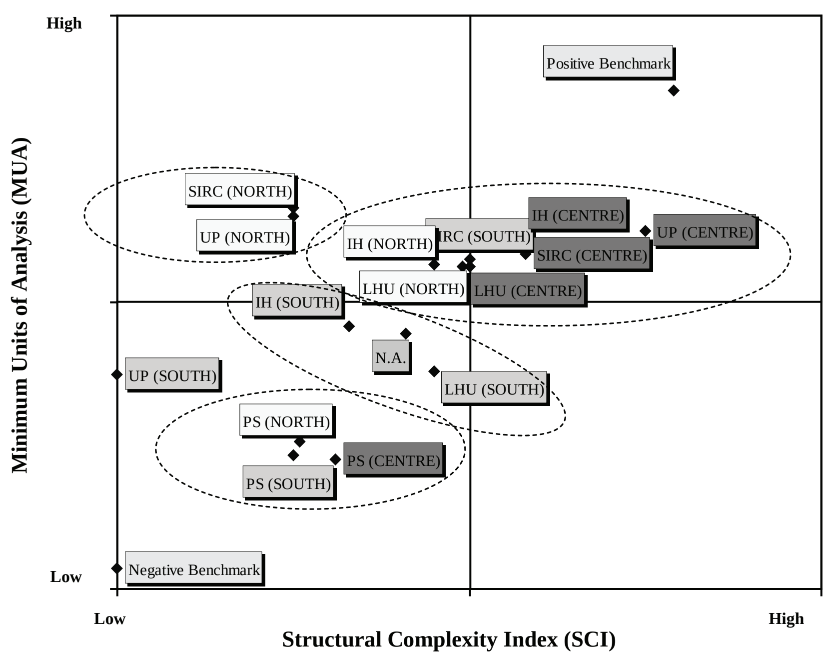
As always, however, more information can be obtained by further analysis. Geographically, despite an overall improvement, there remains a substantial difference between organizations in the north and centre of the country (an average MUA value of 19.2 and 17.33) and those in the south (where the average MUA value is 13.32).

Analysis by type of organization is even more interesting as it makes it possible to outline, in some way, a taxonomy of approaches to the Web strategy according to the individual characteristics of each structure. It affirms that LHUs, IHs, and SIRCs have a presence on the Internet that can be described as established and definitely consistent (the average number of MUAs is respectively 21.76, 23.32, and 25.36, with variation with respect to 2002 of 95%, 72%, and 97%).

The situation is different for UPs and PSs. Regarding the former, of particular interest in the first year was the rather weak, improvised, or inadequate role played by these organizations in the overall picture. The MUA figure of 8.8 was closer to that of private organizations than any other type previously seen. In light of the results of the second year for this and the rest of the analyses, it is confirmed that the presence of UPs on the Net has been transformed: The average MUA value in this sector has increased by 148% reaching 22.00, much more in line with the other main organizations.

For PSs, the trend that emerged in the preliminary analyses already reported in previous pages is confirmed. In brief, considering the results obtained from other aspects of the analysis, private organizations are 3 years behind the other HCOs: The situation shown in the second year of the project (MUA value of 9.70 on average with an increase of 26%) is generally in line with the average figures for the first year. Similar observations to those expressed in earlier lines can be made here regarding the index of structural complexity. Here, too, the average increase

Figure 9. The complexity of Internet presence of Italian HCOs



is consistent (a variation in percentage terms of 128%) by reason of a general improvement in those devices, in particular, site maps and search engines, which allow faster and easier access to the content available.

Considering the combination of the two variables (minimum unit of analysis and index of structural complexity), it is possible to position Italian healthcare organizations regarding the complexity of their presence on the Internet (Figure 9). Included in the HCOs are the following groups:

- A pioneer group of organizations (which includes the LHUs and IHs of the north and the centre, and the SIRCs and UPs of the centre) that invested early in the Internet and that hold that a Web strategy is an integral part of their business strategy and therefore make a substantial quantity of information available, with averages considerably higher than the national average.
- A chasing group of LHUs and IHs in the south that have average figures mainly in line with the national average.
- An anomalous group of organizations comprising the SIRCs and UPs of the north, which analysis reveals has an unbalanced position: The contents of their sites are substantial (above the national average), but they are not backed up by an adequate index of structural complexity.
- A group of latecomers, mainly private HCOs, that have a rather light presence on the Internet, with sites offering basic and essential content, mainly of an informative nature, easily accessible even when lacking navigational aids (measured by the index of structural complexity).
- The negative and positive benchmarks representing the average of 5% of HCOs, presenting, respectively, the best and the worst scores.

The Typology of Internet Presence

The Web strategies of Italian HCOs are still mostly traditional, tending to provide information rather than services: Of the four areas in which the Internet's virtual space can be articulated, in over half of cases only two are used. So, inevitably, utilization of the Internet remains low. Despite steady improvements in recent years, Italian HCOs utilize less than a fifth of the potential that the web offers.

If we consider the results of the second year of the project for this sector, it emerges that Italian HCOs would appear to have some difficulties in getting over this hurdle. In other words, the go-to Internet has undoubtedly occurred and in some instances progress made since 2002 has been consistent (also because in several cases, the starting objectives were on a small scale). In most cases, nevertheless, a clear strategic design is still lacking that sees the Internet not only as a sophisticated instrument of communication, but also a lever through which to carry out company strategy, involving the re-planning of, if necessary, operational methods of healthcare services.

So, progress recorded in the level of colonization of the Internet's virtual space (with an increase of 23%) is undoubtedly a positive, but equally, it should be noted that around 60% of Italian organizations still have a traditional Internet presence based on the distribution or completion of information (VIS).

Investigating the analysis for each type of organization in more depth reveals that there has been consistent progress for LHUs, IHs, and UPs (growth percentages of 33%, 29%, and 43% respectively), rather less for the SIRCs (11%), and absolutely no progress for PSs.

The consistent increase of available content, even if this occurs as previously shown in a rather traditional way, has resulted in a clear improvement in the coverage index with an average increase of 88%.

The percentage variations are really surprising: 133% for LHUs, 90% for IHs, 111% for the SIRCs, a striking 183% for Ups, and, finally, a more modest 40% for PSs.

A glance at the absolute values, though, enables us to put the phenomenon into proportion. The starting values were in fact very low: a national coverage index of 8%, varying between 9% and 10% for LHUs, IHs, and the SIRCs; 6% for UPs; and 5% for PSs.

So, if following the progress made (the national coverage average is 15%), it is easy to see how much more improvement remains to be made.

The overall evaluation of Internet presence typology is thus reached by considering both the colonization index and the global coverage index. Figure 10 shows the following:

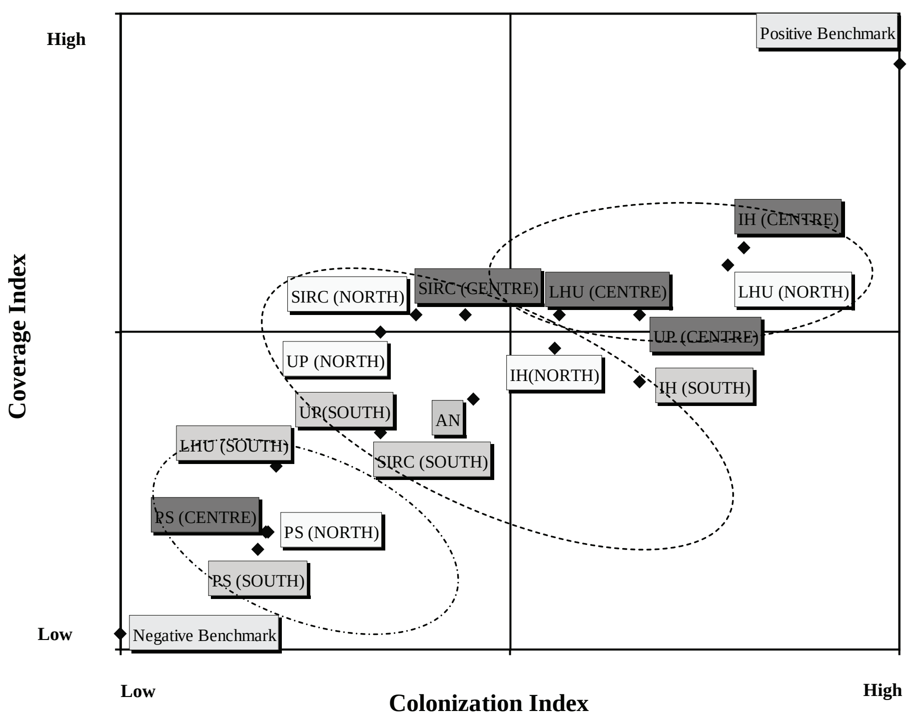
- The pioneers, in this case the IHs, LHUs, and the UPs of the centre to which can be added the LHUs in the north, exploit the Internet in a more homogeneous and broader way when compared with the national average.
- The SIRCs, IHs, and UPs in the north and the south perform mostly in line with the national average and can be classified together with the chasing group.
- The latecomers group comprises LHUs of the south and PSs, which have a less balanced presence (on average in fewer than two areas) and a much lower level of Internet use (particularly in the areas offering greater services such as the VDS, the VCS, the VTS) than the national average.

The Quality of Internet Presence

The quality of Internet presence of Italian HCOs is mainly good regarding both the degree of technological sophistication of the content available and the level of user satisfaction.

In 2002, we recorded for this dimension of analysis good values of reference with differences

Figure 10. The typology of Internet presence of Italian HCOs



both at a geographical level and for the type of organization, basically due to budgets and the consequent possibility or not of utilizing specialized consultants. The second year shows the inevitable improvements following a general pattern common to the other dimensions of analysis.

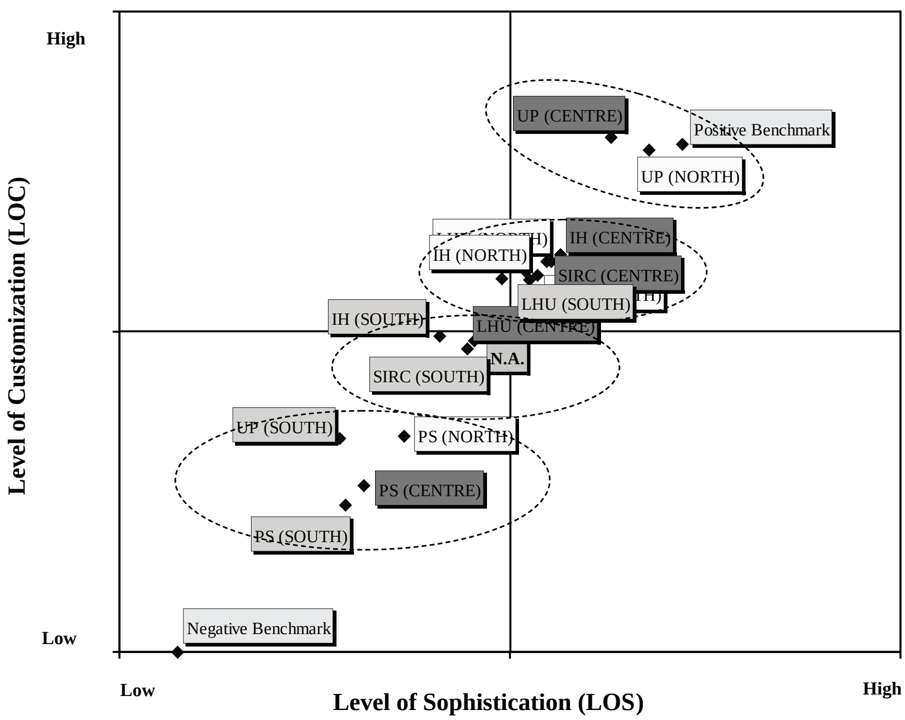
The degree of technological sophistication (LOS) increased by 16% nationally (from 2.44 to 2.82), with the best performance coming from the UPs (a rise of 45%, from 2.15 to 3.12) and the worst from the PSs (no change).

The improvements for LOC are more consistent because the starting values were more modest. Progress on a national scale was 49%, but performances varied in a range from the highest of the UPs (85%, from 1.92 to 3.56) to the lowest of the SIRCs (23%, from 2.71 to 3.33). PSs did have an increase of 33% but recorded the worst overall performance with a LOC of 2.16.

Figure 11 positions Italian HCOs according to the quality of their Internet presence. Overall values do align with results from the other research areas, showing the following:

- The UPs of the north and the centre are very close to the positive benchmark.
- The LHUs, SIRCs, and IHs of the north and the centre take the lead for national averages regarding quality of Internet presence.
- The chasers comprise the IHs and the SIRCs of the south, with a quality of Internet presence that, even if well below that of the leaders, is still in line with average national values.
- A final group of latecomers (mainly the UPs of the south and PSs), regarding this dimension of analysis, is in a generally weak position.

Figure 11. The quality of Internet presence of Italian HCOs



The Effectiveness of Internet Presence

Italian HCOs' Web sites have quite a good visibility on the Net: They can be reached by the most common search engines around 8 times out of 10. Their Internet effectiveness, however, is still limited in terms of overall Web site traffic.

Regarding the Web site visibility index, good results were already seen in 2002. In the national average, improvement was 27%, with a visibility index for search engines rising from 60% to 76%. Regarding the other dimensions of analysis, the best performance was from the UPs (with an increase of 72% and visibility with all the search engines used). The rise for the SIRCs was only 2%, although the visibility index was one of the highest (82%). PSs, despite a positive increase of 19%, are in line with the average values of the first year (visibility index of 63%).

Regarding the Web site traffic ranking, the second year of our research produced results that could be described as somewhat curious in that they are not in line with the results of previous analysis. There being generally consistent improvements in the complexity, typology, and quality of Internet presence of Italian HCOs, we would also have expected an improvement in the Alexa.com ranking. In other words, we thought that the real endeavors of the Italian HCOs to develop their presence on the Internet would have been translated into a greater success in terms of visitor numbers and traffic on their Web sites.

In fact, there is not a great difference between the results of the first and the second years. There has been, even if only slight, a reduction in the average national ranking (-3%) and increases only for the SIRCs and UPs (1% and 11% respectively).

Closer analysis leads to the following conclusions:

- Alexa.com evaluates traffic to the site, providing a global classification of Web sites. Performances are inevitably influenced by the rankings of other sites, be they healthcare related or not, or Italian or foreign.
- The world of the Internet is continually changing and evolving. Italian HCOs have undoubtedly progressed compared to the situation in 2002, but comparison with the international scene shows that the others have not been standing still and that Italian organizations, in several areas, are still behind the USA, Canada, and the United Kingdom (not to mention the abyss that distances Italy from international benchmarks).

Figure 12 positions Italian HCOs according to the effectiveness of their presence on the Internet. It shows the following:

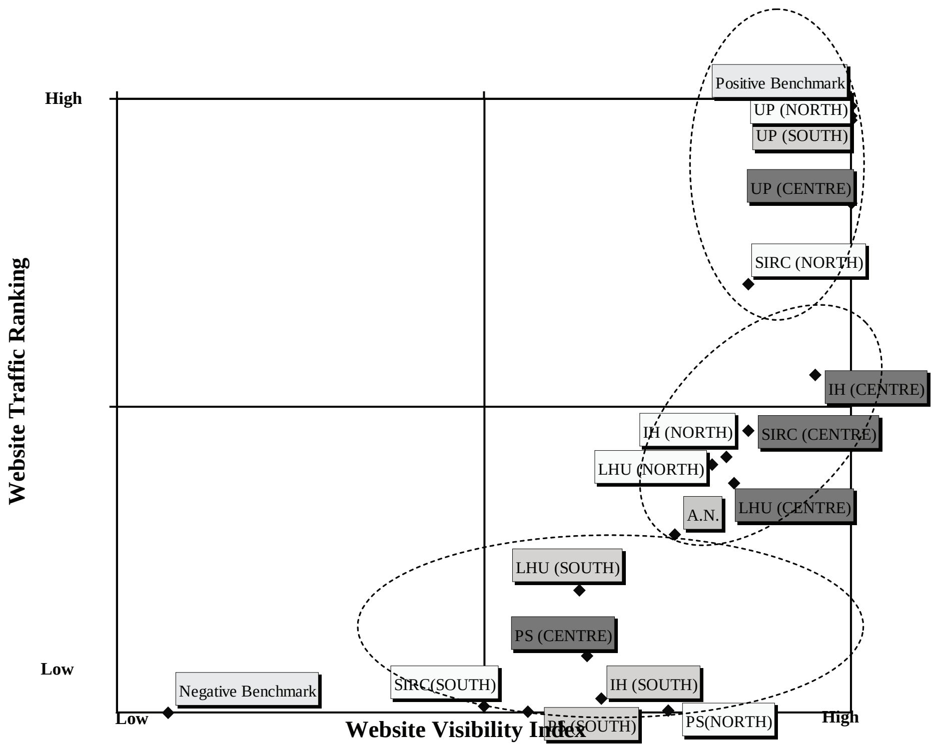
- A first group of organizations, comprising UPs and the SIRCs of the north, in a leadership position with results in line with or very close to national benchmark references.
- A second group of companies, representing IHs and LHUs in the north and centre and the SIRCs of the centre in a chasing position, with results for effectiveness in line with national average values.
- A third group of organizations comprising the remaining Italian HCOs, which, at present, are in a relatively weak position as regards the effectiveness of their Internet presence.

Limitations and Further Research Areas

While aiming to provide a complete summary of the presence of Italian HCOs on the Web, our study nevertheless inevitably suffers from some structural limitations, which can be summarized as follows:

- The research project was carried out to evaluate, through external analysis, how

Figure 12. The effectiveness of Internet presence of Italian HCOs



and to what degree healthcare organizations currently exploit the potential of the Internet through their Web sites. The aim was to understand the strategy of colonization of Web space through analysis of the informative content or services offered. In this phase, we did not consider the internal aspects of the organization in the definition of the Web strategy (definition of the strategy, evaluation of costs, evaluation of performance), which does constitute an essential part of the research we are undertaking.

- The Internet is constantly evolving. Through our research, we attempted to take a picture of the state of the art of healthcare online, nationally and internationally, at two different times, first in 2002, then in 2005. This enabled us to identify the changes that took place over this period, but it was not our aim to define trends, find a way forward, or predict future developments.
- The aim of the research project is that of providing as objective an evaluation as possible of Internet presence. Although accurate scales have been elaborated for the evaluation of LOS and LOC, there remain in this phase some inevitable and unavoidable sources of subjectivity.
- The evaluation of traffic recorded on the Web site was carried out using a site classifier Alexa.com. When sites are hosted by a main domain site (the sites of some LHUs on the regional site, or some PUs on the relevant university site), the figure refers to the main domain.
- An international comparison has been developed through the analysis of HCOs in the capital or similar city of each nation, similar in terms of the structure of the health service. As such, it inevitably provides only a general outline of the state of the art of online healthcare in each nation.

- The results obtained from the international sample, as for those from the survey regarding Italian structures, can be compared and confirm hypotheses only indirectly. This is because at the moment, and at least at a European level, we did not find similar studies about the actual level of exploitation of the Internet by healthcare providers. In this sense, it can be said that the lag shown by Italian structures compared with international benchmarks is basically in line with the limited attitude revealed by Italian companies to invest in technology (in 2003, only 2% of GDP [gross domestic product]) compared with the European average (3% of GDP) and the United States (3.8% of GDP).

Furthermore, the research activity carried out so far represents the first phase of a wider project that is planned for the carrying out of an in-depth analysis of a sample of organizations that will permit the analysis of the path followed in the definition of a Web strategy; its relative impact on organizational, clinical, and management processes; and the results in terms of cost reduction, quality improvement, customer satisfaction, and so forth.

CONCLUSION

"Who doesn't know the Internet?!"

The research undertaken leads to this conclusion: Nowadays, everyone, even in healthcare, knows the Internet; few, however, use it to its full potential.

In a few short years, the Internet has become one of the most widely used technologies in everyday life. In healthcare, however, despite the progress that has been made between the first and second years of our research project, it seems that the full potential of this technology is often not realized.

About the international survey, we can assert the following:

- There is a considerable distance between the benchmark and the other organizations that make up the international sample. HCOs in the United States and Canada perform best, but the European HCOs have reduced the gap in 2005.
- Only the organizations that make up the benchmark have a widespread and homogenous presence on the Internet, fully exploiting its potential. The HCOs that make up the international sample only partially exploit the potential of the Internet.
- If the benchmark organizations are excluded, once more it is the U.S. and Canadian organizations that perform best for the quality of Internet presence.
- Generally, the organizations with the best performances for traffic recorded are those that best exploit the potential the Internet offers and consequently their results are higher in all areas of analysis.

In Italy, many organizations are still unable to exploit this potential, not having activated a Web site. This is particularly true for PSs and those in the south. Public organizations, the SIRCs, and UPs have gradually become more aware of the Internet. The reasons for this change can be found in national health policies, in the increasing simplification of bureaucratic procedures and consequent reduction in costs, and, finally, in the growing awareness of the Internet's importance for the common good (improvement of relations with patients for healthcare organizations, and the facilitation of research and didactics for the SIRCs and UPs).

This has all led to a continual increase in the quantity of information and services offered by Web sites and greater focus on the tools (site maps, search engines, foreign-language versions) that facilitate access to their content. The gap in respect to international reference benchmarks and overseas organizations remains, however, substantially unchanged; this, moreover, is the same for all dimensions of analysis.

The approach to the Internet is rarely strategic, but often improvised, utilizing it simply as a means of communication. There rarely seems to be an awareness that investment in this technology should be in line with the institutional strategy of the organization (Minard, 2001), leading to a rethinking of the main ways of operating and assisting in healthcare.

This inevitably means that the possibilities that the Internet offers are not exploited as fully as they could be.

The quality of the contents available, in terms of technological sophistication and availability of access are, however, of a good level.

Like in the international survey, it is undeniably true that the best performance in terms of traffic recorded on the sites was achieved by the organizations that have invested more effort in this technology through the development of a high-profile Web strategy.

INTRODUCTION

Medical data and digital imaging for medical diagnosis currently represent a very important research area in computer science. The generation of medical information is continuously increasing. More specifically, genomic (molecular and histological) data and images have become key points for diagnosis. The specific processing these data require is more and more requested.

This article describes a Web portal based on the most common current standards. This platform is not only able to integrate the medical information available at several sources, but also to provide tools for the analysis of the integrated data, to use them for the study of any pathology. It will provide a common access point to share data and analysis techniques (or applications) between different groups that are currently working in several fields of health area.

BACKGROUND

Nowadays, several studies are being carried on with regard to the different levels of information about health (population, disease, patient, organ, tissue, molecule, and gene) but none of them integrates the information. The biomedical computer science must play an important role at the integration of these viewpoints and their data.

From a classical viewpoint, computer science in public health has been able to confront and solve problems at different population levels; has effectively managed levels of diseases and patients and lastly; has developed tools for image management and analysis to be used in non-invasive techniques for tissue or organ study. The source of knowledge regarding molecular and genetic levels is greater every day. One of the fields were developing new applications is Genomic Epidemiology, which performs population studies about the impact of genetic human variability on health and disease. Another field, Pharmagenetic, considers the differential genetic aspects among people (e.g., SNPs profiles) when developing new medicines and analyzing its influence after the administration of a medicine.

HUGE NET (from Office of Genetics and Disease Prevention, USA) is an example of this kind of application. Briefly, it is a communication network that allows sharing epidemiological information about Human Genome.

PharmGKB program (from Stanford University) is used in nine universities and medical centers, which investigate pharmacogenetics. The program makes a knowledge base possible with genomic data, laboratory fenotypes, clinic informations, etc.

However, these examples solve just partial aspects of the aim, but not the complete problem. Nowadays, there are not examples of integrated information systems to cover this kind of study completely. The development of such a system will facilitate the studies about complex diseases.

Digital imaging for medical diagnosis is currently one of the most relevant research areas. Since the discovery of the x-ray in 1895, the techniques for acquisition of medical images have evolved to images in digital format.

Every manufacturer used to design its own image storage format, therefore the development of applications should be specific for every device. Therefore, it makes it impossible to transfer information between different machines. A standard named DICOM (Digital Imaging and Communications in Medicine) was published (Bidgood & Horii, 1996; Clunie, 2005; Nema, 2005) as a solution for these problems. DICOM unifies imaging storage criteria for their transmission among heterogeneous equipment by a common procedure, which is open and public.

Another problem related to medical imaging is its accurate management, mainly due to the great volume to store. This way, the picture archiving and communication system (PACS) (Huang, 2004) makes the achievement of an imaging service that might integrate images and clinical information without films or paper documents possible.

The PACS DICOM duet, combined with Web technology provides the specialist with the possibility of gaining access to images and their related information from place, using the legally required security mechanisms (BOE, 15/1999, BOE, 994/1999, Garfinkel & Spafford, 2001).

The existing health databases and Web portals are heterogeneous and physically dispersed. These DBs may be relational, as PACS DICOM, public, as NCBI (NCBI, 2005), or HapMap (HapMap, 2005), etc. Therefore, there also exists a great variety of software for data processing. There are some development platforms for Windows and Linux in different programming languages as Java o C, several commercial tools for image management like Quantity One from Bio-Rad Laboratories (Bio-Rad, 2005), LabImage (LabImage, 2005), Phoretix 1D developed by Nonlinear Dynamics (Nonlinear, 2005), or Label Cell Counter Software create in the Image Management Laboratory, Otolaringology Department, Rochester University Medical Center.

These are potent tools, which cover the requirements of this kind of image, although not always in an automatic way. Besides, they are a commercial software, so it is not possible to add new functionalities and, in most cases, they can deal just with a specific type of images.

The previous circumstances disturb not only the access to information, but also the processing of data and image. For instance, to perform the study of any disease, the first step will consist on locating the different DBs containing the desirable information. Secondly, it is necessary to generate the appropriate queries to the DBs in a specific language and with a specific structure. Finally, obtained data must be adapted to every program wanted for the analysis. The process is, consequently, a tough task.

It would be desirable to have systems able to store, relate, manage, and visualize all the data and the information coming from several studies, and process it as a homogeneous dataset instead of multiple and separate sources.

These systems should be developed ready for their integration in a Web environment; which would facilitate independence of place and time and user personalization. In addition, the easy use of this environment decreases the learning time.

PROPOSED SOLUTION: WEB PORTAL

The proposed solution lies in a Web portal for managing and accessing heterogeneous information stored at several repositories. It also provides the different users with a tool repository for data processing.

The system can work in two different ways. First, it is able to generate specific applications for a given pathology. These applications are Web interfaces for retrieving information from several data repositories. Thus, the user can visualize relevant information and images by means of processing algorithms adjusted to his or her needs.

Besides, the system has a services layer where advanced users can include data he or she wants to analyze. This layer also provides the user with Web services (Colin, 2005, Sun, 2005) for accessing information from any application.

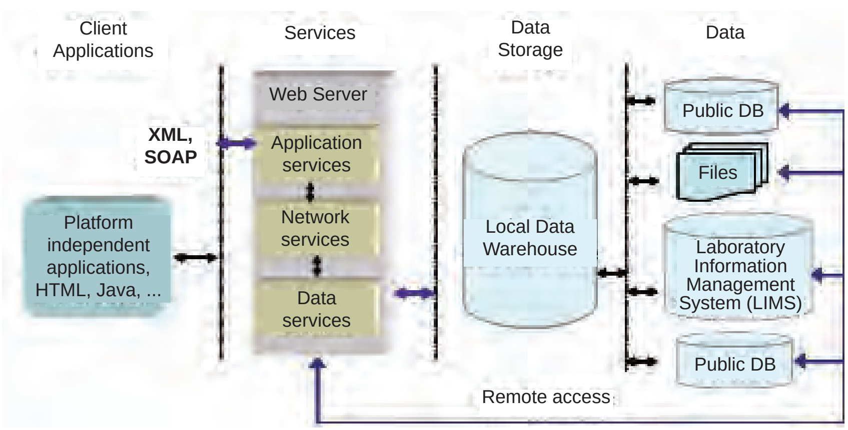
The developed system, which fulfills the previous requirements, is a four level platform: user applications, services, data storage, and data source levels are represented in Figure 1.

Data Management

The data sources level consists of data repositories (public DBs, files, LIMS, etc.) accessible for the portal users. It is possible to add new repositories by "federating" them to the platform.

The data storage level establishes the support for data warehouse and data mining techniques.

Figure 1. Platform architecture



The services level makes it possible for applications to process data from several and heterogeneous sources as if they were homogeneous and unique. It has three sub-layers: application, network, and data services. Application services work as interfaces to communicate the applications with the system. Network services facilitate the location of the data. These services offer a repository of the data model, which contains the definitions of all the objects of the system and also their related attributes and relationships. Network services also provide a security repository, a catalog about the location and function of the existing network systems, and the identification of the service of each group that can obtain data related to an object. Finally, data services carry on the maintenance, consultation, and access control to data.

The client applications level is an XML Web service that facilitate the access to the system and the provided services.

QL is a simplified SQL language developed for this platform. It can perform management operations such as to create, erase, or modify platform elements, as well as to grant or deny privileges regarding these elements. It can also launch consults about a previously defined data source or call on the execution of algorithms offered by a "Web service."

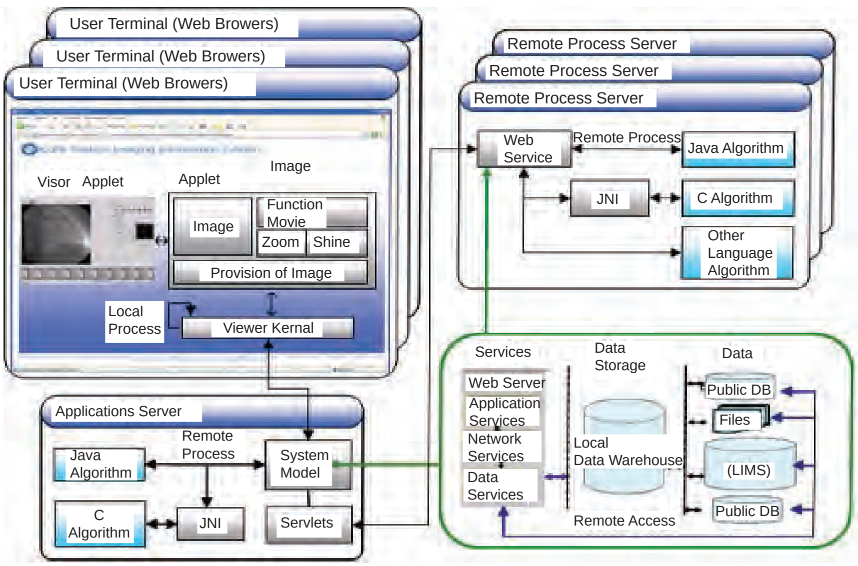
Data Processing

The computational cost of the algorithms used for data processing (data mining, image processing, etc.) varies largely depending on their own complexity and the type of data used. This is the reason why the proposed solution is based on a distributed architecture that enables two ways of processing: local and remote.

Local processing has simple computational requirements. They are basic algorithms that do not require powerful systems for their execution, but the mere ability of the user's computer.

Remote processing needs a more complex computational requirements. The procedures may last for a couple of hours, so it is necessary to use more powerful systems. Examples of this type of algorithms are segmentation and 3D reconstruction.

Figure 2. Structure of remote processing servers



As there are a number of libraries containing different algorithms for data analysis and processing, our architecture enables the reuse of algorithms in different programming languages. This architecture has three well-differentiated parts (see Figure 2): user terminal (viewer), applications server, and process server. These parts communicate among them by using the described platform as central node.

The user terminal is loaded on the user Web browser for visualization, processing, and data analysis. The user selects the data to process and the system will display several environments (known as tools), which are groups of functions to handle a given type of data. These functions (named as components) may vary from information management to digital image processing.

The applications server performs three main tasks. First, it communicates with the tools for both information transfer and obtaining to assure the independence of data access. The second task is data processing by using complex computational requirements (remote processing). Finally, the last task is to give access to the different servers of remote process.

The remote process server is last part of the architecture and its goal is not only to achieve a greater ability for processing and its distribution, but also to enable the integration of algorithms developed in different programming languages.

If processing algorithms have simple computational requirements, their execution would be performed at the user terminal (by using Java Algorithms) as Figure 3(a) shows.

In contrast, the algorithms that need complex computational requirements or the ones in other languages different from Java will run at the applications server or at several process servers. This remote processing bases in Web services developed in *.Net* (MacDonald, 2003; McLean, Naftel, & Willians, 2003; Ramer & Szpuszta, 2005) and *Java*. In this case, the component consists of two parts: local and remote. The local part of the component (i.e., user browser) is where to establish the parameters of the algorithm. See Figure 3(b).

The remote process servers can run together to perform load distribution. In that case, the remote part of the component requests the Web service, which would execute the algorithm and send the result back to the remote server for it to send this result to the local viewer. Figure 3(c) shows this process.

The remote process server proposed here consists of three parts (see Figure 4). The *Web services proxy* collects the external processing requests coming from the information system. These requests are sent to another server where the *processing manager* is located. This part redirects the requests attending both to the type of processing they need and to the original object that sent the request to the Web server. The last part comprises the *remote processing servers*, every one of which can execute one or more different processing algorithms

The ideal processing scenario would involve three or more machines for the processing server.

Figure 3. Processing types

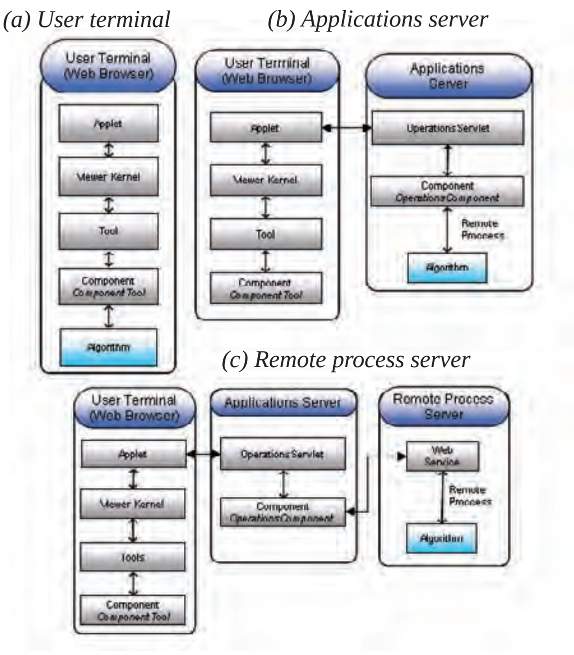


Figure 4. Structure of remote processing servers

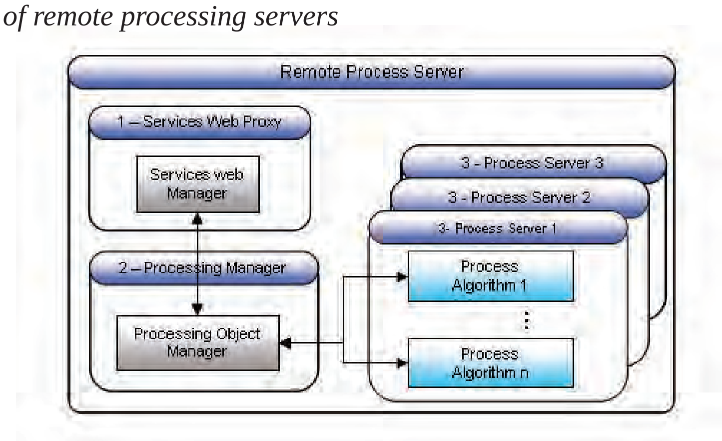

Figure 5. Samples of images

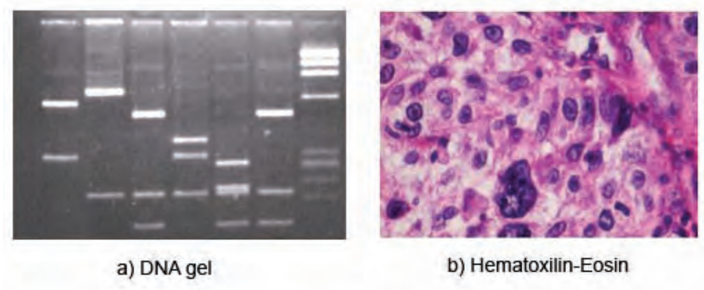


A first machine with a Web server would receive the incoming requests from either the applications server or a stand-alone application by means of Web services. Secondly, a server would keep a processing manager and the rest of the machines would lodge the processing servers.

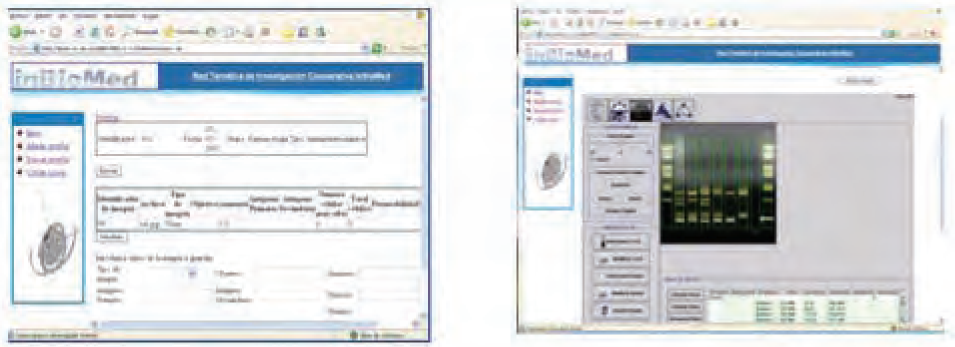
TRIAL BIOMEDICAL APPLICATIONS

In order to validate the concept of platform for the integration of medical data, there have been instituted two data processing systems, each for a different medical specialty.

The Pharmacology group of Santiago de Compostela University (Spain) carries on the research for the development of new drugs, validation of new therapeutic targets, etc. Among the information this group needs for its work, there are images of electrophoresis and DNA gels (see Figure 5(a)). The developed system helps with the storage and visualization of data and images of performed tests. It provides suitable tools for working with this type of information (i.e., image fitness, automatic count, automatic detection of bands and tracks, etc).

The group of epidemiological, environmental, clinical, genetic, and molecular research for urinary bladder cancer disease of Barcelona (Spain) carries on the study of those environmental, genetic, and molecular factors associated with the etiology and prognosis of urinary bladder cancer disease. The developed system uses information and images of Hematoxilin-Eosin (HE) stained slides (see Figure 5(b)). It provides a series of suitable tools for storing, managing, and visualizing data and images extracted from the tests. Tools for automatical cell count or image fitness are some examples.

Figure 6. Information System of the Pharmacology group



The DBs for both groups were federated at the platform, which is physically located at Jaume I University of Castellón (Spain). DBs are located at La Coruña and Barcelona respectively.

Some of the most important tools for information analysis are those relating to image processing. This field has already gone over a long way and currently there are specific bookcases for working with images, numerous algorithms for their processing, etc. As an example, the algorithms implemented with advanced API for JAI (Java Advanced Imaging) (Rodrigues, 2001, Sun, 2005) image processing can be used when performing local processing of images. Some of the processing algorithms federated at the platform are 2D segmentation algorithms, which use region growing algorithms for binary image conversion, algorithms for region extraction, etc.

The system users have a Web environment inside the Web portal, which offer them relevant information and provides them with suitable tools for processing as well as for analysis, attending to the data to visualize. Figure 6 shows two pages of this system. The first one has the data required by the user, the second one shows a tool for the analysis and processing of data coming from DNA gels images.

The information system at the Pharmacology group can be accessed at www.inbiomed.udc.es.

This platform for data management and processing is currently being developed through a project financed by the Health Research Fund (FIS) of the Carlos III Health Institute (Spain). These funds were obtained after the constitution of a thematic network for cooperative research in biomedical computer science, which has been named as Inbiomed. Thirteen research groups of different Spanish autonomous communities, such as Andalucía, Cataluña, Euskadi, Galicia, Madrid, and Valencia, with more than 100 researchers taking part in the network. More information can be obtained at http://www.inbiomed.retics.net/

CONCLUSION AND FUTURE TRENDS

The developed portal intends to relieve the increasing demand for an integrated information system to deal with all the information levels (population, disease, patient, organ, tissue, molecule, and gene) of health studies by integrating all the associated information. Therefore, biomedical computer science fulfills a preponderant role, which also should play with new emerging data and viewpoints.

The federation of databases, files, etc., provides an access to public and private databases by means of a “data warehouse” with consolidated information, which is oriented to requests. Besides, there is a common access to all the available data sources due to the access to the portal by means of a client tool or through Web services. Moreover, as the portal facilitates the federation of processing and analysis tools, there are a group of algorithms that can be either applied to data through the system interface or used as modules of previously developed applications.

Finally, the Web architecture proposed here provides the platform with hardware and software independence due to the integration of algorithms in different programming languages. At the same time, the incorporation of tools and new types of data supports the growth of the system. Another benefit is time and location independence provided by Web applications.

The group will continue the validation of the platform through several systems for data processing, oriented to other medical specialties. This will imply the development of new tools and algorithms for analysis and management of different DBs.

KEY TERMS

Applet / Servlet: Software components that run embedded in another program, for instance a Web browser (applet) or a Web server (servlet) to extend its functionality. Unlike a program, the applet is not able to run independently.

Component: Each concrete function developed to perform a definite function in the system. It will be possible to find the same component in different tools.

Digital Imaging and Communications in Medicine (DICOM): It is a standard for the storage and transmission of medical images. This standard provides TCP/IP transport among the modalities and the systems of image storage (PACS).

Digital Image Processing (DIP): Group of computer techniques applied to digital images to facilitate their study by the expert.

Local/Remote Processing: Different kind of processing depending on needs of computational requirements. While basic algorithms do not require powerful systems for their execution (allowing local processing), more complex actions require more powerful systems than the usual user machine (remote processing).

Picture Archiving and Communications System (PACS): It captures, stores, distributes and displays static or moving digital images such as electronic x-rays or scans, for more efficient diagnosis and treatment.

Tools: Group of concrete and simple functions (i.e., zoom, brightness, filters) and more specific algorithms (i.e., segmentation procedures, tagging) needed for working with a type of image.

Chapter 8.4
Exploring a UML Profile Approach to Modeling Web Services in Healthcare

Wullianallur Raghupathi

Wei Gao
Fordham University, USA

ABSTRACT

The Web services paradigm offers numerous potential benefits to the health care area. These include interoperability, portability, scalability, and compliance with universal standards. However, development of large-scale Web services applications in health care is relatively scarce. Multiple challenges are slowing the diffusion of information technology practices in health care, starting with the absence of modeling tools and methodologies that are the bases for building such technology. This article describes a UML profile approach to developing Web services applications in the health care area, emphasizing the use of such extensions as stereotyping and tagging to model the unique elements of health care processing. We apply these ideas to a health clinic example. From here, one can imagine building incrementally upon these ideas to develop frameworks for Web services applications in health care. The benefits would enhance the overall quality of health care delivery and lower costs.

INTRODUCTION

Web services are self-contained, Internet-enabled applications capable not only of performing healthcare-related activities independently, but also possessing the ability to engage other Web services to complete higher-order business (health) transactions (Papazoglou & Dubray, 2004). The key is modularity characterized by open standard and internet-oriented interfaces. Examples of such patient services include verifying appointment availability, producing a bill, ordering lab tests, prescribing medication, and discharge planning. The platform-neutral nature of Web services (Kreger, 2001) creates the opportunity for building composite services using existing elementary or complex services, possibly offered by different service providers (Meredith & Bjorg, 2003; Yang, 2003). On a larger scale, these services can be considered a set of interoperable technologies and standards, designed to support the integrating of several autonomous and heterogeneous systems. Web services are particularly geared toward the service-oriented computing paradigm, which can be considered a collection of services, coordinating, and communicating with each other to support a system's specific function or concept. Service-oriented computing has the potential to be the healthcare industry's new foundation for distributed systems and internet-based processing. Web services specifications, such as SOAP, WSDL and UDDI, facilitate open, XML-based methods to support application interoperability, service description, and service discovery (Estrella, McClatchey, Rogulin, Amendolia, & Solomonides, 2004).

The rapid adoption and diffusion of service-oriented architecture (SOA) and Web services in various industries indicate that the advantages and benefits (componentization, interoperability, platform-independence, modularity, reusability, etc.) therein could provide similar benefits for healthcare. Overall, there has been a major change in the way large scale software applications are designed, modeled, implemented and used (Stojanovic, Dahanayake, & Sol, 2004). Services are autonomous, platform-independent processes that can be identified and defined, published, discovered, choreographed, and programmed using universally accepted protocols for building health applications that work together seamlessly, both intra-enterprise (i.e. the healthcare delivery organization) and inter-enterprise (i.e. the consortium of healthcare delivery participants). When services are delivered via the Web we call them Web services. These have emerged as a framework for application-to-application interactions, making these applications available as Web services (Vara, De Castro, & Marcos, 2005). While Web applications via the Internet have been used in the healthcare industry for a few years now, these applications are mostly intra-enterprise, that is, services are within the specific healthcare organization using them. There is limited capability for supporting cross-functional and inter-enterprise applications. Recently, however, practitioners and researchers have started to address the distributed and inter-enterprise nature of healthcare delivery (the interaction arising out of the exchange of information among physicians, insurance companies, hospitals, labs, and pharmacies, for example). The desire to exploit the scalability of Web services within the SOA is understandable. Catley, Petriu, and Frize (2004) describe a prototype Web services architecture for physicians designed to provide clinical decision support. The objective is to integrate and access clinical decision support systems (CDSSs) and medical databases from various medical domains. Their rationale for integrating distributed databases is that different medical domains often exhibit complementary abilities in predicting medical outcomes. They give the example of the collective domains that include obstetrical, prenatal and neonatal databases. The overall goals have been multifold: the Web services are expected to integrate different types of CDSSs; provide for a way to link disparate distributed databases on multiple platforms; and making the CDSSs available locally as well as remotely (Catley et al., 2004).

Estrella et al. (2004) describe another application based on grid computing and the SOA. The MammoGrid project is expected to support collaborative medical image analysis. An important objective is to manage federated mammogram databases distributed across Europe. The framework would include regions with varying protocols, lifestyles and diagnostic procedures and would enable a range of functions including data mining, epidemiological studies, statistical analyses, and deployment of a standardized Standard Mammogram Form. The goal is to federate the distributed mammogram sources into a single virtual organization. While these applications are in very specific medical domains, they highlight the potential of SOA-enabled Web services in the health domain. The health domain is more encompassing than the medical domain because it includes business-related services such as patient billing, insurance approval, payment processing and case management. Even so, the groundwork is in place to scale up applications for more encompassing healthcare delivery systems, delivering services via the Internet. In this way, the industry may exploit the natural alignment of SOA-enabled Web services in healthcare processes. At the enterprise level, one can envision the strategic alignment of information technology with a healthcare organization's goal of delivering quality care.

But while the potential benefits are great, particularly the use of the Internet to deliver important health services, so are the challenges. A key issue is the need for robust modeling and development of Web services applications. Healthcare delivery is a highly complex process characterized by a multi-provider, multi-payer system. Modeling and representing healthcare processes—amidst the need for data integrity, privacy, security, real-time processing, interoperability (open system), portability, and scalability—is daunting. One solution is to extend existing techniques, such as the UML, which many consider the de-facto standard. A starting point is the standard UML modeling notation base defined by the W3C Web services group and OMG (Amir & Zeid, 2004). Aspects of the Web services applications across various platforms—such as the roles of service providers, requestors, and registries as well as the three operations of publish, find, and bind—need to be conceptualized in the SOA format. Further, a notation can be defined to support the actions. Moreover, the semantics of healthcare domain concepts have to be described to enable interpretation of their behavior. Additionally, the ontology of healthcare services must be developed.

These challenges in mind, we explore in this article the potential of a UML profile to model Web services in healthcare. We develop an application for a hypothetical health clinic, showing various elements that would comprise such a profile. This clinic is positioned to be an integral part of a larger, distributed healthcare delivery system that encompasses hospitals, labs, pharmacies, and insurance providers, such as HMOs. The diagrams that follow illustrate our model and visually identify its various parts. In this regard, one can use collaboration diagram notation. We propose a hierarchy of service components as the primary building blocks of the Web services architecture via concepts, meta models, and granularity types. Health service components are modeled as contract-based service providers and support the health organization's health processes through a formal orchestration. Simultaneously, they are realized as a composition of lower-level application service components (Skogan, Gronmo, & Solheim, 2004). These can be further mapped to more encompassing software artifacts. Fashioned in this way, the Web services architecture represents layers of abstraction between the healthcare processes and the operational information, minimizing inconsistencies. We introduce the concept of service component as the primary Web services building block. An important aspect of the article is the enunciation of a modeling approach that emphasizes the identification and specification of the service components of varied scope and granularity. This approach enables the evolution of a Web services healthcare solution.

The article is organized as follows. First, we discuss the potential of Web services in healthcare. Next, we explain the usefulness of the UML, particularly the profile in developing models. Then we develop the notion of a partial UML profile for a distributed health clinic example. Finally, we offer our conclusions for future applications and research

WEB SERVICES IN HEALTHCARE

Web services are defined as functional components (processes) situated in a particular domain and available over the Internet. In the healthcare area, these could include online query/response consultation with a physician, scheduling a patient visit, confirmation of a referral, and so on. The architecture would comply with a set of standards, such as those used with HTTP, XML SOAP, WSDL, or others (Vara et al., 2005). Alternatively, it is any service accessible over the Internet which takes XML as input and produces an XML result. The rationale behind a Web service composition is that many smaller tasks already identified as Web services can work together to execute a larger task. Such commands as VERIFY PATIENT DATA, CONFIRM PHYSICIAN, ROOM ASSIGNMENT, DATE/TIME AVAILABILITY, ASSIGN PATIENT TO SCHEDULE, and PROVIDE CONFIRMATION could collectively represent "PROCESS PATIENT VISIT SCHEDULE DATA." At the highest level a Web service implies delivery of high quality healthcare via the Internet. The services can be offered by multiple providers within the confines of the federation, a loosely coupled consortium of healthcare participants, and are typically published in a central repository. Finding the service is coordinated by a brokering mechanism. The Web services paradigm, then, enables the health services consortium to continue to function in a distributed fashion with localized control and use. In this way, applications extend beyond the intra-enterprise boundary to the inter-enterprise. Additionally, redundancy in services can be minimized by a repository. All participants in this "federation" can contribute to the creation of the services and use them. The benefits are numerous. Web services architecture mirrors the healthcare delivery mode and can be strategically dovetailed with the delivery organization functions. Also, middleware provides the interface so that legacy systems are not abandoned. Web services standards enforce compliance by vendors and platforms, thereby providing interoperability. This exploitation of the Internet would lead to maximal use of the health organization's capabilities and offerings, resulting quality patient care and satisfaction. That said, the application of Web services and SOA in the healthcare area is a relatively recent phenomenon. While knowledge about systems development can be transferred from other industries, the healthcare industry is more complex (fueled in part by the multiplicity of payers and providers) than most other industries. While the current trend towards universal electronic health records is a positive one, scalability and portability are important design challenges. Another hurdle is the minimal understanding of healthcare processes and workflow by application designers and vendors. Existing applications are ad hoc, incompatible system implementations. Plus, current standards are not at a level that Web services can be easily implemented. Methodologies and modeling tools are seriously lacking (Gronmo & Solheim, 2004).

But there is a bright side. UML-based approaches can be extended to the healthcare process modeling, providing a solid foundation for the implementation of Web services. For example, consensus on communication rules is important for all participants to succeed. This implies agreement on the ontology (Heuvel & Maamar, 2003). Anchoring the modeling of healthcare processes around the UML can minimize the learning curve because one can draw on the experience and knowledge currently available. The added advantage of bypassing legacy approaches and systems (especially in environments with no prior automation efforts) accrues.

Operationally, applications that are "services" must spell out their functional and non-functional (utility/procedural) requirements and capabilities in a prior agreement. Based on declarative service descriptions, automated service discovering, selection and binding provide the foundation for Web services applications. Therefore, an advantage arising from the dynamic binding is looser coupling between applications (Curbera, Khalaf, Mukhi, Tai, & Weerawarana, 2003). The componentized model emerging out of this process provides for "health services" forming the initial units for creating the application. Service composition and management become critical issues (Casati, Shan, Dayal, & Shan, 2003).

In healthcare, a service composition combines services and follows a certain pattern to achieve a healthcare goal, for example, properly discharging a patient from the hospital. An architecture that supports Web services includes the following aspects:

- The dynamic discovery of registered service, including searching for services that meet certain criteria, especially health criteria such as patient wait time, quality of care, and so forth;
- The intuitive organization of services so that one easily can understand what a service offers;
- The clear description of services, ensuring the proper use of each service.

This includes formats and protocols for invoking the Web service (Leymann, Roller, & Schmidt, 2002). A typical Web service follows this pattern: a service is created; the service is published; the service is located; the service is invoked. (Optionally, the service may be unpublished.) The complex services that a typical medical clinic provides vary widely across the patient group. An effective solution for the management of disparate medical data sources is federation of autonomous multi-center sites which transcends inter-enterprise boundaries. The resources in the federation—such as hospitals, diagnostic labs, and pharmacies—would be governed by the same sharing rules with respect to authentication, authorization, resource, and data access. These rules (protocols) create a highly controlled environment which dictates what is shared, who is allowed to share, and the conditions under which sharing occurs among the medical sites. Federation in this application implies cooperation of independent medical sites. Individually, these sites are autonomous in that they have separate and independent control of their local data. Collectively, those sites participate in a federation, and the federation is governed by the umbrella organization (let's say, a consortium of health providers) (Estrella et al., 2004). The ability of Web services to go beyond the health entity boundary (i.e. the firewall), the loose coupling between applications encouraged by Web service interfaces, and the wide support for core Web service standards by major enterprise software vendors are the key reasons why Web services have the potential to make integration of health applications both within and between health enterprises significantly more effective in terms of ease of implementation and cost savings. Loose coupling means that not only can applications be implemented on different platforms and operating systems, but also that the implementation can be changed readily without affecting the interfaces (Jiang, Xing, He, & Yang, 2005). One of the important modeling and design issues in building Web services is determining the type, scope, and granularity of service components necessary for representing the main architectural abstractions. Moreover, these different types of service components must be put in the wider context of a development process to provide that traceable business requirements are mapped to the software artifacts supporting them.

Having discussed the potential and implications of Web services in healthcare, we now turn to the examination of UML, its extensions and profile to model heath care processes in a robust fashion. How do we derive good service abstractions from high level healthcare domain requirements and health process models?

As a corollary, additional questions arise. What are good (health) services? For example, what is the right service granularity, and what does health process and information technology alignment mean from a modeling standpoint? How can the healthcare automation landscape be transformed into an integrated healthcare ecosystem? From a modeling standpoint, how can well-designed and meaningful service abstractions be characterized and constructed systematically? How are services in a Web service application identified and described? What is the process for developing Web services? How are health processes realized in terms of Web services? Which development approaches are relevant to a Web service? How can legacy systems and packaged applications be adapted as services? All of these questions emphasize the need to use an appropriate modeling approach.

UML PROFILE APPROACH TO MODELING WEB SERVICES IN HEALTHCARE

The identification and construction of a modeling language for Web services pose significant challenges. To provide rich and robust functionality there is a need to focus on the architecturally significant components particular to the Web services in a specific health system and to somehow model them with UML extensions. One way to manage the complexity of Web services is to abstract and model them. In a typical system there are multiple models, each representing a different perspective, layer of abstraction, and detail. Models help us understand systems by simplifying some of their details. But the decision as to what to model has a significant effect on the understanding of the problem (What are the health processes amenable to Web services modeling?) and solving it (How do you enable them?). UML has the potential to answer these challenges (Jiang et al., 2005). UML models and other architectural artifacts such as system context, component interaction and collaboration diagrams can play a key role during analysis and early design (Gronmo, Skogan, Skolheim, & Oldevik, 2004; Zimmermann, Schlimm, Waller, & Pestel, 2005). Also, use case, sequence, and class diagrams can help represent various modeling elements (Conallen, 2003).

A natural starting point for modeling Web services is component-based and interface-based modeling and the standard UML. But to what extent can component-based approaches and the UML fulfill requirements and provide necessary concepts and mechanisms for modeling the Web services, such as componentization, low coupling, high cohesion, interface-based design, hidden implementation, as well as flow of objects and actions? One can develop high-level models in UML, define conversion rules from UML to a target platform, and then use code generation to derive much of the implementation code for a desired platform.

Two key aspects have to be modeled: the service itself, and the workflow. Service modeling identifies which services are to be exposed with their interfaces and operation, while workflow modeling identifies the control and data flows from one service to the next. In a typical inter-enterprise application, one may first discover existing Web services, if any, from a registry. Then, service modeling identifies the interface of the composite Web service and the workflow focuses on reusability. Transformation rules from both models can be specified (Foster, Uchitel, Magee, & Kramer, 2003). The former is mapped to a WSDL document and the latter to a XML document. Finally, the XML document generates the code via a workflow engine. The WSDL document is published as a Web service registry. The UML, having evolved into a standard modeling language, is appropriate to model the service and the workflow. Given its visual format and wide use, the UML is a good candidate for diagramming comprehensible models. Diagrams are a natural part of UML and are used for workflow modeling of Web service compositions. Building composite Web services lacks sufficient support in traditional workflow modeling. Further, the UML seems suitable for expressing Web service patterns (Gronmo & Solheim, 2004). The diagrams and modeling elements can be extended to develop a high level profile of the healthcare process.

UML Profile

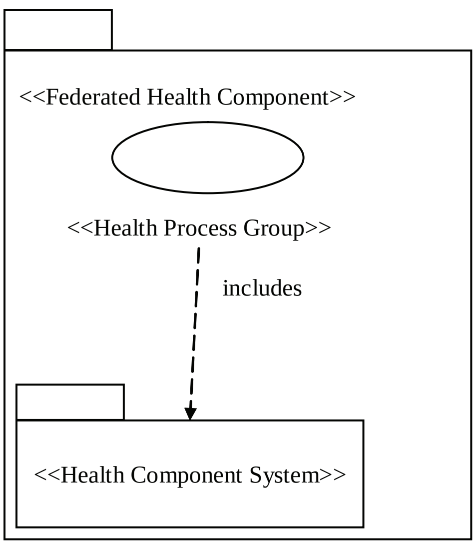
One strength of the UML is its adaptability to specific vertical markets with specific concepts and needs. In the UML standard these are called profiles (Heckel, Lohmann, & Thone, 2003). Various groups working with UML have started to address the customization of UML models for various domains by defining "profiles." The objective for the healthcare process domain is the definition of a generalized UML subset, embellished with UML-compliant extensions, which would permit the annotation of such concepts (Baresi, Garzotto, & Paolini, 2001). Thus, the resulting profile corresponds not to specific domains in healthcare (e.g. diabetes monitoring) but to healthcare processing wherein diabetes monitoring is one service component. While profiles may be standardized in the future, stable initiatives from various groups can form the basis for the definition and standardization of UML profiles (Thone & Varro, 2003). Profiles thus facilitate consideration of the key issues in healthcare processing, namely interoperability, portability, scalability, and universal standards. UML being a complex language, additional features cannot be described easily in the current version, though Version 2.0 may provide extensions. Therefore, UML provides mechanisms such as stereotypes and tagged values to enable extensions (Fontoura, Pree, & Rumpe, 2002; OMG.), and the defined extensions can be grouped into profiles. A UML profile is further defined as an extension of the UML standard language with specific elements. The profile provides new notational elements and typically facilitates specialization of the semantics of some of the elements. Usually the profile builds a hierarchy. The creators of the UML realized that there would always be situations in which, out of the box, the UML would not be sufficient to capture the relevant semantics of a particular domain or architecture. To address this issue, a formal extension mechanism was defined to allow practitioners to extend the semantic of the UML. UML provides two extension mechanisms—stereotypes and tagged values—for describing specific properties of the elements, such as classes, associations and methods (for example, role of "human" as "patient", a patient "visit", and a patient "schedule" in the context of healthcare). The roles and artifacts of the service-oriented style are represented in several diagrams that follow. The mechanism enables one to define stereotypes, tagged values and constraints that can be applied to model elements. A stereotype is an elaboration that allows one to define a new semantic meaning for a modeling element. Stereotypes indicate that the class is an abstraction of the logical behavior of a Web service on either the client or the server. Tagged values are key value pairs that can be associated with a modeling element and allow us to tag any value onto that element. Tagged values are used to define the parameters that are passed along with a link request. The <<link>> association tagged value "parameters" is a list of parameter names (and optional values) that are expected and used by the server page that processes the request. Constraints are rules that define the structure of a model (Fontoura et al., 2002).

One could say each Web service is a UML class. The server side of a Web service can be modeled with one class and the client side with another, distinguishing the two by using UML's extension mechanism to define stereotypes and icons for each <<server page>> and <<client page>>. Using stereotypes makes its easier to model a service's actions and its relationships. Class stereotypes used to model the logical behavior of Web pages means their collaboration with the server side components can be expressed in much the same way as any other server side collaboration (Conallen, 1999). While UML was not originally devised to model health processes or services, one can use the stereotyping capability to develop new extensions to UML. The UML business profile, designed to facilitate business process modeling purposes, is one example.

The Health Clinic Example

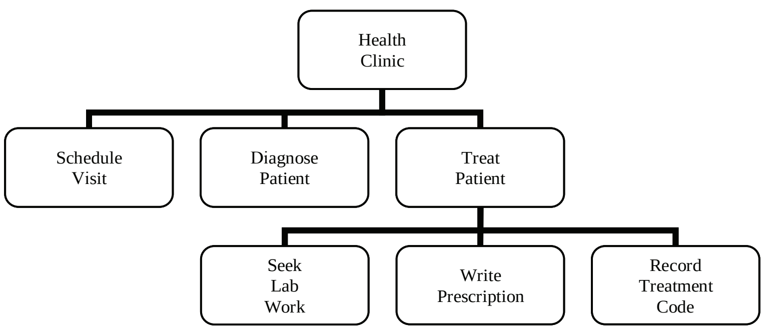
It is possible to provide a UML extension for health service modeling using typical stereotypes. Figure 1 shows the general relationships amongst some of the UML elements. A federated healthcare component performs specialty activities as its services. On the other hand, the specialty itself is decomposed to lower level services, encompassed within a medical entity. It is also similar for other levels of service/process granularity hierarchy. At the architectural level, other types of diagrams are involved, such as class diagrams with interfaces to define signatures and data types of operations, and sequence diagrams as alternative presentations of interactions (Heuval & Maamar, 2003). The Web service domain can be mapped by UML modeling concepts, providing platform independent representation as UML activity and component diagrams. Additionally, a collaboration diagram selected to represent the encapsulation of the binding mechanism as semantically precise as possible and provide all the necessary concepts and capabilities for representing integrations and collaborations of its participating parts. The diagrams, along with structured classes, can support the representation of the composition of interconnected elements representing run time instances, and the collaboration over communication links to achieve common objectives. In particular, collaborations provide the means to define common interactions between objects and other classifiers and assign roles and responsibilities to each. The interaction is similar to providing a pattern of communication between objects playing defined roles. Alternatively, the profile is equated with equivalent meta models. By defining their meta model relationships and interaction mechanisms, one can support the integration and interoperability of their models. In that way one can design complete system models having formalized interaction points and perform model transformations across multiple connected meta models (Staikopoulos & Bordbar, 2005). For example, UML and its standard profiles (CORBA, EJB, and EDOC) can be used to model PIM (Platform Independent Model) or PSM (Platform Specific Model) in the Model Driven Architecture (Brown, 2004). Design decisions can be defined by the UML profile, which provides a set of extensions to UML using the built-in extension facilities of UML, stereotypes and tagged values. The profiles provide a mechanism for managing stereotypes. The profile for healthcare would comprise the range of models derived from UML modeling. The same profile can be used across many projects. Using profiles in this manner (i.e. packages can be exchanged between models) will ensure a standardized approach to problem solving. UML extension mechanisms can help bridge between various models. Using the basics of the class diagram, the systems engineer can model the stack with relative ease. However, for the developer to implement it, he or she will need additional information. UML stereotypes can help clarify

Figure 1. A sample UML representation for health processes and services (adapted from Fatolahi & Shams, 2005)



the stack requirements. In this context, stereotype is a "label" that can be used to "characterize" a model item in some way. For example, an actor could be stereotyped as <<Patient>> <<Clinic>> or <<Service>>. A stereotype is a model element that defines additional values (based on tag definitions) and additional constraints. These can be applied to any model element. Stereotypes label a model element to denote that the element has some particular semantics. UML allows an application model to be constructed, viewed, developed, and manipulated in a standard way at analysis and design time. Just as blueprints represent the design for an office building, UML models represent the design for an application, allowing business functionality and behavior to be represented clearly by business experts at the first stage of development and away from vendor-driven preconceptions. The abstract syntax in UML's meta model is described by UML's class diagram which can represent the abstract syntax structure strictly and precisely (Jiang et al., 2005). For the purpose of health component identification, domain object analysis, and use case analysis are useful sources of input. Domain object analysis defines a domain vocabulary of the system being developed, in other words, information about health concepts in the problem area that should be handled by the system together with their attributes and relationships. Use case analysis is an effective mechanism for defining cohesive sets of features and services on the system boundary because they capture the intended behavior of the system without having to specify how that behavior is implemented. The use cases of the appropriate granularity correspond to the provider's health goals and activities, otherwise known as Elementary Health Processes (EHPs). The cases can be specified in detail according to the use case template that includes name, description, involved actors, goal in the context, scope, level, pre-condition, post-conditions, triggers, main success scenario, extensions, sub-scenarios priority, frequency, performance, etc. Figure 2 depicts a healthcare process hierarchy for this sample case. For simplicity only one thread is decomposed into its EHPs. The stereotyping helps translate the somewhat abstract class diagram into a domain specific platform independent model and platform specific model. For each use case, the use cases that precede it, follow it, perform in parallel with it or are synchronized in other ways with it should be defined. Furthermore, for each use case its super ordinate and subordinate use cases should be defined, providing a composite hierarchy of use cases, (i.e. corresponding business goals). This can be illustrated using a sequence diagram enriched to express the action semantics with the use cases on the horizontal axis of the diagram. Finally, domain information types resulting from domain analysis are cross-referenced with the use cases. In this way, for each use case the information types needed for its performance are defined. A healthcare service may be seen as

Figure 2. Healthcare process hierarchy



a component, which in turn is defined as a self contained health process or service with predetermined functionality that may be exposed through a provider or technology interface. This indicates an implicit relationship between the notions of service, process and component. One can then match the hierarchy of service-components with the hierarchy of healthcare processes in order to gain effective services. Since healthcare processes are significant components of the health delivery architecture and services are the major elements of a Web services' architecture, mapping may be seen as a bridging mechanism between the abstract health service models and the system architectures. A primary healthcare process, called a process group, may contain a series of sequencing process threads. Each thread results in a major added value for a healthcare delivery organization (called a provider), and is composed of its offspring elementary health processes (EHPs), which are the smallest meaningful units of activity for the end user, and which when complete leaves the information area in a self-consistent state. Each EHP may transform to some use cases when designing systems to support its holding thread. Therefore, a process group may decompose to a series of process threads each of which in turn may hold several EHPs. It is necessary to base the services on EHPs. An EHP can indicate which services are required by the enterprise and which of them are provided by the enterprise. Operationally, a health process may be a collection of services. The concepts are illustrated using a "Health Clinic" application that is distributed in residence of the data as well as functionality and use. Table 1 shows the service component hierarchy in the context of healthcare.

A federated health component is a set of services which are common to the various healthcare delivery organizations, including clinics, hospitals, HMOs, labs, and pharmacies. A health component system is a set of health service components assembled to deliver a healthcare solution, such as, providing quality healthcare to a patient. A health component is itself an independent concept, process or service. Distributed

Table 1. Service component hierarchy classifies health services through a hierarchy of granularity/service (adapted from Fatolahi & Shams, 2005).

Health Service Component Granularity	Example
Federated health component	Process group – Consortium of health care delivery participants
Health component system	Process thread – Health clinic
Health component	Use case (EHP) – Process Patient Schedule
Distributed component	Distributed database
Language Class	Method – Verify schedule availability

Table 2. UML stereotyping for health care (adapted from Fatolahi & Shams, 2005)

Service Component Stereotype	UML Element
Federated health component	Package
Health component system	Package
Health component	Package
Distributed component	Component (e.g., database)
Language Class	Class

components and language classes are physical software components (e.g. an underlying database) and classes designed for implementation. It is sufficient to follow the hierarchy of health processes in order to record included services at each level. But this does not mean every process is a service. Identifying the specific services to be implemented using a specific technology, such as a Web service, it may be enough to verify EHPs and decompose each EHP into Derived Logical Processes (DLPs). Each DLP can be a stand-alone process that does not require human intervention. The hierarchy provides a means to package services in well-defined components that are of interest to different users at various levels (Fatolahi & Shams, 2005). Table 2 shows the generic UML stereotyping for healthcare. An EHP included by the schedule is developed here. Figure 3 shows the UML stereotyping for the SCHEDULE VISIT thread for the clinic example. It indicates how the UML stereotyping mechanism may help us in modeling the services in the healthcare processes. The diagram presents the schedule visit thread and some of the linked services. Now consider the medical clinic application that serves as a manager (coordinator) of scheduling and coordinating patient visits. For simplicity, we restrict the functionality to scheduling a patient visit. For this purpose, the clinic software should be able to connect to third party (e.g. referring physician, hospital) information systems. After a patient requests a visit, the system has to query the third party systems as well as internal systems to select appropriate dates/place/location and schedule the patient visit. These requirements lead to a dynamic distributed system where new components can be brought up by the medical facility (e.g. hospitals) at execution-time. The application can be implemented as a Web service as modeled with the UML profile. Models can be differentiated at the various type levels (Baresi, Heckel, Thone, & Varro, 2004). Component diagrams can be used to show the component types of the applications, including the interfaces at the ports. Figure 4 is a partial component diagram of the health clinic example. The patient (or representative) requests to schedule a visit from the clinic. This action links to different delivery organizations. All healthcare delivery organizations need to publish Web services to accept the queries from external

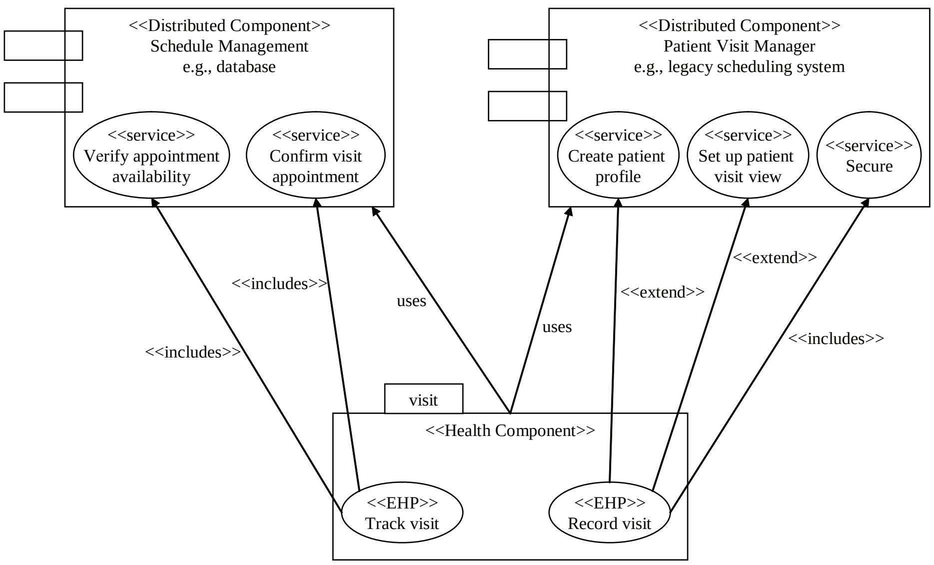

Figure 4. Web services specific component diagram (adapted from Baresi et al., 2004)

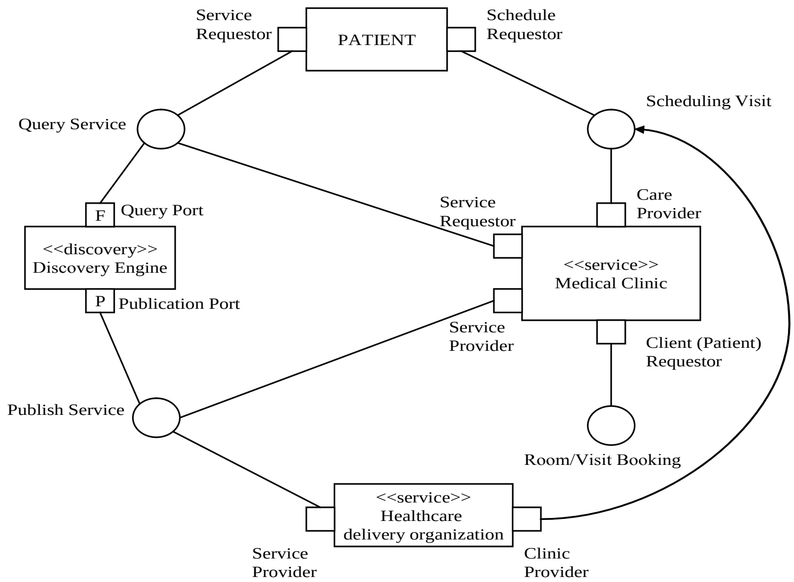

clinic systems in a healthcare UDDI Web services registry. When the clinic system queries third party systems, it discovers the Web services in the UDDI Web services registry, then binds the Web services at their particular Web location, and finally obtains the requested information by execution of the Web services. The UDDI helps integrate the healthcare service across various healthcare delivery organizations in an open environment. While WSDL and SOAP describe the service interface and communication protocol once a specific service is located, UDDI enables the service consumer to reach the service provider through a multitude of Web services available. The Service Provider registers the information about the service in the UDDI Registry by publishing the service, and the Service consumer queries the UDDI Registry to discover services matching certain criteria, all through standard defined UDDI APIs (UDDI.org, 2002).

UDDI becomes a key element in Web services runtime environment and life cycle when the services are dynamic and evolving, and the binding for a service is non-deterministic. It is conceivable that service consumer will eventually discover and use the most desirable service through a streamlined find-bind-execute process without human interaction.

Additionally, the details of the port types and the interfaces may be defined by class diagrams. A partial class diagram is shown in Figure 5. The class diagram also contains stereotyped associations. These define types for links that are available to connect to the various ports. We also need to model packages of the component instances in a run-time scenario. UML collaboration diagrams can be used for this purpose. Figure 6 is an example collaboration diagram for the health clinic. Various labels can be applied to the changed instances and links during run-time. The communication features are shown by assigning messages to the link symbols. Numbers are used to indicate the sequence of the messages. The displayed specification artifacts, such as service descriptions and service requirements, are needed to enable the Web service-specific capability of dynamic service discovery (Baresi et al., 2004). An objective of the health clinic system is to provide integrated scheduling and visit services for patients by loose coupling of providers, cus-

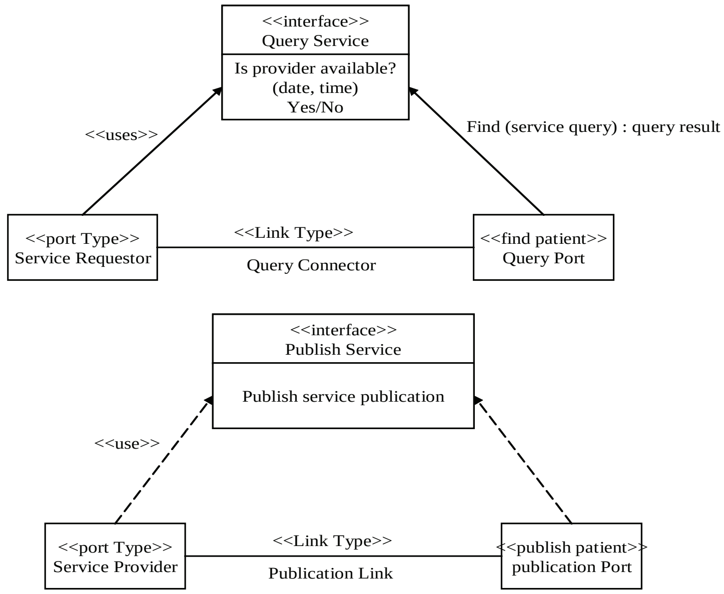

Figure 6. Web services specific collaboration diagram (adapted from Baresi et al., 2004)

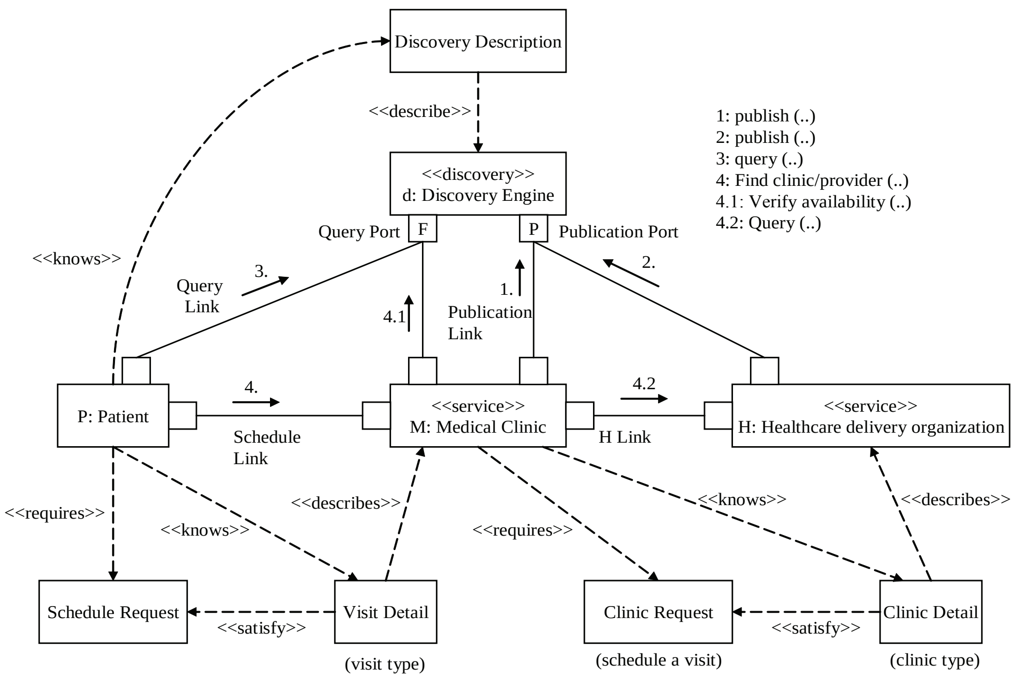
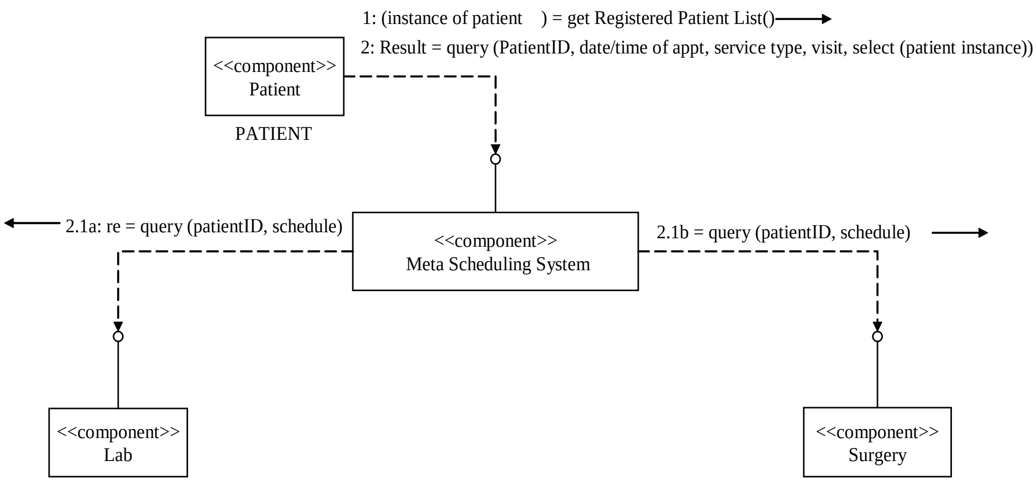


tomers (patients) and related-entities solutions already residing at their sites. Each of these can be accessed via Web service interfaces, and incoming requests are forwarded to all known services (medical; participants). Figure 7 shows a collaboration diagram modeling a hypothetical scenario to execute a query on the meta scheduling system (schedule/visit). Prior to dispatching a query, the client (patient) has to choose the local scheduling systems where the query ought to be run. Then the client retrieves a list of scheduling systems that are registered with the meta scheduling system ("discovery"), for example, the lab, and surgery. The search string is sent simultaneously to all selected scheduling systems. For this situation, a UML component diagram can identify the various components and interfaces for the given system. From the scenario in Figure 7 one can derive the UML component diagram in Figure 8 to identify the (types of) components and interfaces used in the application. The objective to develop UML profiles for healthcare frameworks is a potential definition of UML subsets incorporating extensions and annotating the artifacts. The examples represented by the various diagrams contribute to the overall development of profiles in healthcare.

CONCLUSION AND FUTURE RESEARCH DIRECTIONS

While the Web services paradigm is gaining attention in the development and integration of complex healthcare applications, there is an almost complete lack of modeling approaches. Web services modeling is a challenging task because the service concept further raises the level of abstraction and actually aims at narrowing the gap between the healthcare process and the software. Therefore, for the purpose of Web services modeling, the best practices from object-orientation and component-based design as well as work flow and health process modeling, must be considered and thoroughly integrated. In this article, we propose a UML profile for modeling Web services in healthcare. We describe the various components of such a profile for a hypothetical medical clinic whose interactions are characterized by distributed ness, need for interoperability, portability and scalability. Such profiles developed and standardized over time, will assist the healthcare industry in implementing robust Web services applications for a range of healthcare processes. The paradigm of Web services enables healthcare organizations to shift

Figure 7. Collaboration diagram modeling executing of a query (adapted from Heckel et al., 2004)



from tightly coupled and coarse-grained applications to more dynamic and loosely coupled ones. The UML profile outlined in this article requires further refinement especially if platform-specific details are added. The article has proposed a way to model the services components in a healthcare scenario that enable their realization and the orchestration as the primary building blocks of the Web services architecture. While the research is exploratory one can build on the concepts outlined here to develop comprehensive UML profiles for the various services in healthcare. This would advance the goal of uniform standards for interoperability as health related organizations rapidly develop electronic health record systems, clinical decision support systems and other applications. We advocate the notion of a profile along with the concept of a service component, a paradigm shift from components as static objects to components as dynamic service coordinators. In the future, specific mapping rules for transforming platform-independent models into platform-specific models have to be identified (Stojanovic et al., 2004). We envision health processes as reliable resources to discover services in SOA-enabled Web services (Fatolahi & Shams, 2005) architecture for healthcare delivery organizations (for both, profit and non profit sectors). Also, in the future the UML profile approach developed here can be extended and standardized to facilitate reusability and universal application of Web services in healthcare. Additional research can provide insight into UML extensions and stereotyping in health services as well as enable definition of standards for open source development of applications in healthcare. Finally, integration with HL7 standards has to be addressed. In this way, there is incremental contribution to the advancement of global applications of information technology in healthcare. Loosely federated Web-enabled systems at this level could help track and monitor health issues, such as pandemics, on a global scale.

Chapter 8.5
Evidence-Based Medicine:
A New Approach in the Practice of Medicine

ABSTRACT

The ongoing tension between certainty over uncertainty is the main force that is driving the evidence-based medicine movement. The central philosophy of this practice lies in the idea that one can never take for granted one's own practice, but by using a structured, problem-based approach, practitioners can logically manoeuvre their way through the obstacle course of clinical decision-making. Attending postgraduate educational events and reading various science journals are no longer sufficient to keep healthcare practitioners aware of all the new developments in practice. To gain this knowledge they need to accept that there are questions they have to ask about their practice. Having posed a number of questions, answers should be found to the most important, practitioners should appraise the quality of the resulting evidence and, if appropriate, practitioners should implement change in response to that new knowledge.

INTRODUCTION

Evidence-based medicine (EBM) can be thought of as the conscientious, explicit and judicious use of current best evidence in making decisions about the care of the individual patient. It means integrating individual clinical expertise with the best available external clinical evidence from systematic research (Sackett, 2003).

Medical practitioners see an overwhelming number of patients. Several questions concerning diagnosis, prognosis, treatment and general care may arise during each session. Hence, it is quite possible for a medical practitioner to make many thousands of clinical decisions a year. As per Covell (Covell & Manning, 1995), when asked, general practitioners say that they generate on average two questions per three patients. Forty percent of the questions were factual (e.g., What dose?), 43% were concerned with medical opinion and 17% were nonmedical. On average, the clinician is left with four unanswered questions per surgery or clinic. A colleague typically meets only 30% of physicians' information needs during the patient visit. Further, the reasons for not using printed resources includes lack of knowledge of appropriate resources, office textbook collections are often too old, as well as a lack of time to search for needed information. In addition, there is no proof that the information obtained is 100% up-to-date. Evidence-based practice can be of great help in this scenario of the background of information needed and clinical overload and the general feeling of helplessness. EBM aims to provide the best possible evidence at the point of clinical (or management) contact.

As per the study by Lundberg (1992), in 1900 there were about 10,000 scientific journals; in 1990 there were more than 100,000 scientific journals. Ninety percent of all major scientific advances are in only 150 of those 100,000 publications; 80% of the citations noted by Science Citation Index are to less than 1,000 journals. Not all of this information is valid or useful for patient care. There is a need to be able to identify relevant information and to be able to critically evaluate the scientific methodology and conclusions of the information.

Evidence-based medicine then focuses on converting the abstract exercise of reading and appraising the literature into the pragmatic process of using the literature to benefit individual patients while simultaneously expanding the clinician's knowledge base (Bordley, 1997).

The primary objective of this chapter is to discuss this new approach of practicing medicine. The need for evidence-based medicine becomes even more pronounced in an environment focusing on lowering healthcare costs. However, it is our thesis that in order to realize the full power and potential of EBM we must integrate the strategies, processes, tools, techniques and technologies of knowledge management. Given that the focus of this entire book is on creating knowledge based healthcare organizations, the goal of this chapter is to familiarize readers with the new and growing area of EBM. From this chapter we believe it will then be possible to appreciate the key role of both information and more importantly knowledge to EBM and thus why it is indeed imperative to incorporate a KM focus in EBM.

STEPS IN EVIDENCE-BASED MEDICINE

The practice of evidence-based medicine can be divided into the following components:

1. Ascertaining a problem or area of uncertainty.
2. Converting information into a focused, clinically important question that is likely to be answered.
3. Efficiently tracking down and appraising the best evidence.
4. Estimating the clinical importance of the evidence and the clinical applicability of any recommendations or conclusions.
5. Unifying the evidence with clinical expertise, patient preferences and applying the results in clinical practice.
6. Summarizing and caching records for future reference.

Ascertaining a Problem or Area of Uncertainty

This is the first step within EBM and must be done with utmost care, especially since all the other steps almost completely rely on this step. A bad identification will lead to form an irrelevant question and an incorrect clinical appraisal that leads directly to a wrong conclusion. This wrong conclusion can be very dangerous and even be harmful to the patient.

A considerable amount of time then should be spent to find the area which needs a literature search. The area of uncertainty should be properly focused and narrowed down before proceeding to the process of formulating the question.

Converting Information into a Focused, Clinically Important Question

The amount of work that the practitioners have to complete is sometimes overwhelming and they forget to ask what they are doing. The questioning attitude is what makes good professionals. Medical practitioners must think through carefully if they in fact are doing the right things and if so are they being done in the right way and at the right time. Further, they should be very accurate when forming a question because in extreme cases a question can be so badly formed that its answer is either unrelated or even meaningless.

Consider the following clinical scenario:

John is a new patient who visits a clinic for a routine physical exam. His medical records from his previous physician are available. John is in good health, although he has had hypertension for many years. There is a family history of stroke. He is 67 years old and he goes on long walks almost every day.

John's hypertension has been successfully controlled by Beta-blockers and he expressed satisfaction with this therapy and he has a feeling that he is getting better. However, John's daughter, who sees another physician, has recently been diagnosed with hypertension and was given Captopril. John wants to know if he can use Captopril. So the problem is whether or not Captopril would be a better medication for John.

A relevant question has to be formed for the above problem. Answers may be found more efficiently by structuring the question. It is, therefore, important to try to break the question down into several parts. This process is also known as "anatomy." The question should be framed in such a way that it facilitates the answer.

The question can be broken into:

- Patient or problem
- Intervention
- Comparison intervention
- Outcomes

Patient or Problem

The first part is to identify the problem or the patient. Healthcare problems may not always seem to be about patients. Sometimes the question may be regarding administrative work, other times the "problem or patient" may be the out of hours of the nurses. It is critical in EBM that the question being described is the patient or problem that is seen. The question must not be too specific at this stage as some important evidence might go unnoticed. There is also a balance to be struck between getting evidence about exactly the group of patients and getting all the evidence about all groups of patients.

Intervention

Intervention may in fact be a postponement of an action such as an operation. Most interventions are more straightforward such as types of dressings, drug therapies or counseling. Alternatively, there can be the provision of differing environmental factors. This portion of the question is important as it confirms the future action to be taken regarding the treatment.

Specificity must be as accurate as possible at this stage as there might be a need to back track if any evidence is not found. The way in which the treatment is offered to patients varies from both within and between primary and secondary care.

Comparison Intervention

Sometimes there is a comparison of intervention. For example, a search can be made for papers comparing the use of head lice lotion in children compared with placebo. Most of the treatments come to practice after performing such comparison tests. Comparative studies offer a great deal of information and help when searching for the evidence.

Outcomes

Outcome measures are particularly important when considering the question. It is worth spending some time working out exactly what it is you want. In some life-threatening or life-altering diseases, most of the times it happens that by concentrating on the mortality, important aspects of morbidity might be neglected. For example, the use of toxic chemotherapies for cancer may affect both aspects (Evidence-based Medicine, 2003).

In the case of John, in the example above, the question structure is detailed in Table 1.

Using this anatomy, the focused question for John would be:

In elderly patients, are ACE inhibitors more effective than beta blockers in controlling high blood pressure and minimizing adverse effects?

Efficiently Tracking Down and Appraising the Best Evidence

One of the questions is formulated. The next step in EBM is tracking down the evidence. This again requires attention to several key steps as described here.

Finding the Evidence

It is important that the most relevant and best available resources are to be searched and utilized for the different types of questions. Best information reserves can be gathered by following a systematic approach. The following five questions can be used as a guide for this process (*Evidence-based Medicine*, 2003).

- *Type of question being asked:* It is useful and also necessary to decide the category in which the question fits into. "Clinical findings," "Therapy," "Prevention," "Prognosis," "Harm or risk" and "Quality of life" are some of the varieties of questions.

Table 1. Structure of the question

Patient / problem	High rate of blood pressure, elderly
Intervention	Beta blockers
Comparison intervention	ACE inhibitors
Outcomes	Reduce blood pressure, minimize adverse effects

- *Choice of information that would provide evidence to answer this type of question:* Careful consideration must be given to the issues of qualitative and quantitative evidence. Sometimes qualitative factors that are impossible or difficult to quantify are involved for some types of questions, including some therapy questions. Though cultural perceptions, values, customs or other types of soft complexity make generalization between groups or population difficult, evidence is needed for decision-making.
- *Type of study that would provide such information:* For each particular type of question, various studies and investigations, which supply the information that can be used as strongest evidence to weakest evidence, must be accumulated. Qualitative research may provide information for complex health policy decisions.
- *Varieties of resources that would give access to the results of the above studies:* Resources can be classified into two fundamental types "primary" and "secondary." Primary sources are the ones in which the original studies are published, while the secondary sources are the ones which refer to or give bibliographical access in the form of references to material in primary sources. Among the primary sources, textbooks along with journals and publications occupy the most important position. With the growth of the Internet, the Web as a source of information is becoming a vital resource. Online information with the aid of powerful search engines such as MSN, Google, Altavista, Yahoo, OMNI, etc., provides links to various sites that have relevant primary and secondary sources of information in an organized way, while computer bibliographic databases like PubMed, MedLine, CINAHL, and EMBASE, etc., are the most important types of secondary resources. These online data sources have links to thousands of electronic journals and research papers from all around the world.
- *How can the best use of the available resources be obtained?* A search can be of two types:
  - High Sensitivity/Low Specificity Search: This search gives importance to comprehensiveness — finding everything of any relevance at all.
  - Low Sensitivity/High Specificity Search: This search gives importance to selectivity — finding only the most highly relevant material.

Clearly there exists a trade-off between the above two categories.

Appraising the Evidence

The main goal of a critical appraisal is to identify the quality of the article. There are three key issues to think about when appraising any paper:

- The validity of the results of the study
- The actual results
- The relevance of the results

Estimating the Clinical Importance of the Evidence

In this step, records are verified to see if the evidence obtained is relevant to the patient's problem and also to verify if the evidence or information obtained is of any clinical importance. Any evidence that is not clinically recognizable must be set aside. It can be considered as supplementary information, but must not be taken as the primary source of information to extract evidence.

The following section will describe how to make a decision regarding the usage of the acquired data.

Deciding Whether or Not to Act on Evidence

The process of evidence-based medicine is one that requires change to be monitored (*Evidence-based Medicine*, 2003). The evidence that supports the validity or truthfulness of the information is found primarily in the study methodology. Here, investigators address the issue of bias, both conscious and unconscious. The investigators or the patients must not overly influence the study results. To ensure this, study methodologies such as randomization, blinding and accounting are applied for all patients. To facilitate the rigor of the methodology, the audit cycle as depicted in Figure 1 is often utilized.

Evaluating the medical literature is a complex undertaking. Once it is determined that the study methodology is valid, the results and their applicability to the patient must be examined. Clinicians may have additional concerns such as whether the study represented people similar to his or her patients, whether the study suggested a clear and useful plan of action, and whether the study covered those aspects of the problem that are most important to the patient.

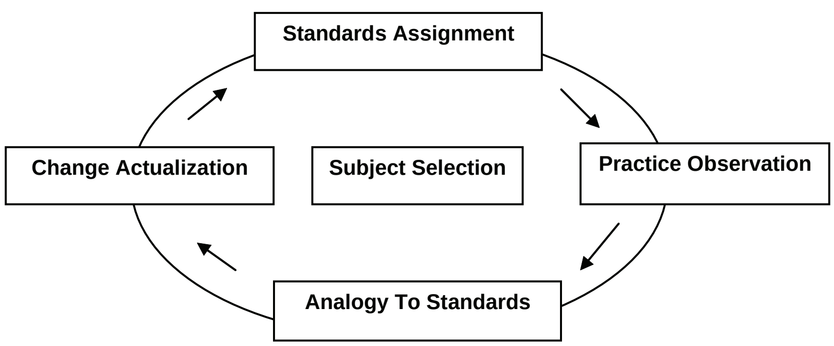
Distinct sources and techniques can be used to achieve and access the clinical importance. Randomized controlled trails are one of the widely used methods. The following are important considerations:

- For the prevention of bias, the groups must be randomized.
- The comparison groups must be similar as different groups might have different characteristics that may lead to bias.
- Patients must be unaware of whether their treatment is experimental or placebo. This is to be considered important as it affects the mental confidence of the patient and may even lead to an altogether different result.
- The length of study must reflect the type of study. It is necessary to have an idea of the natural progress of the disease for determining the appropriate length for a study.
- A good clinical trail requires a complete follow up of both groups. If less than 80% of the patients adequately followed up, then the results may be invalid.
- Appropriate outcome measures must be used in the research of the treatment. It must also be seen that the outcome measures are as accurate as possible.

Unifying the Evidence with Clinical Expertise, Patient Preferences and Applying it to Practice

The final step in the EBM process is to return to the patient and discuss the evidence and suggestions for further treatment.

Figure 1. The Audit Cycle



Suppose, for example, the analysis shows that the evidence is evaluated and accepted and that it meets the criteria for validity. To complete the analysis a review of the results must be performed. Care must also be taken to determine if they are applicable to the particular patient.

Let us return to the example given earlier for the patient John. The following treatment can be suggested. Suppose the results of this study indicate that ACE inhibitors are not more effective than beta-blockers in treatment of hypertension and that they lead to an increased risk of stroke. For John (based on his situation, the physician's clinical judgment, and the evidence) it does not seem appropriate to change to ACE inhibitors. Since there is a family history of stroke, his daughter is not a good candidate for ACE inhibitors, either. A copy of the study can be sent to her to share with her physician so that her physician will have a chance to go through the study to determine if the treatment being offered to John's daughter needs any improvements.

Summarizing and Caching Records for Future Reference

This is the last step in the evidence-based practice. It is not a mandatory step but is highly recommended. As there is a high probability for that physician to get cases very similar to the one he conducted research on, it is always better for him to store and organize all his research. His own work can become the most important resource of information for his future research.

MISAPPREHENSIONS ABOUT EVIDENCE-BASED MEDICINE

Misapprehensions arise naturally regarding any issue. They must be discussed and clarified. In addition, it is important that any of the unintended negative effects must also be taken care of and rectified immediately. While practicing or considering the practice of evidence-based medicine, the nature of the new paradigm is sometimes misinterpreted.

Recognizing the limitations of intuition, experience, and understanding of pathophysiology in permitting strong inferences may be misinterpreted as rejecting these routes to knowledge. Specific misinterpretations of evidence-based medicine, and their corrections, are provided in Table 2.

BARRIERS TO PRACTICING EVIDENCE-BASED MEDICINE

There are some difficult challenges to be faced regarding the practice of EBM. These include but are not limited to: (1) the appropriate literature may not be readily available; (2) economic constraints and counterproductive incentives may compete with the dictates of evidence as determinants of clinical decisions; and (3) sometimes the evidence obtained may be capacious, and there might not be a sufficient amount of time for careful revision relevant to a pressing clinical problem.

Some solutions to these problems are already available. Optimal integration of computer technology into clinical practice facilitates finding and accessing evidence. Reference to literature overviews meeting scientific principles (Oxman and Guyatt, 1998) and collections of methodologically sound and highly relevant articles (Haynes, 1991) can markedly increase efficiency. Evidence-based summaries are becoming increasingly available. Using online health information for obtaining evidence is already in practice. Furthermore, it is gaining importance. Increasingly, scientific overviews will be systematically integrated with information regarding toxicity and side effects, cost, and the consequences of alternative courses of action to develop clinical policy guidelines. The prospects for these developments are both bright and exciting. It is with respect to capturing key knowledge, in particular tacit knowledge, and storing this knowledge so that it can be eas-

Table 1. Evidence-based medicine and their corrections

Misinterpretation	Correction
Evidence-based medicine ignores clinical experience and clinical intuition.	This is not true. Untested signs and symptoms should not be rejected out of hand. They may prove extremely useful, and ultimately be proved valid through rigorous testing. Diagnostic tests may differ in their accuracy depending on the skill of the practitioner.
Understanding of basic investigation and pathophysiology plays no part in evidence-based medicine.	The dearth of adequate evidence demands that clinical problem solving must rely on an understanding of underlying pathophysiology.
Evidence-based medicine ignores standard aspects of clinical training such as the physical examination.	A careful history and physical examination provides much, and often the best, evidence for diagnosis and directs treatment decisions. Evidence-based practice considers the physical conditions of the patient while evaluating the evidence and also before applying treatment to the patient.

ily and efficiently accessed and hence used and reused that we believe the strategies, processes, tools, techniques and technologies of knowledge management have the greatest value in facilitating EBM, addressing its key barriers and enabling it to reach its full potential.

Concerns Regarding Adoption Of Evidence-Based Medicine

Although EBM has heightened awareness of the most effective management strategies, much of the evidence is not acted on in everyday clinical practice. In particular, five main themes have been identified that affect the implementation process (Freeman and Sweeney, 2001). These include:

Personal and Professional Experiences of the General Practitioners

Doctors' personal and professional experiences influence how clinical evidence is implemented. Despite being a relatively homogeneous group, the general practitioner's enthusiasm for the evidence and the way in which they implemented it varied. Thus, there is no proof that whatever approach is assumed as the best depending on the evidence is actually the best or not.

The Patient-Doctor Relationship

Implementation is influenced by the relationships that doctors developed with their patients. Perceived patient characteristics could have a positive or negative effect on implementation. It also depends on the confidence of the patient in the physician and also in the treatment.

A Perceived Tension Between Primary and Secondary Care

Implementation is also influenced by the relationships of doctors with secondary care doctors. Specialists approached evidence-based practice differently, treating "diseases rather than patients." Based on the same evidence, a general practitioner may think one approach as the best one, while a cardiologist might think the same approach as the least approachable.

General Practitioners Feeling about Their Patients and Evidence

Clinical evidence is not just an intellectually celibate commodity that is lifted out of medical journals and transferred to a patient. It has an emotional impact on practitioners and patients. Sometimes the knowledge that the evidence existed, waiting to be applied, was seen as a burden in itself. It may make the patient more anxious. Some practitioners may forgo applying the evidence due to the patient's unwillingness to a new kind of treatment.

The Logistical Problems

Some tricky logistical problems make the doctors less enthusiastic about implementing clinical evidence. Many physicians find it risky and a hassle both for doctors and patients to start a new treatment. Some patients might feel the same. Many of the problems can be resolved by the incorporation of knowledge management. For some problems, using the knowledge management concepts can reduce the intensity of its effect.

CONCLUSION

Based on an awareness of the limitations of traditional determinants of clinical decisions, a new paradigm for medical practice has arisen. Evidence-based medicine deals directly with the uncertainties of clinical medicine and has the potential for transforming the education and practice of the next generation of physicians. These physicians will continue to face an exploding volume of literature, rapid introduction of new technologies, deepening concern about burgeoning medical costs, and increasing attention to the quality and outcomes of medical care. The likelihood that evidence-based medicine can help ameliorate these problems should encourage its dissemination.

EBM is still in its infancy. Further, it requires new skills of physicians and other medical practitioners. While strategies for inculcating the principles of evidence-based medicine remain to be refined, initial experience has revealed a number of effective approaches. An evidence-based approach is robust, informative and feasible. It also promotes the quality and consistency of healthcare delivery, and it ensures that the services are cost effective. This chapter has served to highlight the key issues pertaining to EBM. By doing so, it highlights the integral role for KM within any EBM initiative to facilitate the generation, capture, storing, use and reuse of critical medical knowledge. We close by calling for further research into this key area of healthcare in today's 21st Century.

ABSTRACT

As health organizations strive to improve operational efficiencies and increase worker productivity, new forms of health information technologies (HITs) are constantly being developed. This article surveys the extant HIT literature and adopts a case analysis approach to identifying emerging health information technologies. The understanding of HIT trend is further enriched through the applications of technology-forecasting techniques, specifically, scenario analysis and U.S. patent searches. The article focuses on five emerging HITs and their impact on the future of U.S. Healthcare Services Delivery.

INTRODUCTION

The advent of information technology (IT) and telecommunications has altered beyond recognition the traditional business processes in many industries. The impact of IT on the health industry is also gaining attention. In the past, researchers have noted the lag of IT diffusion across the health sector vis-à-vis most other industrial sectors. With the diffusion of health databases and automated data warehouses, routinely extracted health data from multiple sources can now be more fully integrated and mined to evolve a new type of knowledge that promises to transform the health industry. Physicians, aided by intelligent clinical support systems and automated devices, for example, can now provide better patient care by drawing on programmed reminders and alerts and other computerized protocols of guided treatments for specific diseases. Emerging IT has made physician practices more efficient and effective while new research in the area of optimizing user interface designs for physicians and other health professionals promises to further enhance such capabilities (Zheng et al., 2005).

In this age of knowledge explosion, health information technology (HIT) is beginning to permeate many areas of human life. Tan (2005) documented the various strategies and speed with which emerging HITs are transforming the healthcare industry. Telemedicine today encompasses a common infrastructure including physical facilities, and equipment used to capture, transmit, store, process and display voice, data and images. Technological advances such as fiber optics, satellite communications, and compressed video have minimized expansion costs and limitations, thereby initiating a growth of public and private sector interests. These newer, alternative modalities of healthcare delivery are beginning to affect the cost, quality, availability and accessibility of healthcare. HIT has become a crucial part of the routine practices of healthcare professionals. It is not unusual nowadays for health consumers to check medical conditions of their own or those of their significant others on the Internet. A recent Forrester survey of 1,300 doctors reports that 80% of physicians believe technology "makes life easier."

Specific to changing the patient-physician relationship and the role of organizational health services delivery in the United States (U.S.), emerging technologies are clearly dictating people to take a greater and more active role in maintaining their own health. The result is a proactive prevention-oriented, consumer-driven model for healthcare that includes capabilities such as "smart devices" that can "think," customized wearable devices, electronic patient records, and wireless Internet-linked systems. Over time, these technologies are expected to deliver more convenient, user-friendlier, and more consumer-driven, home-healthcare services, unlike traditional services delivered at a physical and distant medical facility. For consumers, this could mean added convenience, reduced travel time and costs. They will enjoy easy-to-use homecare systems and products that teach them to monitor themselves with gizmos that give timely warnings of illness so that they can turn to their physicians early when appropriate interventions will do the most good. For doctors, it could mean more timely and effective patient care.

In this article, a selection of emerging HITs with a focus on their potential impact on the future of organizational health services delivery is reviewed. The analysis of emerging HIT applications is based on key observations of Providence Health & Services (PHS) organizations, one of the leading health providers in Pacific Northwest that implements cutting-edge technologies to improve patient care and reduce healthcare cost.

The review of PHS presents the necessity of HIT applications. Onsite formal and informal interviews and discussions with key experts helped identify emerging HITs deserving attention. Experts were also consulted to verify the interview results. A twofold approach followed the interviews. Specifically, a combination of technology forecasting tools including "Patent Analysis" and "Scenario Analysis" was used to predict the future of these emerging technologies.

Each of the technologies identified is either replacing an existing one or evolving as a new technology, for example, radio frequency identification (RFID) in healthcare is replacing barcode technology whereas e-health is an emerging paradigm. This article therefore, represents the initial steps of a larger research framework for assessing and forecasting the diffusion of particular HIT and their potential impact on the U.S. healthcare services delivery system.

BACKGROUND

Research on technological assessments in the health sector has grown over the last several years. Table 1 highlights key but selective literature on efforts to implement HITs across the spectrum of healthcare services organizations. Three themes arise from this review: common HIT applications, health decision support tools and emerging HIT applications.

Unfortunately, the adoption of IT has not always been successful. Indeed, there is evidence to show that many system implementations across all industry sectors ended as failures when measured by the ability of top management to ensure timely delivery of a specific product within budget (Ein-Dor & Segev, 1978; Ginzberg, 1981). In particular,

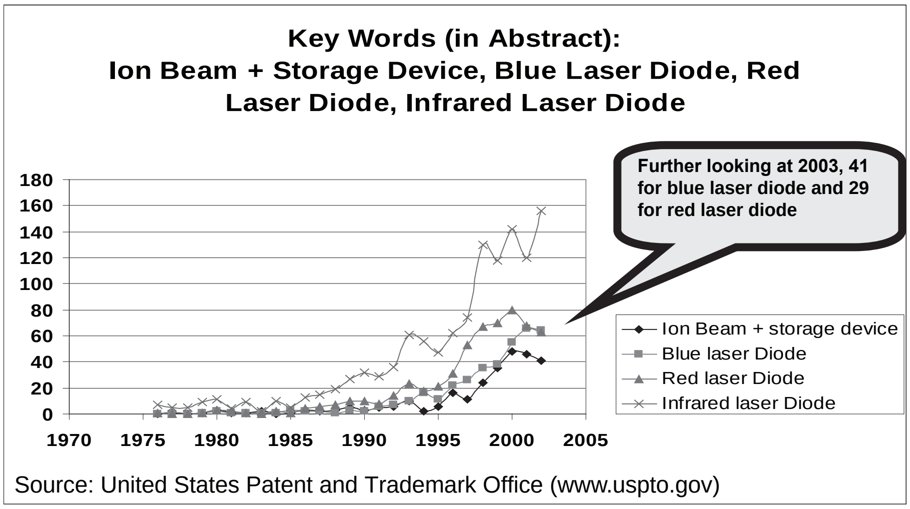
a factor that can also cause implementation challenges encountered among academic healthcare centers is the lack of "across-the-organization", top-down leadership philosophy (DeWitt & Hampton, 2005). Owing to the way in which healthcare provision is organized, Lorenzi and Riley (2000) observed that small group theory might be highly applicable to an evaluation of success factors for implementing HITs in these centers. Anderson (1997) further noted that organizationally mandated initiatives are not generally met with success, and in fact, might result in "evasive actions or even sabotage." The organizational dimensions of successful HIT implementation is of keen interest and has been noted as an area in need of further research (Larsen, 2003; Meijden, et al., 2003; Ash, 2004).

Technology Forecasting

Little research has focused on the application of technology forecasting methods to HIT applications. To narrow the focus of our analysis, we home on those emerging HITs that may significantly impact health services based on experts' opinions. Additionally, we are only interested in HITs that will directly improve patient care or result in rapidly improved organizational efficiencies within the U.S. healthcare services delivery system. Technology forecasting is aimed at predicting future technological capabilities, attributes, and parameters. It is a step in the process of anticipating and bringing about tomorrow's evolving technologies (Martino, 1983).

IT forecasting has become a widely valued technique during the past decade from the perspectives of both individual companies and entire industries. Innovation, based on new technology,

Figure 1. The number of U.S. patents by technology



plays an enormous role in any company's success. Innovative companies generally enjoy greater sales, profitability and global market share. To accelerate the pace of innovation, it is essential that there is sharing of greater collaboration among partners having common innovation goals. Several alternative methodologies are used in technology forecasting. Cauffiel and Porter (1996) use Delphi method to explore Electronics Manufacturing in 2020. Linstone (1999) uses multiple perspectives to assess any decision regarding future applications of a technology and demonstrated its use for technology forecasting. Kayal (1999) is a leading researcher who has used patent analysis for forecasting technologies. Watts and Porter (1997) introduce the use of bibliometrics for the same purpose. Sager (2003), Winebrake et al. (2003) and Silberglitt et al. (2003) use scenario analysis to explore biotechnology, hydrogen fueling systems and energy futures.

Daim et al. (2006) use patent analysis and bibliometrics to trend emerging technologies. Figure 1 depicts a graphical analysis of one of their study results. As shown, emerging technologies under exploration reach a plateau in terms of granted patents at a certain time period. In the case of blue laser diode, it was in and around the year 2000 that this plateau was reached and in late 2006, we are witnessing commercial applications just being released, which may be explained as the time required for commercializing the technology.

Governmental decisions to support some technologies and not others will also impact differently on the speed of technological innovation and development to market. If technological forecasting predicts that a certain capability is technologically feasible and is within our reach in the near future, and if the government chooses to support research and invest in this area, it is more likely that the technology will be developed and marketed successfully.

The major techniques for technology forecasting may be divided into two categories: (a) methods based on numeric data and (b) judgmental methods. The tool applied to forecast each technology was based on individual technology's characteristics. "Patent Analysis" was used for technologies grouped under the category of emerging technologies whereas "Scenario Analysis" is appropriate for studying technologies that are more suggestive of an evolving concept. In our analysis, both of these approaches will be applied to HIT forecasting.

THE PROVIDENCE HEALTH AND SERVICES (PHS) CASE

Providence Health & Services (PHS), with information systems centered in Seattle, is a nonprofit health provider organization with presence in Oregon, Alaska, California, Washington and Montana. PHS includes 28 hospitals, more than 35 non-acute facilities, physician clinics, a health plan and education facilities. Figure 2 maps out PHS services in the different regions.

PHS is the sixth largest Catholic system in terms of net service revenue and the largest healthcare provider in Oregon, Alaska and Washington as well as the largest employer in many communities. In 2005, PHS had seven million visits, which is equivalent to filling every NFL stadium in the country to three times their capacity.

In the Oregon region, PHS offers the following services:

1. **Benedictine Nursing Center:** Founded in 1957 by Benedictine Sisters, the center offers different level of services, including in-home services, nursing center, garden home, orchard house, rehabilitation services and home health
2. **Home Services:** This is a fully integrated Division of Providence Home & Community Services, including home infusion, offering an alternative to lengthy hospital stays for medically stable patients requiring IV

Figure 2. Maps of providence health & services

therapies; home health, providing round-the-clock skills, support and assistance for patients and in-home caregivers; home oxygen and medical equipment, servicing a wide variety of products and related patient services at home

3. **Outpatient Diabetes Education Program**
4. **Behavioral Health Services:** The program offers a complete array of services, from acute inpatient stay to outpatient follow-up
5. **End of Life Program**, including hospice care: Tailored to meet each individual resident and residents' family needs and desires at the end of life; personal and palliative care; and center for healthcare ethics
6. **Children's Services:** This program provides specialized medical care and support services to meet the needs of children and family
7. **Financial Assistance:** The financial aid program offers several ways to help patients with their medical bills
8. **Center on Aging:** The geriatric program offers wide range of services to meet differing needs of seniors
9. **Volunteer Services:** This program offers an avenue for the involvement of volunteers
10. **Brain Institute:** The brain program provides services for treatment of stroke, Alzheimer, Multiple Sclerosis, neurosurgical conditions and epilepsy
11. **Employer Services:** This program offers a variety of services to meet the needs of every workforce

At PHS, a significant number of different HIT applications are supporting key healthcare services. Table 2 lists and maps various support HIT applications to PHS services.

Today, the rapid rate of technology evolution demands technology planning in terms of both forecasting and management. Forecasting technologies is among one of the most formidable challenges that IT managers face. Indeed, it may be argued that getting ready for future HIT is key to managing well in any organization and to gain a market competitive advantage. Our

Table 2. PHS key services and supporting IT applications in the Oregon region

Service	Application	Function
Behavioral Health Services	BHCD	Provide Client Encounter Database for BHS Programs.
Benedictine Nursing Center	PathLinks	Financial and Clinical. Patient-centered, process-oriented software system that helps long-term care facilities manage clinical and financial business operations
Radiation Oncology	Impac	Primary function to monitor dosage and record radiation treatments for Oncology Patients. Secondary functions Physician Notes, Scheduling, Report delivery, & Transcription
Medical Foundation	Donor-II	Used for tracking donor information and contribution.
Diagnostic Imaging	STAR Radiology	Supports daily operational functions of the Radiology departments.
	Mammography Reporting System	Radiology application used to store patient demographics, orders and results for the mammography department.
	UltraPacks	Ultrasound image archive and review system with electronic reporting
Surgical Services	HSM	Surgical Services Case Management, Perioperative Charting, and Supply Management System.
	ORTracker	Manages daily surgery cases, actively tracks equipment and patients in surgery area, and displays nurse call info.

interviews with the IT experts concur with this observation.

Emerging HIT Applications

Americans are living longer and better: by 2050, it is projected that there will be one million centenarians, up from 71,000 today (usatoday.com, 2005). Hence, it is becoming critical to identify key technologies to help improve healthcare services, especially for the U.S. aging population.

Emerging information-intensive technologies in healthcare are converging to revolutionize self-care. This leads to consumers playing a greater role in maintaining their own health. Technologies such as wireless, sensor, wearable and radio frequency identification devices (RFID) are clearly coming in support of a prevention-oriented, consumer-driven model of healthcare. The U.S. patents database is searched to identify emerging HITs and to understand emerging technological trends, along with a comprehensive review of current literature and the Internet. Interviews with several key industry experts yield the following five emerging HIT as an extrapolation from our PHS case analysis: (a) E-Health; (b) Semantic Web; (c) Wearable Monitoring Devices; (d) RFID; and (e) Artificial Intelligence (AI).

E-Health

E-Health is the new paradigm for convenient medical information exchange from one site to another via electronic communications to improve and monitor patient health status. The World Health Organization (WHO) defines "e-Health" as "the cost-effective and secure use of information and communications technologies in support of health-related fields, including health-care services, health surveillance, health literature, and health education, knowledge and research." If sensibly deployed, e-health is expected to improve healthcare quality, cost-efficiency, and patient care. Key benefits for e-Health initiatives include improved provider inefficiencies, greater care accessibility, cost containment, better performance reporting and process efficiencies, enhanced patient safety and quality, reduced distance barriers in healthcare, and increased speed and quality of information capture, storage, organization and retrieval.

E-Health adoption involves overcoming several key barriers. The lack of interoperable systems is a major barrier. Reimbursement of e-visits is another source of concern to physicians as they face consumer demands for greater access to a limited resource—their time. The startup cost for e-Health may also be high as it often requires significant change in health IT infrastructure, training of healthcare professionals as well as anticipated changes in patients' behaviors. Cross-state licensure is another issue; in essence, a health provider or pharmacy must be licensed in every state in which it serves clients. Moreover, one of the areas, which remain challenged when it comes to the future of e-Health, is aligning economic interests across the U.S. healthcare delivery system. For example, there remains a real need to dissect the entire value chain of traditional prescribing and truly understand where digitizing the process saves money, time, or human lives. Understanding who benefits, when they benefit, why and to what extent they benefit is critical to understanding who should invest, why and to what level. For example, if the provider physician receives little to no economic value from digitizing the prescription order entry, why should s/he pay for this benefit? Finally, privacy standards, guidelines for creating healthcare sites, and language barrier are all key challenges facing the adoption and diffusion of e-healthcare. Medical Web sites, more that any other type of site on the Internet, should follow strict personal privacy codes to prevent individuals' personal medical information being compromised.

Scenarios and Strategies

The domain of e-Health is very broad, ranging from Electronic Medical Record (EMR) to e-Prescription and e-Visit, to telemedicine and tele-care services. Each of these areas may be further conceptualized in terms of a series of related projects. Using patent analysis in such a broad domain will not be very helpful in providing any insight into technology forecasting. Instead, scenario analysis for e-Health forecasting is proposed.

The healthcare environment is very volatile. The uncertainty surrounding market forces such as employee benefit structure, the future of Medicare managed care, and the impact of consumer behavior will all affect healthcare future. In the last decade, consumer expectations and their needs are one of the driving forces for change in healthcare. Other forces driving change are genetics, medical technology, population demographics as well as profile of disease. Today, consumers are taking greater responsibility for their own health. They are increasingly demanding choice, quality, convenience, and personalized services in healthcare. Scenario analysis overcomes this limitation by acknowledging the uncertain healthcare environment and articulating a set of plausible alternative futures. Scenario analysis is especially suited for analyzing the current healthcare climate as characterized by the significant level of uncertainty surrounding critical market forces. Key market forces today include: (a) collective bargaining of physicians; (b) health plan consolidation; (c) employee benefit structure; (d) Medicare managed care; (e) healthcare inflation; (f) consumerism; (g) provider payment structure; and (h) physician practice structure.

As depicted in Table 3, with PHS and other health services organizations, there are four possible scenarios that could provide insights into e-health technology forecasting. Analysis of alternatives under these various scenarios will

Table 3. E-health scenarios

Increasing Healthcare Cost	Choice of Freedom
Scenario Healthcare cost is exceeding general inflation. Employers would move to a defined and fixed healthcare coverage. Solution Consumers would make their own decision regarding the purchase of insurance and healthcare services.	Scenario Again, employer healthcare cost wouldn t be growing faster than general inflation. Employers would continue to offer limited choices. Solution Consumer-driven choice and low inflationary pressure have several strategic implications for hospitals and physicians.
Federal Government Role	**Medical Inflation**
Scenario Federal Government may pass series of reforms to manage healthcare costs for both providers and payers. Solution Federal scrutiny would force providers to shift their focus on corporate compliance and policy development. It would shift focus from payers to hospitals and physicians.	Scenario Managed care payers would be the dominant market force, setting contracting and coverage parameters and, thus, making the greatest profits. Solution Payers would require providers to submit information that would allow quality evaluation to occur.

provide better future readiness for healthcare service providers.

- **Increasing medical cost:** In this scenario, the increase in medical costs greatly exceeds general inflation, and the consumer chooses to take an active role in healthcare decision making. Employers would move to a defined-contribution approach to health coverage and provide employees with a fixed dollar amount every month. Consumers would make their own decisions regarding the purchase of insurance and healthcare services, seeking value from hospitals, physicians, and insurers. The combination of individual purchasing discretion and greater demand for information would lead to new models of e-Health contracting.
- **Choice of freedom:** Because employer healthcare costs would not be growing significantly faster than general inflation, companies would continue to offer their employees a choice of plans and providers with a defined benefit. Consumers would take an active role in healthcare decision making within the defined limits of their coverage. Although freedom of choice would exist, the market forces of supply and demand would serve to ration care and access. Consumer-driven choice and low inflationary pressure have strategic implications for hospitals and physicians such as competing on health services portability.
- **Federal government role:** Concerned with the high rate of medical inflation, the Federal government would pass a series of reforms that would establish active Federal oversight and regulation of both providers and payers. Faced with increased Federal scrutiny, providers would focus a significant portion of their resources on corporate compliance and policy development. It would shift risk from payers to hospitals and physicians primarily through capitation. Hospitals and physicians would re-evaluate the role of the integrated delivery system to optimally match their organizational structure with the industry's risk-based payment system.
- **Medical inflation:** In this scenario, managed care payers would be the dominant market force, setting contracting and coverage parameters and, thus, making the greatest profits. In an attempt to define and measure provider quality, payers would require providers to submit information that would allow quality evaluation to occur. Because of consumer indifference to choice among healthcare providers, there would be a shift from open-access products to closed-panel models presided over by gatekeepers. Federal legislation would wane because employers would be content with the relatively low rate of medical inflation, and consumers would not demand governmental intervention, as perceived problems would be minor. Hospitals and physicians would consider aggressive responses to the payers' strong market position. Hospitals would consider consolidation in an attempt to increase their bargaining power.

Semantic Web

Traditionally, pharmaceutical companies have relied on research about how specific diseases work and drawn on knowledge that is in the public domain as its starting point for the discovery of new medicine. In *Pharma 2010: The Threshold of Innovation*, IBM described how the molecular sciences will help the industry define diseases more accurately and create healthcare packages for patients with specific disease subtypes, rather than making one-size-fits-all drugs for patients with similar symptoms but essentially different diseases (Arlington, 2003; IBM, 2004). Similar to the views expressed by IBM, Dr. Allen Roses, worldwide VP of genetics at GlaxoSmithKine, clearly believes that the future of pharmaceuticals lies in being able to target drugs to a smaller number of patients with specific genes and disease subtypes, rather than in selling as many drugs as possible to as many patients as possible (Connor, 2003).

Still, the development of targeted treatment solutions hinges on a much more precise understanding of disease, including the mechanisms and pathways involved in particular disease states and the differences between related disease subtypes. Tools that can map the genes associated with susceptibility to particular illnesses will be vital in developing targeted treatment solutions. A British researcher, Tim Berners Lee, who also introduced the concept of the Internet in 1989, first introduced the "Semantic Web" concept in 2001. The Semantic Web would represent a World Wide Web of connected data, radically different than today's Web of discrete data. It could be the answer to affordable electronic health record.

The Semantic Web makes it easier for data on the Web to be shared and reused by people and applications. The technology allows taking better advantage of information on the Web. It allowed users to perform machine-readable queries and aggregate similar data and information. It is based on the W3C's Resource Description Framework (RDF), which uses XML to integrate applications. The technology has the potential to change the way the health industry behaves; it can also change the way health researchers share and access data. But like any new technology, there is an adoption cycle that must be overcome. With Semantic Web, data from different Web sites are collected into a network, which knows how to gather and assemble data. It allows users to change the information presented based on the interest. With one click, users can view all the information collected about the target; moreover, with another click in the dashboard, users can explore the relationships between various data entities.

The World Wide Web Consortium (W3C) (2005) has developed standards:

- RDF - data description and identification
- Web Ontology Language (OWL) - an ontology language
- A Semantic Web Rule Language (SWRL)

The Semantic Web uses these standards in conjunction with existing data formatting and tagging such as XML and Life Science Identified (LSID). In Semantic Web, elements are defined in statements called Semantic Web triplets, which contain a subject, predicate, and object.

According to W3C, embedding of semantics into medical and research information will offer researchers and health providers better access to information needed to find cures for diseases, make drugs safer and more affordable, and enable them to offer individualized clinical management. On November 22, 2005, W3C announced the formation of the Semantic Web for Healthcare and Life Sciences Interest Group, which is to deploy standardized Semantic Web specifications to provide services defined by the user community. The Semantic Web contains three layers: XML as a syntax layer, a RDF to provide machine-readable descriptions of data that can be parsed; and a third layer, OWL, to combine ontologies, or descriptions of specialized knowledge on the Web. The Semantic Web leverages some existing technologies as well as defines some new technologies. It leverages XML (Barners Lee et al., 1998), a data representation format that allows data to be tagged so that it is easier to distinguish among different pieces of data. It also leverages uniform resource identifiers (URIs) (Butler, 2003), a way of distinguishing elements not just within a document, but also within the space of all documents. URIs make it possible to identify resources and properties.

Major challenges of Semantic Web include:

- **Metadata:** One prerequisite for Semantic Web is that authors of Web sites and Web documents provide richer machine "processable" information, that is, metadata.

Until 1999, there were several ways to link metadata to Web documents. The W3C tried to unify these different approaches in the form of RDF. The RDF allows describing a concept rather than a Web document. Yet, Web content is still largely devoid of metadata labels.

- **Semantic word:** The word semantic is interpreted in different ways, oftentimes causing confusion. People are often willing to argue the advantage of RDF over XML. This different interpretation is illustrated in Note (Butler, 2003). In Computer Science, "Semantic" refers to a description that explains how to interpret a particular syntactic structure in the context of an abstract language (Butler, 2003). In linguistics, "Semantic" connotes formal symbol manipulations, which do not have any intentionality; they are quite meaningless; they are not even symbol manipulations, since the symbols do not symbolize anything. Hence, in the linguistic jargon, there is only syntax but no semantics.
- **Multiple vocabularies:** The Semantic Web supports the philosophy that central naming authorities are unrealistic. It is based on the fact that multiple vocabularies are reality of life and it will be necessary to interoperate among them. It should be possible to map property from one vocabulary to another vocabulary if both are associated with URIs but there is no standard way of doing this in RDF.
- **Technology barrier:** One barrier in the adoption of Semantic Web is RDF complexity, leading to another issue. Programmers, when faced with complexity, often adopt dirty and workaround tricks. When people encounter complexity, it prejudices them against Semantic Web. Implementing RDF parsers is complex and difficult and the best tools are hopelessly slow. These are the most basic and fundamental tools the Semantic Web needs to operate.
- **Business barriers:** If the Semantic Web is implemented, the current e-business models will be intensely disrupted. Ebay, Google,

Table 4. Semantic Web scenarios

Integrated Access to Biological Data Scenario Provide an unified point of access to different biological data repositories accessible through the Internet. Solution Application of semantic technologies to solve the inherent features of the biology field	**Hospital Information System** Scenario Data in a healthcare information system is dispersed and heterogeneous in a setting where speed of access and common presentation are important. Solution Integration and subsequent mediation of medical databases at the semantic level.
Data Warehousing in Healthcare Scenario A large health insurance data warehouse to ensure data integration and consistency. Solution Introduce a common terminology for healthcare data and wrap all legacy data in this terminology.	**Managing Biomedical Research Notes and Raw Data** Scenario Biomedical research notes and raw data are difficult to share because they are not understandable to others unless they are well structured. Solution A flexible and simple to use system for entering notes in both a structured and flexible manner, with complex interlinking.

and Amazon—virtually all mainstays of web-businesses—will have to significantly adjust their business and technology models.

As with other industries, these same challenges in applying Semantic Web apply to the healthcare industry. To look into its future in the healthcare industry, scenario analysis is suggested for Semantic Web because of the need to analyze the current healthcare climate, which is characterized by a significant level of uncertainty regarding IT adoption.

Table 4, which is self-explanatory, provides the scenarios and potential solutions for applying Semantic Web in healthcare. No matter how slow the health industry is in adopting new IT solution, these scenarios will drive Semantic Web technology in mainstream healthcare.

Just as with the e-Health domain, Semantic Web is a topic requiring a very broad search and Patent Analysis would provide little, if any, insight.

Wearable Monitoring Devices

The U.S. and international patient monitoring markets have grown rapidly in recent years due to factors such as population demographic trends, increased incidence of heart disease and other conditions requiring close patient monitoring, along with technological developments such as wireless remote monitoring. Shorter hospital stay and better community care are expected to be the future trend of national health services. Wearable devices represents the next big frontier in the push for the always-on, always-active, and always-connected environment of the future healthcare.

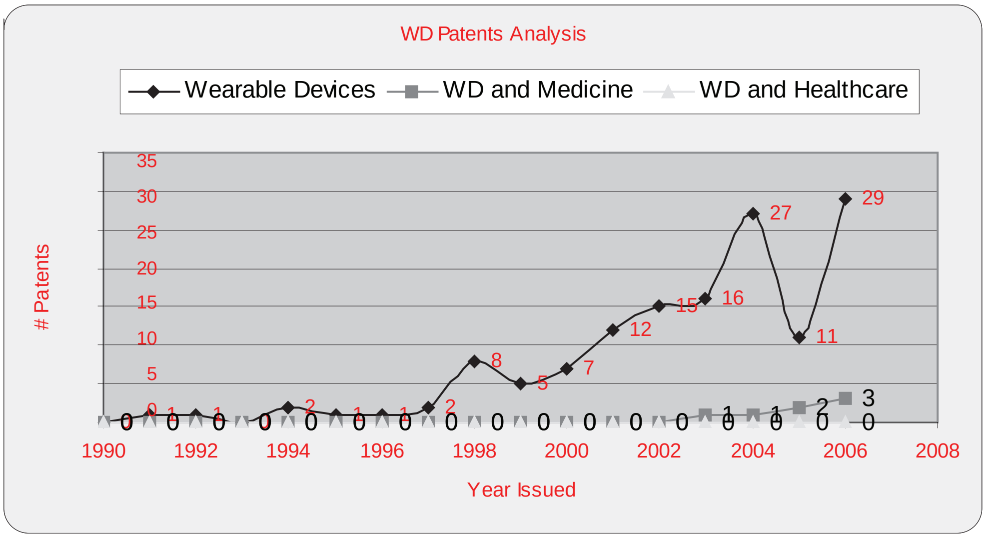
Wearable healthcare monitoring devices aim at a continuous monitoring of vital signs to provide assistance to patients. They are particularly vital to the world's growing aging population and their potential clinical value, particularly for chronic disease management, is increasingly being recognized. Advances in sensor networking and communication technology form the fundamental basis for a new generation of healthcare assistance systems. Patient monitoring products measure, display and document physiological information obtained at regular intervals over time from sensors attached to the patient or other input devices.

Several issues play a critical role in determining the success or diffusion of wearable monitoring devices. In order to make these devices more practical, a series of technical, legal, and sociological barriers need to be overcome. Just as with challenges faced in the context of e-Health, the list of challenges for wearable monitoring devices include: (a) battery life, (b) privacy and security, (c) invisibility and social acceptance, (d) usability, (e) language barriers, and (f) data standards. The inability to overcome these challenges can lead to increased costs, and difficulty in building the needed system-based answers, presenting a significant barrier to entry for new businesses.

The idea of wearable computers dates back to the 1960s, but early attempts to create these types of systems were hampered by the size of the hardware. In order for a computer to be "wearable", it has to be fairly small, lightweight, be able to be attached to clothing, or even be integrated into clothing fibers. A third or more of the 78 million baby boomers and 34 million of their parents may be at risk for the development of devastating diseases including cardiovascular disease, stroke and cancer. Experts predict that pre-symptomatic testing could save millions of lives and dollars in the coming decades (Stemberger, 2002). The implications and potential of these wearable health-monitoring technologies are paramount. These technologies assist healthcare providers in early detection of health deterioration and will alert them in critical situations.

Figure 3 depicts a segment of U.S. patent database to forecast the trend in wearable device technology. Between 1990 and 2005, there

Figure 3. Wearable devices patent analysis



were a total of 173 patents filed in the U.S. The maximum number of patents was filed between 1999 and 2003, totaling 115. The 1990s saw the widespread acquisition and use of laptop computers. Gartner predicts that by 2010, 40% of adults and 75% of teenagers will be utilizing wearable devices, and 70% of the population will spend ten times longer per day interacting with people in the e-world than in the physical world (John McCarthy, 2004).

Apparently, the next decade may be dominated by the production and use of wearable IT systems. Wristwatches, pagers, cell phones, pocket calculators, PDAs, and Blackberries are all examples of simple wearable information systems that are already in use. However, the next generation of wearable systems is still being incubated. While still on the "leeding edge", it may be time for some of the larger, more technologically advanced healthcare institutions to begin collaborating on further research, development, and pilot testing of wearable IT systems in the healthcare setting.

RFID

Approximately between 44,000 and 98,000 people die every year in the U.S. because of medical errors (Institute of Medicine, 1999). In the case where the patient survives due to a medical mishap, it costs hospitals about $47,000 per Adverse Drug Event (ADE). Apart from medical errors, there are people, events, assets and decisions in hospitals that need to be tracked. There are doctors, nurses, patients, visitors and medical equipments, which must be tracked in the event of emergency. Radio Frequency Identification (RFID) technology will facilitate such tracking and help in reducing healthcare costs.

RFID is a technology that uses radio waves to automatically identify people or objects. It has been around since as early as the 1970s, but then it was too expensive and limited to use in commercial applications. RFID has both positive and negative implications for companies as well as consumers. Unlike bar code technology, radio waves can travel through most non-metallic materials. If tags can be produced inexpensively, it can solve most of the problems associated with bar codes. The RFID tags can hold hundreds of characters of information, whereas bar codes can hold only 12 to 15 characters. These tags can be used to trace entire lifecycle of goods, including how and where the items were made, shipped, consumed, and disposed of. RFID technology supports two kinds of implementations: active versus passive. In an active RFID application, signals are continuously transmitted between transponders and transceivers. Passive RFID systems require a reader to be waved near a transponder with an RFID chip.

Implementation of RFID technology in healthcare may be done through sequencing applications in the context of particular hospital settings. The RFID technology requires a semi-conductor chip that emits digital signals that can be picked up by a scanner. Its implementation, therefore, requires hospitals to have basic computer infrastructure that supports an RFID network. Although not a requirement, experts recommend using a wireless network. Indeed, healthcare is one of the top four industries in which RFID is going to have a significant impact: while the bar code has been given a boost through patient safety initiatives and has helped to automate many hospital tasks, it requires a line of sight and manual (physical) scanning in order to register information. In other words, someone must scan the bar code. In contrast, active RFID takes automation one level beyond and decreases the potential for human error because it requires no human interaction and can be read automatically by sensors that may not be seen physically.

The RFID technology is proven but still not fully exploited. This is due partly to the early stage of global software and network standards. As well, tags and readers are still expensive to produce. A real challenge lies in building the hospital-wide infrastructure and overcoming all the attendant back-office hurdles as back-end infrastructure is required to support RFID technology. The integration of everything, from patient and clinicians tracking to medical equipment tracking, is another major task.

Altogether, key barriers to RFID adoption stem from high technology cost to making changes in the healthcare business models. The following factors should be considered in order for RFID technology to mature:

- **Cost:** Cost is a major barrier as RFID tags may be expensive to produce. However, that price is expected to decrease significantly. Cost of RFID tags had dropped from $1 in 2000 to 20 cents in 2004, and by 2006, it is expected to fall to 5 cents. In 2004, readers cost about $1,000 but are expected to fall to $200 by 2006 (3M, 2004). Cost is a major barrier especially in South Asian countries where labor is very cheap compared to the U.S. In these countries, the costs of implementing expensive technology infrastructure far exceed the costs of hiring extra labor.
- **Infrastructure:** While high technology costs is a barrier, the payback periods for RFID have typically been longer than desired. Tagging medical devices and placing readers in doorways at hospitals will require an initial deployment and a change in protocols for locating assets. Lean IT budgets mean that new technologies need to demonstrate compelling business cases and short paybacks on investments. Companies are skeptical if the costs cannot be offset by the promised benefits. Hospitals are therefore hostile to radio frequencies of all kinds. The construction materials and the typical layout of the hospital result in the propagation of RF signals within the structure that is highly attenuate, reflected, and refracted. High infrastructure cost include tag readability, tag price points, system integration costs, hardware and setup costs, management, ownership and sharing of data, business process changes, privacy concerns, and standards.
- **Wireless Network:** Many healthcare organizations are concerned about the wireless network infrastructure. These organizations want to be able to use existing wireless net-

works rather than a dedicated RFID network for tracking.

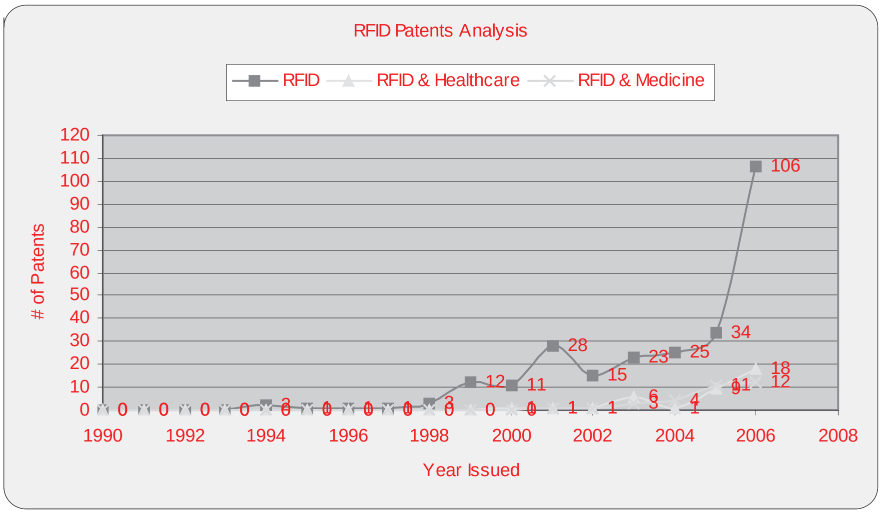
- **Security:** The idea of putting something in your head or in your arm frightens people and stirs up privacy worries. Americans have been warned to protect their personal privacy. Companies should be able to query tags securely while unauthorized parties should not be able to trace them. The possibility that a business loosing control of the privacy of its information is one of the largest risks associated with RFID. The information inside RFID tags is vulnerable to alteration, corruption and deletion.
- **Global Standards:** An additional barrier to RFID technology investment stems from the view that applicable standards are lacking. Currently, there is a tremendous push for consolidation of RFID technology with regards to capability. Yet, with multiple standards and developers seeking to gain the upper hand through their own intellectual property, many businesses are adopting the technology before it is fully ripened, which includes any unresolved issues surrounding security. Some questions include: "What type of number should be used as a unique identifier: the embedded NDC number or a randomly generated number to protect privacy and mask product identity?" and "What common fields/information should be included in an electronic pedigree?"
- **RF Impact:** It is a concern among consumers that radio frequency may have negative impact on drugs. However, based on preliminary information and hypothesis, RF does not have significant thermal impact on solid dosage form. An FDA CDRH lab has done some preliminary research analyzing the heating effect of 915 MHz RFID fields on a placebo, simulating a pharmaceutical. Results showed a very modest rise in temperature, of unknown significance. We are just learning to know the impact of RF on certain products.

A patent is a property right granted to an inventor "to exclude others from making, using, offering for sale, or selling the invention throughout the U.S. or importing the invention into the U.S." for a limited time in exchange for public disclosure of the invention when the patent is granted (www.uspto.gov,). The U.S. Patent office has granted a handful of RFID patents. Today, a growing number of new establishments are applying for RFID patents. Between 1970 and 2003, 1,256 U.S. patents containing the specific term 'RFID' were issued. Of these, 62% were issued in just the last four years. Also, surprisingly, 22% of these U.S. patents went to foreign firms, mostly in Germany and Japan. Even though the number of patents filed and issued for RFID technology is increasing every year, a recent survey by InformationWeek (www.informationweek.com,) shows that technical skill shortage is slowing RFID adoption. Seventy-five percent of business professionals believe there is an insufficient skilled workforce to design and deploy RFID technology strategies, and 80% think adoption rates will suffer.

The U.S. Patents database (www.uspto.gov,) search on "RFID and Healthcare" , as shown in Figure 4, indicates that the number of patents filed in the last ten years is inconsistent. Between 1990 and 2006, there were a total of 262 patents issued, but interestingly, 50% of these patents were issued between 2005 and 2006 alone. This indicates that RFID in healthcare will take another 3-5 years before it matures and replace bar code technology.

In spite of this, the progress of RFID towards maturity in commercial market has been forecasted. As forecasted by IDTechEx, in 2006, IDTechEx expected 1.3 billion tags to be sold, with 500 million RFID smart labels for pallet and case level tagging but the majority falling into a range of diverse markets from baggage and passports to contact-less payment cards and drugs. By 2016,

Figure 4. RFID patent analysis



IDTechEx expects the value of the total market including systems and services to skyrocket to $26.23 billion from $2.71 billion in 2006.

Most health executives believe that RFID technologies are strategic to their business in a number of ways such as patient safety, operational management, and supply chain management. The U.S. healthcare companies are increasingly seeing the adoption of RFID technology as a major potential contributor to safety across the industry. Yet, it is the biggest healthcare players that are generally able to move the quickest and invest in large deployments of the RFID technology.

Artificial Intelligence

Artificial Intelligence (AI) is the study of how computer systems simulate intelligent processes such as learning, reasoning, and understanding symbolic information in context. Human memory is very short and limited. We also have very limited capability to incorporate information in decision making. Our short-term memory can retain and utilize optimally four to seven data items. If we try to utilize more data items or groups, then our decision process may not be very effective (www.ai-depot.com). AI helps in overcoming this limitation and its use combined with informatics can contribute to elevate patient care in many ways. For example, computer-based robotics can help to discover ways to reduce cost, optimize clinical effectiveness, and improve patient care.

Humans have always speculated about the nature of mind, thought, and language, and searched for discrete representations of their knowledge. Traditional computer software is based on adding and multiplying binary number. AI, in healthcare, is an architecture that is designed more closely to a biologic neural system. The basic processing unit of an AI system is a series of neuron-like registers that sum inhibitory and excitatory stimulus, which in turn excites or inhibits a second set of sensors. The strength of AI is its ability to learn by example; this means that programmed procedures may not be necessary and rules do not have to develop by clinical experts. The AI systems in healthcare are intended to support health providers in the normal course of their duties, assisting with tasks that require manipulation of knowledge and data.

The field of AI in medicine has been slow to make its mark and the adoption of AI in healthcare involve overcoming the following barriers:

- **Ethical Challenge:** The efficient and effective use of computers in healthcare requires training, experience and education. Inadequate education and training in the use of computer systems and decision support tools will only result in disaster. Trying to determine who should be allowed to use HIT application is another ethical challenge. Major ethical issues related to AI in healthcare include confidentiality of electronically stored patient information; appropriate selection and use of informatics tools in clinical settings; the determination of who should be assigned to use such tools; the role of system evaluation; the obligation and reliability of system developers, maintainers and vendors; and the use of computers to track clinical outcomes to guide future practice and informatics engenders many important legal and regulatory questions.
- **Physician Resistance:** In medicine, a patient's life may be at stake. Inappropriate use of computer devices or decision influenced by decision support systems may result in an uncontrollable situation. To diagnosis a patient or render a prognosis requires more than a statistical operation performed on raw data. Understanding complex issues and how these issues relate to the patient are not elements that can easily be programmed or computerized. The key problems when using clinical AI to determine policy or aid in patient care are: (a) human cognition is still superior to machine intelligence; and (b) decisions about whether to treat a given patient are often value-laden and must be made relative to treatment goals.
- **Consciousness:** Computers follow algorithms in their thought process, much like the human minds. The difference is that humans can adjust their algorithms to new situations in very complex ways, whereas computers are only beginning to gain the ability to "learn" and adjust their algorithms to new situations. There is no evidence that computers have self-awareness, subjective emotions, abstract thinking, or strategic thinking. Another interesting question is whether these attributes are possible, or if there are real barriers to ever developing AI.
- **Cultural Differences:** Humans have a very wide range of emotions. Can we define each emotion? Is it possible to a non-human machine to differentiate between disappointment and sadness? The intelligence attributes could be a part of emotion, creativity, and spirituality. Although the concept of emotional machine is day-by-day becoming more convincing and compelling, the concept is still very raw.
- **Rule-Based Approach:** Many of the early efforts to apply AI to medical challenges have used a rule-based approach. Such programs are typically easy to create, because their knowledge is cataloged in the form of 'if, then, else' rules in chains of deductions to reach a conclusion. However, most serious clinical problems are so complex and broad that using the rule-based approach will encounter major difficulties. Problems arise principally from the fact that rule-based programs do not embody a model of disease or clinical reasoning. Given the difficulties encountered with rule-based systems, more recent efforts to use AI in medicine have focused on neural networks and programs organized around models of disease.

AI in medicine is created to support healthcare workers in the normal daily duties; they are best at assisting with tasks that rely on the manipulation of data and knowledge. An AI forecasting in healthcare environment describes a future healthcare possibility. It helps industry leaders and consumers to understand where technology will be in the next 5-10 years. Accordingly, we used U.S. patent database to forecast AI technology.

The search against "AI" keyword in the U.S. Patent database resulted in 14,971 hits while that against "AI and Healthcare" keywords resulted in 96 hits and "AI and Medicine" resulted in 652 hits. Figure 5 suggests that AI technology is being incorporated into a growing number of commercial products.

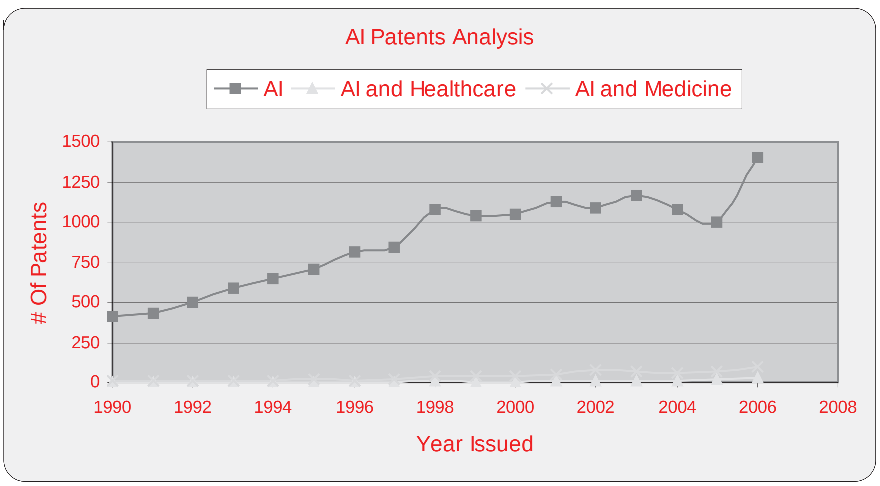
We also searched AI patents filed in other areas. The results indicated that the number of patents in AI, expert systems, and neural networks jumped from fewer than 20 in 1988 to more than 120 in 1996, and the number of patents citing patents in these areas grew from about 140 to almost 800. The number of AI-related patents in the U.S. healthcare system increased exponentially from approximately five in 1990 to more than 15-20 in 2000. In summary, the technological investment in AI and healthcare is enormous and we can expect to see more successful commercial AI products in the near future.

CONCLUSION

Apparently, IT is changing the way we deliver healthcare. New capabilities of IT have the potential to transform health services from primarily reactive to a proactive mode. In a recent press release, for example, a passenger became the first traveler on a commercial airline to have an electrocardiogram (ECG) recorded in flight and transmitted via satellite to physicians on the ground, who correctly diagnosed a heart attack and supervised successful emergency treatment administered by the flight attendants. The convergence of wireless, sensor, wearable and RFID will make scenarios such as this increasingly common.

In spite of rapid technological advances and breakthroughs, the high cost of healthcare in the U.S. prevails. This may be attributed to a number of factors, ranging from the rising cost of medical technology, aging population, to increasing administrative costs resulting from the complex multiprovider and multipayer system in the U.S. healthcare system. The growing shift from non-profit to for-profit healthcare is also contributing to the increasing cost of healthcare. Interestingly, the U.S. is the only developed country in the world, except South Africa, where all of its citizens do not have access to affordable healthcare. According to the most recently available figures, 42.6 million people in the U.S. do not have access to healthcare in 1999. The lack of health insurance

Figure 5. AI patent analysis



for a significant number of Americans has also other far-reaching consequence, as hospitals or providers are forced into cost shifting.

In this article, we discussed five emerging HITs. Our research supports that all the five technologies (RFID, Semantic Web, Wearable Devices, e-Health, and AI) are anticipated to have a future in the healthcare industry. In the U.S. and other developed countries, the healthcare industry is moving from an era of incremental cost control to an era in which the overarching need will be managing the growing demands of an aging population in a creative and affordable way. The state of the art in forecasting and futuristic thinking is in business entrepreneurship rather than in academic research. There is no doubt that these HITs can make a difference in the quality of care. While these technologies can help, impact is limited as long as healthcare remains the poster child for dysfunctional business models. However, these technologies are clearly coming in support of a prevention-oriented, consumer-driven model of healthcare.

The United States has by far the most expensive healthcare system in the world. As discussed, one reason for the high cost in U.S. can be attributed to medical errors. If we deploy emerging HITs intelligently and effectively, it will assist in reducing medical errors and healthcare administration cost. Automation is the key for success as it reduces manual work and errors. Like other healthcare industries, PHS is also trying to reduce administrative cost and medical errors by deploying these emerging HITs. Providence is doing a pilot project in the Oregon region to automate data capture at the point-of-care to reduce paper work and improve efficiency for clinical and nursing staff. Providence is also initiating several projects internally in e-health arena to improve patient-to-provider capability in the Oregon region.

As IT aligns more closely with medicine, new ideas will emerge to challenge entrenched care delivery paradigms. IT technology will pervade clinicians' everyday work lives. Today, automation of redundant and repetitive tasks and the elimination of paper still offer potential payoffs for healthcare organizations. Collaboration around direct electronic data interchange transactions between payers and providers, eliminating manual steps in the business office and in denial analysis, and facilitating electronic clinical documentation are good examples. In the future, the pace of combined medical IT innovation will quicken and be nonlinear. Figure 7 and Table 5 summarized the discussions provided in this article.

Figure 7. Patent analysis summary

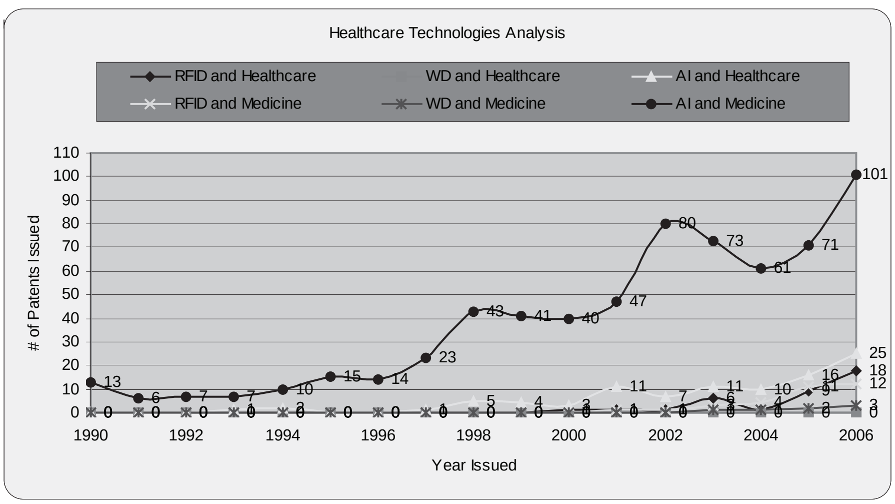


Table 5. Analysis summary

Technology Name	Forecasting Method	Forecast
RFID	Patent Analysis	5-7 Years
Artificial Intelligence	Patent Analysis	5-7 Years
Wearable Devices	Patent Analysis	3-5 Years
Ehealth	Scenario Analysis	3-5 Years
Semantic Web	Scenario Analysis	5-10 years

As seen, our approach for technology forecasting is based on literature search, Internet resources and proven forecasting techniques. In this article, we placed considerable emphasis on searching various literature sources. Typically, each literature reference cites to other references that lead to a constantly expanding database. Patent analyses are indicating that the major R&D efforts are completed for these technologies as the patent curves have started to go down. This indicates that future commercial products are close to being released.

As mentioned previously, many of the technologies we chose embrace a wide range of technologies and market opportunities and, thus, a number of different projections are required for a meaningful forecast of that field. Our next step will be to gather more data for forecasting these technologies. One consideration is to use Delphi Method and incorporate experts' advice in the forecasting process. It would be interesting to incorporate the downfall of existing technologies and emergence of some of these newer technologies. A further step would be to analyze how these newer technologies help in direct patient care, reducing healthcare cost and providing healthcare in remote and rural areas.

ABSTRACT

The aim of this chapter is to share recent findings and understanding on how information systems can be better adopted to support new ways of work and improve productivity in public funded healthcare. The limits of transferring explicit and tacit knowledge are discussed and moreover, the chapter elaborates barriers to the widespread use of knowledge management tools among clinicians. The impacts of an inter-organizational system used for remote consultation between secondary and primary care providers are examined. Furthermore, the authors suggest that issues related to clinical knowledge management such as the varying information and knowledge processing needs of clinicians from various medical expertise domains should be examined carefully when developing new clinical information systems.

INTRODUCTION

It is reasonable to expect information technology to bring benefits to healthcare organizations just as it does to any other business. But recent studies demonstrate that the introduction of information technology does not in itself improve employee effectiveness in healthcare (Littlejohns, Wyatt, & Garvican, 2003). Moreover, it has proved particularly difficult to evaluate information systems in healthcare. This may involve the "evaluation paradox": we refuse to use a new technology until an evaluation study of its use has proved it useful. Particularly true in the healthcare sector, this cautious approach can be seen as a virtue, considering that hospitals fortunately were never taken in by all the information technology hype; but on the other hand the healthcare sector is regrettably slow in adopting even the best new practices. Although successful adoption of inter-organizational systems in healthcare still lacks a substantial body of research we argue that a key issue to be addressed may well be the natural logic of information and knowledge processing in various medical areas.

The term "telemedicine" covers the application of information technology to medical care chains. Conventional operations can always be pushed up a notch with state-of-the-art technology. In many cases it would also be more efficient to reorganize the operations altogether. For example, an e-mail application is at its most useful when its users are considered as active users of information rather than passive recipients. An organization can learn new ways of profiting from this new communications channel, which lies at the medium level according to the information richness theory introduced by Daft and Lengel (1986). A good example may be found in the healthcare sector, where new technology has managed to loosen the shackles of conventional thinking.

The electronic consultation model in medical care emerged in the early 1990s, beginning with an experiment at the internal medicine department of a hospital in southern Finland, where referrals were returned with care instructions in cases where lab results coupled with the information on the referral were sufficient for an accurate diagnosis. If the specialist receiving the referral considered that the case had not been examined sufficiently, the referral would be returned with instructions as to further tests or examinations. The new model evolved naturally from this practice. The information entered on a referral is often sufficiently comprehensive to enable remote consultation, and under the new model about half the patients referred to the hospital could be treated at their local health center on the basis of instructions provided by specialists through an information network.

There are many phenomena at play in shaping the practices of the healthcare sector. Identifying and allowing for these phenomena may be the key to successful telemedicine projects, indeed even more important than the technology itself. In the case of the new model described above, the innovation was supported by studies in the field: over half of all referrals in Finland and, for example, in Britain contain enough information for making an accurate diagnosis. So why are these patients being sent to hospital if there is already enough information for a diagnosis to be made at the health center? Convention, insecurity, financial incentives and similar factors have been cited as possible reasons.

This chapter aims to share recent findings and understanding on how information systems can be better adopted to support new ways of work and improve productivity in public funded healthcare. The effects of an integrated electronic referral system used for remote consultation between secondary and primary care providers is examined in a case study of two healthcare units in southern Finland. The study demonstrates how costly investments in videoconferencing in orthopedics yielded lesser benefits than the cheaper investment in e-mail-type application in internal medicine. Evidently internal medicine relies on fixed-format information, whereas orthopedics is more dependent on direct sensory inputs and tacit knowledge (Sternberg & Hovarth, 1999). Consequently, the natural logic of information and knowledge processing needs to be examined carefully before investing in information technology.

DEVELOPMENT TOWARD KNOWLEDGE INTENSIVE SYSTEMS IN HEALTHCARE

The information system presented in this chapter is representing information systems of new generation. The amount and meaning of these knowledge intensive systems will be highly expanding in the field of healthcare in the future. The progress of information system presented here is concluded based on theoretical frameworks of information systems in different disciplines. Phases of information system development in organizations have been dived from two to five phases by information system science researches. Most explanatory model seems to be Friedman and Cornford's (1989) intensive study (Checkland & Holwell, 1998; Korpela, 1994).

Friedman and Cornford argue that information system development can be seen as the interaction of changes in the core technology with changes in applications, linked by activities which mediate between them. These three elements are acting upon agents of change. The agents of change are technical development, changes in applications, market pressures and internal pressures, such as management culture (Friedman & Cornford, 1989).

After given this analysis, researchers see the history of development of the information systems in terms of three phases, each defined by a "critical factor" that has limited the development of computerization during that period. These phases are (1) hardware, (2) software and (3) user relation constraints. According to Friemdan and Cornford (1989) the first phase was approximately until the mid-1960s, the second one lasted from the mid-1960s until the early 1980s and the third one was early in the 1980s at least until their research was published in 1989.

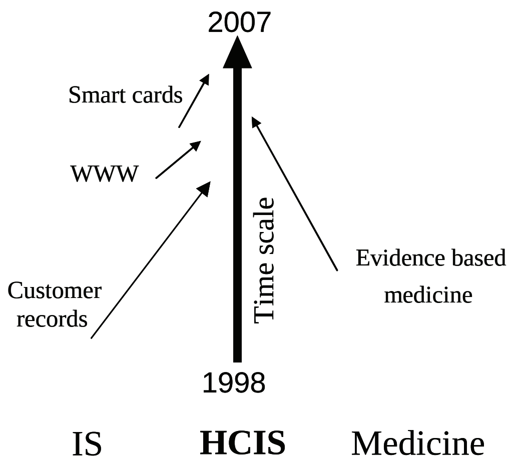
In the year 1989, Friedman and Cornford speculated that a fourth phase might be organization environment constrain. The fourth phase could be also divided into sub-phases. At the first issue of developing systems is to make large-scale organizational systems and after these problems have been solved the main concern is to build inter-organizational systems. These inter-organizational systems are often customer orientated information systems (Friedman & Cornford, 1989).

Not every organization is going causally through these four phases. The development of information systems in the organization depends also on time when computerization has started in the particular organization or on other issues such as size of organization and ability to change organization (Checkland & Holwell, 1998; Friedman & Cornford, 1989).

At the moment, the state of healthcare information systems resembles that found in other fields in the early 1990s. As a rule, the field seems to be 10 years behind other areas (Ragupathi, 1997). However, the development of healthcare information systems is not exactly linear. Some innovations are put into use in healthcare faster than others (that are not seen very useful in healthcare). For example, Intranet technologies have been applied fast in healthcare organizations at least for non-medical purposes. Also (medical) knowledge intensive solutions are implemented fast in the field of healthcare (see Figure 1) (Turunen, Forsström, & Tähkäpää, 1999). The use of knowledge intensive systems have seen already in other fields, thus this same development is expected to happen also in healthcare.

General development of information systems in the 1990s as well Friedman's genuine work is clearly concluding that healthcare information systems will develop into the direction of customer orientated systems. This progress is in some cases passing through organizational environment constraints. It is possible that organizational phase is skipped over, if the particular organization is innovative, small or organic ones (cf. Courtright, Fairhurst, & Rogers, 1989). The more organic organization is relation to its environment the more capable it is to react the demands of customers and adapt the new technology. Naturally, the

Figure 1. An example of diffusion time of IT innovations and medicine into the field of health care information systems (HCIS)



rapid development is also helped by new Internet technology.

Because of information intensive medical work (see right side of Figure 1) these new applications are in the healthcare strongly knowledge intensive ones. As a matter of fact, medicine can be considered as a knowledge-based business, which in practice means that experienced doctors use about two million pieces of information to manage their patients (Pauker, Gorry, Kassirer, & Schwartz, 1976; Smith, 1996; Wyatt, 1991). About a third of doctors' time is spent recording and combining information and a third of the costs of a healthcare provider are spent on personal and professional communication (Hersch & Lunin, 1995). Still most of the information doctors use when seeing patients is kept unrecorded in their heads and unfortunately some of this information is out of date or wrong. Thus the interest in applying networking media, like Internet in medical practice has arisen from the ever greater demand of meeting the needs of patients by drawing on the knowledge accumulated by medicine over 5,000 years.

New information may not have penetrated and the information may not be there to deal with patients with uncommon problems (Smith, 1996). These problems have become more serious as the rate of change in medical knowledge has accelerated. There are new scientific findings every day and at the moment the medical knowledge is estimated to increase fourfold during a professional lifetime (Heathfield & Louw, 1999; Wyatt, 1991). This inevitably means that doctors cannot practice high quality medicine without constantly updating their knowledge and finding information to help them with particular patients. The historical arrangement, in which doctors individually held the responsibility for ensuring an adequate supply of knowledge to guide their practice, is now failing to meet the knowledge needs of modern healthcare (Smith, 1996; Tannenbaum, 1994). Therefore diverse organizations, also health authorities, spread a vast amount of information to doctors.

It seems that knowledge intensive inter-organizational systems are the latest result of evolution in the field of healthcare. Healthcare organizations will adopt these kinds of systems sooner or later. Thus, it is important to understand the use of these knowledge intensive inter-organizational systems.

MANAGING EXPLICIT KNOWEDGE: TOWARDS OPTIMAL ALLOCATION OF SUPPLY AND DEMAND

The demand for healthcare services in both quantitative and qualitative terms is growing constantly. The aging of population will cause more pressure on healthcare organizations in several countries. The demand for healthcare services is greater, almost double among the old when comparing to average adults (Bethea & Balazs, 1997). Managing supply and demand between the primary parties, doctors and patients, seems to be a simple constellation of resources and requests. However, when managing supply and demand within the public funded healthcare system, the constellation changes into allocation of information resources of varying proficiencies and cost structures. By tradition, the tool used for this allocation has been the referring process.

The traditional referring process has its roots in the late 19th century England. There were three medical proficiencies operating in hospitals: surgeons, doctors and pharmacists. The third group was later called general practitioners, and before the turn of century they were pressured to leave hospital premises. As a result, citizens had no longer free passage to hospital care without seeing a general practitioner first.

REENGINEERING THE ONE-WAY INFORMATION PROCESS: A CASE STUDY

In the following example we concentrate to analyze the factors behind the startling change that took place when paper referrals were replaced with electronic referrals. Our example is based on a study that took place in southern Finland focusing on cross-functional processes within two healthcare units (Harno, Paavola, Carlson, & Viikinkoski, 2000). The process chosen for the study was simple: a health center general practitioner referring a patient to a specialist at a regional hospital. While one unit began to utilize information system when referring a patient to hospital, the other send referrals traditionally by ordinary mail. Parts of the study are reported in TQM and Human Factors conference, Sweden (Lillrank, Paavola, Harno, & Holopainen, 1999).

Both healthcare units, Peijas Hospital and Hyvinkää Hospital, consist of a hospital and several health centers serving 150,000 people. Both healthcare units use similar internal administrative processes, however, Peijas has an Intranet-type system connecting the hospital with health centers while the information process between the parties in unit Hyvinkää is done traditionally with paper documents. All internal medicine cases that were referred from health centers to the hospitals during the study are included.

The process of making diagnosis goes in short according to following. First, in health center a general practitioner begins to diagnose by taking the anamnesis, that is, a preliminary case history of a medical or psychiatric patient. Patient explains the matter in his or her own words and general practitioner uses interviewing technique to lead the conversation in order to confirm or dispatch any presentiments of diagnosis that well forth in mind. Based on the anamnesis and verbal communication general practitioner can also decide to take laboratory tests in order to make the diagnosis more accurate. The diagnosis can be then defined and the treatment process can begin.

In roughly 95 percent of visits, the health center can handle the whole case. The remaining five percent of cases require specialist's resources for diagnosis, tests, treatment or all of these. In such cases a referral is sent to a hospital. The behavior behind the sending of a referral can be explained by several factors that may all have an effect to tip the scale in favor of referring (Coulter, Noone & Goldacre, 1989).

At the hospital, after examining an incoming referral, the specialist decides its level of urgency, again in one out of the three categories. Within the given time period the patient will be invited to hospital for consulting. The other option would be to send the referral back to the general practitioner if the specialist decides the case does not warrant specialist care. In practice, however, almost all referrals lead to a hospital visit. During our study the specialists working with traditional paper documents estimated that one out of five cases could have been treated at a health center with the help of some consultation. However, they felt that inviting a patient in for consulting that takes normally 20 minutes was less troublesome and took less time than writing and mailing instructions back to the general practitioner. Further, there were no economic incentives to take this trouble, since the local governments paid hospitals by the number of patients that were actually called in. In sum, the traditional process had neither procedures nor incentives for optimal resource allocation.

The Peijas hospital was built in the early 1990s. The health centers in the corresponding healthcare unit Peijas were linked to the new hospital with a tailor-made Intranet-type system. Initially it was assumed that the system would simply replace paper forms and mail, and allow electronic filing. The effects were assumed to be speedier traffic of information. There had been some plans to use the new information route also to integrate secondary and primary care providers with an electronic referral system linked to an electronic medical record. However, it was not known what the new process would look like, or even less, if the procedures were going to work at all. The precautions were justified since the effects of an integrated electronic referral system used for remote consultations had not been studied.

For a few years the system was utilized as such, a speedway for one-way referral traffic giving the predictable, but rather minor impact on the performance of the whole system. Only after a few specialists in the internal medicine area started, on their own initiative, to utilize the system for remote consultation with promising results, the other specialists in the same area joined in. Eventually the local governments had to revise their economic system to hospitals to include remote consultations as well as actual visits as basis for remuneration. Thus, a new business process supported by remote consulting had emerged in internal medicine.

The basic assumption when the integrated referral system was installed was that some 20 percent of referral cases could be treated at a health center with the help of remote consultation. In practice, the amount was more than double. The ratio of referrals that were returned to the health center grew to 50 percent of all referrals.

The consequences from this were, first, that the number of patients who were asked to actually visit a specialist was reduced to half thus reducing the burden on specialist resources. According to the doctors involved, this happened in 75 percent of the cases without any observable problems to fulfill of the appropriate treatment. Second, it was discovered that the rate of remote consultations given by specialist varied depending on referral urgency. Only 10 percent of the most urgent, priority I referrals lead to the use of remote consultation, while the percentage was 30 for category II, and over 50 for the category III referrals. Consequently, the major cycle time reduction came to the least urgent cases. Third, the number of health center patients whose problems got the attention of a specialist through remote consultation, roughly doubled that is from five to ten patient visits out of hundred. This was due to the learning experience to utilize cooperation with specialists in borderline cases. As a fourth effect it can be added the hard to measure effects that frequent exchange of experiences had on learning on health center side.

Encouraged by the positive results achieved in internal medicine, the possibility of expanding the system into other disciplines was discussed at Peijas hospital. Orthopedic surgery was used as a comparative case, since its business process is in many ways different. Internal medicine is, by and large, an intellectual process where specialists make conclusions from pieces of information of symptoms, medical histories and laboratory tests. The information used is reasonably well structured and treatment is often medication. Orthopedic specialist's were not inclined to use e-mail consultations, therefore a videoconferencing system was installed allowing the specialist's to study x-ray images and the patient located at health center while interacting with the general practitioner. In half of the cases videoconferencing was found to work satisfactorily, however, it did not reduce the number of patients that were eventually sent to the hospital. Thus, the relatively cheap e-mail system in internal medicine yielded a better return on investment than the costly videoconferencing system in orthopedic surgery.

MANAGING IMPLICIT KNOWLEDGE IN MEDICINE: CHALLENGE FOR SHARED KNOWLEDGE

The limits of transferring knowledge as well as managing it only the basis of rational view of man has proved to be inconsistent with the reality of medical experts in many ways (Ferlie, Wood, & Fitzgerald, 1999; Patel, Arocha, & Kaufman, 1999). Medical professionals produce a great amount of knowledge, which a doctor has but is unable to articulate or quantify easily. In frame of transferring technology managing knowledge refers more explicit than implicit knowledge. To be more precise, most of medical experts transfer more data than practical know-how to each other. The problems with sharing knowledge among a specific districts of medicine rises from the fact that every each of doctor attach a different meanings to data on the basis of their experiences of previous patients. However, studies of social construction, learning and tacit knowledge gives us a opportunity to approach the dilemma in promising way (Argyris, 1999; Berger & Luckmann, 1966; Dixon, 1994; Koskinen, 2001; Polanyi, 1966; Polanyi & Prosch, 1975; Sternberg & Horvarth, 1999).

It is commonly accepted scholars that are two basic types of knowledge: explicit knowledge that can be verbalized, such as knowledge of facts and concepts; and implicit knowledge that cannot be made verbal, such as intuition and knowledge of procedures (Patel et al., 1999). Even if the conventional synonym of implicit knowledge is tacit knowledge, some of scholars use the concept of tacit meaning structures as well (cf. Dixon, 1994). Tacit knowledge, by definition, refers to the inarticulate aspects or meaning structures that cannot be taught explicitly and therefore are only learnt via direct experience (Dixon, 1994; Patel et al., 1999). According to Polanyi and Prosch (1975) textbooks of medicine are so much empty talk in the absence of personal, that tacit knowledge of their subject matter. Therefore evaluating explicit knowledge (e.g., education) is pretty easy to do, but to evaluate its impact on tacit meaning structures of orthopedic specialist's is almost impossible.

In management literature the meaning of intuition for leaders has not been studied very much even if the importance of it for management was found already in 1930's (Barnard, 1938). However, for example Patel et al. (1999) outlined a systematic approach to the study of medical expertise in order to understand the role that the acquisition of tacit knowledge plays in competent and expert performance. According to them intensive care decision-making is characterized by a rapid, serial evaluation of options leafing to immediate action. In this real-time decision-making, the reasoning is schema-driven in a forward direction toward action with minimal interference or justification (ibid.). Practically this means that doctors are tend to attach meaning to data more on the basis of their experience than logical interpretation of facts. On the other hand we may say that the scientific knowledge is in part socially constructed in different ways in a case of general practitioner who is sending data compared with medical expertise who is interpreting it (cf. Ferlie et al., 1999). Therefore managing knowledge should be always understood in the terms of socially construction reality among a certain group of professionals.

The importance of tacit knowledge in decision-making is proved to be more important than explicit knowledge (Leprohon & Patel, 1995). In one study (ibid.) decision-making accuracy was significantly higher in nurses with 10 years or more of experience than in nurses with less experience, which is consistent with that we know about acquisition of expertise in their domains.

Managing the tacit knowledge may easily sound the answer for the problems of electronic referring system. However, the tacit knowledge is also the issue of cooperation between medical professionals. To some extent there will be always deliberate amount of 'tacit knowledge' in healthcare organizations. Clinical professionals will retain a monopoly of knowledge as far as professionals are forced to compete each other in terms of budget and resources (cf. Ferlie et al., 1999).

Barriers to open communication between different medical experts is understandable when the goal of medicine is not integrated (cf. primary care vs. special care, science vs. clinical care in university hospitals). Findings of Smith and Preston (1996) are pretty common: senior management have problems regarding the interface between junior doctors and other professional groups. An elite of professional workers secures easily a high degree of autonomy for itself on the basis of possession of expertise (Ferlie et al., 1999). However, tacit knowledge is said to be the primary basis for effective management, and the basis for its deterioration (Argyris, 1999; Nonaka & Takeuchi, 1995). Understanding the management of knowledge in the frame of rational man leads us easily situation where the benefits of electronic referring system are limited (cf. Breite, Koskinen, Pihlanto, & Vanharanta, 1999).

KNOWLEDGE MANAGEMENT ISSUES FOR CLINICAL APPLICATIONS

When utilizing applications of information technology in product-line orientated organization aspects such as the level of utilization becomes important. For example if only every third salesman in a company types his or hers orders in a given database the benefits of using an enterprise resource planning system barely exists at the shop floor. In knowledge intensive organizations, on the other hand, the quality and usefulness of the information content seems to play a leading role.

Information collected and stored in product-line orientated organizations is normally fixed-format information, for example, ordering codes that typically consist of numbers and letter acronyms. When storing qualitative data in knowledge intensive organizations the case becomes more complex. Storing personal notes is a trivial case, since one understands all the matters that are relevant and connected with the stored information. On the other hand storing qualitative information for other people's later interpretation is a greater challenge. One must presume the form that the data will be later most useful in; that is, one must understand the context the data will be later utilized in. In order to fulfill the validity and relevance requirements of users the rationale behind the information must be somehow included in the stored data. Until we learn to do that we must grapple with the quest of various oracles and gurus to explain us the true nature of knowledge management.

Slawson and Shaughnessy (1997) determine the usefulness of medical information according to the following equation (Figure 2). Since in practice the fixed consulting hours of doctors set limits to the dispersion or flexibility of the work amount, we can argue that the more validate and relevant information the practitioners get within constant time to access it the better.

A cautious approach to introduce knowledge management issues in clinical applications can be seen as a virtue. Sackett et al. (1997) argue that still 80 per cent of all treatments are not based on scientific proof but on believes. Validity can be determined as the probability of the information being true. For example the fact that an article is published in an academic journal does not guarantee that the information is true. One such article presented findings from a research that demonstrated how sodium fluoride effectively prevents contracting osteoporosis. Later another

Figure 2. Usefulness of medical information

$$\text{USEFULNESS OF MEDICAL INFORMATION} = \frac{\text{RELEVANCE} \times \text{VALIDITY}}{\text{WORK}}$$

more validate research findings proved that there truly was causality between these two—only the effect sodium fluoride had on the illness was just the opposite (Slawson & Shaughnessy, 1997).

One barrier to the widespread use of knowledge management tools is the psychological need of clinicians. Weinberg, Ullian, Richards, and Cooper (1981) found that 81 American doctors in a distant geographical area consulted 23 experts, logging 11 calls to experts each month. Six of these experts received over 90 percent of the calls, about 90 each a month. Doctors consult experts, because it is a quick, cheap, and easy method. The other doctors can also provide the psychological benefits that are not available from books, journals, and computers. On the other hand, the doctors "answering" the questions may sometimes not be much more knowledgeable than the doctors seeking answers.

Also a review article by Smith in 1996 which looked at the information needs of general practitioners made several similar conclusions, one of which was that doctors are looking for guidance, psychological support, affirmation, commiseration, sympathy, judgement, and feedback. Smith (1996) argues that this aspect of doctors' information needs is particularly poorly explored, and yet it may well be the most important need and the biggest stumbling block to a technical solution. The electronic consultation and knowledge management tools, such as decision-support systems, could support each other in various ways. Doctors could use the knowledge system for retrieving required information before referring to the specialist. They could for example check what are the necessary laboratory tests that should be done before referring. This would save specialists' time in electronic consultation as wouldn't need to separately ask for those tests. In addition that would be convenient for the patient.

CONCLUSION

Within the healthcare sector, different types of process can be identified with different demands on the quality of information and knowledge required. The amount of reference information needed to make a diagnosis differs from one specialization to the next in a hospital. In some fields, the information required by a doctor consists mainly of basic data, observations recorded in numbers and text, whereas in other fields an image or video clip is considered crucial for drawing conclusions. While the significance of what is known as tacit information is important in some fields, in the majority of cases it is explicit information that is required; and it is in care chains relying heavily on explicit information that the potential of information technology can be put to the best use.

We examined the impacts on adoption of a new inter-organizational system in healthcare. The consequences from using the Intranet-type referral system in the example case were, first, that the number of patients who were asked to actually visit a specialist was reduced to half thus reducing the burden on specialist resources. This was due to the replying option in the system. According to the doctors involved, this happened in 75 percent of the cases without any observable problems to fulfill the appropriate treatment. Secondly, the rate of consultations was varied depending on referral urgency. The major time reduction came to the least several cases. Thirdly, 5 out of 100 general practitioners' patients normally treated also by specialists was doubled to 10. However, there were differences between the benefits in different medical areas according to nature of information related to education of different specialists. This should be considered more carefully in the future, when new information systems will be planned and developed.

Evidently in internal medicine, specialists make conclusions from pieces of information of symptoms, medical histories and laboratory tests. The information used is explicit, reasonably well structured and treatment is often medication. Intranet referral system both increased the utilization of specialist consultation and decreased the need for secondary care services by transferring information and knowledge to primary care. The system allowed more patients to be treated at lower expense. Because all patients were thoroughly examined beforehand, the numbers of repeat visits as well as direct costs remained lower.

In orthopedic surgery the situation appeared to be different, as the diagnostic process is based more on tacit knowledge and the specialist frequently rely on direct observations. In orthopedics the specialists were not inclined to use e-mail consultations, therefore a videoconferencing system was installed allowing the specialists to study x-ray images and the patient located at health center while interacting with the general practitioner. In half of the cases videoconferencing was found to work satisfactorily, however, it did not reduce the number of patients that were eventually sent to the hospital. The relatively cheap e-mail solution in internal medicine yielded a better return on investment than the costly videoconferencing system in orthopedics. Consequently, the natural logic of information and knowledge processing in various areas needs to be examined carefully before investing in new information technology solutions.

Although it has been said that it is possible to ease sharing of tacit knowledge by using computer environment that is simulating real world (see Breite et al., 1999), it seems to be expensive task in healthcare. To optimize relatively small resources it should be invested more for developing sharing knowledge systems in those medical areas (like in internal medicine) that are using explicit information. In those medical areas that are using more like implicit information (like in surgery) development knowledge sharing systems should be delayed until we have effective mass-products that are supporting multimedia features. However, even then the development of those systems that are supporting open communication between different specialists and more generally between different professional groups should be encouraged. This would ease the change of working culture into the direction of non-hierarchical knowledge sharing.

Chapter 8.8

Documents and Topic Maps: An Original Way to Manage Medical Records

Frédérique Laforest

Christine Verdier
LIRIS CNRS UMR 5205, France

ABSTRACT

Medical records have been used for a long time with different forms, aims, and usages. This heterogeneity is the result of different professions, ways of working, and needs. It is but prejudicial to querying and sharing data and documents. Moreover, we consider that the system must be as close as possible to a more classical, noncomputerized way of working, such as paper-based medical record, and should thus manage documents. Medical records are often loosely or semistructured documents, impeding easy retrieval. In our approach, a medical record is considered as a set of documents and a set of data. In this article, we propose a software system useful for extracting data from loosely-structured documents coming from different sources and for querying them in a hybrid way. Querying can be done in a navigation space which represents extracted data or entire documents. Two main parts are described: the extraction of data in loosely-structured documents and the navigation in a unified view of documents and data.

INTRODUCTION

Computerized medical information systems have been developed for a long time. One can find two main types of such systems. Each system of the first type has been defined for one specific medical service. It is highly suited to its organization, but it misses openness and generalization. Communication with other systems is difficult, and adaptation to other services or specialties is not trivial. Systems of the second type have been defined for a broad use (many services and many specialties). Some contain common storage for selected critical data, but most of the time they do not adapt to the specific needs of each specialty. Others have tried to offer everything that any specialty requires and have become unusable spaghetti dishes.

But the communication of medical information to each practitioner has become compulsory for quality of care and costs management. As the medical record of a person is dispatched in many places, and as legacy systems have provided very heterogeneous data formats, structures, and ways of working, the gathering of the whole is a big challenge today. Exchange platforms have been proposed. They base their exchange on semistructured data (e.g., XML documents) empowering e-mail concepts by proposing joining documents (letters, images, reports, etc.). Consulting such an exchange platform is easy and convenient for daily care. But it is not sufficient for a profound patient care analysis or even for inter-patient studies. Data are not structured and multiviews on data are not provided.

Such platforms have brought a pleasant way of working. Care practitioners use electronic documents to store and exchange information, strict forms are not provided. This can be viewed as a step backward to the paper-based patient record. But we believe this is rather a new way of imagining computerization, offering a user interface as close as possible to the noncomputerized way of working. We have to couple such systems with new engines that allow for the retrieval of data inside documents, for the gathering of distributed information, for its processing, and for navigation purposes. This is the subject of this article. We present here our ideas and prototypes for the extraction of relevant data in documents, for the gathering of data coming from heterogeneous sources, and for the hybrid navigation among extracted data and documents. Our objective is to make a presentation of the medical record based on user's needs, rather than in a chronological or thematic way.

COMPUTERIZING THE MEDICAL RECORD

Characteristics of the Medical Record

Degoulet and Fieschi (1991) provide a globally agreed definition of the medical record:

The medical record is not limited to doctor's written observations neither to nurses notes. It encompasses all that can be stored about a patient, from demographical data to electro-physiological data or to images. According to this role, the patient record is and remains the main tool for the centralization and the coordination of medical activities.

Another concept is interesting: the encounter concept permits knowing all actions on a patient. At each encounter, the care practitioner builds a document. Encounter documents allow following the temporal rhythm of the patient care. Each document has a factual nature. Contained information concerns a fact and describes this fact. Documents are independent the ones from the others; they are solely understandable. Each new document can be seen as a transaction (using the databases sense of this term) as it has the same ACID (atomicity, coherence, isolation, and durability) characteristics.

Documents may be of different types, according to the encounter type (surgery report, biopsy results, and clinical examination notes). Each document becomes a new piece of the medical record. One can thus provide a new definition for the medical record:

The medical record is a collection of documents, each document providing information about an event in the medical history of the patient.

The medical record has specific characteristics that make it a complex element to study. Among them, the two following elements interest us. First, the medical record is more and more a coordination and collaboration tool. All care practitioners enter the medical record to learn what they need to know and to provide what they need to transmit to others. Computerized tools must provide a view on information that is adapted to the care practitioner profile and to the patient case. Another important point concerns the distribution of information and the mobility of people. It implies two things. First, we require tools for the transparent access to distributed data. Second, the mobility of patients and care practitioners necessitates the introduction of pervasive information systems, including mobile terminals (e.g., PDAs or mobile phones).

Hospitals are today the less distributed organization of the medical domain. Care networks include all types of partners collaborating for patients care: hospital staff, private nurses, pathology laboratories, pharmacies, and nonprofessionals like family. Home hospitalization is built on top of the coordination of care practitioners. The medical record is used as the collaborative tool. Information needs and information management functionalities are different from one care practitioner to the other. Writing means and reading shapes should be adapted to each actor category. Documents-based user interface can provide flexibility and adaptability for end users.

General Architecture of the Project

Information exchange and distant access are now available thanks to the last advances in terms of communication, multimedia, and documents. New principles for numerical documents and information access have allowed thinking of the use of documents as a central computerization mean. These are worldwide topics today. But using documents as an end-user paradigm should not reduce data management. Structured data are still unavoidable for many purposes, as getting graphics on numerical values, activity reporting, but also simply for the navigation in paragraphs of text.

That is the subject of this article. Documents of the patient record are analyzed to extract important information that is used to fill in a database. This database can then be used in a classical way, or as an index for documents retrieval. The use of topic maps permits a combined information search, in documents and in data. Topic maps interest does not stop here, they also allow for the integration of data coming from different sources.

Our proposition consists of an architecture for (1) extracting data from loosely-structured documents and storing them in a database, (2) gathering distributed extracted data and merging them in a XML format for knowledge representation (XTM), and (3) querying the system in a simple browsing way through a graphical user interface based on topic maps. In this architecture, the user is at the beginning and the end of the system. At the outset, the user produces loosely-structured documents (medical record). At the end, the user receives data gathered in a navigation tool. Two types of data are considered: atomic values (fever temperature, glycaemia rate, etc.) and original documents themselves (encounter documents). The global architecture is provided in Figure 1.

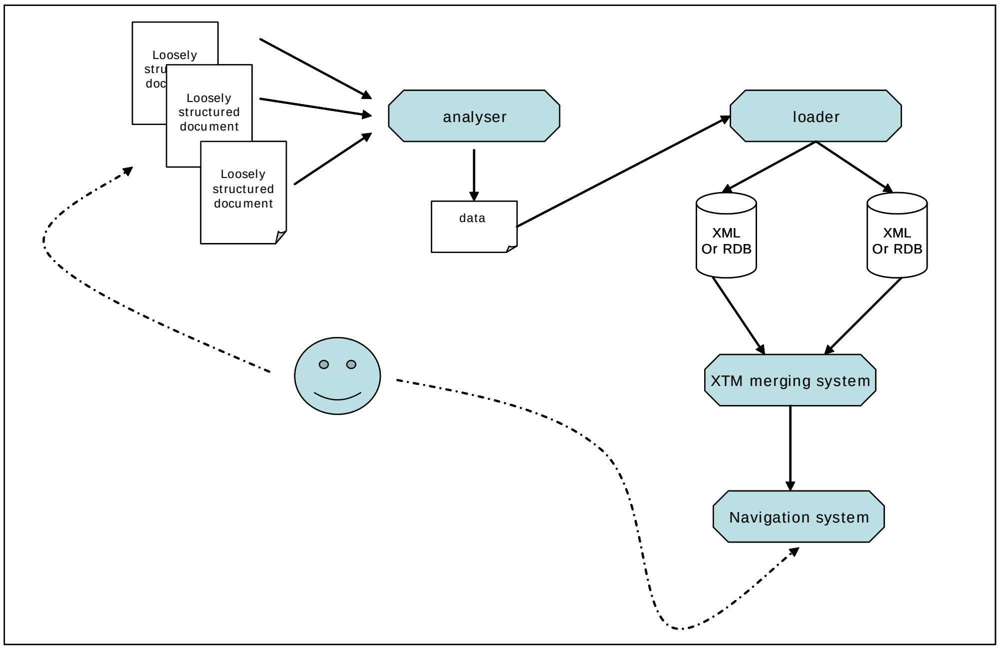
In the following, we first present documents analysis for database filling. Then, we explain what topic maps are, how they are used for data integration, and for the navigation in data and documents.

FROM LOOSELY STRUCTURED DOCUMENTS TO STRUCTURED DATA

Loosely Structured Documents Concepts

Semistructured documents are documents containing information and tags. Tags provide the se-

Figure 1. Global architecture



mantics of information chunks (Abiteboul, 1997). The most used language today is XML (Bradley, 2000; W3C, 1998). With XML, it is possible to define a grammar that defines the allowed tags and the composition rules of tags. Semistructured documents have allowed experts to write documents following a logical organization. For this reason, they are interesting for the care practitioner; medical documents capture is closer to documents writing than to forms filling.

Tags in *loosely-structured documents* do not embrace data but paragraphs. Each paragraph contains a portion of free texts (generally a few phrases) in which many atomic data are drowned. For example, one can define a paragraph to provide the diagnosis information, another paragraph provides a medication prescription, and past medical history is given in a third paragraph type. In a past history paragraph, one can read a date, a family connection, and a disease, but none of these data chunks is tagged. This definition differs from the classical semistructured documents used for data exchange in which all data chunks are tagged. We

Figure 2. Loosely-structured document vs. data centric documents

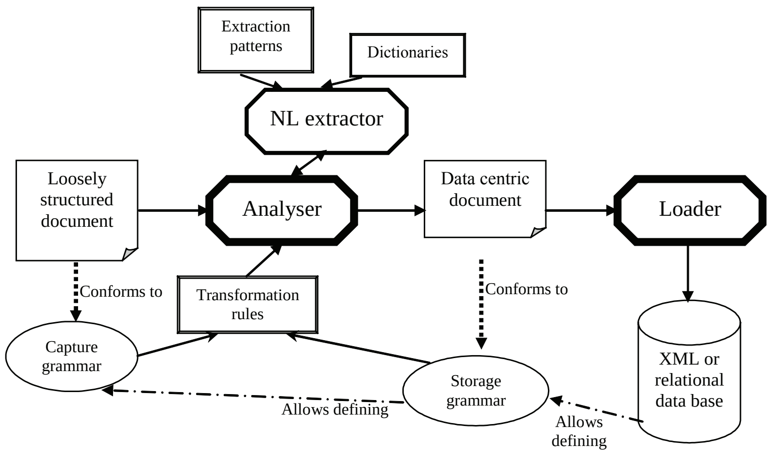
<pastHistory> the patient mother has diabetes. Known since 1990</pastHistory>

<pastHistory> the patient <familyConnection> mother </familyConnection> has <disease id=123> diabetes </disease>. Known since <date> 1990 </date> </pastHistory>

call such documents *data centric documents*, as they are used to organize data. Figure 2 presents the same information piece but written in two ways: first in a loosely-structured document style, and second in a data centric document fashion. This distinction has also been made by Bourret (2000).

Loosely-structured documents provide a new way for capturing information: the end user is guided by paragraphs, but free to write information in a personally preferred way. It is really more comfortable than filling forms or even than

Figure 3. Architecture for the extraction of data from loosely-structured documents



using data centric documents. Such an information capture releases the "computer-related" constraints, allows the user save time, and permits thinking of more intuitive user interfaces. But this also augments the computer work, as data are still required at the end. The computer has to extract data chunks from paragraphs. This extraction allows for building data centric documents and/or for filling a structured database and thus providing the processing power of standard data management systems.

General Architecture for the Transformation

We have designed and developed a prototype of a transformation tool that builds a data centric document from a loosely-structured document (Badr, 2003). Figure 3 provides a synthetic view of our extraction prototype. The analyser takes as input a loosely-structured document and transformation rules. It extracts paragraphs and interacts with a natural language extractor that uses extraction patterns and dictionaries for data chunks extraction in paragraphs. Transformation rules thus define how extracted data should be processed and structured to provide the data centric document. A database loader is finally used to fill in a relational database, or a XML database.

All kinds of documents must conform to a grammar. For each document type (e.g., surgery report or nursing report), two different grammars (DTDs) can automatically be processed from the database schema: a capture grammar that allows validating the loosely-structured documents, and a storage grammar that allows validating data centric documents (see section 4.3.1). The grammar for loosely-structured documents is a simplification of the corresponding data centric document grammar, removing all tags at depth greater than 1.

Steps of the Transformation Process

Data generation from a loosely-structured document contains the following steps:

Step 1: Select paragraphs
Step 2: Extract relevant information
Step 3: Process extracted data
Step 4: Restructure it according to a storage grammar

These steps are described under the form of transformation templates, similar to template-patterns in XSLT. Transformation templates are

Figure 4. Transformation template

```
//transformation template
<Transform paragraph='XPath_Expression' >
      //extraction, structuring and processing rules here
</Transform>

//structuring rule
<Construct frame='tagname' type='frag | defrag'>
//insert here extraction or processing rules
</Construct>

//extraction rule
<Extract pattern = 'Extraction_pattern_name' >
   <dataChunk  name='chunkName1'/>
            …..
   <dataChunk  name='chunkNamen'/>
</Extract >

//processing rule
<value-of operation = 'operation' />
```

gathered in documents called *transformation sheets.* We have built a *transformation processor* that reads a document and gets the transformation sheet associated with its capture grammar. The transformation processor is an augmented XSLT processor. Each transformation template is defined by a *transform* element. Rules are elements inserted in this element.

- A selection rule is a match pattern that identifies paragraphs by operating on the document logical structure. The *paragraph* attribute of the *transform* tag and its value specify the selection rule under the form of an XPath expression.
- An extraction rule (*extract* tag) can be viewed as a function call that specifies arguments and returned values. The function locates matching sequences of words within a selected paragraph. In other words, it makes the data chunks extraction from the selected paragraph. The body of this function is defined internally as an extraction pattern under the form of customized finite state transducers (FSTs) (Silberztein, 2000), as explained later in this article (section 3.4). Within an extraction pattern, each matching sequence of words marks out a *data chunk*. An extraction pattern can return many data chunks.
- Structuring rules (*construct* tag) are used to tag data chunks and insert them into the target document. They do operations like generating constant text, removing XML elements content, moving or reordering XML elements, or duplicating text. Structuring rules put data in a format that is easy to feed the database. They present a super-set of standard XSL elements (xsl:element, xsl:attribute, xsl:copy, and xsl:value-of). We have added the *construct* element type to gather a combination of extraction rules into the target output within a single element. Extracted information are tagged and copied to the target document. If the *type* attribute value is "*defrag*," the entire source text is put into the target document. Otherwise,

only extracted data are inserted.

- Processing rules (*operation* attribute of *value-of* tag) apply operations on extracted information. The result is tagged and inserted into the target document. The basic categories of operations are string operations (comparison, substitution, etc.), arithmetic operations (+, -, /, *, etc.), and mathematical functions (ceiling, floor, etc.).

At the end of the transformation of all paragraphs of a loosely-structured document, extracted data chunks are organized in a XML data centric document. This data centric document also keeps a reference to its source loosely-structured document. The data centric document is thus used to fill in a relational or XML database.

Extraction Details

The natural language extractor (Xtractor) makes the extraction of data chunks in selected paragraphs. After preprocessing the paragraph, it applies FSTs to point at data chunks. FSTs are built by compiling a set of user-defined extraction patterns.

Paragraph Preprocessing

In a loosely-structured document, elements are tagged paragraphs of natural language text. One motivation for document fragmentation is to construct small fragments of a mixture of grammatical and free text; identifying data chunks is thus easier. Since our work is an application oriented system, it uses natural language dictionaries and domain specific dictionaries. In extraction patterns, users can refer to these dictionaries by metasymbols, such as <disease> to refer to any disease in the disease dictionary.

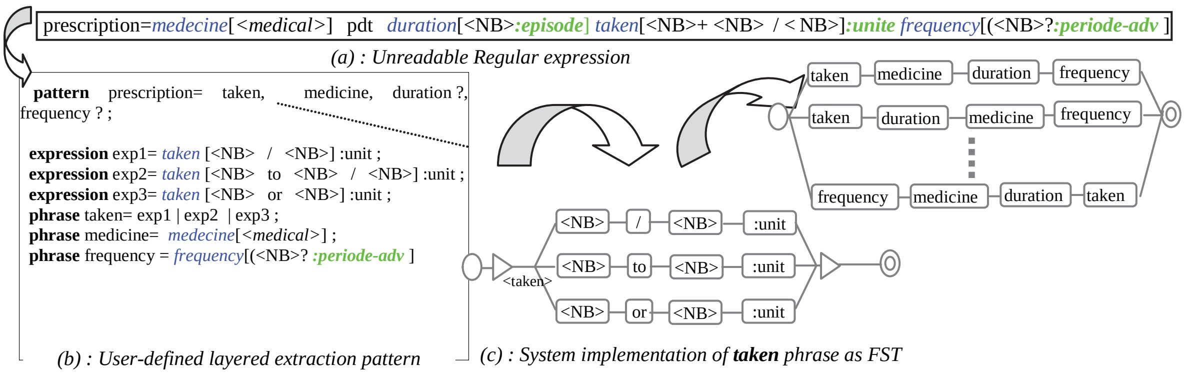
In order to extract relevant information, Xtractor applies its dictionaries against documents paragraphs and defines a scenario of text language preprocessing as follows: (1) validation ensures that the input is a text and it is clean of control characters, (2) preprocessing identifies sentences in paragraphs, delimits unambiguous compound words, and marks off special tokens such as elided words, (3) lexical analysis consists of applying language dictionaries and domain specific dictionaries, and (4) disambiguation removes ambiguity when a word corresponds to more than one entry in dictionaries. After the preprocessing stage, the result is a text vocabulary and indexed dictionaries. Various search operations can thus be done by applying extraction patterns.

User-Defined Extraction Patterns

We provide end users with a high level specification language to build dictionaries of extraction patterns. It is based on regular expressions but includes additional functionalities. We supply a compiler to check the syntax and to translate each extraction pattern into a finite state transducer (FST), as it is required by Xtractor. Figure 5(a) presents a complex extraction pattern. It is not easy to maintain such a pattern. It becomes more readable if it is decomposed into layers as presented in Figure 5(b). We have defined four layers:

1. The *term* layer is composed of a finite set of terms. A term is either (1) a form, that is, a sequence of letters delimited by separators, for example, whitespace, and so forth, and (2) a metawords to describe a number <NB>, a word <MOT>, an empty word <E>, or a reference to lemma in dictionaries.
2. The *expression* layer contains a finite set of expressions; we denote by an expression a concatenation of terms separated by a separator. We say that an expression holds if we find a sequence of words that matches the expression.
3. The *phrase* layer is made of alternates of expressions; we say that a phrase holds if one of its expressions holds. Unary operators

Figure 5. Extraction pattern for prescription paragraph and its equivalent FST



could be applied on expressions in a phrase such as zero or more (*), optional (?), and one or more (+).

4. An *extraction pattern* over a paragraph is a finite and unordered set of phrases. Conditions over phrases may modify the possible combinations. Unary multiplicity operators over phrases increase search paths and a restriction over a phrase sequence reduces possible combinations.

Extraction Patterns Implementation as FSTs

Xtractor uses FSTs to recognize some sequences of words or terms in the input, and associates them with some outputs. All possible combinations defined in an extraction pattern can be illustrated by a graph (Figure 5[d]) with one start node and one end node where every path represents one and only one possible combination of phrases. The skeleton graph of an extraction pattern can be translated into a FST and each phrase can be replaced by its equivalent elementary FST (Figure 5[c]).

Assuming that a FST can reproduce the matching sequence in the output, we can insert additional nodes within the FST to tag relevant sequences and merge their outputs within the original text. That is why we have introduced *named term* as an identifier assigned to a term in order to add semantics and to delimit it by tags in the output. Formally, we note a named term as identifier[term].

Applying FSTs on Documents

Creating a new document type requires effort for describing extraction patterns in the user language we have defined. It may also require defining new dictionaries.

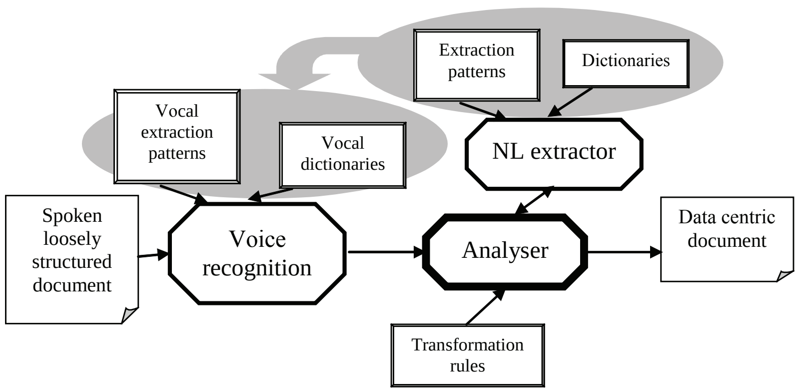
For each new document written by an end user, the analyser sends paragraphs to Xtractor. After preprocessing, it applies FSTs. It results in data chunks identification. These data chunks are returned to the analyser, which continues its transformation steps. For our prototype, we have used the Intex extractor (Intex, 2006). It is a French academic tool provided with French dictionaries and a java API.

User Interface for Documents Capture

The capture of information is here based on the capture of loosely-structured documents. We have studied two ways for the capture of such documents. The first way is the standard one, using a graphical user interface for the end user to type documents. Figure 6 provides a snapshot of our

Figure 6. Standard loosely-structured document capture user interface

Figure 7. Architecture of user interfaces for the capture of spoken loosely-structured documents



prototype. The main central part of the GUI allows the end user to write paragraphs in a free grammatical way. A right click on a paragraph permits the user to define the paragraph type, so that it gets tagged.

But such a GUI cannot be used on a mobile device (even if they nowadays get more and more processing power as well as a bigger and bigger screen). There are many other situations in which the use of a keyboard is not convenient: during surgery for example, or simply when used by a naive end user. That is why we have also prototyped a vocal user interface that allows for the dictation of paragraphs to build the loosely-structured document. We have coupled our basic architecture with a voice recognition tool, as shown on Figure 7. The voice recognition tool receives the dictated voice document. We call voice document a speech flow provided by the end user. The voice recognition tool receives a speech grammar. This grammar mainly contains the description of the capture grammar. Each time the speech tool has coupled a sentence and a paragraph, it sends it to the analyzer for further processing. We also have studied the recognition of more precise data chunks during speech analysis. To do so, we have also provided some (rewritten) extraction rules to the speech recognizer. It can easily identify words coming from a dictionary (like medication names). It thus reduces the further analysis made by the analyzer and the natural language extraction tool.

For the speech recognition prototype, we have used the IBM ViaVoice system. As it has a java interface, it has been easily coupled to our analyzer. The rules for the speech recognition are written in the Java speech grammar format (Sun, 1998). We have validated our speech recognition prototype on medication prescriptions. It has proved that the doctor can dictate the prescription in a "normal" sentence way, without indicating the logical organization of the sentence. The speech flow is continuous and regular. No stop is required between words or phrases.

FROM DISTRIBUTED DOCUMENTS AND DATA TO A UNIFIED VIEW

After a first part dealing with data extraction from loosely-structured document, we present the architecture of hybrid navigation in a space gathering data and documents. This architecture is based on topic maps, a paradigm useful for knowledge representation.

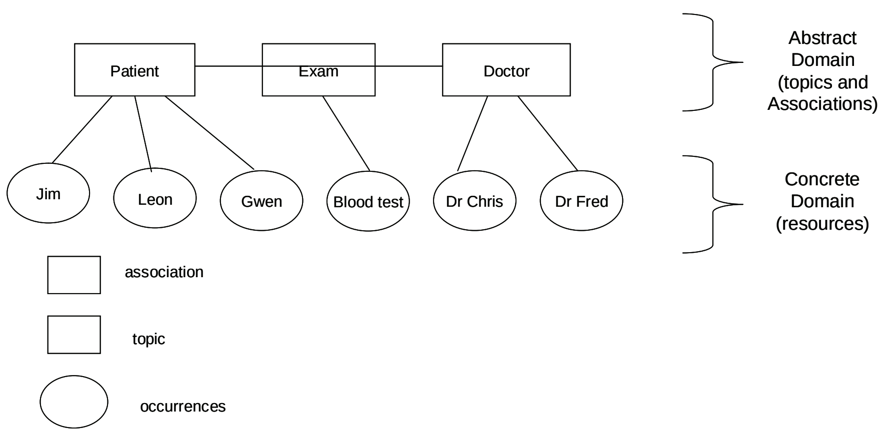
Topic Maps Concepts

In 1999, a standard defining the topic maps model and its syntax was edited by ISO. This standard has been completed in 2002 (ISO, 2002). According to the ISO definition, topic maps are a paradigm used to formalize and organize human knowledge to make creation and retrieval easier in computer processing. It is also used as a mechanism for representing and optimizing resources access. Other definitions put their aim forward. For Fresse (2000), topic maps build a structured semantic link network on resources. According to Widhalm and Mueck (2003), topic maps are a standardized modelling approach for the semantic annotation and description of resources. They enable an improved search and navigation among information stored in semistructured information spaces.

According to Biezunski (2003), topic maps represent a tool useful to organize information in a way that is optimized for navigation. It addresses the problem of infoglut that we are facing in the Web environment. Too much information is almost equivalent to no information, unless there are ways to filter and to extract it efficiently.

A topic map is built from topics linked by associations. Topics and associations represent

Figure 8. A topic maps representation



the abstract part of a topic map. The concrete part is represented by occurrences. A topic occurrence can be any information that is relevant to a given topic. Associations are used to express knowledge at the topics level and not at the occurrences level. Figure 8 shows the representation of a topic map.

The abstract (topics and relations) and concrete (occurrences) parts allow for coupling topic maps with any technique associating data and structure. The most natural approach, proposed in this work, is to couple topic maps with XML (documents structures and documents instances). Another is to couple topic maps with description logics (ABox and TBox).

We use the following main concepts of topic maps: subject, topic, association, and role:

- **Subject:** In the most generic sense, a subject is anything regardless whether it exists or has any other specific characteristics, about which anything may be asserted by any means. In particular, it is anything on which the author of a topic map chooses to discourse. In order to discourse on a subject within the topic map paradigm, that subject must be reified by a topic.
- **Topic:** A topic is a resource that acts as a proxy for some subject; it is the representation of that subject. The relationship between a topic and its subject is a reification relation. Reification of a subject allows topic characteristics to be assigned to the topic that reifies it.
- **Association:** An association is a relationship between one or more topics, each of which plays a role as a member of that association. Each individual association is an instance of a single class of association (also known as an association type) that may or may not be indicated explicitly. The default association type is defined by the "association" published subject.
- **Role:** A role expresses the nature of a topic's involvement as a member of an association.

General Architecture for the Unified View Construction

According to our architecture in Figure 3, the data integration part consists of using XML or relational databases to build a unified view under the form of a topic map schema. This schema represents the conceptual basis for the querying. Two main goals have thus to be achieved: (1) to offer a friendly graphical user interface to navigate through a coherent data space, and (2) to offer access to original documents from selected data.

The global architecture of this part is represented by three main steps: the merging of XML documents (representing the data sources), the creation of the global topic map (base of the navigation), and the interactive creation of a document resulting from a map navigation (see Figure 9).

Steps for Data Integration Based on Topic Maps

The integration of data coming from multiple data centric documents is a complex process. In this paragraph, we explain the main steps of this process, which include exporting the relational database into an XML format (for relational database storage of data), merging the XML documents, and building the topic map.

Database Exportation in a XML Format

Rules used to create a XML document from the DB conceptual schema are the following:

- An *element* is created for each table (the element's name is the table's name). For example, Table Patient produces the XML

Figure 9. Architecture of integration and navigation process

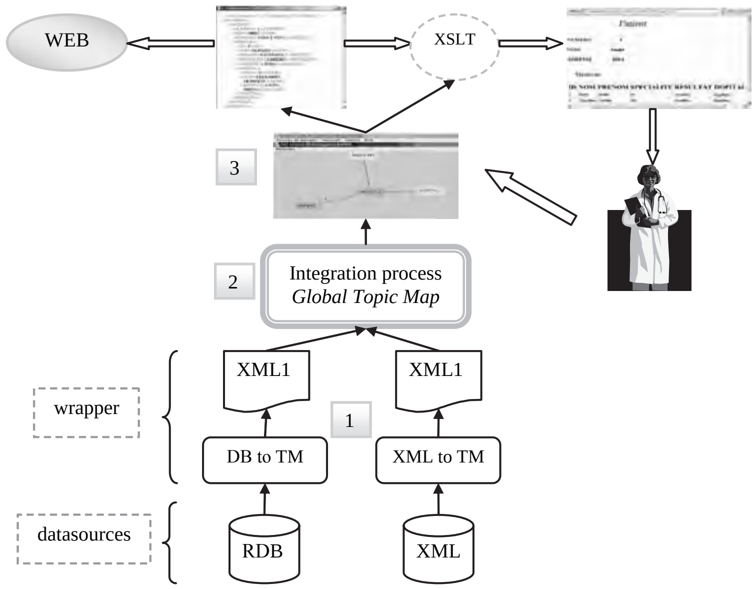


Figure 10. XML translation of 1-N association

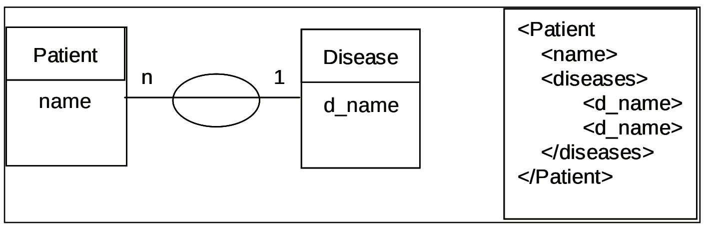

element <Patient> …….</Patient>.

- For each *(1-n) relation*, the XML element of the table, which is the source of the functional dependency (cardinality 1), is a subelement of the table element (Figure 10).
- For each *(n-n) relation*, two representations can be done in two views (Figure 11).

XML Documents Merging

The process of integration is shown using an example. Let us consider two XML documents. The merging intends to produce a XML global document which keeps the data semantics and includes data without information loss.

A XML document can be represented using a graph structure G(V, E) in which the vertices represent the document elements (attributes, classes, etc.) and the edges represent the links between the vertices. An edge is a binary relation (association between 2 elements). In our example, (Patient, Doctor) represents an oriented edge from the Patient element to the Doctor element.

Let the G1(V1, E1) and G2(V2, E2) be two graphs representing the XML1 and XML2 documents.

V1 = {Patient, Doctor, Hospital, Treatment}

Figure 11. XML translation of N-N association

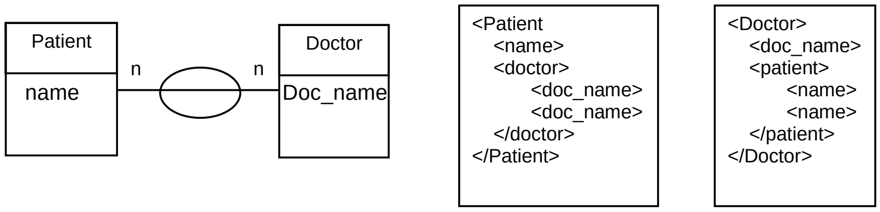

Figure 12. Graph representation of a XML structure

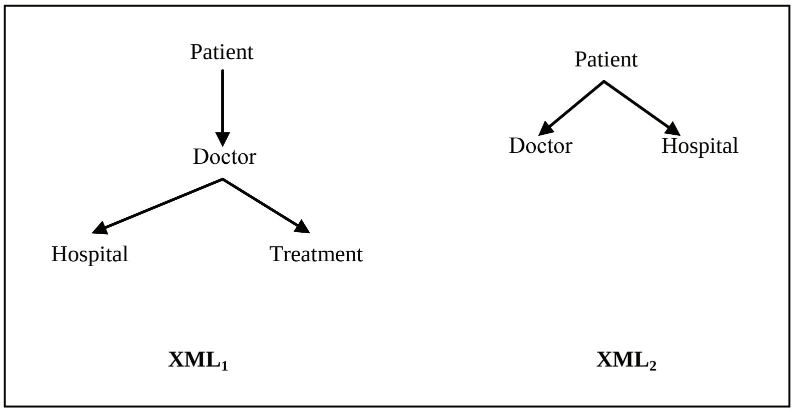

Figure 13. Data merging

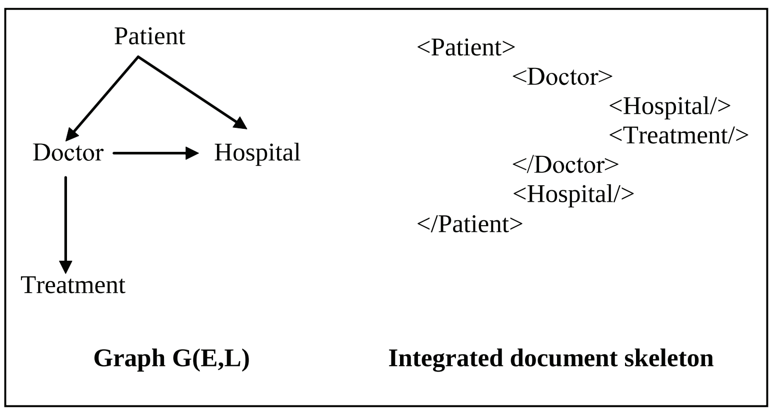

E1 = {(Patient, Doctor), (Doctor, Hospital), (Doctor, Treatment)}
V2 = {Patient, Doctor, Hospital}
E2 = {(Patient, Doctor), (Patient, Hospital)}.

The merging results in one graph (Figure 13) called $G(V,E) = G1(V1, E1) \cup G2(V2, E2) = G(V1 \cup V2, E1 \cup E2)$ and gives a new XML document:

$V = V1 \cup V2$ = {Patient, Doctor, Hospital, Treatment}
$E = E1 \cup E2$ = {(Patient, Doctor), (Patient, Hospital), (Doctor, Hospital), (Doctor, Treatment)}

The final document can contain redundancies. In our example, the Hospital element is represented twice in two different places in the graph. The edge (patient→hospital) is included in the edge (patient→doctor→hospital). The first edge says "a patient *p* is cared by a doctor *d* in a hospital *h*." The second edge says "a patient *p* is cared in the hospital *h*." On syntactic aspects, the first edge is contained in the second one. But in case of both sets disjunction, the redundancy cannot be suppressed. A link will be suppressed only if intentional and extensional redundancies can be suppressed. Let us consider the example seen in Figure 14.

The link (patient→hospital) is structurally redundant but the edge values are different in the documents. The hospital h3 in XML2 is not an instance of XML1 and cannot be represented in the path (patient→doctor→hospital). There is no link between hospital h3 and any doctor in both data sources. So the suppression of the link (patient→hospital) is not possible in the resulting document.

Topic Map Building

The previous step gives a XML document representing the merging of database. This step represents the topic map building. Tags in the global XML document are used to produce our topics. We define two types of tags. A composition tag is a unit of data essentially corresponding to a relational entity. The tags <doctor>, <patient>, and <treatment> are composition tags. A data tag corresponds to a relational attribute (e.g., <id_patient> and <doc_name>). Data tags are not translated as topics, they are descriptors of topics.

A composition tag will be translated into a topic in the topic map. The display name of a topic is the name of the composition tag it comes from. These topics are represented in a graph structure as composed vertices. A relation between composition tags is translated into a link between the corresponding topics. The content of each topic is stored using a dedicated XML structure that includes its data tags. The result of this step is a global topic map in which the user chooses the topics to query.

User Interface for Hybrid Navigation

The user should browse the topics space in the easiest way. The interface is built dynamically. When the user selects a topic, the GUI presents this topic and other topics directly linked with it. The structure of a topic can be shown (Figure 15 upper) and its content is displayed as a table to the end user (Figure 15 lower).

Figure 14. Document's instances XML1 and XML2

```
<patient id=p1>
        <doctor id=d1>
            <hospital id=h1/>
            <treatment/>
        </doctor>
        <doctor id=d2>
            <hospital id=h2/>
            <treatment/>
        </doctor>
</patient>
```

XML_1

```
<patient id=p1>
        <doctor id=d1>
        <hospital id=h1/>
        <hospital id=h3/>
</patient>
```

XML_2

Valid Topic

At the beginning of a browsing session, the topic map is centred on a start topic which represents the valid topic at the moment. Only a part of the global topic map is displayed. This part, called valid part, is composed of topics directly linked with the start topic and of associations between the displayed topics. The construction of the valid part can be designed with a specific algorithm (not given in this article).

As the valid part has been created, it is displayed as boxes (topics) connected with straight lines (associations). The user navigates these boxes in two ways: using a graphical SQL-like querying system, or browsing through the global topic map.

Each topic produces two links: one at the semantic level and one at the instances level.

- **Semantic level:** When the user navigates from a topic t_1 toward a topic t_2, the result is the topic t_2 **of** t_1. Navigating from the Patient box to the Doctor box through the care association, the result is doctors caring for one or more patients.
- **Instances level:** A knowledge base is built with the resources of the data sources. Relevant instances are extracted to be displayed according to their content and the query of the user. The cardinality is displayed on the links between topics and the content can be displayed. The instances are considered at two levels. The first level concerns data (relational or XML data) and the second level concerns the source document of data. The number of instances relevant for the query is displayed on the topic map.

Topic Map Querying

We have proposed algebra to manage dynamic querying (Ouziri, 2003). The operators of this algebra are used to translate the real time actions of the user into actions on the presented topic map. At each graph node, the system calculates the next node according to the user action. This algebra

Content of the Doctor topic (XML coding) partially uses the Xpath syntax (Berglund, 2006) and extends it with operands *This, Next, Previous,* and *Currents* and with other algebraic operators of *Project, Select*, and *Access.* These last operators are useful for the graph querying and for the graph updating at each step of user navigation. The Next and Previous operators are not usually used in the graph theory. The main approach in this theory is to calculate optimal paths in a static graph. But in our case, the graph structure changes every time the user makes a navigation action. So, the navigation operators recalculate the graph structure and instances.

The Access, Next, and Previous operators produce a graph structure that is built according to the semantic links extracted from data sources and restricted to the constraints defined by the user during the navigation. The Access operator browses the graph to calculate the instances linked to the start concept. The Previous operator is the exact (semantic) opposite of the Next operator but does not produce necessarily the same results. For example, the Next operator used from Patient to Doctor gives for each patient the doctors. The opposite (Previous) operation gives for each doctor the list of patients. The Access operator is a generalization of the two operators Next and Previous. It allows for reaching all instances from the "source" topic following a chosen path.

These operators allow for the navigation in the graph. The graph structure is modified according to the user query so that only relevant information is displayed. The screenshot in Figure 16 shows in the background the topic map presentation to the end user. We can see two boxes representing two topics and links showing their associations. Values on links represent occurrences numbers. In the popup window there is a form which allows for the selection of an item.

RELATED WORKS

Works on relations between documents and databases can be seen under three directions: information retrieval, information extraction, and databases.

Information retrieval aims at selecting a subset of documents from a collection based on a user query (Witten, Moffat & Bell, 1994, p. 519). The user browses the results to get the desired information. Indexing techniques allow fast access. But the semantic ambiguity of natural language is not taken into account. Structured documents databases allow using the structure in queries. But anyway, information retrieval does not allow

Figure 16. Navigation between patient to doctor

applying manipulations on data inside documents. Relevant data hidden in text are not structured and they are not accessible for efficient processing.

Information extraction from textual documents intends to extract information and to encode data into a format suitable for populating a database (Muslea, 1999). They are based on extraction patterns built within a learning phase, such as Sundance (Riloff, Wiebe & Phillips, 2005), PALKA (Kim & Moldovan, 1995), and LIEP (Huffman, 1996). Extraction patterns are rarely accessible to the user. On another hand, wrappers are specialized information extraction systems dedicated to Web sites. TSIMMIS (Garcia-Molina, Papakonstantinou, Quass, Rajaraman, Sagiv, Ullman et al., 1997), RoadRunner (Crescenzi, Mecca & Merialdo, 2001), RAPIER (Califf & Mooney, 1999), and NoDoSE (Adelberg 1998) are well-known wrappers generators. Most of them focus on HTML delimiters and do not provide any specification about how to map extracted information to a database.

The database community has studied the retrieval, manipulation, and restructuring of structured documents stored in databases. Some have defined new XML databases, such as Timber (Jagadish, Al-Khalifa, Chapman, Lakshmanan, Nierman, Paparizos et al., 2002), and Tamino (Schöning & Wäsch, 2000), others transform the hierarchical XML model to a relational or object-relational model to store documents in such databases as XML-DBMS (Bourret, 2000), and X-Ray (Kappel, Kapsammer & Retschitzegger, 2001), and some works also provide built up documents as results to queries, but cannot get documents as input (SQLserver, 2000).

Works concerning navigation are essentially oriented towards the semantic Web and information retrieval. The Web is considered as a graph of documents connected by hyperlinks (Pinkerton, 1994). Some drawbacks have an impact on keyword search and on navigation. The user navigates a large collection of pages following the hyperlinks defined by the Web page designer. The resulting document represents the only and unique granularity of the result. Finding a specific term in a document is not possible. For example, getting all the blood pressure values of a patient is not possible. The smaller granularity is the Web page. To improve information search, many works have been done to face the problem of infoglut and irrelevant documents. We can cite Pant, Bradshaw, and Menczer (2003) who propose to link better a crawler and the search engine to improve the focusing on a specific community's interest. Some works are interested in information retrieval (Baeza-Yates, 2003), Web query processing (Diao, Lu, Chen & Tian, 2000), semantic Web (Koivunen, 2001), and adaptive Web navigation (Dolog, Henze, Nejdl & Sintek, 2003).

Other research works face the problem of querying. In these projects, queries are based on the content of Web pages and on the link structure connecting Web pages. A first group of works try to structure Web querying with ordered arc-labeled trees. Among them, we can find works by Arocena and Mendelzon (1999), Fernandez, Fisher, Gruber, and Mandelbaum (2006), and Konopnicki and Shmueli (1998).

CONCLUSION

In this article, we have described a software system useful for extracting data from loosely-structured documents. The extraction allows the expert (physician, computer scientist, etc.) to retrieve data or parts of medical documents. The extraction phase gives a very precise data and document representation. The retrieval phase is made easier with a navigation based on a topics cartography that presents the semantically correct information space to the user and helps with navigation. This navigation is intuitive, easy, and secure. As a further work, we intend to build a full integrated prototype to test our application on real medical data.

ABSTRACT

Emergency Medical Services (EMS) are not only responsible for providing prompt and efficient medical care to many different types emergencies, but also for fully documenting each and every event. Unfortunately, the vast majority of EMS events are still documented by hand. The documents are then further processed and entered manually into various billing, research, and other databases. Hence, such a process is expensive, labor intensive, and error prone. There is a dire need for more research in this area and for faster, efficient solutions. We present a solution for this problem: Prehospital Patient Care Record (PCR) for emergency medical field usage with a system called iRevive that functions as a mobile database application. iRevive is a mobile database application that is designed to facilitate the collection and management of prehospital data. It allows point-of-care data capture in an electronic format and is equipped with individual patient sensors to automatically capture vital sign data. Patient information from the field is wirelessly transmitted to a back-end server, which uses Web service standards to promote interoperability with disparate hospital information systems, various billing agencies, and a wide variety of research applications. In this chapter, we describe the current state of EMS, the iRevive application, a mini-trial deploying iRevive in real scenarios, the results, and a future direction for our solution.

INTRODUCTION

There are times when an individual's life may depend on the quick reaction and competent care of emergency medical technicians (EMTs). These highly trained, prehospital healthcare providers are dispatched by 911 operators to incidents as varied as motor vehicle crashes, heart attacks, near-drowning events, childbirth, and gunshot wounds. Their first priority is to stabilize a patient's cardiopulmonary status. They must then determine the nature and severity of the patient's condition and whether the patient has any preexisting medical problems. EMTs follow strict rules and guidelines in their provision of emergency care and often use special equipment such as backboards, defibrillators, airway adjuncts, and various medications before placing patients on stretchers and securing them in an ambulance for transport. At a medical facility, EMTs transfer the care of their patients to emergency department personnel by reporting their observations and actions to staff.

Equally important is EMS personnel documenting the care they provide. They do so in the form of a prehospital record, which must be completed for each patient who is treated or transported by them. The prehospital record is a medical and legal document used by emergency medical technicians to record a variety of data concerning a patient's current illness or injury, past medical history, treatment rendered, and subsequent improvement or worsening of the patient's condition (Mann, 2002). This type of prehospital documentation is used to support the actions of the crew, the transfer of care, and to justify reimbursement from various insurance companies; it is also used for quality improvement programs and research. Unfortunately, the vast majority of EMS events are still documented manually by hand on paper. This leads to an extensive amount of manual data processing as the often illegible handwritten data must sometimes be deciphered, then manually entered into various billing, research, and other databases. The whole process is expensive, labor intensive, and error prone.

The rest of this chapter is sectioned as follows: first, an overview of the current state of EMS workflow, documentation methods, and research is provided. This section emphasizes the National Highway Traffic Safety Association's goals for EMS in the future, including the call for a national EMS database and improved information systems, so that prehospital information can be linked with the hospital record. The next section is a description of one solution called iRevive, a mobile database for EMS professionals that streamlines data capture, communication, reimbursement processing, quality assurance, and research. It takes advantage of tiny wireless sensors to automatically record vital sign data. It permits multilevel decision support; the local EMT over his/her patient, the regional commander over a selected vicinity, and the central level of control over all the events occurring at a particular time. Actual deployment of iRevive, for live field-testing by Professional Emergency Services of Cambridge, Massachusetts, is examined and critiqued. This trial version was conducted without sensors or multilevel decision support. Finally, a future vision of iRevive is described, including the addition of many different types of sensors such as chemical sensors and GPS devices for location information. All exchange of data will be interfaced through Web services and conform to standards such as HL-7 to help the increase of data exchange and interoperability.

Background

Ambulances of the early 1900s were regarded as a means of transportation for the sick and injured from homes, work site, and public places to hospitals, where real treatment could begin. It was not until the advent of cardiopulmonary resuscitation (CPR) and the 1966 publication of a National Academy of Sciences paper entitled, "Accidental Death and Disability: The Neglected Disease of Modern Society," that modern EMS systems came into being (Callahan, 1997). Later, with the introduction of cardiac defibrillation by trained crewmembers and more extensive airway training, the back of ambulances became the sites of true life-saving treatments. While emergency medical services have grown rapidly over the past 30 years, the scope of EMS research has not. Most EMS research focuses on a single intervention or health problem, and it rarely addresses the inherent complexities of EMS systems (Delbridge, Bailey, & Chew, 1998).

It is estimated that EMS systems treat and transport up to 30 million patients per year (NHTSA, 2001) and it is assumed that EMS intervention positively affects patient outcomes, but this is difficult to quantify. Studies have shown that early defibrillation and administration of certain drugs save lives, but other interventions including certain instances of intubations in the field may in fact cause more harm than good (Adnet, Lapostolle, Ricard-Hibon, Carli, & Goldstein, 2001; Vahedi, Ayuyao, & Parsa, 1995). The fact that so few therapies have been examined in outcome studies illustrates a lack of evidence regarding the benefits of many prehospital interventions.

The lack of EMS systems data can be attributed in part to the healthcare industry's delay in utilizing technology; it is one of the last industries to transition to the use of computers for daily operation (Cheung et al., 2001; Foxlee, 1993; Mikkelsen & Aasly, 2001; Tello, Tuck, & Cosentino, 1995). Although some elements of the system are automated (e.g., computer automated dispatch), most EMS personnel record clinical information and other run data using paper and pen. Data collection is therefore limited and highly inefficient. In addition, the patient care report (PCR) that is completed after each EMS transport does not contain data regarding overall patient outcome. The reason for this is that outcome data is held by several different entities, sometimes including other ground and air transport services, hospitals, rehabilitation centers, and physician offices. These various healthcare entities may be affiliated with each other, but seldom are they officially linked and rarely do they exchange prehospital patient information. This lack of information exchange is further hampered by patient privacy laws, incompatible (proprietary) systems, limited data mining methods, and little impetus to form a continuous patient care record. The resultant lack of outcome data severely limits the type and amount of EMS research that can be carried out (Dunford, 2002). Compounding the overall problem is the recognition that serious medical errors can arise in the setting of incomplete data (Foxlee, 1993; Tello et al., 1995). These errors in the handing off of patient care can range from duplicative or delayed therapy to complete lack or inappropriate therapy.

Current Methods

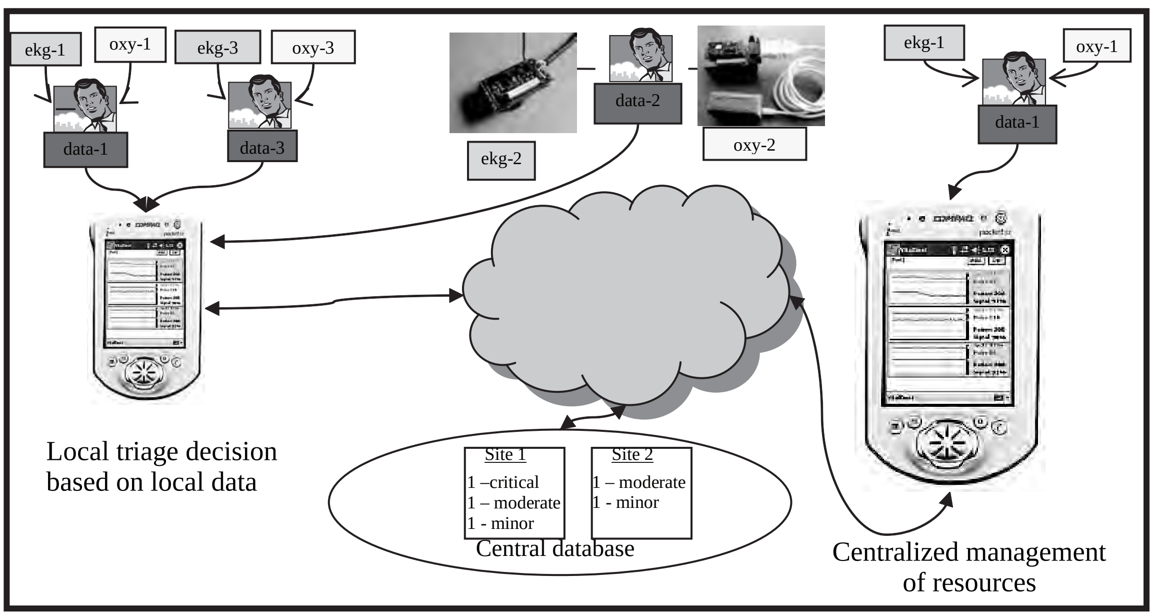
EMS personnel usually work in teams of two and divide the workload at a particular event. While one provider tends to the patient, the other interviews family members or bystanders, sizes up scene conditions, and searches for medications, identification cards, and insurance cards. The NHTSA currently mandates a data set of 40 items to be collected for each patient for each event, including such items as incident location, crewmember identification numbers, patient's social security number, and physical exam findings. Additional insurance and billing information is required by ambulance services so that patients can be billed, while Medicare calls for waivers and prescription forms. It is when the patient's condition is more critical that EMS team members must give their full attention to patient care, forgoing any attempts at data capture or documentation. It is data from these types of events, however, that are of greatest interest to emergency department personnel, researchers, and system administrators. And as EMS systems evolve to offer more advanced care, more time is needed for hands-on patient care and, in turn, more information must be documented (Mears, Ornato, & Dawson, 2002). To overcome these obstacles to better patient care, EMS systems must adopt information systems that streamline the recording, storage, retrieval, and application of quality information.

New methods are being developed to quantify and organize the plethora of data. In 1996, the NHTSA published an article entitled, "EMS Agenda for the Future: Implementation Guide". This article stressed the need for a standardized EMS information system, based on uniform data elements and uniform definitions (NHTSA, 2001). In order to accurately draw conclusions there must be more information regarding care in the field, transportation, emergency department care, hospital care, and final patient disposition. To achieve these goals, EMS information systems must develop new ways to store and retrieve patient data so that patient information is always available. Data must be pooled from a communications center, ambulance personnel, emergency department staff, and finally, other agencies including fire departments, police departments, and medical examiners. Only then can there be a complete database containing all of the information necessary to describe an entire EMS event and facilitate continuous EMS system evaluation and research across multiple systems and to support patient care and EMS-related research (Delbridge, 1998). Our system, iRevive, attempts to address these problems and provides a novel solution in streamlining the data collection. The next section describes the iRevive system built to generate prehospital patient care record.

iREVIVE: THE MOBILE DATABASE SYSTEM

In working toward this vision of compatible EMS database systems that support healthcare data integration, changes must start with regard to how data is originally collected. iRevive is a mobile prehospital database system that allows point-of-care data capture in an electronic format. It consists

Figure 1. Current iRevive system architecture



of a network of wireless, handheld computers running the iRevive application. Wireless vital sign sensors, called VitalDust motes, automatically capture and integrate patient vital sign data directly into each developing patient care record. All of this information can be sent wirelessly from the field to a server that stores and relays selected patient information to receiving hospitals. The stored data is accessible to authorized users for billing and research purposes using Web services (Figure 1).

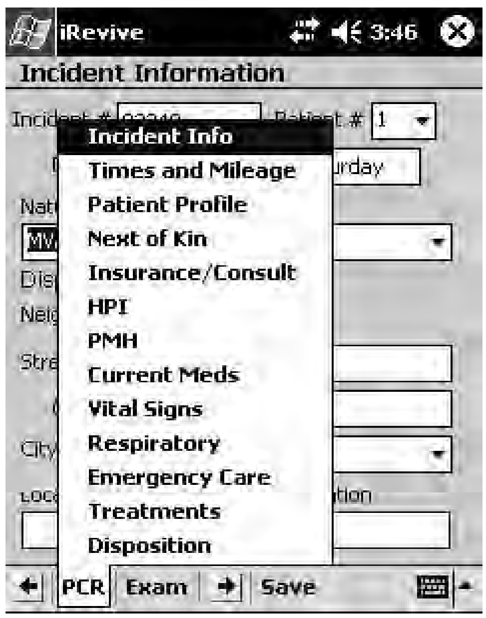
iRevive explores improved documentation of EMS events by streamlining data capture and providing essential prehospital information for subsequent integration with the developing hospital record. Data entry is designed to be logical and intuitive. iRevive can "walk" an EMT through an assessment and remind him/her, for example, to evaluate a patient's neurological response, an essential step that could easily be left out during the high-paced transport of a critically ill patient. Real-time sensors, which collect heart rate and blood oxygen saturation, provide real-time monitoring and enrich the data collection process. During transport or soon after arrival at a hospital, the EMT may choose to complete the PCR using a preset narrative template on the handheld computer. Alternatively, he/she can enter his/her own narrative using either the handheld computer's pen pad or a computer terminal in the receiving hospital's emergency department. Once the PCR is complete and electronically signed, it can be saved (in the central database) and printed (at the hospital) so that it can be included in the patient's paper-based hospital record. The administrative back end aggregates the raw data into summary reports and statistics for operational analysis, performance measurement, and effective managerial decision making.

Prehospital Patient Care Records

The iRevive prehospital patient care record consists of and captures three types of data. The first type of data is the information captured by the EMT which contains the preexisting conditions and the current conditions. Specially, it contains demographic information, a history of the patient's illness or injury (HPI), past medical history (PMH, including medications and allergies), procedural information (e.g., IV access, splinting, and endotracheal intubations), and disposition information (Figure 2). The HPI section includes standardized narratives for more than 30 common complaints, which range from allergic reactions to "dead on scene." The use of standardized narratives allows EMTs to quickly describe each incident using a series of drop-down option boxes, rather than writing an entire incident out in prose—a difficult task on a PDA. The addition of pertinent negatives and additional information in the event of special circumstances is also allowed. These narratives enrich the database and, in the future, will aid in the development of new knowledge-based treatment algorithms.

The second type of data captured is the documentation of critical examinations. It is devoted to an extensive physical exam including head, neck,

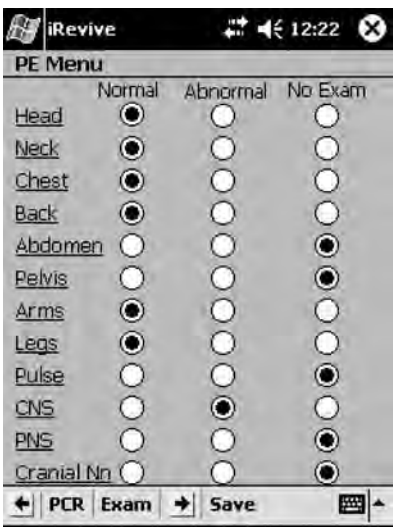
Figure 2. iRevive patient care report sections



chest, abdomen, pelvis, extremities, and nervous system. From the physical exam main menu, users may select and describe any part of the anatomy that has been found to be abnormal (Figure 3a). Selecting an "abnormal" button brings the user to additional pages where abnormal physical findings may be documented in detail using a series of pull-down lists (Figure 3b).

Finally, the third type of data captured and recorded is the sensor data from motes such as the pulse-Oxometer and Vital Dust (Figure 4). The vital signs, such as the pulse rate and SP02 levels, from the patient are automatically recorded and sent continuously from the sensor to the PDA. Critical changes can be immediately noted by the EMT. The EMT no longer has to physically monitor the patient's vital at regular intervals. He/she is automatically provided with more readings which results in a more accurate state of the patient at any particular time.

Figure 3a. iRevive physical exam main menu. If a normal button is selected, a statement is entered in the PCR indicating a normal exam. If an "abnormal" button is selected, then a detailed exam screen opens (CNS = central nervous system; PNS = peripheral nervous system; Cranial Nn = cranial nerves).



Current Application Architecture

The iRevive application is written in C# under the .NET environment and therefore built to run on many types of mobile devices including PDAs, laptops, and wearable computers (Figure 5). iRevive provides a graphical user interface that users can navigate with a stylus. The application is primarily menu driven with customizable drop-down menus that increase efficiency by allowing for quick navigation and data collection. Once the data have been uploaded to a central database, a Web-based interface can be used to edit the PCR on any Internet-enabled PC.

Once field data have been synchronized with the iRevive database, EMS and hospital personnel can instantaneously track current patients and a complete patient care report can be generated and printed. Specific providers have access to the entire record base for billing, supply tracking, and continuous quality improvement (CQI) applications. Other users have the ability to access deidentified data that are nonconfidential for use in overall emergency service research and systems

Figure 3b. A detailed exam screen for the central nervous system (CNS) is shown (GCS = Glascow Coma Score, React. = papillary reactivity).

Figure 4. Sensor Data information transmitted wirelessly to the PDA.

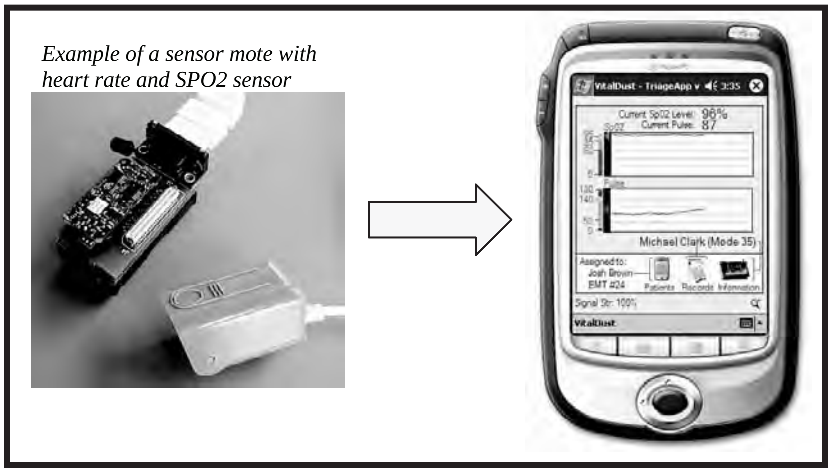


Figure 5. The Future iRevive System Architecture

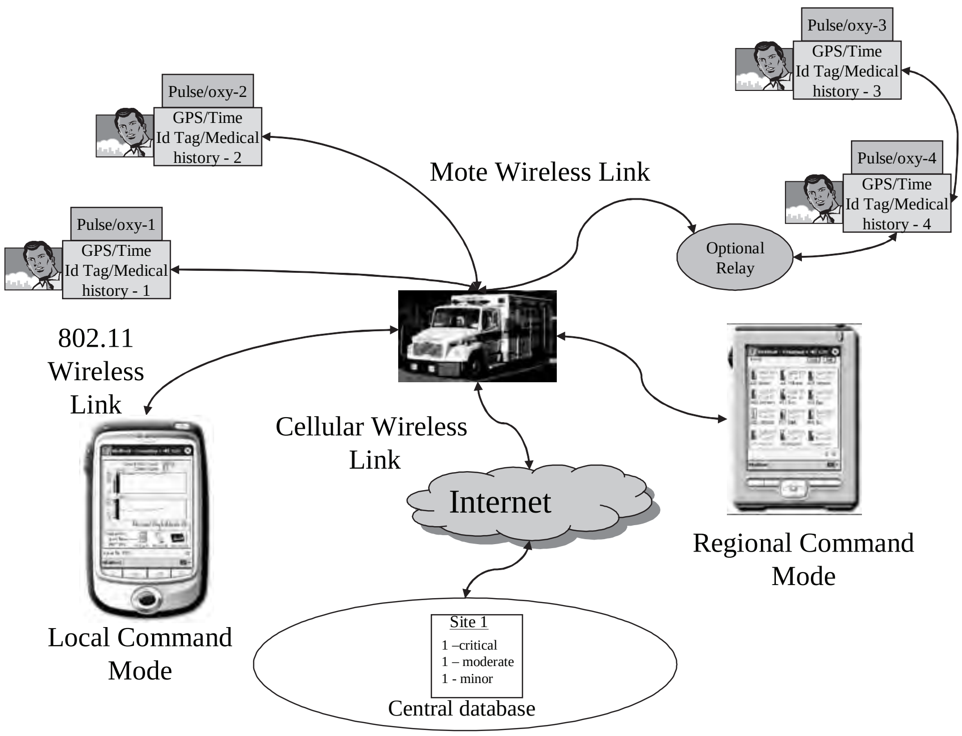

management. All data transfer is Health Insurance Portability and Accountability Act (HIPAA) compliant and the security is end-to-end (using standard Transport Layer Security). Users must be authenticated to use the system and only authorized users can view specific types of data.

To encourage interoperability, the iRevive system is built around emerging standards such as the National Highway and Traffic Safety Board

Uniform Prehospital EMS Data Set (NHTSA-UPDS) and the Data Elements for Emergency Departments Standard (DEEDS), which is the Centers for Disease Control and Prevention's (CDC's) specification for emergency department data that was created to assist data integration across information resources.

FIELD TRIAL ANALYSIS WITHOUT SENSORS

One ambulance from Professional Emergency Services (Pro) of Cambridge, Massachusetts, was selected to field test iRevive. Pro is a moderate-sized private ambulance company with eight ambulances and 50 emergency field providers who respond to over 16,000 emergency calls per year. iRevive was used in parallel with the service's existing handwritten documentation methods during emergency responses. Data were collected using a Hewlett Packard iPAQ Pocket PC, which was synchronized with a laptop satellite station before being uploaded to the server at the end of each shift. In an attempt to steer further product development, users focused on how the iRevive application could be improved. The effectiveness of iRevive in integrating and streamlining data capture was studied, along with its ability to merge with the current workflow of EMS professionals. Factors examined included ease of use, documentation completion, and content. The use of iRevive in the field was observed by a proficient user and ambulance crew chief. This was further examined via interviews with other ambulance crew members. Printouts of iRevive PCRs were then compared to handwritten reports from the same events.

A Case Study

In one real-life scenario, a call concerning chest pain and difficulty breathing was dispatched to an ambulance. While en route to the location, one EMT began to enter data into iRevive. Information included the incident location, type of response, and other pertinent dispatch information known at the time; the time of response was recorded in the times and mileage page. Upon arrival at the scene, time was recorded again while dispatch was notified of arrival via the radio. The time of arrival at the patient's location in the third-floor apartment was also recorded. The first EMT began an initial assessment, obtaining vital signs, attaching a heart monitor, administering oxygen, and prepping an IV site. At the same time, the second EMT interviewed the patient and bystanders in order to gain a detailed account of the patient's medical history, allergies, medications, and a history of the present illness. All pertinent information was recorded using pull-down menus within the iRevive program.

After recording placement of an IV catheter, oxygen delivery rate, and the type of oxygen device used, the medics determined that the patient should receive one dose each of nitroglycerine and aspirin. This was also recorded in iRevive. Once the patient was placed in the ambulance, a second set of vital signs indicated the need for a second dose of sublingual nitroglycerine, which was recorded in iRevive with a time stamp. En route to the hospital, the first EMT took over use of iRevive to record the time of transport and to complete additional sections as necessary. At the hospital, a verbal report was given to the emergency department staff as the patient's care was transferred to an emergency physician. The iRevive PCR was then completed by an EMT with additional supplemental data pertaining to the transport and final patient disposition. A standardized narrative was completed to finish the event documentation. The PCR was then saved on the handheld and uploaded to the 10Blade server allowing immediate access to the PCR for emergency department, ambulance service, and billing.

Results

iRevive was used in conjunction with the standard method of EMS documentation at Professional Ambulance for 16 emergency transports. Of these transports, 12 were calls for medical help, 3 for trauma, and 1 for an assist. iRevive was used by 12 of the 50 field providers at Pro.

It was noted that both the methods captured the same type of data. However, as the iRevive data were electronic, once captured, they were easily ported to the necessary storage and are now available for any further research or analysis. There were difficulties encountered while capturing the data using iRevive which are presented in the next subsection. These difficulties were taken into consideration for the next version of iRevive.

Difficulties

The main goal behind deploying iRevive in the field was to obtain feedback and find out what problems should be addressed for the next release. Problems experienced can be categorized into two main categories: usage problems and need for more data points (Tollefsen, 2003).

Usage Problems:

- History of present illness page had to be navigated prior to discovering key information. This page would be better placed at the end of the report.
- Placement of times and mileage page at the beginning of the PCR required jumping back from pages in use to record times during procedures.
- Dispatch, scene arrival, scene departure, and hospital arrival times are recorded by the dispatch center; this information could be automatically synchronized with the 10Blade server in place of manually recording each time in iRevive.
- Program did not allow a PCR to be saved unless certain fields were completed.
- Inability to return to saved PCR until synchronized with server caused inability to continue to update report.
- Lengthy pull-down menus for certain items took too long to navigate; these could be improved by reordering or starting in a more appropriate range.

Need for More Data Points:

- Lack of appropriate values in some pull-down menus required manual entry of these values.
- Insufficient space to record multiple allergies.
- Inability to draw a picture of patient or scene. Addition of human figure in order to point to areas injured is recommended. Integration with a digital camera was suggested.

Discussion

Overall, the ability of capturing data in an electronic manner proved to be a huge success. Having electronic data available automatically and as soon as the data are captured is a huge gain from the current state of the art. However, in this domain, the granularity for the type of data and the data content are very important. Even though the current version of iRevive contains all 40 points of the Massachusetts Office of EMS prehospital data set, the need for additional data points was recognized. In order to capture as many data points as possible and make iRevive more attractive to a broader number of EMS providers, several additions have been proposed, including the following:

- Type of response: lights and sirens vs. with traffic flow.

- Location type: to explain difficulties or irregularities (e.g., if the incident occurred at a school, parents would not be present).
- Additional patient information, such as estimated weight.
- Signs and symptoms of chief complaint, such as headache or syncope associated with a cut on a patient's head.
- EMT's impression of the event and patient state (e.g., psychiatric issues).
- Cause of trauma and additional information about the cause, such as severity of automobile damage, and whether the patient was wearing a seat belt.
- Reason for transport (e.g., generalized weakness).
- Additional information about the pain a patient is experiencing during the physical exam.
- Condition of the patient's skin.
- Additional transport information, including position of patient and traffic delays.
- Signature page for capture of patient receipt.

FUTURE VERSION OF iREVIVE

The future version of iRevive aims to increase the usability and efficiency of the complete system. This will be done by the addition of more devices and functionality and increasing the role the ambulance plays (Figure 5).

It was observed the ambulance can play a key role in helping communications and transactions that take place during a response. In the future version of iRevive, the ambulance will play the role of a hub bridging real-time communication from the PDA to the hospital housing the central command. The ambulance will contain a wireless network connection (satellite, cell) as well a global positioning system (GPS) tracking its location and time. Information from the PDA to the central command will be exchanged in real time; the EMTs will be able to receive the patient's information immediately as well as be able to send the condition right away allowing for the hospital to make important decisions such as which hospital can facilitate to the patient's needs. This real-time data exchange will help routing of the ambulances efficiently. Furthermore, the PDAs as well as the sensor motes will also be equipped with GPS and wireless connections. EMTs will be required to match the PDA with the sensor mote of the patient to acquire the vital sign information.

The New Architecture

We plan to acquire and implement the following components (devices):

1. **Sensors:** We plan to integrate additional customizable sensors, medical and nonmedical, that are capable of patient monitoring, data filtration, and ad-hoc networking. An example of such sensors would be chemical sensors to detect levels of toxicity and the GPS sensors to record time and location.
2. **Web services:** In order to ease construction of exchange partnerships and increase flexibility of integration with hospital legacy systems and yet-to-be-released communication protocols, the exchange of data will be transitioned into using Health Level-7 (HL-7) Web services. HL-7 is a widely used data definition and delivery standard that has been recommended by the National Committee on Vital and Health Statistics. The HL-7 data format, a Web service based on open standards that are being accepted by the medical community at large, allows any client to access iRevive's Web service as long as he/she has permission and follows the standards set forth in calling the data. A server node will be the manager of sensor streams. A default is a manager of sensor streams on ambulance which manages data

for connected PDAs and GPS sensors. Other modes for the server node may include:

- Operating with attached databases for further storage.
- Acting as a forwarder to another server that is running with an attached database.
- Act as an aggregator of multiple server nodes running on multiple ambulances.

An example of such a server node would be a daemon running on the ambulance listening for PDAs and hospital databases.

3. **Client device:** A PDA will subscribe to an ambulance to receive sensor streams as well as send PCR data for storage/transmission. Laptops may also be employed at different locations that receive the complete information of which ambulance and sensors are in which locations, and the type of conditions that are being treated. This will help create a FedEx routing of the ambulances.

CONCLUSION

The current methods employed by the EMS for gathering and recording data are out-dated, time consuming, and error prone. New technologies and solutions must be employed to improve the system. iRevive provides a solution to overcome many of the problems. EMTs can save time and efficiently capture the necessary information. Furthermore, the data are in electronic format readily available for exchange and analysis with many different systems. A wireless environment for the exchange of data saves time and provides up-to-date real-time information. Also, iRevive can be employed on a variety of different platforms and devices, including but not limited to PDAs, laptops, tablets, and so forth. It was tested in the field and many improvements were made. More innovative changes are in the process: addition of many more emerging sensor and sensor network technology, embracing of industry standards and accepted data formats, a new level of prehospital care is on the horizon. In time, broad deployment of prehospital applications such as iRevive will allow healthcare providers to monitor and document in real time how various procedures and types of therapy affect patient status and outcome. As more data are accrued, new algorithms will be developed to accurately guide and control all types of medical care. Eventually, automated acute care algorithms will be developed to enable sensor-based, computer-controlled patient care.

Chapter 8.10
Outsourcing of Medical Surgery and the Evolution of Medical Telesurgery

Shawna Sando
University of Arizona, USA

ABSTRACT

With rising and often unreasonable costs in the U.S. healthcare system, Americans are becoming more inclined to seek cheaper alternatives. In some cases, Americans do not have to search for such alternatives on their own because their employers are offering them incentives to receive care from a foreign institution. Employees can go abroad to countries, such as India, in order to receive medical services for prices that are at least half of what the procedure would cost in the U.S. This emerging market seems to be beneficial to all involved except U.S. healthcare providers; however, this outsourcing of healthcare services sends a powerful international message. It seems that the U.S. has a healthcare system that cannot adequately serve all economic classes of the American public. In contrast, though India has the proper facilities and professionals, there are concerns regarding malpractice litigation, postoperative care, and possible negative effects on the Indian public. Having given consideration to all affected constituencies, it seems that the outsourcing of medical procedures is in the best interest of lower- and middle-class Americans as well as medical professionals in India. In reality, though medical tourism is receiving much attention, it will most likely not be a pressing concern for the American market in the near future. A widening discrepancy in the Indian public may, however, be cause for nearer concern. This new trend does foreshadow a push for more preventative changes in the business of U.S. healthcare, such as the development of information technology specific to the growing international healthcare market. Whereas, it will initially be beneficial to send patients abroad, with the evolution of technology, the latter ideal will instead be to have medical professionals abroad that care for patients located in the U.S.

INTRODUCTION

The cost of healthcare in the United States seems to be approaching a level that is beyond the economic means of the general public. Even with insurance, expensive surgeries sometimes require thousands of dollars in out-of-pocket costs. Americans have found the cheaper alternative of seeking less expensive healthcare in a foreign country. This practice, which is often coupled with sightseeing and actual tourism, is appropriately referred to as medical tourism. Since there are plenty of advantages for both Americans and their foreign counterparts, medical tourism seems like the natural solution in the short run, and has the potential to become a rapidly growing market. However, when taking all constituencies into consideration, in the long run, this growing market could have some indirect, unfavorable side effects.

ENCOURAGEMENT OF FOREIGN PROCEDURES

Perhaps the largest instigators in this recent trend are the employers. They could be playing a large role in the development of medical tourism simply by introducing the idea to their employees and, in some cases, even offering some economic incentive. In an effort to save on insurance fees, several companies have begun to promote foreign healthcare options.

Blue Ridge Paper Products, based in Canton, North Carolina, is one such venturous company. Their healthcare claims were initially projected to be $36 million by 2006; however, due to these foreign alternatives, their actual claims in 2006 were closer to $24 million (U.S. Senate Hearing, 2006). These savings will be to the advantage of the company and its employees because they will be able to internalize more revenue as well as keep wages reasonable.

Carl Garrett is a technician at a Blue Ridge paper mill who had plans to receive two medical operations in New Delhi, India. The 60-year-old needed both his gall bladder removed and his rotator cuff mended, and was delighted at the opportunity to avoid paying $10,000 in deductibles and out-of-pocket fees (Milne-Tyte, 2006). The cost for Blue Ridge was so low in comparison to the charge that the company would have incurred from U.S. medical fees that they actually offered to return a portion of their savings to Garrett.

In another case, Howard Stabb, a successful business owner, sought physicians in India rather than in the United States. Stabb had chosen not to have health insurance and found that he could save over $150,000 by receiving heart surgery out of the country. He brought a patient advocate with him, and both of them agreed that his decision to seek services abroad was best for both his personal well-being and for the financial stature of his company (U.S. Senate Hearing, 2006).

THE PREFERENCE TOWARDS INDIA

One might wonder, of all the third-world countries where one might be able to receive care, why would India be a good choice? Why would the global leader in importing foreign patients be half-way around the world? Though a possible reason could be coincidence, as in, Indians were the first to create such a market, there are more likely, tangible reasons for this phenomenon. For instance, there is less of a language barrier in India as opposed to some other possible foreign destinations. Most Indians begin learning English in school at a young age, so odds are that the healthcare professionals would be able to communicate with an American in English. Also, helping to make their foreign patients feel secure with the care that they will be receiving, many Indian physicians have been trained in the west (Rai, 2006). Much American hesitation to travel abroad for care comes from uncertainty about the quality of care and knowledge and experience of the foreign physicians. Thus, knowing that an Indian physician has an American medical education would make the possibility more appealing.

Not only might the qualifications of the physicians testify to the care that they can provide, but the experiences of former patients can also be a strong point of persuasion. If individuals that are considering receiving care abroad know someone that can give a recommendation based on experience, they are much more likely to do it themselves. With the volume of medical tourism in India, half a million patients per year and growing, they have a large constituency that can vouch for the quality of care provided in the country (Hutchinson, 2005). Maggie Ann Grace, patient advocate for Howard Stabb, has stayed with patients both in India and the United States. She noted in a statement to the U.S. Senate that she, "would sooner leave her loved ones in the care of doctors and nurses in the Indian Hospital" (U.S. Senate, 2006). She attributed this opinion mostly to the fact that nurses in the U.S. are too busy and because of this, care is given based on the level of the patient's severity and the nurse's schedule.

Cost is also to India's advantage, not only in comparison to U.S. prices, but to other countries as well. In a 2005 comparison of estimated fees for a coronary artery bypass graft surgery, India's more expensive hospital was still $15,000 less expensive than a Mexican hospital and $5,000 cheaper than Thailand (U.S. Senate, 2005). Thus, for reasons that range from financial to human interaction, India is a strong competitor in the international market for medical tourism.

THE AMERICAN PERSPECTIVE

American disdain for the healthcare system has the potentional of becoming a detriment to U.S. society. The situations of both Carl Garrett and Stabb seem to favor medical tourism. It is a favorable option for the patient and their employer, but are there possible adverse affects? On a larger scale, considering all constituencies both directly and indirectly involved, there is a variation in those that benefit from this particular form of outsourcing. For the growing constituency that benefits from and is in favor of medical tourism, there is an opposing set of constituencies that will find this disadvantageous. From 2002 to 2005, there was an increase of 350,000 foreigners that traveled to India for care, this number is projected to increase by 30% each year (Hutchinson, 2005). If this pattern of receiving healthcare abroad does continue to progress, it does not present a sustainable future for the present state of our domestic healthcare system.

Howard Stabb was operated on in India, stayed for a month, and returned with a positive impression of the care provided. His cardiologist in the States reported that he was healthy and that the operation had been successful (U.S. Senate, 2006). That was the best option for Stabb personally, but on a societal level, Stabb's, advertisement for medical tourism may have a negative impact.

Carl Garrett received his operations in the U.S. instead of in India as intended, due to strong opposition. Garrett is part of the United Steelworkers Union, who saw this growing trend toward medical tourism as an excuse to lower the quality of care and a denial of the right to safe healthcare. Stan Johnson, a speaker for the Union, stated that outsourcing healthcare would lead to corporate profiteering and that if we allow traveling abroad for treatment to remain a feasible option, it may one day become the only option (Milne-Tyte, 2006).

Bruce Cunningham, president of the American Society of Plastic Surgeons, presented other concerns, while providing what would most likely be the shared opinion of many American physicians on this subject. He could understand the desire to receive healthcare at a lower cost, but warned of the potential to increase risks (U.S. Senate, 2005). Travel done shortly after having surgery can be risky. Also, many procedures require follow-up care; if an American provider will be administering postoperative care, they should be found and agree to provide care before the patient leaves the country.

There was no evidence found that would justify American physicians having a fear of losing revenue. On the contrary, American physicians and hospitals may begin to feel some reprieve from a diminished patient load. This seems to be the optimistic view of UK physicians. In 2002, it was the National Health Service (NHS) of the UK that began to encourage citizens to seek care abroad in order to alleviate long wait lists (Maini, 2005). Also, patients that would not be eligible for a procedure under NHS would travel abroad to receive it. Thus, it seems that for the present time, such outsourcing is beneficial. For long-term concerns, there is comfort in the fact that for many procedures, proximity is essential. For instance, childbirth and emergency care are not services that could withstand the 20-hour flight.

IndUSHealth, one of many companies that coordinate visits for medical tourists, caters to interested Americans by providing direct information and offering assistance with planning the trip and procedure. Their Web site will most likely convince Americans with limited financial resources that this is their best option for receiving medical care. The company assigns each patient a personal case manager that handles the details of their visit (IndUSHealth site, 2005). Their Web site is subjective; it sheds a positive light on all aspects of receiving care in India. Interested patients should investigate their own reasons for going and whether or not they find any ethical bias against it. Overall, the American perspective is torn. Not necessarily a question of quality vs. cost, there are several factors and variables to consider.

THE INDIAN PERSPECTIVE

The healthcare system in India is complex. The healthcare facilities are divided first into two categories, government and private, and under each of those two categories are three main branches: tertiary, secondary, and primary (the lowest level of care) (Van Hollen, 2003). The government institutions are generally considered inferior to the private due mostly to overcrowding, less funding, and less expensive care. As one goes further from the city, the medical facilities become less technologically advanced, have minimal staff, and lowered sanitation standards. The divide between the private and public sector is growing. In fact, the spending on public healthcare is the sixth lowest in the world. On the other hand, India is among the top 20 nations for spending in the private sector (Nundy & Sengupta, 2005). This is due to spending on healthcare being a lower priority. To compensate, the government encourages growth in the private sector. The government uses subsidies and tax exemptions as some methods of encouraging the private sector. This increasing divide between public and private healthcare factors into not only the care provided, but also the providers of the care. Healthcare professionals prefer working in the private sector due to higher wages and a more pleasant working environment. It is this lack of interest in public sector employment that has propelled entrepreneurial endeavors such as venues for medical tourism, because the Indians involved in the development and implementation of these endeavors do benefit from them.

Unfortunately, there does also seem to be negative repercussions for Indian patients both in the private and public sectors. It seems probable that their care and access to the best physicians might be compromised by the influx of foreigners with more elastic checkbooks. One large downfall of the private sector is that it is not regulated so there are no standards of quality or costs (Nundy & Sengupta, 2005). Thus, their success is measured by profit rather than the actual care being provided. Unfortunately, the private sector also tends to pull the focus away from the public health situation. Since India has plenty of internal health concerns such as widespread diseases and rural communities with minimal healthcare facilities, it seems that a greater focus should be put on the public sector. The problem is that the attraction to the private system is prevalent both to the care providers and patients. In such a profit driven situation, to make this shift from privately to publicly focused is challenging.

COMPARATIVE DATA

All Indian hospitals involved are approved by the WHO supported Joint Commission International. The mission of the Joint Commission International is to improve the safety and quality of care in the international community. Many contributing Indian hospitals are part of a private national chain; for instance, the Apollo Hospitals in Chennai and New Delhi and the Wockhardt Hospitals, one of which is in Mumbai. There is also a chain in Delhi, Fortis Healthcare.

Just as the market for medical tourism has grown in India due to enticing profit margins, reciprocally, American consumers are similarly convinced by the savings. All of these options have a major financial advantage over U.S. providers.

Americans also benefit from some insurance relief since some insurance companies that traditionally only covered emergency, out of country procedures have evolved to a coverage plan for non-emergency situations. BCBSAZ, Cigna, Humana, and Aetna are examples of providers that support the concept of receiving healthcare abroad (personal communication, March 3, 2007). Aetna would only be willing to cover a non-emergency if it is proven to be medically necessary. Perhaps the growing popularity of coverage for procedures conducted abroad has a correlation to the rising insurance premiums. According to the Kaiser Family Foundation, insurance premiums have risen 87% in the last 6 years (Galles, 2007). In 2006, the average annual premium for coverage for a family of four was $11,500 (Fitzpatrick, 2004). That means that the premium was greater than the gross earnings for a full-time minimum wage worker. It would be economically impossible for them have insurance, which explains why 43 million people in the U.S. do not have health insurance (Hutchinson, 2005). This trend of forcibly keeping people from having insurance seems to be a force that is perpetuating the outsourcing of medical care.

THE MALPRACTICE ISSUE

Speaker of the Union, Stan Johnson, expressed an additional concern that most would not consider, having already been strongly convinced by the savings that receiving care abroad affords. However, consumers should consider the possibility of a malpractice lawsuit and who, if any, would be the responsible party. In accordance with their agenda, IndUSHealth has a reasoned response to concerns about malpractice litigation. They claim that India has a similar court system to the U.S. and American patients have the right to file cases there. In reality, however, it seems that though American patients would have the right to file a case in India, the proceedings of a lawsuit would differ from the American process. The major difference between the systems of the two countries is that in the U.S., such a case would be tried in a state court, while in India there are more specific consumer courts. The trend in U.S. courts is to present the patient as victimized and almost guilt the jury into awarding the patient a large sum of the rich doctor’s income. In India, on the other hand, there is a less-biased perspective. Awards are given based on damage; lawyers are not permitted to accept cases that may have facetious intentions. Culturally, doctors in India are so highly respected that most patients would not challenge the decision of their doctor, though there is a possibility that India’s system may be swaying toward the favor of the consumer. In 1992, the Kerala High Court proposed an extension to the Consumer Protection Act to include malpractice and negligence. Due to opposition from physicians, the proposal was reviewed by the supreme court but, to the favor of consumers, was upheld. It was not only upheld in Kerala, but courts were established in all states to handle the complaints of consumers (Studdert, Mello, & Brennan, 2004).

However, there has not been much change toward the American mentality of a more persuasive litigation process. This is dually reflected in the contrasting price of malpractice insurance. According to the Pacific Research Institute, Indian doctors pay $4,000 per year for insurance while American doctors have been known to pay 25 times that amount (Brunell, 2007).

Although this may seem to correlate with the view of foreign malpractice laws as being too relaxed, within both healthcare systems there is a problem of keeping record of errors and any resulting injuries. There is currently an emerging program in the U.S. to hold doctors and hospitals accountable for recording errors (Studdert, et al., 2004). No such program has been initiated in India, but perhaps that will change with an increased influx of foreign patients. A responsible system to track liability would, in turn, keep malpractice suits in both countries honest and less biased.

Overall, even if an American patient were willing to chance a system that had no tendency to be in the consumers' favor, considering the financial aspect of such a process may cause them to reconsider. Financially, there is the added cost of traveling back and forth, as well as lawyer's fees. Also, if compensation is awarded, it would be a much smaller amount than one would expect in the U.S. (Milne-Tyte, 2006).

TECHNOLOGICAL INNOVATIONS

Consider a more cooperative approach to cross-cultural care, where liability is spread amongst providers in two separate countries; there are several technicalities that tend to hamper innovation in healthcare. However, new developments may also serve as solutions to greater struggles. It seems that advances in technology will correlate with the popularity of medical tourism.

Telesurgery, a specific branch of telehealth, provides the opportunity for surgeons that are physically located in different locations to communicate through operative videoconferencing. One surgeon observes the procedure through a camera and then offers visual and auditory feedback to the surgeon at the operating site (Cheah, Lee, Lenzi, & Goh, 2000). Among the more developed teleradiology, telepathology, and teleoncology, telesurgery seems to be the branch of telecommunications that is directly applicable to medical tourism. International telesurgery proved to be successful in two laparoscopic cases between the United States and Singapore. More specifically, an experienced U.S. surgeon observed a less experienced surgeon perform both a radical nephrectomy and a varicocelectomy (Lee, Liew, Fabrizio, Li, Jarrett, & Kavoussi, 2000). This practice would be beneficial to the medical tourism market both by alleviating the distrust of foreign physicians, as well as keeping cost minimal by still undergoing the procedure in a foreign institution. A more recent 2003 study of procedures conducted between the United States and Brazil noted a feasible future for telesurgery. In two cases of telepresence surgery, a U.S. surgeon directed a robot attached to a laparascope in a bilateral variococelectomy, and the other robot was used for needle placement in a percutaneous nephrolithotomy (Rorigues, Mitre, Lima, & Fugita, 2003).

However, there are barriers to implementing this technology, the language divide, for one. One would assume the physicians in this example corresponded in English, but it cannot always be assumed that that will be feasible. Additionally, the cost of higher bandwidth communication lines is still expensive, which makes it difficult for such technology to access foreign countries (Lee, &

Png, 2000). The financial emphasis on healthcare is truly an overpowering barrier, which explains why the success of telehealth relies on the private sector. It seems that an established relationship with a university that is willing to do research and provide resources, as well as a partnership with several private healthcare organizations to incorporate, is key to establishing a successful telehealth program. Not only is a structural foundation necessary, but a substantial need for such an innovation is also required. The success of the UltraClinics telehealth solution to mammogram screening was due to the yearly demand of over 48 million mammograms and the one million additional that require biopsy (Weinstein, et al., 2007). As of now, though there are crowded emergency rooms and stymied appointment schedules in the U.S. and UK, the demand is not overpowering, thus, there has been no push for the combination of medical tourism and telesurgery.

Beyond financial barriers it seems that in the future, when demand as well as technology has increased, this may be a strong asset to the growing medical tourism market. Telesurgey supplements both problems of communication and postoperative care. Comprehensive hospital information systems, such as the system implemented at the U.S. Veterans' Affairs institutions, have initiated electronic health records. With the correct considerations of patient privacy, the ability to transfer records with such technological ease will improve communication and understanding across country borders. Based on the UltraClinics example, increased use of technology can keep the patient more informed, accelerate their care, and allow more time for the physician to care pre- and postoperatively (Weinstein, et al., 2007). There are more benefits than detriments to the globalization of healthcare, but it will require a more cooperative attitude toward sharing advances in research, techniques, and technologies.

CONCLUSION

Medical tourism will most likely continue to grow in popularity. Though it is negative propaganda for the arguably outrageous cost of healthcare in the U.S., it is helping to ease some strain on the American system. Essentially, American physicians are keeping most of the patients that can afford the procedure, losing middle-income patients that opt to save money abroad, but still have the burden of the low-income population that cannot afford the less-expensive option. This seems to prove that the medical environment in the U.S. is now driven by money rather than the desire to provide quality care to each patient. However, the money lost (see Table 8.1) to foreign markets seems to have little effect on the U.S. healthcare market. As long as there are overcrowded emergency rooms and the need to schedule doctor's visits months in advance, like the UK, the U.S. will probably consider this new trend to be beneficial. The fact that the market in India has a 30% consumer increase yearly is significant, but not enough to severely damage the American market in the near future. If we do come to a breaking point where benefit becomes burden, the U.S. healthcare system would be forced

Table 8.1. (Chart: U.S. Senate, 2005)

Procedure	**U.S. Cost (appr)**	**Indian Cost**	**Airfare (appr)**	**Money Saved**
Heart Bypass	$70,000	$6,000	$2,000	$62,000
Angioplasty	$41,000	$6,000	$2,000	$33,000
Hip Replacement	$37,000	$5,000	$2,000	$30,000
Spinal Fusion	$55,000	$8,000	$2,000	$47,000

to make some changes, such as the compromise of telesurgery, that would attract the middle-class constituency and minimize the outsourcing of medical services.

No major preventative changes have been made as of yet, due mostly to one major barrier; policymakers and government officials cannot agree on the best way to control costs. Some possible solutions would be implementing price controls or strict budgets (Fitzpatrick, 2004), although it may be time to consider a system that provides healthcare to every American citizen. With millions of uninsured citizens, people will avoid seeking care until it is necessary. The U.S. still spends more on healthcare than any other industrialized nation. As with many shifts toward outsourcing, the need for change originated in the home country, which led to the need to seek out supplementation, not substitution, in foreign markets.

FUTURE RESEARCH

There is still much to be determined about the future of medical tourism and economic solutions to healthcare, domestically. Though price difference and the savings to be had abroad are well advertised, there are few documented patient experiences. It would be beneficial, both for prospective patients and providers, to have a well-rounded description of the medical tourism industry. Inclusive in such a description should be what drove each patient to seek care abroad, their experience throughout the process, whether they benefited overall from the savings and what recommendations they would give to prospective patients. Such documentation should also include reasoning behind choosing the country in which care was given, it seems that regional specificity may emerge along with this growing trend (i.e., for cardiac surgery one would seek care in Mexico, while facilities in India would specialize in dentistry). Realistically, it would be to the advantage of foreign providers to specify their fields of care, in the effort to heighten the quality of care that they can provide. Though this may reduce some of the competition in the market, it will increase the appeal to American consumers who are wary about the quality of care provided abroad.

Telesurgery, an innovative technology that may prove to be a solution to several problems, has already been successful in a few operations. However, there will have to be a great deal more data collected to ensure the usefulness of this innovation. Additionally, the cost of such a procedure would have to be reduced before it would be willingly adopted into the market. Overall, since this market is still in its fledgling stages, there is little data from which concrete conclusions can be made, making further research essential to future progress.

Chapter 8.11
Towards Cognitive Machines:
Multiscale Measures and Analysis

Witold Kinsner
University of Manitoba, Canada

ABSTRACT

Numerous attempts are being made to develop machines that could act not only autonomously, but also in an increasingly intelligent and cognitive manner. Such cognitive machines ought to be aware of their environments, which include not only other machines, but also human beings. Such machines ought to understand the meaning of information in more human-like ways by grounding knowledge in the physical world and in the machines' own goals. The motivation for developing such machines range from self-evidenced practical reasons such as the expense of computer maintenance, to wearable computing in health care, and gaining a better understanding of the cognitive capabilities of the human brain. To achieve such an ambitious goal requires solutions to many problems, ranging from human perception, attention, concept creation, cognition, consciousness, executive processes guided by emotions and value, and symbiotic conversational human-machine interactions. An important component of this cognitive machine research includes multiscale measures and analysis. This article presents definitions of cognitive machines, representations of processes, as well as their measurements, measures, and analysis. It provides examples from current research, including cognitive radio, cognitive radar, and cognitive monitors.

INTRODUCTION

Computer science and computer engineering have contributed to many shifts in technological and computing paradigms. For example, we have seen shifts (1) from large batch computers to personal and embedded real-time computers, (2) from control-driven microprocessors to data- and demand-driven processors, (3) from uniprocessors to multiple-processors (loosely coupled) and multiprocessors (tightly coupled), (4) from data-path processors to structural processors, for example, neural networks (Bishop, 1995), quantum processors (Nielsen & Chuang, 2000) and biomolecular processors (Sanz, Chrisley & Aaron Sloman, 2003), (5) from silicon-based processors to biochips (Ruaro, Bonifazi, & Torre, 2005), (6) from vacuum tubes to transistors to microelectronics to nanotechnology, (7) from large passive sensors to very small smart active sensors (Soloman, 1999), (8) from local computing to distributed computing and networkwide computing, (9) from traditional videoconferencing to telepresence (e.g., WearTel and EyeTap; Mann, 2002), (10) from machines that require attention (like a palmtop or a wristwatch computer) to those that have a constant online connectivity that drops below the conscious level of awareness of users (like autonomic computers; Ganek & Corbi, 2003; IBM, 2006), and eyeglass-based systems (Haykin & Kosko, 2001; Mann, 2002), (11) from crisp-logic-based computers to fuzzy or neurofuzzy computers (Pedrycz & Gomide, 1998), as well as (12) from control-driven (imperative) systems to cognitive systems such as cognitive radio (Haykin, 2005a), cognitive radar (Haykin, 2006), active audition (Haykin & Chen, 2005), and cognitive robots. These remarkable shifts have been necessitated by the system complexity which now exceeds our ability to maintain them (Ganek & Corbi, 2003), while being facilitated by new developments in technology, intelligent signal processing, and machine learning (Haykin, Principe, Sejnowski, & McWhirter, 2006).

Since the 1950s, philosophers, mathematicians, physicists, cognitive scientists, neuroscientists, computer scientists, and computer engineers have debated the question of what could constitute *digital sentience* (i.e., the ability to feel or perceive in the absence of thought and inner speech), as well as machine consciousness or artificial consciousness (e.g., Cotterill, 1988; Dennett, 1991; Klivington, 1989; Kurzweil, 1990; Rumelhart & McClelland, 1986; Minsky, 1986; Neumann, 1958; Posner, 1989; Searle, 1980; Penrose, 1989, 1994; Searle, 1992). Consequently, many approaches have been developed to modeling consciousness, including biological, neurological, and engineering (practical). The approach to cognition taken in this article is mostly engineering in which the behavior of a system can be observed, measured, characterized, modeled, and implemented as an artifact, such as a cognitive robot (either isolated or societal) to improve its interaction with people, or a cognitive radio to improve the utilization of a precious resource, that is, the frequency spectrum. In general, the intent of such cognitive systems is to improve their performance, to reduce waste in resource utilization, and to provide a testbed for learning about cognition and cognitive processes. If an approach is purely reductionist, it may not be capable of describing the complexities of cognition. Since our engineering approach considers not only the individual components of a system, but also their interactions, it may be capable of describing the dynamics of cognitive processes. Although engineering approaches have serious limitations (e.g., Chalmers, 1997; Parsell, 2005), they are intended to produce a range of specific practical outcomes.

The next section provides a few definitions and models of consciousness, and serves as a preamble for several applications. The article also identifies a few problems with the current status of cognitive machines.

What Is Cognition?

According to the Oxford Dictionary, cognition is "knowing, perceiving, or conceiving as an act." The Encyclopedia of Computer Science (Ralson, Reilly, & Hemmendinger, 2003) provides a computational point of view of cognition consisting of the following three attributes: (1) cognition can be described by *mental states and processes* (MSPs) intervening between input stimuli and output responses, (2) the MSPs can be described by algorithms, and (3) the MSPs should lend themselves to scientific investigations.

Another view of cognition is suggested by Pfeifer and Scheier (1999) as an interdisciplinary study of the general principles of intelligence through a synthetic methodology termed *learning by understanding.*

Cognition also includes language and communications, as studied in different forms (e.g., Fischler & Firschein, 1987; Roy, 2005; Roy &

Pentland, 2002). Although the language and communications of humans and machines differ significantly, their roles are similar. More specifically, Haikonen (2003) defines cognition as the association of auxiliary meanings with percepts, the use of percepts as symbols, the manipulation of these symbols, reasoning, response generation, and language.

COGNITIVE MACHINE MODELS

Haikonen Model

Pentti Haikonen of the cognitive technology at Nokia in Helsinki has advanced the concept of cognitive machines in the context of the mind-body problem. He sees emulation of the cognitive process of the brain through a cognitive architecture (consisting of the flow of perception, inner speech, inner imaginary, and emotions), rather than the classical architecture involving rule-based artificial intelligence and neural networks. His architecture does not involve rule-based computing. To explain the scope of the architecture, Haikonen gives a good illustrative example of five classes of behavioral machines (mobile robots) that have external environmental sensors to monitor the environment, and internal self-sensors to monitor the internal states of the machine itself:

1. *Simple-Reflex Machine.* In response to an obstacle, the robot backs off and turns a little so that it could avoid the obstacle. This behavior is driven by *recognition* (i.e., sensing, characterization, and classification) alone, and its operation requires no memory. Although the robot is "aware" of the obstacle (by detecting it) and responds to it, this behavior is too primitive to call it a conscious act.
2. *Simple-Reflex Machine with Smart Memory.* If memory and some processing capabilities are added, the robot not only can sense the obstacles, but also can record their locations and the responses to each obstacle, and then can compute the "best" path by deleting any loops in the path, using known optimization algorithms. Thus, its "awareness" has been expanded from the encounter with the obstacles to the layout of the maze traversed. However, this behavior is still too simple to call it consciousness.
3. *Machine with Meaningful Perception and Associative Memory.* If an associative memory (Hinton & Anderson, 1981; Kohonen, 1987) is added to the previous robot, the robot cannot only sense, but can also perceive its environment, and can learn from the experiences encountered so far. Furthermore, if a *cost function* is established within the robot (i.e., a function capable of discriminating between a "pain" for dangerous obstacles, and a "pleasure" for useful objects) then the "seen" obstacle can evoke "images" of its past encounters, and a response can be produced even before the actual contact with the object. This *perception* goes beyond recognition in that it is an active process of searching and finding threats and opportunities through evoked "imagery" of the object and associated actions. In a way, such a machine exhibits an *attention* process, seeking "satisfaction," as controlled by a good-bad discrimination criterion and its own needs.
4. *Machine Associative Memory and Reporting.* If representational symbols (words) and a corresponding symbol system in the form of a language (e.g., Chomsky, 2006; Dawkins, 1990) are established within the robot, then the robot not only can exhibit the behavior just described, but also can report (declare) on its perception and actions during and after the perceived events, as well as on its inner self-sensed percepts. The robot can

also associate meaning with the declaration of its peers.

5. *Machine with Self Awareness and a "Mind."* The previous two classes of behavior were based on an "open-loop" control process. If feedback is added to the flow of percepts, then the robot could perceive its own declarations and understand them silently, without the need to act upon them. This would allow the robot to distinguish between the percepts caused by the external environment and those caused internally. The "inner images" could lead to "imagining." If another good-bad criterion could be developed and applied to the "inner images," then the robot could develop a "mental content" or a form of a "mind."

In summary, the Haikonen cognitive machine architecture involves (1) sensory preprocessing circuits to derive representations of the sensed external events, (2) introspective feedback loops that discriminate between the external representations, and broadcast the outcomes to other loops, (3) associative cross-coupling of those loops, and (4) attention control through adaptive thresholding.

Such a machine requires: (1) distributed signal representations, (2) associative processing and learning, (3) perception processes, (4) sensory attention and inner attention, (5) the flow of inner "speech" and "imagery," as well as (6) evaluation of the significance (relevance) of reasoning, motivation, and action. Thus, consciousness might emerge spontaneously in such a complex system. A demonstration of a low-complexity system exhibited emotions, but not consciousness (Haikonen, 2004).

Similar emergent consciousness in autonomous agents is described by Freeman (2001) and Cotterill (2003). Both approaches are consistent with Grossberg's view of the mind and brain in which new states are being synthesized continuously to form a better adaptive relationship with the environment (Grossberg, 1982) and with Grossberg's adaptive resonance theory (ART) (Grossberg, 1988), as well as with the dynamic system approach to consciousness and action (Thelen & Smith, 2002).

A major criticism of Haikonen's model is that there is no systematic approach to measuring the basic system reactions or emotions or perception of time (Parsell, 2005). This article addresses a part of this problem.

Franklin's Model

Functional consciousness of an autonomous agent (in the form of an intelligent distribution agent, IDA) was described by Stan Franklin from the Conscious Software Research Group at the University of Memphis (Franklin, 1995, 2003). An IDA can exhibit several functions of consciousness as elicited by Bernard Baars under his *global workspace theory* (Baars, 1988). An implementation of the concept includes a system to communicate with U.S. Navy sailors in a natural language.

Aleksander's WISARD and MAGNUS

Igor Aleksander of the Neural Systems Engineering group at the Department of Electrical and Electronic Engineering at the Imperial College of Science, Technology and Medicine in London has an extensive background in neurocomputing, including parsimonious neural networks (Aleksander, 1989). He has been working on a neural pattern recognition system called WISARD (Aleksander, 1998) and a neural representation modeler called MAGNUS (Aleksander, 1998, 2003) and the artificial neural consciousness system (Aleksander, 2003, 2006). His model adds the ability to predict (anticipate) foreseeable events. Aleksander considers *prediction* as the key feature of consciousness.

Taylor's CODAM Model

John Taylor of the Department of Mathematics at King's College in London has developed many models of perception and consciousness, with focus on attention as the prerequisite for consciousness. His thesis is that the application of engineering control theory to attention could show how consciousness is created. This view is motivated by his extensive knowledge of experimental data of visual illusions, memory, attention, and motor control through a number of imaging techniques. One of the techniques is the *magnetoencephalography* (MEG), capable of detecting the very small (femtoTesla) magnetic fields generated by the brain. MEG produces a fine temporal resolution (milliseconds), but poor spatial resolution (millimetres). The problem of spatial resolution can be resolved by the functional *magnetic resonance imaging* (fMRI) and *positron emission tomography* (PET) whose temporal resolution is poor (tens of seconds), but spatial resolution is very good. His studies identified the parietal lobe as an important brain region in the creation of biological consciousness. This has lead to the development of the *corollary discharge of attention movement* (CODAM) model (Taylor, 2001, 2002, 2003). This model has been used to study mental diseases such as schizophrenia and autism.

Over 15 other models amenable for implementations have been described at a Workshop on Models of Consciousness (Sanz et al., 2003). A brief review of the state of cognitive systems engineering is presented in Hoffman, Klein, and Laughry (2002).

EXAMPLES OF COGNITIVE SYSTEMS

The models described in the previous sections are designed to provide insight into the development of cognition and consciousness. Practical applications may not require the complexities involved. To this end, Simon Haykin of the Adaptive Systems Laboratory at McMaster University in Hamilton has defined (Haykin, 2005b) a cognitive machine as an intelligent system that (1) is aware of its surrounding environment (i.e., outside world), (2) uses understanding-by-building to learn through interactions with the environment and other means, and (3) adapts its internal states to statistical variations in input stimuli by making corresponding changes in adjustable system parameters in real-time with specific objectives (e.g., reliability, efficiency, active sensing) as determined by the application of interest. The essential attributes of such a machine includes awareness, intelligence, learning, adaptivity with temporal and structural reconfigurability, action, and real-time operation. This characterization of cognitive machines is mostly behavioral, and leads to systems realizable with today's technologies.

Cognitive Radio

The electromagnetic radio spectrum can be considered a precious natural resource that should be utilized efficiently. Some frequency bands are used heavily, while others are underutilized. The utilization of the bands also changes with location and time. By being aware of the actual utilization of the bands, and by dynamic spectrum management (i.e., through frequency allocation and adjustment of the transmitted power), this resource could be used more efficiently.

Cognitive radio based on the software-defined radio (Dillinger, Madani & Alonistioti, 2003) can achieve this goal. A comprehensive description of such a cognitive radio system is provided by Haykin (2005a).

Cognitive Radar

Similar to cognitive radio, cognitive radar is aware of its environment, utilizes intelligent signal processing, provides feedback from the receiver to the transmitter for adaptive illumination based on the range and velocity, and preserves the information contents of radar returns. A network of such systems can also be set up to collaborate with one another as multifunction radars and noncoherent radars. A description of such a system is provided by Haykin (2006).

Active Audition

Active audition involves sound localization, segregation of the target source from interference, tracking of the source, and learning from the experience to adapt to the changing environment (Haykin & Chen, 2005). This problem has many applications, including improved devices for hearing-impaired persons.

Meaning Machines and Affective Computing

Deb Roy of the Cognitive Machines Group at the MIT Media Laboratory has been focusing on human-machine language development for conversational robots (Roy, 2005). Others from that group have been developing machine recognition of affective (emotional) states and their synthesis in order to accelerate and improve learning of individuals (Kort & Reilly, 2002).

Autonomic Computing Systems

Autonomic computing (AC) is a scaled-down form of cognitive machines (Ganek & Corbi, 2003; IBM, 2006; Kinsner, 2005a; Wang, 2003, 2004, 2006). The systems are evolving earnestly because the cost-performance of hardware improvements (speed and capacity) has lead to escalating complexity of software (features and interfaces). However, this increased complexity requires elaborate managing systems that are now six to ten times the cost of the equipment itself. Autonomic computing is intended to simplify this problem by making the systems self-configuring, self-optimizing, self-organizing, self-healing, self-protecting, and self-telecommunicating, thus leading to increased reliability, robustness, and dynamic flexibility. This involves not only the traditional fault tolerant computing (i.e., tolerating hardware and software faults), but also tolerating various faults made by human operators and users, thus shifting attention from the *mean-time-between failures* (MTBF) to the *mean-time-to-recover* (MTTR) in order to make the systems more available. AC applies to desktop computing, portable computing, pervasive computing, and embedded systems.

Other Projects

Sandia Laboratories have been developing several projects related to cognitive machines, including human emulation, augmented cognition, knowledge capture, episodic memory, and naturalistic decision making. UCLA Cognitive Systems Laboratory has been involved in several projects, including evidential reasoning, default reasoning, learning, constraint processing, and graphoids (UCLA, 2006). James Anderson of the Department of Cognitive and Linguistic Sciences at Brown University in Providence has been developing the Ersatz brain project (Anderson, 2002, 2005), among many other neurocomputing projects.

PROCESSING AND METRICS

What do the theoretical models and practical implementations of cognitive machines have in common? The key distinguishing features include (1) intelligent signal processing that is robust and embedded in the machine itself, (2) real-time learning prompted by the awareness of the external and internal environments, and interaction with both, (3) closed-loop feedback control systems engineering so that past experiences could be used in the future, and (4) state and quality metrics to discern between the desirable and undesirable actions.

Intelligent Signal Processing

From the perspective of applied and industrial mathematics, a signal is an electrical representation of various ubiquitous, quantifiable physical variables such as temperature, pressure, flow, and light intensity. Such signals can be analog (continuous with very high resolution), discrete (sampled, but with very high resolution), digital (sampled and quantized to a finite resolution), boxcar (step-wise analog) functions over time (e.g., speech), space (e.g., images), or both (e.g., volumetric Doppler radar). The digital signals are of particular importance to computer-based signal processing which deals with the modeling, analysis/synthesis, feature extraction, and classification of such signals in order to gain insight into the underlying physical process, or to perform specific control tasks with the process.

Signal processing is used in nearly all fields of human endeavor from signal detection in the presence of noise, to fault diagnosis, advanced control, audio and image processing (restoration, enhancement, segmentation, reconstruction, coding, compression), communications engineering, intelligent sensor systems with reconfigurable architectures, business, and *humanistic intelligence* (HI) (Haykin & Kosko, 2001) which utilizes the natural capabilities of the human body and mind, as well as *cognitive informatics* (CI) (Wang, 2002) .

Intelligent signal processing (ISP) is treated in literature very thoroughly (e.g., Haykin & Kosko, 2001). Since many real-world physical systems are time varying, complex (high-dimensional), nonlinear, statistically nonstationary, non-Gaussian, nonlocal, sometimes chaotic, and subjected to unwanted signals (noise), the classical *statistical signal processing* (SSP) (e.g., Oppenheim, Schafer & Buck, 1999; Proakis & Manolakis, 1995) must be augmented by ISP and CI because of the required autonomy and interaction with humans. ISP has been found to be a more useful approach as it employs adaptation and learning to extract the essential information from the acquired signals and noise, without any assumed statistical models of the signals or theirs sources. These signals no longer exhibit additive invariance (short-range dependence), but multiplicative invariance (self-affinity with long-range dependence). The ISP tools include supervised and unsupervised learning through adaptive neural networks (Bishop, 1995), wavelets and their variations (Mallat, 1998), fuzzy rule-based computation (Pedrycz & Gomide, 1998), rough sets (Pawlak, 1991), granular computing (Bargiela & Pedrycz, 2002), genetic algorithms and evolutionary computation (Goldberg, 2002), and blind signal estimation (Haykin & Kosko, 2001). Algorithms for ISP must be implemented to satisfy the B-robustness property (Gadhok & Kinsner, 2006) because of higher-order statistics involved.

CI is concerned with (1) the extraction of characteristic features from signals obtained from measurements and observations, and (2) the measurement and characterization of patterns (i.e., order and correlation) in processes related to perception and cognition (i.e., interaction with humans).

Signals obtained from physical dynamical processes appear to be very complex. Much attention has been given to deterministic and stochastic linear-time-invariant (LTI) signals with a limited-bandwidth power spectrum density and short-tail distributions, leading to processing with finite moments. However, many physical signals are fundamentally different from the LTI signals in that they are invariant to scale rather than to translation (Wornell, 1996). Such signals have different degrees of singularity as measured by their noninteger (fractal) dimensions (Kinsner, 2005b). Correlation in such signals persists from short to very long ranges, with distributions having long tails (infinite moments). In contrast to the well-established LTI system theory, the nonlinear scale invariant (NSI) system theory and applications are still developing. There is also another class of signals, the chaotic signals, originating from nonlinear dynamical systems, such as the AC systems (Kantz & Schreiber, 2004; Principe, Euliano & Lefebvre, 2000; Sprott, 2003). Research is being conducted to measure and characterize such systems.

Real-Time Learning

Real-time learning may not be achievable due to the curse of dimensionality. A partial solution to this problem seems to be forthcoming through approximate dynamic programming (de Farias, 2002; de Farias & Van Roy, 2003, 2004; Haykin, 2005b). This approach is based on Bellman's dynamic programming, and it can be used as an optimal policy to guide the interaction of the learning system with its environment. Other approaches include neurofuzzy (Pedrycz & Gomide, 1998), granular (Bargiela & Pedrycz, 2002), and evolutionary computing (Goldberg, 2002).

Control With Feedback

This component can be implemented in many different ways, from classical control system to neurofuzzy (Pedrycz & Gomide, 1998).

Metrics

Cognitive systems cannot operate without some specific good-bad discriminating criteria, which, in turn, require metrics. Such metrics are being developed (e.g., Kinsner & Dansereau, 2006). The classical energy-based metrics (such as the scalar peak signal-to-noise ratio, PSNR) must be augmented by vectorial information-based or entropy-based metrics, such as the Rényi entropy spectrum, the Rényi fractal dimension spectrum (Kinsner, 2005b), or the *relative* Rényi fractal dimension spectrum (Kinsner & Dansereau, 2006). The latter can also be used for subjective quality metrics to evaluate images and video.

CONCLUDING REMARKS

Intelligent signal processing, real-time machine learning, and cognitive informatics are essential in solving some design and implementation issues of cognitive machines. Although the examples of cognitive radio, cognitive radar, active audition, cognitive robotics, and autonomic computing indicate that such cognitive systems are now feasible, much work must be conducted in all the areas to make the ambitious goals of such systems more practicable. Particular attention must be given to metrics and cognitive informatics.

ACKNOWLEDGMENT

Partial financial support of this work from the Natural Sciences and Engineering Research Council (NSERC) of Canada is gratefully acknowledged.

Chapter 8.12
Biotechnology Portals in Medicine

Yoosuf Cader
Zayed University, UAE

INTRODUCTION

The 2005 global revenues of publicly traded biotechnology companies have grown by 18.1% to $63.1 billion (Donn, 2006). Many countries are now investing in research and development in the biotechnology industry as it is believed this 30 year-old industry is moving toward profitability. The stock value in this industry has outperformed the average stock value in many countries. In the pre-genomic era, a typical life sciences company would have marketed diagnostic kits, assays, chemicals, measuring equipment, and research products to name a few. In the genomic era, a new range of products is marketed focusing on molecular medicine. Among these new products are bioinformatics software solutions, storage systems, biotechnology systems, and solutions researching into genes and proteins, tools for analysis of genetic sequence data, integrated systems and solutions for disease research, and new drug discovery (Cader, 2004). The need for biotechnology portals is now more than justified and will be a useful information and knowledge source.

A biotechnology portal is a gateway of comprehensive source of information and knowledge to those interested in knowing about biotechnology and the benefits this industry is offering. It should be considered as the first point of reference for those seeking reliable, quality, and current information and knowledge about issues in biotechnology. In addition, it should be interactive and have the appropriate tools to enable a community of users to share information and knowledge among them. There should also be a commercial component to the biotechnology portal, which should be to generate revenue through advertisements and offers to its target visitors. This revenue is essential to ensure the maintenance and survival of the portal and offer value to all its stakeholders. A biotechnology portal will not be complete unless it provides information on biotechnology stocks to potential investors seeking insights into this industry. A biotechnology portal is like any online business with various objectives such as profits, growth, market share, and innovation.

BIOTECHNOLOGY IN MEDICINE

This article will concentrate on biotechnology in medicine although the benefits of biotechnology have influenced other disciplinary areas such as agriculture and environmental sciences. In medicine, hundreds of biotechnology drug products and vaccines are currently in human clinical trials in advanced countries with many more in the new product development stage.

Linking to Web Sites

A good starting point is to link up with the site http://www.ornl.gov/hgmis/ sponsored by the U.S. Department of Energy Office of Science, Office of Biological and Environmental Research, Human Genome Program. This site gives information on the Human Genome Project (HGP), news and announcements, planned user facilities, educational resources, research progress, impacts of research, GTL documents (potential microbial documents), science, technologies behind GTL, Gene Gateway (tools for exploring the sequence), and related department of energy sites. There are also links to related sites.

The biotechnology portal should also link up to an excellent Web site, which makes available several DNA and Gene images (http://www.ornl.gov/hgmis/graphics/slides/images1.html) in an image gallery.

The Wellcome Foundation in the UK (http://genome.wellcome.ac.uk/) gives the latest news, features, and background, and a lot of information about the human genome—exploring genes and its impact on health, disease, and society. The Wellcome foundation is also the primary funding source for the Sanger Institute at Cambridge University (http://www.sanger.ac.uk/). The Sanger Institute is a genome research institute whose aim is to further the knowledge of genomes, particularly through large scale sequencing and analysis.

Another interesting site in the UK that should be included is http://www.geneservice.co.uk/. Geneservice Limited is a contract research organisation and biological resource centre, which supplies genomic products and technical services to both academic and commercial research organisations. These services include whole genome amplification, DNA sequencing, micro-satellite, and SNP genotyping including 10K and 100K mapping, and expression array analysis.

An interesting European Web site is http://www.litbio.org/. This is a Laboratory for Interdisciplinary Technologies in Bioinformatics (LITBIO) applied to genomics, transcriptomics, proteomics, and metabolomics providing international research and development programs with the new analysis strategies of biomedical and biotechnological data. The laboratory consists of five collaborating partners whose links are listed as follows:

- CILEA (http://www.litbio.org/cilea.htm)
- CNR/IEIIT (http://www.litbio.org/ieiit.htm)
- Universita' degli Studi di CAMERINO (http://www.litbio.org/camerino.htm)
- Universita' degli Studi di GENOVA (http://www.litbio.org/genova.htm
- Eurotech S.p.A. (http://www.litbio.org/eurotech.htm

Another interesting link is to this Japanese Web site http://www.genome.ad.jp/kegg/. The Kyoto Encyclopaedia of Genes and Genomes (KEGG) is a bioinformatics resource developed by the Kanehisa Laboratories in the Bioinformatics Center of Koyoto University and the Human Genome Center of the University of Tokyo. They are working toward representing a complete computer representation of the cell, the organism, and the biosphere. This will enable computational prediction of higher-level complexity of cellular processes and organism behaviours from genomic and molecular information.

The biotechnology portal should also be linked to other informative Web sites in other countries including the Australian Web sites.

This Web site (http://www.csiro.au/pub-genesite/index.htm) explains what Australian scientists are doing in the area of biotechnology research. For information about gene technology, policy, and regulations, there should be a link to biotechnology Australia's gateway site at www.biotechnology.gov.au. Another useful link should be to the Victorian government biotechnology Web site. This Web site offers an overview of biotechnology in Victoria and links to industry sectors and biotechnology centres. It also includes the biotechnology strategic development plan for Victoria.

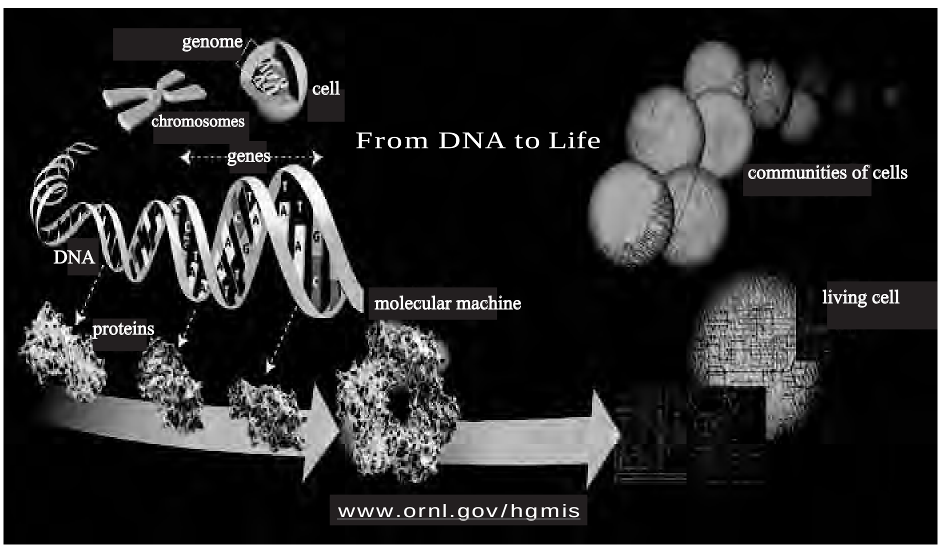
This Web site (http://www.business.vic.gov.au/BUSVIC.458954/INDUSTRY/1226260600/PC_60362.html) offers an overview of biotechnology in Victoria and links to industry sectors and biotechnology centres. It also includes the biotechnology strategic development plan for Victoria. Another useful link would be to http://www.ausbiotech.org. Ausbiotech is the industry body representing the Australian biotechnology sector.

The molecular biology database collection is a public online resource listing key databases. The online version of this journal (Nucleic Acids Research) article has been published under an open access model (Galprin, 2006). The biotechnology portal must definitely be linked to this up-to-date database, which is intended to serve as the initial point from which to find specialised databases that may be of use in biological research. This database includes 858 updates in the 2006 version. It includes major public sequence repositories, gene expression, gene identification and structure, genetic and physical maps, genomic databases, intermolecular interactions, metabolic pathways and cellular regulations, mutation databases, pathology, protein databases, protein sequence motifs, proteome resources, retrieval systems and database structure, and varied biomedical content.

Icelandic's "Decode Genetics"

This is an Icelandic biopharmaceutical company. Its Web site (http://www.decode.com/) shows the type of work it does. The nature of work became

Figure 1. Courtesy of the U.S. Department of Energy Human Genome Program



of much interest worldwide because the company started developing a genealogical database. When the information from this database is combined with health care data (diagnosis, treatment, prognosis, measurement of values in blood, etc.) it will help identify genes linked to certain diseases. The concept is to look at the community as a system of data that can be mined for knowledge.

UK Biomedical Population Collection

A similar study in the UK called "*UK Biomedical Population Collection*" was established between the Wellcome Trust, the Medical Research Council, and the Department of Health, which looks at the interaction between lifestyle, environment, and genetic makeup that causes diseases. This project will collect key medical and lifestyle information from participants between the ages of 45 and 64 over a period of at least 10 years. The Web site associated with this study should also be linked to the biotechnology portal. Further details can be seen in http://www.phgu.org.uk /ecard?reference_ID=2688.

Stem Cells, Embryonic Stem Cells, Embryonic Stem Cell Line, Somatic Stem Cells

The National Health Institute Web site is a useful resource for all one wants to know about stem cells and the ensuing debate about stem cells research (http://stemcells.nih.gov/info/glossary.asp).

Apart from the previous National Health Institute (U.S.) Web site, another useful Web site to which the biotechnology portal should be linked is the National Human Genome Research Institute Web site (http://www.genome.gov/10004765). According to this Web site, the term "cloning" is used by scientists to describe many different processes that involve making duplicates of biological material. In most cases, isolated genes or cells are duplicated for scientific study and no new animal results. The experiment that led to the cloning of Dolly the sheep in 1997 was different. It used a cloning technique called *somatic cell nuclear transfer* and resulted in an animal that was a genetic twin—although delayed in time—of an adult sheep. This technique can also be used to produce an embryo from which cells called *embryonic stem* (ES) *cells* could be extracted to use in research into potential therapies for a wide variety of diseases. This Web site also discusses ethical concerns, policy and regulation, and cloning for the isolation of Human ES Cells.

Content of the Biotechnology Portal

A good biotechnology portal should be innovative and interactive rather than just be a source of information. The design should be creative and welcoming to the browser. The content should offer quality material, which is regularly updated. The technology should enable the portal to be user friendly and fast.

CONCLUSION

Mentioned above are only some of the possible links to the portals and Web sites of the numerous genomic and medical Web sites originating in almost every country. Eventually a good biotechnology portal will be a gateway to most of these Web sites. The portal should be linked to all the biotechnology *hotspots* in the world. The *hotspots* refer to biotechnology research centers and institutes involved in biotechnology research and development activities.

There are numerous other Web sites of private companies that should be liked to the biotechnology portal but they are too numerous to be mentioned here.

Agricultural and environmental aspects of biotechnology are also important components of a biotechnology portal. Other aspects are an executive search section for biotechnologists and links to online publications such as "nature," "science," "today's life science" etc., to name a few of the many academic journals in biotechnology. For a biotechnology portal to be viable, it needs to offer advertising space for a fee for companies wanting to market related products and knowledge sources.

KEY TERMS

Bioinformatics: A new and exciting field, which developed due to the power of super computers enabling faster processing and storage of terabyte levels of data, using computer software tools in storing, organising, and computationally analysing biological information.

Biotechnology: It is the application of knowledge based on cellular and molecular processes of living organisms and its ability to act as molecular machines to make new proteins with the potential to become new drugs; to develop new industrial processes and new genetically modified high yielding crops. There is also a convergence of rapid advances in information technology with the rapidly growing knowledge of the cellular and molecular processes resulting in the new opportunities.

Biotechnology Portal: It is a gateway of a comprehensive source of information and knowledge to those interested in knowing about biotechnology and the benefits this industry is offering. It should be considered as the first point of reference for those seeking reliable, quality, and current information and knowledge about issues in biotechnology.

Chromosomes: The DNA molecule containing a cell's genome. These strands of DNA form the 23 pairs of chromosomes inside the cell nucleus with approximately 3 billion DNA sub units or chemical base pairs called nucleic acids, denoted by the letters A, T, G, and C. Each pair of nucleic acid is called a base pair. These are like rungs on a spiralling staircase.

Cloning: The term cloning is used by scientists to describe many different processes that involve making duplicates of biological material. In most cases, isolated genes or cells are duplicated for scientific study, and no new animal results (http://www.genome.gov/10004765)

DNA: Deoxyribonucleic acid (see Nucleic acids) is known as the molecule of life.

Drug Discovery: The process involved in discovering new drugs.

Embryonic Stem Cells: Primitive (undifferentiated) cells derived from a 5-day preimplantation embryo that have the potential to become a wide variety of specialized cell types (http://stemcells.nih.gov/info/glossary.asp)

Embryonic Stem Cell Line: Embryonic stem cells, which have been cultured under *in vitro* conditions that allow proliferation without differentiation for months to years (http://stemcells.nih.gov/info/glossary.asp)

Gene: A specific sequence of nucleotides in DNA (deoxyribonucleic acid) or RNA (Ribonucleic acid). There are 26,261 genes distributed along the 23 pairs of chromosomes in humans. Each gene contains a particular set of information coding for a particular protein in a cell.

Genome: The sum total of an organism's genetic material.

Nucleic Acids: There are approximately 3 billion DNA sub units or chemical base pairs, called nucleic acids in the human genome, denoted by the letters A, T, G, and C. Each pair of nucleic acid is called a base pair. These are like rungs on a spiralling staircase.

Pharmacogenomics: Field that uses information about an individual's genetic makeup to maximize the efficacy of treatments, while at the same time minimizing the unwanted side effects (Krane & Raymer, 2003).

RNA: Ribonucleic acid (see Nucleic acids).

Somatic Stem Cells: Non-embryonic stem cells that are not derived from gametes (egg or sperm cells) (http://stemcells.nih.gov/info/glossary.asp)

Stem Cells: Cells with the ability to divide for indefinite periods in culture and to give rise to specialized cells (http://stemcells.nih.gov/info/glossary.asp).

Georgia State University, USA

ABSTRACT

This chapter introduces the decision fusion as a means of exploring information from distributed medical data. It proposes a new method of applying soft data fusion algorithm on the grid to analyze massive data and discover meaningful and valuable information. It could potentially help to better understand and process medical data and provide high-quality services in patient diagnosis and treatment. It allows incorporation of multiple physicians into one single case to recover and resolve problems, and integration of distributed data sources overcome some limitations of geographical locations to share knowledge and experience based on the soft data and decision fusion approach.

INTRODUCTION

Healthcare service is a complex industry nowadays. It is one of the most critical components of the modern human-oriented service. Informatics is an essential technology to health care (Dick & Steen, 1991) and has been applied to this field as long as computers have existed. Information technology can be one of the major drivers of e-health activity, both directly and indirectly. E-health offers new opportunities to further improve the quality and safety of services because technology makes possible the high level of information management. However, it raises an important issue of how to utilize and integrate an impressive amount of medical data efficiently to provide high-quality and safe services.

Grid computing has emerged to address this issue. It was first developed in the scientific community and can be used as effective infrastructures for distributed high-performance computing and data processing (Foster, Kesselman, & Tuecke, 2001). The features of grid computing make the designation of an advance decision support system possible.

How to apply data fusion in a distributed medical decision system on the grid is still an open problem. In our previous research on this subject, the following observations were made that should guide our further work:

1. Massive data are collected in different organizations. With an explosion in size of database, discovering meaningful and valuable information from different datasets on grids is still a critical issue that affects decision-making in this area. There is an urgent need for a new computation technique to help service providers to process, analyze, and extract meaningful information from the rapid growing data.
2. The need for efficient, effective, and secure communication between multiple service providers for sharing clinical knowledge and experience is increasing. Traditional techniques are infeasible for analyzing large datasets that may maintain over geographically distributed sites.
3. The need for finding an efficient way to integrate data, knowledge, and decision from different parties is increasing.

These first two observations suggest an answer: build a grid-based system that enables the sharing of application and data in an open, heterogeneous environment. The last observation suggests an answer to build a soft fusion mechanism to do summarization, and it may result in higher accuracy of diagnosis and better treatment.

RELATED WORK

There are several research groups whose work can contribute to grid-based data fusion on e-health. We first discuss decision support on the grid in the grid community, then we will introduce some related works about the medical decision support from the health community, and finally we will present some related works about soft data fusion and our proposal for solving this problem.

Decision Support on the Grid

A decision support system is defined as any computer program that assists decision-makers to utilize data and models to solve problems (Gorry & Morton, 1971; Keen & Morton, 1978; Sprague & Calson, 1980). Usually, it requires access to vast computation resources and processes a very large amount of data to make a decision. Grid computing is one approach to solving this problem. It has emerged as a paradigm with the ability to provide secure, reliable, and scaleable high-speed access to a distributed data resource. Compared to traditional distributed techniques, it has many advantages like resource sharing, high-performance services. The grid offers significant capability for designation and operation of complex decision support system by linking together a number of geographically distributed computers (Ong et al., 2004).

A grid-based decision support system can be used in a broad range of problems, from business to utilities, industry, earth science, health care, education and so on. Most researchers focus on simulation and visualization for specific processes such as air pollution (Mourino, Martin, Gonzalez, & Doallo, 2004), flooding crisis (Hluchy et al., 2004; Benkner, et al., 2003), and surgical procedures (Narayan, Corcoran-Perry, Drew, Hoyman, & Lewis, 2003; CrossGrid project) and then support decision-makers to make decisions on the basis of simulation results.

Medical Decision Support

The term medical decision support system describes a set of computer applications that are designed to assist health service providers in clinical decision-making. It can provide assessment or specifics that are selected from the knowledge base on the basis of individual patient characteristics (Hunt, Haynes, Hanna, & Smith, 1998; Delaney, Fitzmaurice, Riaz, & Hobbs, 1999). It is typically designed to integrate a medical knowledge base, patient data, and an application to produce case-specific advice.

The decision support system has been used in health care since the 1960s. There is evidence that using a medical decision support system may increase compliance with clinical pathways and guidelines and reduce rates of inappropriate diagnostic tests (Australia's Health Sector). It can support increased use of evidence by clinicians in direct patient care, resulting in better patient outcomes. However, the use of computerized medical decision systems is not commonplace. The results achieved have been rather low and the progress is slow (Reisman, 1996). Two identified barriers are lack of sources of knowledge and system development (Shortliffe, 1986), and lack of communication among profusion of different systems (Hobbs, Delaney, Carson, & Kenkre, 1996). As many researchers say, there is a rapidly growing need to improve medical decision-making in order to reduce practice variation, preventable medical errors (Poses, Cebul, & Wigton, 1995; Bornstein & Emier, 2001; Sintchenko & Coiera, 2003) and become feasible in the real world.

Soft Data Fusion

Data fusion is the amalgamation of information from multiple sources. It can be classified as either hard fusion and soft fusion.

All data fusion efforts are initiated to be used in particular research areas. It is still a "wide open field based on the difference in technology, the expectations by the users, and the kinds of problems that biologists and life scientists try to solve" (Freytag, Etzold, Goble, Schward, & Apweiler, 2003). Fusion system application can be found in the domain of hydrological forecasting (Abrahart & See, 2002), health care and medical diagnose (Laskey & Mahoney, 2003), and engineering (Chow, Zhu, Fischl, & Kam, 1993).

There are different approaches in the literature to fuse data. Some approaches use statistical analysis, while others use AI techniques like fuzzy logic (Chen & Luo, 1993), learning algorithms based on neural networks (Myers, Laskey, & DeJong, 1999), and Bayesian networks or uncertainty sets (Singhal & Brown, 1997) to handle the uncertainty.

RESEARCH PROBLEM

In the healthcare industry, many organizations that could be located in different places collect data. In the traditional way, data is fragmented, and it is inconvenient for service providers to share experience and knowledge. Physicians would change medical decisions if they had enough "knowledge." Assume that they may collaborate under some agreements on some concerned problems. The following are some typical scenarios of example processes in e-health:

- Health service providers collaborate on the analysis of newly discovered disease or pathogenic bacteria.
- Health service providers collaborate on the estimate of the patient's state and providing appropriate treatments.
- Health service providers share the experience and knowledge with others.
- Health service providers get the support from others to make decisions for uncertain cases.

In these scenarios, collaboration across geographical location is needed to enable the sharing of data and knowledge and then make a decision. Greater benefits can be achieved if data integration is used rather than simply data collection

(Sensmeier, 2003). Our research problems can be described as the following:

- **Quality of the medical decision.** Liability and reliability are two main issues of the medical decision system. Decision support tools must be carefully designed so that they are reliable and accurate (Sloane, Liberatore, & Nydick, 2002). How does one utilize grid computing to perform the data process? How does one use grid-based distributed data mining to discover knowledge? How does one make use of massive distributed data to improve the quality of service?
- **Collaboration.** How do the different parties collaborate with each other? How can we get data about patients and transmission through the Internet? Can data be integrated in different levels? How does one integrate the data, information, knowledge, and decisions from different organizations?

The following are our goals:

- **For service providers.** Share knowledge and experience to make high QoS decisions and choose the optimal treatment for the individual patient.
- **For patients.** Get better medical care that includes more accurate diagnosis results and better treatments.

RESEARCH PLAN

In order to achieve all the requirements to make a system available, we need to integrate the network with multiple health service providers and patients. Grid computing allows flexible, secure, coordinated resource sharing among dynamic collections of individuals, institutions, and resources; it can be used as effective infrastructures for distributed high-performance computing and data processing (Foster, Kesselman, & Tuecke, 2001). The grid-based system of logical architecture is presented in Figure 1.

Figure 1 shows the logical architecture diagram of the system. The computers with service provider applications are the nodes of the grid. Health service providers communicate, exchange data, and share experience and knowledge through the grid service. Computers on the grid can be desktop, laptop, pocket PC, cell phone, and so on. Users of this system can be doctors, specialists, and assistants. They — users and computers — can communicate with each other through standard or wireless Internet. The typical data workflow is described in the following scenarios:

- Data of patient's current situation is sent to doctor.
- Decision support system starts to analyze data.
- Decision support system invites other doctor / system on the grid to participate in the diagnosis.
- Decision support system collects results from the grid and fuses results, then it generates decision.
- Doctor sends back results to patient.

In order to perform such tasks, the decision support system has three integrated modules: grid service module, fusion service module, and user service module. The software architecture is shown in Figure 2.

Several modules work in the system to carry out tasks. The user friendly interface can accept tasks from and send back responses to users; the grid service agent module is used to provide basic services to manage the grid, coordinate actions, and resolve resources among nodes. The fusion agent module is used to implement different levels of data fusion. The data analysis agent module is used to analyze data and make diagnosis and decisions. Both fusion and data analysis modules work with the medical database. These three com-

Figure 1. Logical architecture

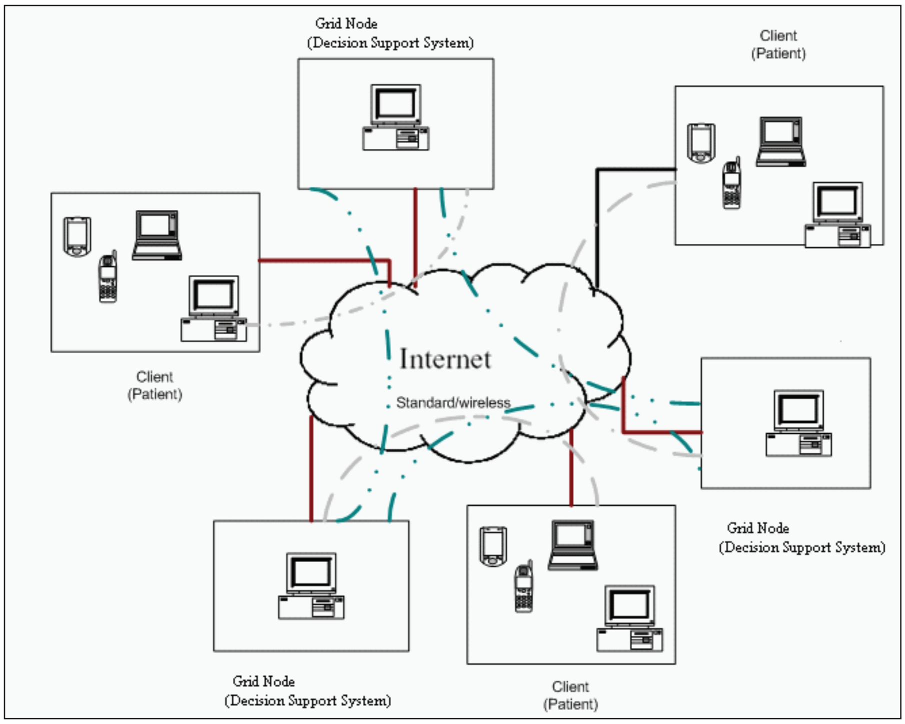

Figure 2. Software architecture

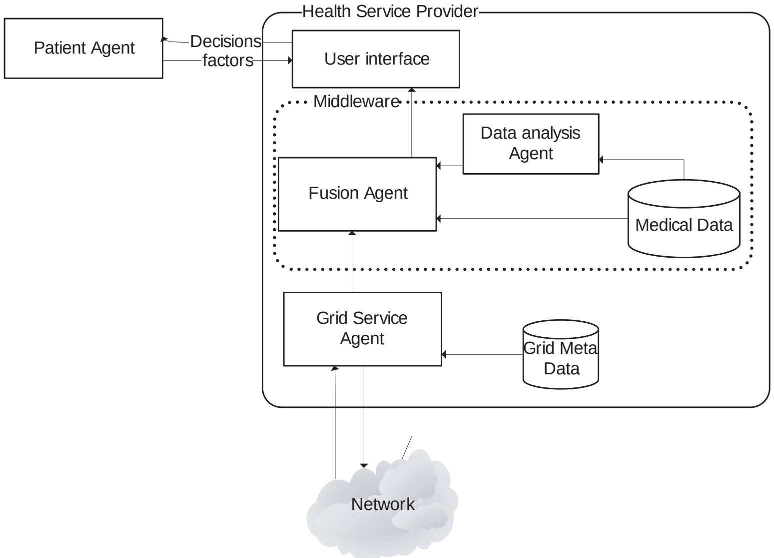


ponents are composed of middleware to provide services to the user.

To illustrate how this will work, we will first describe some key issues that are associated with grid-based distributed knowledge management technologies, as well as methodology for decision-making. We will then discuss plans to develop a feasible fusion mechanism for data, knowledge, and decision assembly.

Knowledge Management Technologies

Some factors that influence the quality of a medical decision system include: the quality of the underlying knowledge base used in the system; the incomplete dataset; and the conversion of knowledge into electronic form. Grid-based distributed data mining is used in this system to solve these problems and thus improve the quality of decisions. We will discuss these following issues:

- **Data privacy.** Medical data are sensitive and proprietary (Shamos, 2004); many hospitals and organizations treat health and medical data as their own property and are not willing to share with others. Proposed solutions to this issue include de-identification (Tracy, Dantas, & Upshur, 2004; Li & Chen, 2004; Kline, Johnson, Webb, & Runyon, 2004) and data-centered (Du & Zhan, 2002; Kantarcioglu & Clifton, 2002). We propose to follow both ways to protect data privacy.
- **Data preparation.** One barrier that influences the quality of a decision is the quality of medical data. They are often incomplete or out of time. The crucial information is missing when the decision is made. Data preparation is important to generate a high-quality decision. Conceptual reconstruction is one of options to be used to solve this problem (Aggarwal & Parthasarathy, 2001).
- **Data communication.** There is a security concern about this system. The use of grid security infrastructure (GSI) (Welch et al., 2003) allows secure authentication and data exchange over an opened network.
- **Data mining methods.** Using data mining in medical decisions can generate a decision of high accuracy (Kusiak, Kern, Kernstine, & Tseng, 2000). Several data mining algorithms are available for a decision-making system including: classification trees, case-based reasoning, neural network, genetic algorithm, fuzzy set approach, SVM, and so on. Our ongoing work is based on SVM and case-based reasoning. We will test and evaluate other algorithms in our future research.

Grid Toolkit

Grid computing is one of the innovative distributed computational models. It can offer high-performance computing and data processing abilities for the distributed mining and extraction of knowledge from data repositories. Grid applications are used in many fields including scientific computing, environmental monitoring, geohazard modeling, and business. It can be used as an effective infrastructure for distributed computing and data mining (Foster, 2001).

Grid technology is growing up very quickly and is going to be more and more complete and complex both in the number of tools and in the variety of supported applications (Cannataro, 2001). Compared to traditional distributed techniques, it has many advantages like resource sharing and high-performance services. Many existing tools are designed to provide functionalities of integration, resource management, access, process large datasets, and support the knowledge discovery process.

Globus Toolkit (Globus project group) is one candidate to implement grid management. It is a well-known grid middleware for providing grid resource management, security management, and other grid facilities. Globus Toolkit 3.0 is the first grid platform to fully support the OGSA/OGSI standard. It provides functionalities to discover, share, and monitor the resources. It also provides abilities for the mutual authentication of services and protection of data (Butler, 2000). The fusion module and application module are built on the base of Globus Toolkit.

Distributed Knowledge Discovery

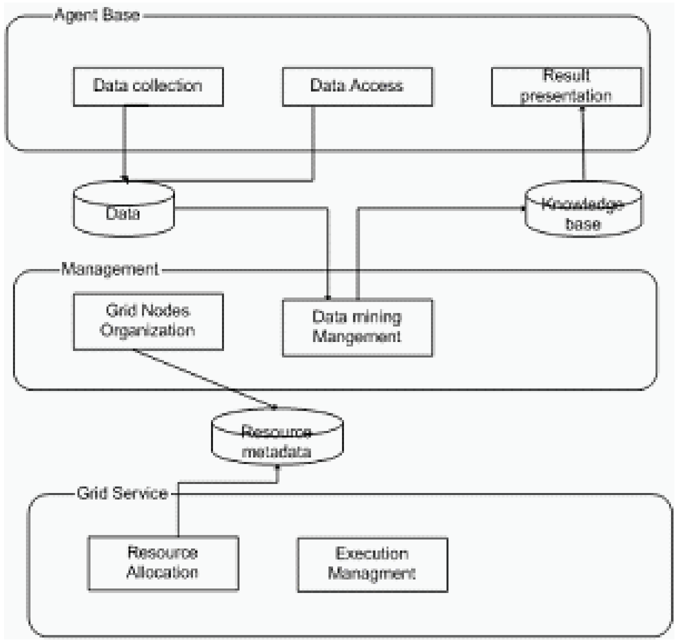
The distributed knowledge discovery is a process that applies artificial intelligent theories and grid techniques to extract knowledge from distributed databases on the grid. Such processes can be implemented in the following steps:

1. **Data preparation.** The first step of this process is data preparation. Data retrieved from different databases on the grid needs to be pre-processed for two main reasons:
    - *Medical data is sensitive.* The data in this domain cannot be obtained without privileges. In order to protect data security, we follow two different ways: de-identification and data-centered. For de-identification, medical data in all organizations can be categorized into two parts: One part is pure medical data without any identified personal information of patients, it is accessible for all partners on the grid; the other part is full dataset with private patient information, it is only accessible for the owner. For data center, data processing is performed on a local data source. After processing, analysis results are based on data not data itself exchanged among the grid. Data and different levels of analysis results can be input of different level of fusion agent.
    - *Medical data may not be complete.* In order to minimize noise caused by incomplete data, pre-process data is necessary. The idea of conceptual reconstruction can be used to fill the missing data. One refill process is performed by calculating the mean and deviation of individual data values of each attribute; the other one is performed by finding the approximate patterns and calculating the mean of patterns. Different algorithms are used to calculate and fill missing values.
2. **Data exchange.** The second step of this process is data exchange. Grid tools provide secure, high-throughput data transfer. This model is set in terms of layer, just like many other grid-based knowledge discovery systems. Services provided by this model are set in a three-layer infrastructure as depicted in Figure 3.
3. **Data analysis.** The third step is data analysis. Several methods are used to analyze data. To take advantage of the grid, different data analysis applications can be used on different machines. Statistical algorithms and data mining algorithms are used to train medical data and generate results for a given case. In addition, they are used to discover useful knowledge on the distributed database. The knowledge explored includes membership functions and fuzzy rule sets. It aims to generate a number of fuzzy rules and membership functions by applying data mining algorithm to a collection of dataset on grids.
4. **Fusion analysis.** The system has the self-developing ability to analyze fusion results. Fusion logs are kept in a database, which enable system learning from outside resources.

Fusion Technologies

In real-world applications, a very large amount of data may be kept in the distributed database and

Figure 3. Three-layer grid-based architecture



can be accessed at an acceptable rate. Collaboration among many organizations is an important issue in making decisions with high accuracy. To combine data, information, and decisions from different parties, fusion is used in some research (Azuaje, Dubitzky, Black, & Adamson, 1999; Phegley, Perkins, Gupta, & Dorsey, 2002). The fusion technologies can be applied to different application domains.

We propose four possible levels of fusion with interactive discussion including different approaches to manage the fusion process. The integration of data and decision can occur in these four distinct levels — data, information, knowledge, and decision. Fusion service is based on basic grid mechanisms. It is built on top of grid services. Decisions made on the basis of local data are collected and fused. Such process aims to generate reliable decisions for health service providers by applying data mining algorithm and AI technologies to a collection of dataset on grids. It overcomes the disadvantages of human fusion and machine fusion: The former is limited by knowledge and subjective experience, while the latter is inflexible and relies on data excessively.

On account of the features of medical data, we propose soft fusion in our work, including fuzzy logic and simple weighting / voting. Neural network fusion and Bayesian fusion would be our future test.

Four-Level Fusion

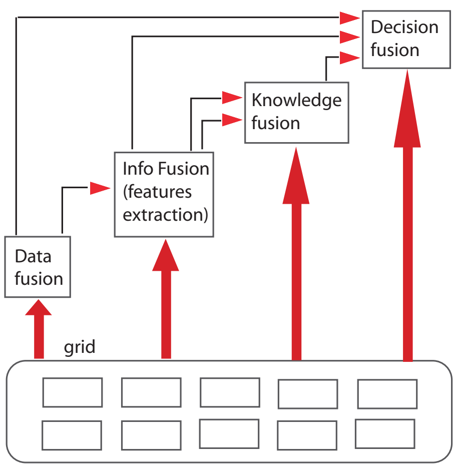
A four-layer fusion framework is proposed for integration. It includes data fusion, information fusion, knowledge fusion, and decision fusion.

- **Data fusion.** This is the lowest level of fusion. The system collects data from multiple sources on the grid and provides categorized data that requires further processing and analysis to users. Users can make decisions or the system can generate decisions based on the process results of collected raw data.

- **Information fusion.** This is the second level of fusion. The system collects data that have common features from multiple sources on the grid and produces a more informative dataset for the users.
- **Knowledge fusion.** This is the third level of fusion. The system finds relevant features of data for each data source on the grid and summarizes knowledge from multiple nodes into a new knowledge base. Users can make decisions using knowledge base.
- **Decision fusion.** This is the highest level of fusion. The system gathers decisions and combines decisions coming from multiple nodes on the grid. The result is given as a system decision. In this chapter, we propose a dynamic decision fusion mechanism. The decision-making process is a negotiable process. It is not only a gather-and-combination procedure, but also allows decision-makers who have different opinions to discuss the issue of concern and make a final decision.

The four-layer frame work is presented in Figure 4.

Figure 4. Four-layer fusion



Hybrid Interactive Fusion

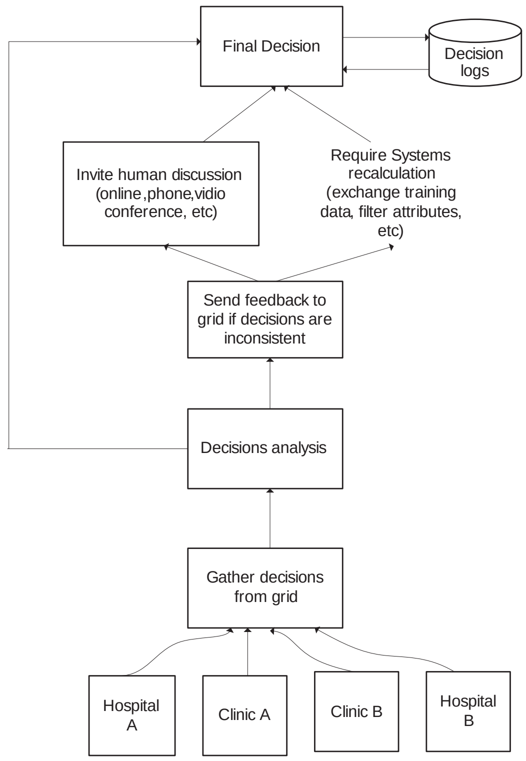
To the best of the authors' knowledge, most of the current fusion systems have one feature in common: They fuse data or decisions on the basis of gathered items. They follow the simple flow — gather data, summarize, and give results. The limitation is clear; it is inflexible and relies excessively on computers.

We propose a dynamic fusion system with interactive discussion between different nodes on the grid. When the gathered decisions are not consistent, some further actions are performed. If service providers are available, they are invited to take a Web conference or telephone conference to discuss among each others. If they are not available, the system may be required to re-draw conclusions by exchanging training datasets or processing training datasets, including filter some unnecessary attributes using different algorithms to handle incomplete data. Compared to traditional fusion systems, it offers higher reliability and diagnosis accuracy by allowing users to confer with others in order to get consistency. This fusion process is described in Figure 5.

The dynamic fusion process simulates the human decision-making process. In the real world, such processes may involve decision-making, discussion, and re-decision-making. The dynamic fusion process is carried out as follows:

1. Systems analyze local datasets separately. Different data analysis applications, such as SVM, gene algorithm, and neuron network, can be used in different sites. The size of datasets varies from node to node.
2. Consistent threshold is set by the user. It includes information about the number of users with consistent and confidence. It provides an indication of how certain we are about the decision fusion and what the acceptable fusion is. Consistent threshold is measured as <X, Y>. X and Y are values between zero to one. A value close to 1 for

Figure 5. Fusion process



X means high consistency and for Y means high certainty. Similarly, a value close to 0 for X means low consistency and for Y means low certainty. <0.7, 0.7> is one example of consistent threshold, which means the acceptable result is that at least 70% of the decisions with average confidence 0.7 are identical. The higher the values of X, Y are, the more difficult to get satisfied answers but the more reliable results are.

3. Collect decisions from the grid and calculate consistent parameter <x, y>. Assume set S and set T are declared as decisions with the same results and total decisions, respectively.

   x = (size of S) / (size of T)
   y = mean of confidence values in S

   For example, there are eight systems in this medical group, and for some given case, six systems have the same diagnosis with confidence (0.8, 0.6, 0.5, 0.9,1, 0.75).
   So, x = 0.75
   and y = 0.76

4. If consistent confidence is less than consistent threshold, that is,

   <x, y> < <X, Y>, x< X and y < Y,

   the further fusion process is activated. Otherwise, results with confidence from different resources of the grid are input of fusion algorithm like voting/weight and neural network to generate the final system result.

5. Results come from the grid and the final system results are written into the database

as fusion history. Every result counts in this system because it will be used as input by fusion algorithm and make contribution for future fusion. Systems accumulate knowledge in this way.

In the best case, all decision-makers on the grid have the same results in the first round of fusion. In this situation, no further fusion is needed. But in the worst case, decisions coming from different makers can be very different. Eight people may have eight different results for the same case. Exchange of opinions and discussion are necessary. Some decision-makers may change their decisions after discussion, and the fusion process is not implemented until it gets satisfied results.

Potential users of this system are doctors, physicians, specialists, and their assistants. The system can provide partial functionalities without human interactions in certain conditions. There are three types of the further fusion processes according to different types of users in the context of the grid:

- **Human-to-human.** The fusion process is implemented in a human-to-human environment. It occurs when users of systems are available and the system works as a decision assistant. The purpose of the system is to provide suggestions for users to make decisions by getting consistent results from group users. Once the system collects results from the grid, it determines the degree of consistency and compares it with the threshold. If it is lower than consistent, the system activates the further fusion including online discussion, e-mail, phone conference, and video conference. Doctors will discuss as to the given case just like the real-world situation. The system fusion decision starts again after some doctors change decisions.
- **Machine-to-machine.** The fusion process is implemented among machines. It occurs when systems work automatically without human interactions. Once the system determines to carry out the further fusion process, one of the two proposed methods can be implemented: re-analyze data using a different training dataset; or re-analyze data using the same training dataset, but only some important attributes are take into account. The first method involves data exchange and low-level data fusion, the latter one involves data preparation and middle-level information fusion. This process may repeat several times until it gets satisfied consistency.
- **Human-to-machine.** Not all doctors are available on the grid. The fusion process is implemented in a hybrid way. If the system needs to carry out the further fusion, it can have two parts: invite available doctors to discuss directly like in the human-to-human situation; or suggest system re-analyze data by providing part of the local set to remote systems or determining the attributes that are used for further analysis. Then, fuse the results again.

The proposed fusion mechanism follows the way humans make decisions. The AI technologies make it smarter and more reliable.

CONCLUSION

A novel method for data fusion with interactions among decision-makers is described. This method takes advantages of observation of other decision-makers' opinions and then modifies the result. This method simulates the process of human decision-making. It involves decision-making, decision fusion, discussion, and re-making, re-fuse. It can improve reliability and flexibility of the fusion system.

The goal of this project is to develop a generalized decision-making and fusion system on grid approach to improve accuracy of diagnose.

A system using SVM for learning from medical data and fuzzy logic for making decisions is designed. Simulations based on Wisconsin Breast Cancer database and Heart Disease (UCI ML Repository) show that the new system is effective in terms of decision accuracy. Even more promising is that higher accuracies are possible if other AI techniques are used.
