- The health care industry is very dynamic and rapidly changing (for example, standard of health information, medical protocols). The adaptation to a changing process for swarm agents is less complex than the adaptation for deliberative agents. This is mainly due to the deliberative agents containing a large amount of knowledge about the system that is hard to substitute. Swarm agents, on the other hand, contain only the necessary knowledge to perform a specific task, and coordination between swarm agents is self-directed. So a swarm agent system will be able to tolerate changes in the health care industry more effectively.

Thus, we see that the properties of swarm agents (simple, interchangeable, distributed, dynamically add/delete) and the features of the agent swarm system (self-organization, self-regulation, collective action, ant forging) can be effectively applied to real-world problems in the health care domain.

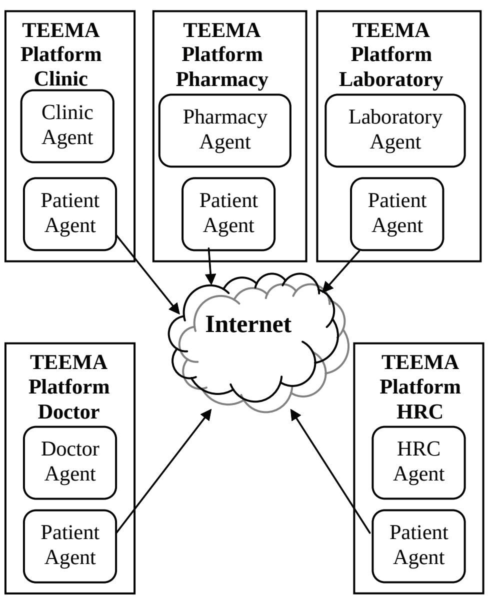
System Components

The agent-based electronic health record system is developed using the TEEMA platform. A system overview is shown in Figure 1. Each TEEMA platform represents a certain physical location, such as a clinic or laboratory. In each platform, there are a single stationary and mobile agent. The system contains five different types of stationary agents and one mobile agent.

Stationary agents

- Clinic agent (CA) is responsible for verifying the identity of the patient, and creating a mobile patient agent if a patient arrives at a clinic and requests medical services. It can be seen as an agent interface between the patient, clinical staff, and the patient agent.
- Doctor agent (DA) is responsible for managing the doctor's evaluation of the patient. It can be seen as an agent interface between the patient agent and the doctor.
- Pharmacy agent (PhA) is responsible for verifying the identity of the patient agent, retrieves prescriptions from the patient agent, and sends notification to the patient agent when the patient or owner wishes to pickup his/her prescription. It can be seen as an agent interface between the patient agent and the pharmacist.
- Lab agent (LA) is responsible for verifying the identity of the patient agent, retrieves lab work orders from the patient agent, sends notification to the patient agent when the patient or owner arrives at the lab, and sends notification to the patient agent when the test result for its owner is prepared. It can be seen as an agent interface between the patient agent and the laboratory technicians.
- Health record central agent (HRCA) is responsible for controlling access to the health record database that holds the personal and medical information of all patients. It can be seen as an agent interface between the patient agent and the central database.

Figure 1. An overview of the ABEHRS architecture



Mobile agents

- Patient agent (PA) is responsible for updating the patient health record that is stored in the patient's storage device card, transferring records to the health record central, and if there is a prescription and/or lab test needed, the patient agent will clone itself and migrate to pharmacy and/or laboratory. It can migrate to all of the different platforms in the simulation.

Typical Actions of Patient Agent in Different Medical Sites

The process begins when a patient visits the medical clinic. The patient places his/her health storage device card (SC) into a card reader, and the clinic agent performs verification (for example, fingerprint) on the patient's identity. If the verification is successful, a patient agent is created, and the PA copies the patient's entire health record from the SC into its payload area. If the verification fails or any other incidents (for example, the patient forgets to bring his/her SC) take place, then the clinical staff will be involved to resolve the incidents. The first operation of the PA is to review the medical service request log (for example, request lab work order) from the patient's record. By doing this, the PA will have enough data to decide what actions to perform next. If the patient's record is not up to date (for example, missing lab test result), then the PA will clone itself. The PA clone will migrate to health record central (HRC), retrieve the latest record from HRC database, migrate back to the clinic with the record, send the new record to the original PA, insert the record into the patient's SC, and finally destroy itself. After the cloning process, the original PA will migrate to the platform of the doctor that has been chosen by the patient, and inform the doctor agent about its owner/patient who needs the consultation service. The original PA will then wait at the doctor platform for the examination to be finished.

During the examination of the patient, which is performed by the doctor, the doctor is able to review the patient's completed and consistent health record. This access to the complete health record will allow the doctor to provide a diagnosis quickly and effectively. After the doctor finishes the examination of the patient, the DA will save the results of the medical evaluation into a specific location on the doctor's storage device, and then the DA will send a notice to the PA to retrieve the medical evaluation (for example, diagnosis, prescription form, lab work order form) of the patient from that specific location. After the PA retrieves the evaluation, it will migrate back to the clinic platform to perform actions required to serve the patient.

Once the PA migrates back to the clinic, it will check the doctor's evaluation for any medical services requested by the doctor. If the medical services are requested, then the PA will clone itself, and the clone will migrate to the platform of the medical service provider that is chosen by the patient. For example, if the requested service is filling a prescription, then the PA clone will migrate to the platform of the pharmacy that is chosen by the patient. This cloning process will be repeated until all requested medical services have been looked after. At the end of the process, the original PA will save the medical evaluation to the patient's SC. Finally, the original PA migrates to HRC and appends the newest medical evaluation to the complete set of the patient's health record in the database, and then destroys itself.

When the cloned PA arrives at the platform of the patient's chosen pharmacy, it will first verify itself to the pharmacy agent at the pharmacy service site. If the verification is successful, then the PA will send the prescription content to the PhA and hibernate. If the verification fails, then the PA will destroy itself. When the patient visits the pharmacy and wishes to pickup his/her prescription, then the PhA will inform the PA about the arrival of the patient, and this will trigger the PA to de-hibernate. Once the PA de-hibernates, it will perform verification on the patient's identity and the prescription content inside the patient's SC, and the cloned PA will destroy itself after a successful verification. If the verification fails, then a notice will send to PhA, which in turn sends a notice to pharmacy staff. And the process of verification will be repeated until a successful verification occurs or a verification override is executed by the facility staff. At the end, the PA will be forced to act as if there is a successful verification and destroys itself.

When the cloned PA arrives at the platform of the patient's chosen laboratory, it will first verify itself to the laboratory agent at the laboratory service site. If the verification is successful, then the PA will hibernate. If the verification fails, then the PA will destroy itself. When the patient visits the laboratory and wishes to go through the lab testing procedures, the LA will inform the PA about the arrival of the patient, and it will trigger the PA to de-hibernate. Once the PA de-hibernates, it will perform verification on the patient's identity and the work order form in the patient's SC. If the verification fails, then a notice will be sent to the LA, which will in turn send a notice to laboratory staff. And the process of verification will be repeated until a successful verification occurs or verification override is executed by the facility staff. After a successful verification, the PA will send the lab work order to LA and re-hibernate until the lab test results are ready to be retrieved. After the lab technician generates the test results for the patient, the LA will inform the PA, and it will trigger the PA to de-hibernate again. Once the PA is de-hibernated, it will retrieve the results and go through the process of cloning. The clone of the PA will migrate to HRC, update/append the lab test result to the complete set of the patient's health record, and then destroy itself. After the cloning process, the PA will migrate back to the clinic where it was originally formed, store the test results into a specific location, inform the doctor (whom the patient consulted with) via the doctor's DA about the test results and the location of where the test result is stored, and finally destroy itself.

Once the PA arrives at the HRC, it will verify itself to the heath record central agent before it can access the centralized health information database. If the verification fails, the PA will destroy itself. If there is a successful verification, the PA can either retrieve or update health information from or to the complete set of patient's health record. If the operation of PA is updating, then it will destroy itself after completion. If the operation of PA is to retrieve information, then after the information is retrieved, it will migrate back to the clinic's platform where it originated.

The actions of PA in different locations within ABEHRS can be summarized by the following flowcharts, as shown in Figures 2 through 6. Based on the above actions and interactions, the concepts of self-completing, self-regulating and self-organizing can be achieved in our proposed system architecture.

SIMULATION SETUP

In order to demonstrate that the architecture of ABEHRS presented above can achieve the concept of health record self-organization, a simulation approach has been applied to ABEHRS. We chose to use the simulation approach because actual physical prototype will have a greater potential to exhibit unexpected or unplanned system behaviors related to the self-organization processes. At the same time, we examine the global system dynamics for the self-organized processes, so agent population at each medical site can be measured. The parameters of the simulation also help formulate our macroscopic mathematical model of the system. Therefore, the simulation results will be used as a contrasting representation for the comparison to the numerical results we generate from the mathematical model. In this section, the structure and conditions of the simulation are presented, as well as the results and the discussion.

Structure and Conditions

A simple computer environment was setup to simulate the necessary scenario. Several computers were used in our simulation, and they are interconnected via 100Mbps Ethernet. Each computer executed at least one TEEMA platform, and each TEEMA platform represented one specific physical medical site; the number of

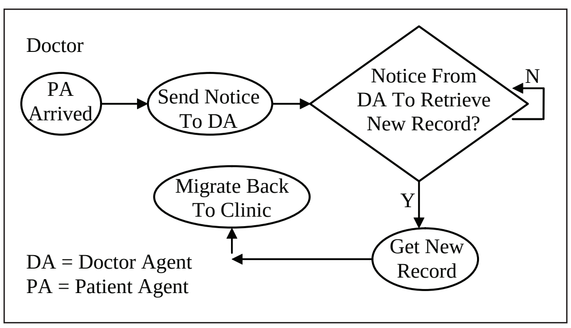

Figure 4. Pharmacy actions flowchart (flowchart representation of the actions of patient agents at the pharmacy platform)

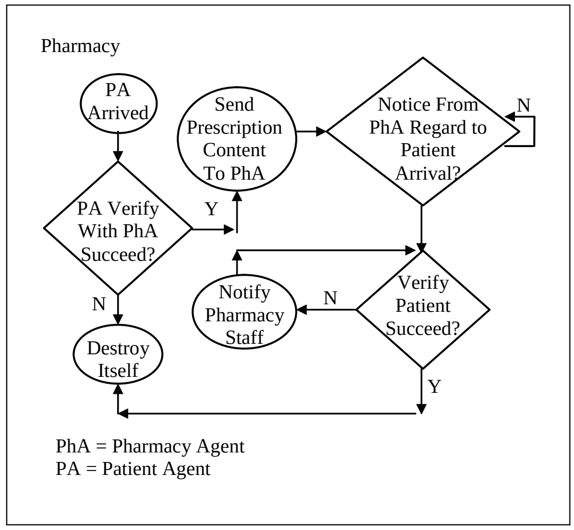

Figure 5. Lab actions flowchart (flowchart representation of the actions of patient agents at the lab platform)

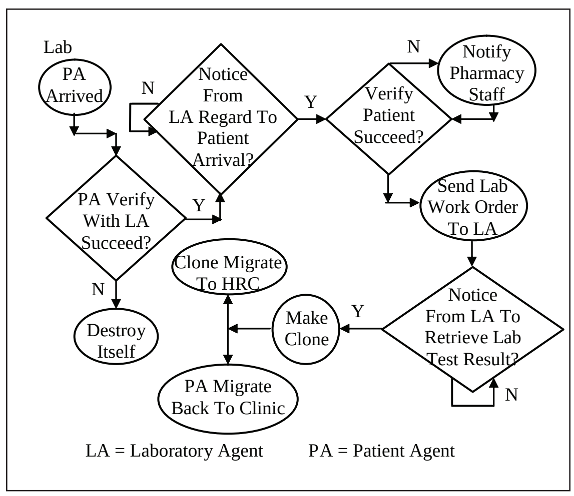

Figure 6. Health record central actions flowchart (flowchart representation of the actions of patient agents at the health record central platform)

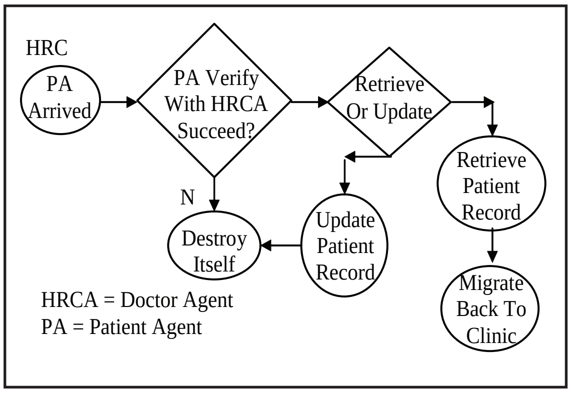

platforms used depends on the structure of the simulation. For this simulation run presented in this work, we used: one clinic, two doctors in the clinic, one pharmacy, one laboratory, and one HRC; thus a total of six TEEMA platforms were used, and they are executed on two computers: TEEMA platforms for one clinic and two doctors are executed on the first computer, and TEEMA platforms of one HRC, one lab, and one pharmacy are executed on the second computer.

Basic conditions and assumptions used in the simulation are listed next:

1. Doctor evaluation, prescription content, and lab test results are predefined to be fixed-length text. The combination of this content is considered the health record of a patient.
2. Even though the health records are randomly generated, records in the storage device card and records in the HRC are correlated. If the record in the storage device card indicates there is an absent of lab test result, then the record in the HRC must contain the lab test result, and it must be ready for the patient agent to retrieve.
3. There are several random behaviours used in the simulation, and they are represented by different kinds of random numbers. The behaviours are shown below:
   - **Patient preference behavior:** This behavior describes a patient's wish to choose a specific doctor. For simplicity, a uniform distributed random number is used to represent this behavior.
   - **Patient necessitated behavior:** This behavior describes the need for a specific medical action. This includes the need for prescriptions and lab work. A Bernoulli random number was used to describe this type of behavior. Since the need for a prescription/lab work is binary, the chance that a patient will need this type of medical service when he or she visits the clinic is 50/50.
   - **Patient arrival behavior:** This behavior describes the rate of patient arrival at the clinic. For simplification, a constant mean rate of arrival was used and set to one patient arrival at the clinic every minute.
   - **Professional service behavior:** This behavior describes the service time of any medical services provided to the patients. This includes physicians, pharmacists, and lab technician patient processing time. For simplicity, a uniform distributed random numbers between one and five was used to represent this type of behavior in the experiment.

Simulation Result

The results of a typical simulation run are shown in Figure 7. From Figure 7, we see that there are many events occurring in each platform, especially for Clinic_1. These events are the indication of agent actions/interactions at different platforms or medical service sites. To show that ABEHRS

does achieve health record self-organization as defined in the section of self-organized health record, we first examine the health information files in HRC at the end of the simulation and all the self-organization related events occurring during the simulation. By reviewing the files, we are able to see that each patient's health record does contain the newly created record, and it was appended to the complete set of patient history of health information. This indicated that every piece of health record generated at different medical sites did indeed combine into one complete and consistent data set for the patient.

Although the results in Figure 7 do not represent the entire range of behaviours exhibited by the system, it is possible to identify some relevant observations, and they are:

- We notice there are several cluster formations at Doctor_A, Doctor_B, Pharmacy_1 and Lab_1 platforms. It seems that the cluster size of PAs at Doctor_B has the same cluster size of PAs at Doctor_A, which is ~ 5. Cluster formations at the Pharmacy_1 and the Lab_1 platforms are also similar to the cluster sizes at both doctor platforms. Each PA arriving at those medical service platforms waits for an event (for example, patient arrives at the lab) to trigger the action of the next task, and this causes the size of the cluster to grow continuously. Even though there are events (for example, patient picks up his/her prescription) to cause the PAs to either destroy themselves or migrate to other platforms, the occurrences of these events were not high enough to limit the cluster growth due to the arrival of PAs at those platforms. Clearly, we can solve this problem by changing the patient's arrival rate and/or the service rates of these facilities to overcome the increase of the cluster size. Conversely, we can take advantage of this growing cluster size of PAs, since cluster formation is a valuable behaviour in a system where a group of agents can perform a task more effectively than a single agent can. So, a large cluster size means a large number of PAs grouping together, and there could be tremendous gains for group or batch processing from the agent cluster.
- We observe the total number of clones produced by the PAs during simulation period, since an agent-cloning approach is used to replicate agents into a group of agents to perform the self-organizing health record-related tasks, as mentioned in the section on agent cloning. Generally, each PA can clone itself zero, one, two, or four times during the process of self-organization. Maximum clones produced for each PA are four, which is counted as follows: one for HRC update, one for prescription, and two for lab work (the clone created in the lab platform will be included as the clone produced by the original PA). So, for the period of 30 minutes, 30 unique PAs are created (since the patient's arrival rate is ~1 per each minute, PA's creation rate is also ~1 per each minute), and there could be a maximum of 120 clones produced during the simulation period. As stated above for patient necessitates behaviours, if there are 30 PAs, then the number of clones produced for pharmacy and lab should be 15 and 15, respectively. Therefore, the cloning effect can be easily model by a Bernoulli random variable, which in turn we can apply it to our mathematical model. Moreover, by observing the number of clones produced, we are able to observe any overpopulation of PAs at each medical service site.

DYNAMIC MODEL

Using the flowcharts as a guide, we are able to construct a macroscopic model that treats agent population at each medical site as the fundamental unit, hence directly describing the characteristic of the system. The mathematical model captures the dynamics of the self-organization process by examining agent population at each platform. This model contains a set of coupled rate equations that describe how the agent population at each platform evolves over time. The following is our general mathematical model of ABEHRS that contains n number of clinics, m number of doctors in each clinic, x number of pharmacies, y number of laboratories, and one health record central. See Box 1.

The dynamic variables in the model are:

- $N_{Cn}(t)$ is the number of agents in clinic n, where $n \geq 1$
- $N_{CnDm}(t)$ is the number of agents in the doctor m in clinic n, where $m \geq 1$
- $N_{Px}(t)$ is the number of agents in pharmacy x, where $x \geq 1$
- $N_{Ly}(t)$ is the number of agents in laboratory y, where $y \geq 1$
- $N_{HRC}(t)$ is the number of agents in the health record central

And the definitions of the parameters used in the model are:

- λ is the patient's arrival rate at the clinic, which is equivalent to the creation rate of agent
- δ is the rate of agent cloning occur at the clinic platform, which is $\sim \lambda * \beta_A + (\Sigma (1/\tau_{CnDm})*(\beta_B+\beta_C))*$
- τ_{CnDm} is the examination time of a doctor on a patient
- τ_{AvgD} is the average of all τ_{CnDm}
- τ_{Px} is the service time for an individual agent in a pharmacy service site (prescription fill time + prescription pickup time)
- τ_{Ly} is the service time for an individual agent in a lab service site (time for a patient to come to the lab + test result production time).
- τ_{SPC} is the service time for an individual agent to perform necessary task in the clinic platform
- τ_{SPL} is the service time for an individual agent to perform necessary task in the lab platform
- τ_{HRC} is the service time for an individual agent in a HRC

Box 1.

$$\frac{d}{dt}N_{Cn}(t) = \lambda+\delta+\sum_{i=1}^{m} 1/\tau_{CnDm}+\beta_A*\alpha_{CnR}*N_{Cn}(t-\tau_{HRC}) +\beta_C*\alpha_{CnLy}*N_{Cn}(t-\tau_{AvgD}-\tau_{Ly})*\theta(t-\tau_{AvgD}-\tau_{Ly}) - \sum_{i=1}^{m}1/(\tau_{CnDm}+\tau_{SPC}) - \alpha_{CnD}*N_{Cn}(t+\tau_{SPC}) -\beta_A*\alpha_{CnR}*N_{Cn}(t) -\beta_B*\alpha_{CnPx}*N_{Cn}(t-\tau_{AvgD}) - \beta_C*\alpha_{CnLy}*N_{Cn}(t-\tau_{AvgD}) -\beta_A*\alpha_{CnR}*N_{Cn}(t-\tau_{HRC}+\tau_{SPC}) - \beta_C*\alpha_{CnLy}*N_{Cn}(t-\tau_{AvgD}-\tau_{Ly}+\tau_{SPC})* \theta(t-\tau_{AvgD}-\tau_{Ly}) \quad (1)$$

$$\frac{d}{dt}N_{CnDm}(t) = \alpha_{CnD}*N_{Cn}(t)* \beta_{Dm} - 1/\tau_{CnDm} \quad (2)$$

$$\frac{d}{dt}N_{Px}(t) = (\beta_{PPx}* \sum_{i=1}^{n} \alpha_{CiPx}*N_{Ci}(t-\tau_{AvgD})* \beta_B - 1/\tau_{Px})* \theta(t-\tau_{AvgD}) \quad (3)$$

$$\frac{d}{dt}N_{Ly}(t) = (\beta_{PLy}* \sum_{i=1}^{n}\alpha_{CiLy}*N_{Ci}(t-\tau_{AvgD})* \beta_C + 1/(\tau_{Ly}-\tau_{SPL}) - 2/\tau_{Ly})* \theta(t-\tau_{AvgD}) \quad (4)$$

$$\frac{d}{dt}N_{HRC}(t) = \sum_{i=1}^{n}\alpha_{CiR}*N_{Ci}(t)* \beta_A + \theta(t-\tau_{AvgD}-\tau_{Ly}) * \sum_{j=1}^{y} 1/\tau_{Lj} - 1/\tau_{HRC}+ \sum_{j=1}^{n} \sum_{i=1}^{m} 1/(\tau_{CjDi}+\tau_{SPC}) \quad (5)$$

- β_A, β_B, β_C are the probability of a patient who needs an update or a prescription or a lab work, respectively
- β_{Dm} is the probability of a specific doctor being chosen by a patient; it is set to 1/(# of doctors in the clinic), since we assume each doctor is to be chosen equally
- β_{PPx} is the probability of a specific pharmacy chosen by a patient; it is set to 1/(number of pharmacies in the system), since we assume each pharmacy is to be chosen equally
- β_{PLy} is the probability of a specific lab chosen by a patient; it is set to 1/(# of labs in the system) and we assume each lab is to be chosen equally
- α is the transition rates of agents between different medical platforms, for example, α_{CnPx} is the rate at which PAs leave the clinic n platform to the pharmacy x platform. α_{CnR} is the rate at which PAs leave the clinic n platform to the HRC platform
- $\theta_{(t-\tau)}$ is a unit step function to ensure certain variables are zero during $t < \tau$

Instead of providing a detailed explanation of what each team in each equation means, we will only provide a general explanation. For the terms with a minus sign in front, they are describing the patient agents (PAs) that leave the platform for other platforms. The terms having the plus sign in front describe PAs who enter the platform from other platform. In addition, in most of the terms, there is a time delay inside a dynamic variable (for example, $N(t-\tau)$), which illustrates that some of the agents that entered a platform at $(t-\tau)$ time are now exiting this platform and migrating to other platform. For example, $N_{Cn}(t-\tau_{HRC})$ illustrates that there are several patient agents that entered the HRC platform at $(t-\tau_{HRC})$ time and which are now exiting the HRC platform and migrating to the clinic platform.

The number of terms in each equation in the above model is too large and the equations are too complex to be solved numerically. In order to further minimize the number of terms, we assume τ_{SPC} and τ_{SPL} are negligibly small. So, the equations in the above model will change to a general minimized model, as shown in Box 2.

Using the minimized model above, we can represent the same number of platforms as in our simulation, and we have six dynamic variables, $N_{C1}(t)$, $N_{C1D1}(t)$, $N_{C1D2}(t)$, $N_{P1}(t)$, $N_{L1}(t)$, and $N_{HRC}(t)$. The equations in Box 2 will be changed to those in Box 3.

The equations in Box 3 illustrate the self-organized health record process in the sense that each term in the equations is modeling part of the process that are required to achieve self-organized health record.

Numerical Result

This is an initial investigation of the model focused on the self-organized health record by examining the agent population at each medical site. The results have shown that mathematical analysis is not only robust but yields obvious results. For simplicity, we assume the following when solving the equations:

- All α to be uniformly distributed in some space, which is set to 1.
- All β to be a constant value 0.5, except for β_{PP1} and β_{PL1}, which is set to 1.
- τ_{C1D1} and τ_{C1D2} are set to be a constant value of 3, τ_{P1} and τ_{L1} are set to a constant value of 6. These values are the expected value of the uniform distributed random number in our parameters used in the simulation. τ_{HRC} is set to be a constant of 0.787.
- $\lambda = 1$ and $\delta = 7/6$.

We use a built-in function named “dde23” in Matlab to solve the time-delay differential equations in our model. The following is the solution of solving the differential equations (11-16) in our macroscopic model, and the solution is shown in Figure 8.

Box 2.

$$\frac{d}{dt}N_{Cn}(t) = \lambda + \delta - \alpha_{CnD}*N_{Cn}(t) - \beta_A*\alpha_{CnR}*N_{Cn}(t) - \beta_B*\alpha_{CnPx}*N_{Cn}(t-\tau_{AvgD}) - \beta_C*\alpha_{CnLy}*N_{Cn}(t-\tau_{AvgD}) \quad (6)$$

$$\frac{d}{dt}N_{CnDm}(t) = \alpha_{CnD}*N_{Cn}(t)*\beta_{Dm} - 1/\tau_{CnDm} \quad (7)$$

$$\frac{d}{dt}N_{Px}(t) = (\beta_{PPx}*\sum_{i=1}^{n}\alpha_{CiPx}*N_{Ci}(t-\tau_{AvgD})*\beta_B - 1/\tau_{Px}) * \theta(t-\tau_{AvgD}) \quad (8)$$

$$\frac{d}{dt}N_{Ly}(t) = (\beta_{PLy}*\sum_{i=1}^{n}\alpha_{CiLy}*N_{Ci}(t-\tau_{AvgD})*\beta_C - 1/\tau_{Ly}) * \theta(t-\tau_{AvgD}) \quad (9)$$

$$\frac{d}{dt}N_{HRC}(t) = \sum_{i=1}^{n}\alpha_{CiR}*N_{Ci}(t)*\beta_A + \theta(t-\tau_{AvgD}-\tau_{Ly}) * \sum_{j=1}^{y}1/\tau_{Lj} - 1/\tau_{HRC} + \sum_{j=1}^{n}\sum_{i=1}^{m}1/(\tau_{CjDi}) \quad (10)$$

Box 3.

$$\frac{d}{dt}N_{C1}(t) = \lambda+\delta-\alpha_{C1D}*N_{C1}(t)-\beta_A*\alpha_{C1R}*N_{C1}(t)-\beta_B*\alpha_{C1P1}*N_{C1}(t-\tau_{AvgD})-\beta_C*\alpha_{C1L1}*N_{C1}(t-\tau_{AvgD}) \quad (11)$$

$$\frac{d}{dt}N_{C1D1}(t) = \alpha_{C1D}*N_{C1}(t)*\beta_{D1} - 1/\tau_{C1D1} \quad (12)$$

$$\frac{d}{dt}N_{C1D2}(t) = \alpha_{C1D}*N_{C1}(t)*\beta_{D2} - 1/\tau_{C1D2} \quad (13)$$

$$\frac{d}{dt}N_{P1}(t) = (\beta_{PP1}*\alpha_{C1P1}*N_{C1}(t-\tau_{AvgD})*\beta_B - 1/\tau_{P1}) * \theta(t-\tau_{AvgD}) \quad (14)$$

$$\frac{d}{dt}N_{L1}(t) = (\beta_{PL1}*\alpha_{C1L1}*N_{C1}(t-\tau_{AvgD})*\beta_C - 1/\tau_{L1}) * \theta(t-\tau_{AvgD}) \quad (15)$$

$$\frac{d}{dt}N_{HRC}(t) = \alpha_{C1R}*N_{C1}(t)*\beta_A + \theta(t-\tau_{AvgD}-\tau_{L1})* 1/\tau_{L1} + 1/\tau_{C1D1} + 1/\tau_{C1D2} - 1/\tau_{HRC} \quad (16)$$

From Figure 8, we see that there is a small oscillatory effect that occurs in the value of $N_{C1}(t)$ at the beginning of the result. The reason may be that there are many PAs being created, and they are cloning themselves at the same time, causing an increase in $N_{C1}(t)$. As the PAs leave the Clinic_1 platform to either Doctor_A or Doctor_B platform, this situation causes $N_{C1}(t)$ to decrease. Thus there are forces increasing and decreasing the agent population in the Clinic_1 platform. As time goes by, the number of agents in each platform becomes stable or predictable in the form of an upward straight line. This suggests that the system is adjusting itself to the changes of PA population in each platform. To show that this solution is reasonable, we calculate the number of agents in each platform at the end of 30 minutes. If the patient arrival rate is 1 patient/minute, then there will be 30 PAs created in the 30-minute simulation. The agents will divide themselves up between the Doctor_A and Doctor_B platforms, since there are only two doctors they can choose from. As indicated above, each doctor's examination time is three minutes on average. So, at the end of 30 minutes, Doctor A and Doctor B platform should have five PA left, on average, which is only slightly different from what we observe in Figure 8. Similar calculations for the pharmacy and lab platform indicate that there should be six PAs in Lab_1 and six PAs in Pharmacy_1. It is very similar to what we observe in Figure. 8.

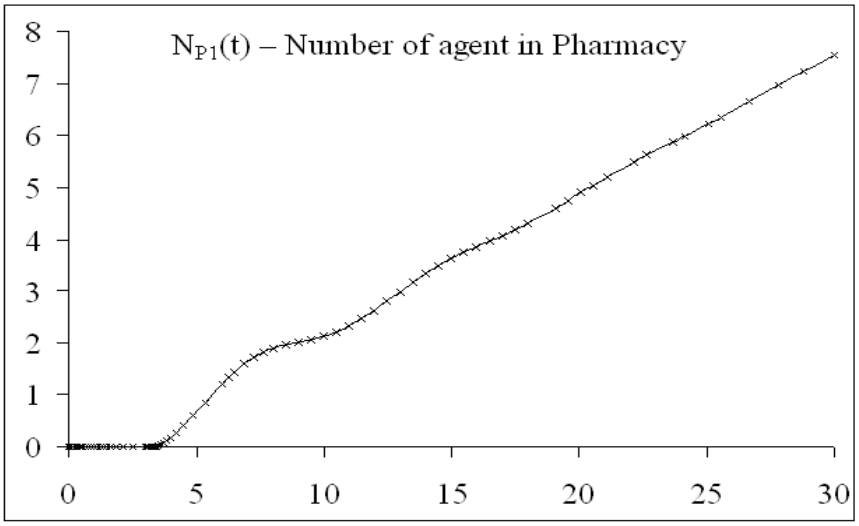
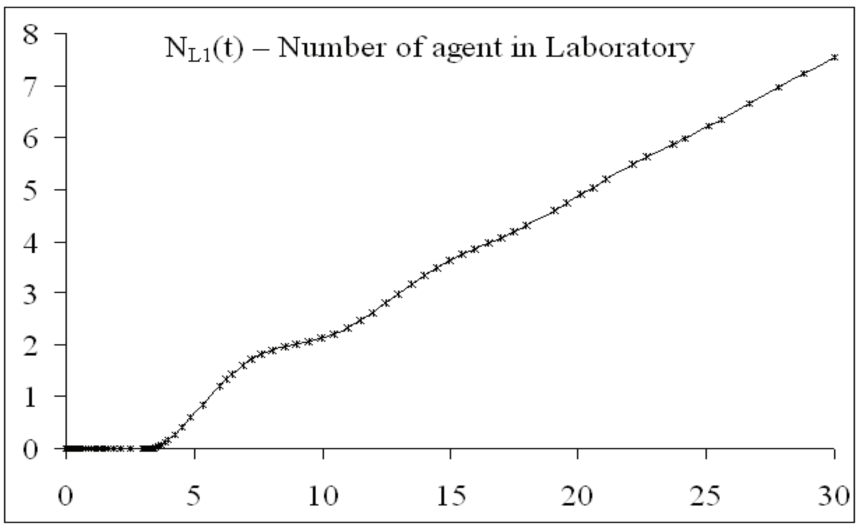
Figure 8e-f. Numerical results of the macroscopic model of ABEHRS (x-axis is time, y-axis is agent population)



(e) Numerical Solution for NP1(t)



(f) Numerical Solution for NL1(t)

The above numerical results are subject to our initial assumption of setting all the parameters to some constants that we used in the simulation. Many parameters in the model are free parameters, such as λ, β_A, β_B, β_c, τ_{C1D1}, τ_{C1D2}, τ_{P1}, τ_{L1}. These free parameters are tied to the process of self-organized health records in a sense that they are affecting the time it takes an individual health record to recover from a chaotic state and back to a well-ordered state. For example, if τL1 is large, then the time it takes for the test result to be appended to the HRC database will also be long. Therefore, the values for these parameters are up to the agent designer to choose. Note that all the parameter values used in the model must be positive.

RESULTS COMPARISON BETWEEN MODELS

Since the numerical results give us the dynamics of average quantities of agent population at each medical site, the simulation results must also be formulated as an average. Therefore, we executed 30 simulation runs and the average of these simulation results, and then compare them to the numerical results obtained from the macroscopic mathematical model. The mean square error (MSE) is calculated to indicate the difference between the simulation results and the numerical results. We proposed that an acceptable value for the MSE for our study would be 10 (for now); however, this value can be set arbitrarily by agent designers. As shown in Figure 9, we can clearly see that both models for Clinic_1 and HRC platforms have settled to a steady state, and the MSE for Clinic_1 is 1.59, and MSE for HRC is 0.58, and this indicates our parameter values for these sites in our macroscopic model are acceptable. The clusters of PAs (or agent population) in both doctor platforms increase linearly, and in both simulation and numerical results. However, the MSE between simulation and numerical results for Doctor_A is 24.63, and MSE for Doctor B is 20.37. This indicates our parameter values for the both doctor's equations in our macroscopic model need to re-adjust. The cluster of PAs in pharmacy and lab platforms are also exhibited linear aviation. We have only MSE = 6.63 for the pharmacy and MSE = 9.58 for the lab, and this indicates our parameter values for these sites in our macroscopic model are barely acceptable.

FUTURE TRENDS

Mobile agent technology has been used to solve most of the problems in health care domain for more than a decade, and its reputation and popularity have only increased. There are numerous studies on applying mobile agent architecture to different fields in the health care domain. For example, medical image retrieval (Liu, Martens, Paranjape, & Benedicenti, 2001), organ and tissue transplant and management (Moreno, 2003), health services scheduling and collaboration (Kirn, 2002), and optimization and management of clinical processes (Heine et al., 2005) all examine the application of mobile agent technology. We believe that in the near future, the mobile agent paradigm will become a dominated force in telemedicine application and in the telemedicine industry. This trend will likely keep increasing until new network computing technology that is even more flexible than mobile agent technology is developed.

There are several challenges, not mentioned in the section of The Electronic Health Record but presented in Moreno (2003), that also need to be addressed before we can expect useful multi-agent systems to the real health care domain. One such challenge is the slow in adoption of new information technology by medical professionals. Many medical professionals feel a loss of control when the information technology becomes too central to the access and retrieval of medical data (Moore, 1996). This is more critical, especially

for the technologies that contain a high level of automation, like mobile agents. Before we can see an increase in the rate of adoption by medical professionals, we need to see an acceptance by the general public. Thus, if we see mobile agent enabled cellular phones or PDAs and services (such as agent-controlled appliances, agent-based stock exchange) in our normal day lives, as shown in Kirn (2002), then only will we see acceptance in the medical community.

Intelligent swarms have given the agent designers a new perspective of developing multi-agent system. If an agent system consists of thousands of simple autonomous and distributed agents, then their collective power arising from the interactions between the agents is tremendous. The intrinsic properties of the swarm system can be very significant. We believe that swarm intelligence and multi-agent systems will have a strong impact of solving problems in health care domain.

CONCLUSION

In this chapter, we have presented a general framework and the basic concepts behind ABEHRS. These concepts encapsulated the fundamental principles of self-completing, self-regulating, and self-organizing data sets by using the strength of agent mobility and automation. Based on the principles of the swarm paradigm, we have designed and implemented an ABEHRS model using the TEEMA system. Initial simulation results from modeling ABEHRS have been presented, and from these results it is shown that the fundamental goals of ABEHRS are achieved. It also shown that cluster formations occur in specific sites of the health care system (for example, doctor, pharmacy, and lab platforms). The existence of these clusters, and their growth rate, identifies new challenges and new opportunities for the health care system. These cluster formations can identify valuable collective behaviour in the system, as also seen in Lerman and Galstyan (2001).

In addition to the design and simulation of ABEHRS, we also presented a macroscopic mathematical model of the ABEHRS, which contains a set of differential equations. These equations describe the global dynamics of mobile agents in the ABEHRS. Our numerical analysis of these equations strongly matches our simulation results. However, both the numerical and simulation results are subject to the initial conditions and assumptions, which can significantly alter the behaviour of the system. Further work using different initial conditions and assumptions should be used to help better understand the macroscopic behaviour of the ABEHRS. Also, we may want to look for some parallel to the current health record system to demonstrate that there is a relationship between what we propose in this work and the actual health system in use today.

Finally, our current simulation and numerical work on the ABEHRS does not show any extraordinary or catastrophic collective swarm behaviour. The global simulation dynamics of ABEHRS compares well to the mathematical model. However, our work is only very preliminary, and we have not attempted to push the system to any extremes. This type of testing and analysis is critical in order to ensure that the system will always be stable.

ABSTRACT

Adverse drug events impose a large cost on the society in terms of lives and health care costs. In this article, we propose an information technology architecture for enabling the monitoring of adverse drug events in an outpatient setting as a part of the post marketing surveillance program. The proposed system architecture enables the development of a Web-based drug effectiveness reporting and monitoring system that builds on previous studies demonstrating the feasibility of a system in which community pharmacists identify and report adverse drug events. We define the key technical requirements of such a monitoring and reporting system, identify the critical factors that influence the successful implementation and use of the system, and propose information technology solutions that satisfy these requirements.

INTRODUCTION

Adverse drug reactions have been estimated to result in more than 2.1 million injuries and 100,000 deaths each year in the U.S. alone (Lazarou, Pomeranz, & Corey, 1998). The annual economic cost of adverse drug events is estimated to be more than $75 billion (Johnson & Bootman, 1995). Mitigating the impact of adverse drug events requires the implementation of a comprehensive mechanism for monitoring and detecting adverse drug events. Such a mechanism can save lives and reduce health care costs.

Reliable detection adverse drug events is a difficult problem. Although some adverse drug reactions are detected early on during clinical trials, serious adverse drug effects can still go undetected during this phase due to the practical limitations associated with the size and duration of the clinical trials. Recent examples of such cases include Rofecoxib and Cerivastatin (Fontanarosa, Rennie, & DeAngelis, 2004). The FDA monitors for adverse drug events in the post-marketing phase through the MedWatch program (www.fda.gov/MedWatch/report.htm). The MedWatch program, which is mainly a voluntary reporting program, suffers from several limitations, the most critical of which are the under-reporting of adverse events and the lack of a denominator reflecting magnitude of exposure.

In a 1996 article titled "The Clinical Impact of Adverse Event Reporting," the FDA estimated that only 1% of the adverse drug events are reported through the MedWatch program (Food and Drug Administration [FDA], 1996, p. 5). An alternative mechanism for detection of adverse drug events is the use of longitudinal medical records and hospitalization records. However, the availability of data from such records has been limited and obtaining longitudinal medical records is an expensive and time-consuming process. In addition, the extraction of meaningful conclusions from such data is difficult due to data integrity, heterogeneity, and missing data problems.

Several information technology-based solutions have been suggested to help monitor and reduce the adverse drug event problem. Most of the proposed solutions and studies conducted have been limited to inpatient hospital settings. Although a major part of drug dispensing and medications takes place in an outpatient setting, there is limited literature on the detection of adverse drug events in an outpatient setting. In this article, our focus is on methods for the detection of adverse drug events in an outpatient setting and in the post marketing phase using a Web-based reporting system. Specifically, our focus is developing the IT architecture for enabling a large-scale data collection mechanism to support the detection and quantification of previously unrecognized side effects and drug interactions for drugs, especially those newly introduced into the market. We propose an IT architecture for enabling a Web-based reporting and surveillance solution called the Drug Effectiveness Reporting and Monitoring System (DERMS). The DERMS system is based on a community pharmacy-based safety network and proposes the participation of community pharmacies for the collection of clinical response and adverse drug event information from patients. We describe the information technology architecture that forms the supporting infrastructure for the surveillance system and discuss the requirements and success factors necessary for successful implementation of the system.

This article is structured as follows. In the second section, we describe the post marketing effectiveness and safety surveillance program and discuss the limitations of the system in its current form. In the third section, we review previous literature discussing technological solutions to the adverse event detection problem. We briefly describe the Drug Effectiveness Reporting and Monitoring System and propose the enabling IT architecture in the fourth section, and discuss the success factors for its implementation in the fifth section. We discuss the limitations of the system in the sixth section, and make concluding observations in the seventh section.

POST-MARKETING SURVEILLANCE

An effective surveillance process that follows the introduction of a new drug into the market requires the efficient flow of information among the different affected entities including patients, drug companies, the FDA, and healthcare professionals such as doctors, nurses and pharmacists. This should include information on drug usage, patient exposure, interactions, adverse effects, and treatment outcomes. At present, the primary mechanism of disseminating information from the drug companies and FDA are through sales representatives, visiting lecture series, press releases. At present, the primary mechanism of disseminating information from the drug companies and FDA are through press releases, information services, and pharmacy databases that enable timely dissemination of information on drug interactions and labeling information.

While the FDA and drug companies are able to use broadcast mechanisms and information services exist for disseminating information to physicians, pharmacists, and patients, there are currently no widely implemented mechanism for the reverse flow of information on adverse events and medication and treatment outcomes from patients and health care practitioners to the FDA on an ongoing basis. This channel is weak, and is currently confined to MedWatch and other limited mechanisms.

The FDA conducts postapproval monitoring through postmarketing surveillance programs such as the MedWatch system. The MedWatch system relies on voluntary submission of reports by patients and health care providers. In this program, patients and health care providers can submit an adverse event report via several mechanisms including an online report form, fax, phone, and mail. The Medwatch reports, along with adverse event information reported by pharmaceutical companies, are stored in the Adverse Event Reporting System (AERS) database. The database is publicly available for download by clinical reviewers and researchers on a quarterly basis for analyzing drug interactions and monitoring drug safety. (Center for Drug Evaluation and Research [CDER], 2005).

While the MedWatch program has been successful at identifying critical side effects that

Figure 1. Information flows in the post approval phase

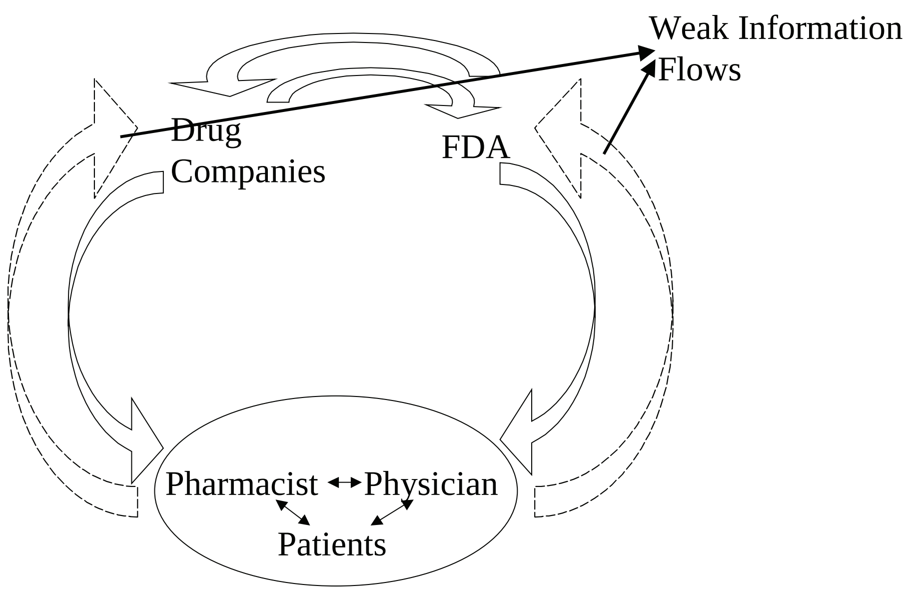

exhibit in the early stages after drug marketing, it suffers from several major limitations that prevent the faster detection of the adverse drug effects. For example, although 19 drugs were withdrawn from the market between 1997 and 2007 based on MedWatch data, it took an average of 6.6 years post introduction ofthe drugs into the market to identify their adverse effects and remove these drugs from the market. In addition, the system is far less effectiveat identifying adverse effects that result from prolonged administration of drugs (Brewer & Colditz, 1999; U.S. Department of Health and Human Services, 1999).

The limitations of MedWatch system include the poor quality of submitted reports, duplicate reporting of events, under-reporting of adverse events, and the absence of the denominator or baseline information required to make meaningful conclusions from the data (Fontanarosa et al., 2004). In addition, the detection of adverse effects resulting from prolonged use of drugs requires the collection longitudinal medical records, which are not readily available to the MedWatch system. Longitudinal medical records are necessary for the detection of adverse effects that manifest late in the chronic administration of a drug, such as in the case of Vioxx, where the increased risk of heart attacks and strokes on prolonged use was not detected by the MedWatch system, but rather through controlled clinical studies.

The MedWatch system is also deficient in providing background data a on number of patients being administered a particular medication. Background rates of information, such as the number of events per number of patients exposed, is essential for the scientific evaluation of adverse event data. Other factors contributing to the noise and biased nature of MedWatch data include increases in adverse event reports in response to media publicity and "dear health care professional" letters. Given the various limitations with current adverse event reporting mechanisms, there is a need for a comprehensive adverse event data collection mechanism that can provide better quality data and serve as an early alert system for newly introduced drugs.

PREVIOUS WORK

Several studies have been conducted analyzing the use of information technology (IT) in managing Adverse Drug Events (ADE). Literature in this area focuses on the detection of adverse events using computer-based mechanisms and the prevention of ADE using IT tools. Computerization and the use of information technology tools for automating health care workflow have resulted in significant improvements in health care delivery and in the prevention of adverse drug events (Bates et al., 1999; Bates et al., 2001; Evans et al., 1992). Computerization and health care information technology systems, such as computerized order entry and clinical decision support systems, have led to a significant reduction in medical errors and improvements in quality of care (Bates et al., 2001).

Surveillance mechanisms for the detection of adverse drug events can be classified as outpatient-based monitoring mechanisms and inpatient-based monitoring mechanisms. Bates, Evans, Murff, Stetson, Pizziferri, and Hripcsak (2003) studied the effectiveness of various information technology tools in detecting adverse events in inpatient and outpatient settings. They determine that information technology tools that analyze administrative data recorded using ICD9 codes are of limited value in identifying adverse drug events, while rule-based detection mechanisms that rely on laboratory test results and occurences of antidote use are able to detect a significantly larger portion of the adverse events. Another finding of the study is the need for natural language processing tools to process free text data for the detection of adverse events. A significant portion of the patient related information such as visit notes, admission notes, progress notes, consultation notes, and nursing notes are stored in the form of free text. Although rule-based mechanisms are able to identify a significant portion of the adverse events, they still underperform chart review-based methods for adverse event detection. This is primarily due to the inability of rule-based mechanisms to identify symptom changes, which are mostly recorded in free text form (Classen, Pestotnik, Evans, & Burke, 1991).

In outpatient care, free text processing tools greatly outperform rule-based mechanisms that rely on ICD-9 codes for the detection of adverse events. Honigman, Lee, Rothschild, Light et al. (2001) reported that code-based mechanism were able to detect only 3% of the adverse events when applied to outpatient data, while free text processing mechanism were able to identify 91% of the adverse events. Anderson, Jay, Anderson, and Hunt (2002) present results from a simulation study designed to analyze the effect of information technology in reducing adverse events. Their primary focus is on the use of information technology tools to reduce prescription errors by automating the prescription workflow using electronic means and the prevention of adverse events by verifying prescriptions against a database of known drug interactions. A detailed review of various methodologies for the detection of adverse events is given in Murff, Patel, Hripcsak, and Bates (2003).

Although several systems have been developed for the detection of adverse drug events given various patient data, the reporting and collection of adverse drug event information itself has not been extensively investigated. Moreover, most of the proposed systems are limited to inpatient settings and single organizations. There is relatively limited literature analyzing the use of information technology for large scale adverse event reporting in an outpatient setting. A study by Gandhi et al. (2000) reports the incidence of adverse drug events in outpatient care to be common and that most such events are not documented in the medical records. A majority of the events is preventable and proper monitoring for symptoms, response, and adequate communication between outpatients and providers can prevent most of the adverse drug events (Tejal et al., 2003).

A series of studies have been conducted over the past few decades to evaluate alternative mechanisms for collection and reporting of adverse drug events in an outpatient setting. Fisher, Bryant, Solovitz, & Kluge (1987) conducted a study to analyze the effectiveness of post-marketing surveillance using outpatient adverse drug event reports. Based on their studies, they conclude that outpatient-based post-marketing surveillance programs that rely on patient initiated reports can be used to complement existing physician-based surveillance systems. Fisher and Bryant (1990) observed that patients are correctly able to differentiate adverse drug events from other adverse clinical events under certain conditions. They observed. They observe that the discrimination between adverse drug events from other adverse clinical events was better when the reporting was initiated by a staff member and the reporting was spontaneous as opposed to an interviewer probed systematic enquiry. Data from patient drug attributions has been observed to be consistent with alternative monitoring methods, such as physician assessments and epidemiological data, and can also be used to improve the discriminatory power of such methods (Fisher, Bryant, Kent, & Davis, 1994). In addition to the Fisher et al. studies, a recent study by Cohen, Kimmel et al. (2005) analyzed the effect of interventions by pharmacists in a community pharmacy setting. The study showed a considerable reduction in adverse events through an audit of discharged patients and a subsequent 9-month follow-up.

A community pharmacist-based outpatient post marketing surveillance system has several potential uses such as early detection of adverse drug reactions, discovery of new therapeutic benefits of the newly introduced drugs (Fisher & Bryant, 1992), and comparison between alternative medications (Fisher, Bryant, & Kent, 1993; Fisher, Kent, & Bryant, 1995). However, the previous studies were limited to short time period and did not explore the use of emerging information technology to leverage the surveillance and monitoring mechanism.

The Critical Path Institute (C-Path, 2005) has proposed a community pharmacy-based surveillance model that is characterized by the following aspects: (1) the data collection is set in an outpatient setting and involves community pharmacies, which are visited by patients more frequently than hospitals, (2) The community pharmacy-based model focuses on pharmacists and pharmacy technicians to collect large-scale data on adverse events and drug effectiveness, and (3) The model is designed to collect baseline information and information on background rates to help conduct rigorous data analysis.

In this article, we propose a Web-based information system, the Drug Effectiveness Reporting and Monitoring System (DERMS). The DERMS system was one of the models developed for consideration toward satisfying the requirements of the Community Pharmacy Safety Network (CPSN) developed by the Critical Path Institute. Although it is currently not a part of the CPSN, the DERMS system can be adapted to serve as a general pharmacy-based patient safety system.

DRUG EFFECTIVENESS REPORTING AND MONITORING SYSTEM

In this section, we give a brief overview of the Drug Effectiveness Reporting and Monitoring System, previously described in Gupta el al. (2007), describe the key processes of the DERMS system and propose a system architecture for supporting the key processes to be implemented in the DERMS system.

Overview

The key requirements of the DERMS system are derived from the community-pharmacy based model for post-marketing surveillance proposed by the Critcal Path Institute. The community pharmacy based model includes a large-scale data collection mechanism that involves pharmacists and pharmacy technicians in identifying and collecting of adverse event information. After medical evaluation, pharmacists and pharmacy technicians usually constitute the first point of contact with patients as outpatients. Hence, they can potentially collect and maintain evolving historical information on the patient's medication history. Such history would include comprehensive information on the various types of medications taken by the patient, along with the corresponding duration of use for each medication. Such records can serve as an alternative source of information for evaluating the long-term effects of clinical medicines. The perceived direct and indirect benefits of such as system include the following: (1) the creation of longitudinal medical records by integrating patient medication history with baseline and periodically collected follow-up information on the patient's medical condition, and (2) Faster detection of adverse events using a systematic monitoring procedure implemented at the point of medication dispensing and (3) assessment of comparative effectiveness.

Key Processes

The drug effectiveness reporting and monitoring system is characterized by three key processes that include the data collection process, surveillance and monitoring process, and surveillance administration process. We describe each of these processes in detail below.

Surveillance Administration Process

The surveillance administration process basically captures the key tasks of the agency responsible for administering the surveillance mechanisms and the infrastructure. The surveillance administration process involves the identification of newly introduced drugs that need to be monitored. It also includes the identification of appropriate data items that need to be captured and the design and development of questionnaires for eliciting and capturing adverse event information. The questionnaires developed in this process are used in the data collection process, which we describe next.

Data Collection Process

The data collection process is illustrated in Figure 2. The process is initiated when a patient visits a pharmacy to fill a prescription. If the prescribed drug has been selected by a surveillance administrator for surveillance, the pharmacist proceeds to collect further information about the patient with the patient's consent. For patients who are not already in the system, a basic patient information questionnaire is used to collect information on patient demographics.

A baseline information questionnaire is administered at the start of a medication to collect basic information about the patient's health status before begining the new medication. At the time of each refill, a follow-up questionnaire is administered to the patient to record the patient's health status and query for any adverse drug effects. In the case of severe adverse drug effects, a MedWatch report is filed by the pharmacist. Each of the questionnaires administered to the patient was designed during the surveillance administration process.

The questionnaires vary based on the type of the drug being monitored. In order to design these questionnaires, the research team studied previous examples and the work of others. This included examination of post-marketing surveillance programs of FDA, as well as of the allied research and monitoring endeavors. Further, the research team studied questionnaires designed by researchers of the Arizona Center for Research Therapeutics (AzCERT). Based on different needs, five types of forms were delineated. These were: the basic patient information form; the baseline information questionnaire; the routine follow-up questionnaire; the special follow-up questionnaire; and the adverse event reporting form. The special follow-up questionnaire is used for medications that are known to have potential harmful side effects usually occurring after a certain period has elapsed. A screenshot of the data collection process within the DERMS system is shown in Figure 3.

Surveillance and Monitoring Process

While the data collection process is executed by the pharmacist, the surveillance and monitoring process is primarily executed by research and quality improvement organizations. An overview of the process is given in Figure 4. In this pro-

Figure 2. Data collection process

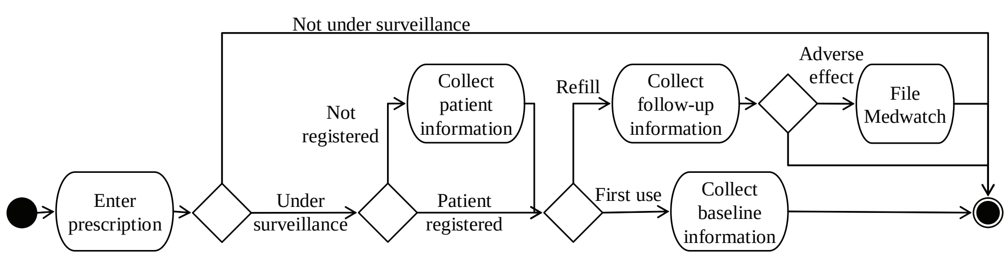

Figure 3. Data collection forms

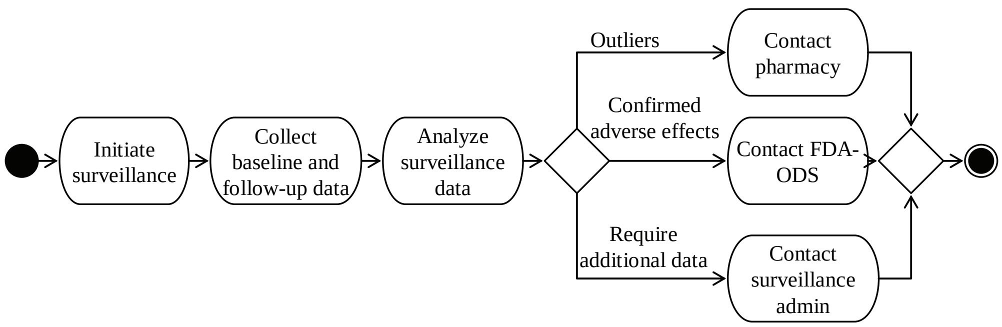
Figure 4. Surveillance process



cess, the data collected during the data collection process is analyzed by researchers to identify possible drug interactions and signals suggesting serious side effects.

Following the analysis, three possible actions are supported by the DERMS system. In the case of suspect data points or outliers, a researcher can contact the concerned pharmacy for follow-up information. In the case of confirmed adverse effects, a report can be sent to the FDA's office of drug safety. If the researcher requires the collection of additional information through follow-up questionnaires, the surveillance administration can be contacted for modifications or the design of specialized follow-up questionnaires to be administered during the surveillance process. A screenshot from the surveillance process within the DERMS system is shown in Figure 5.

Figure 5. Surveillance visualization screenshot

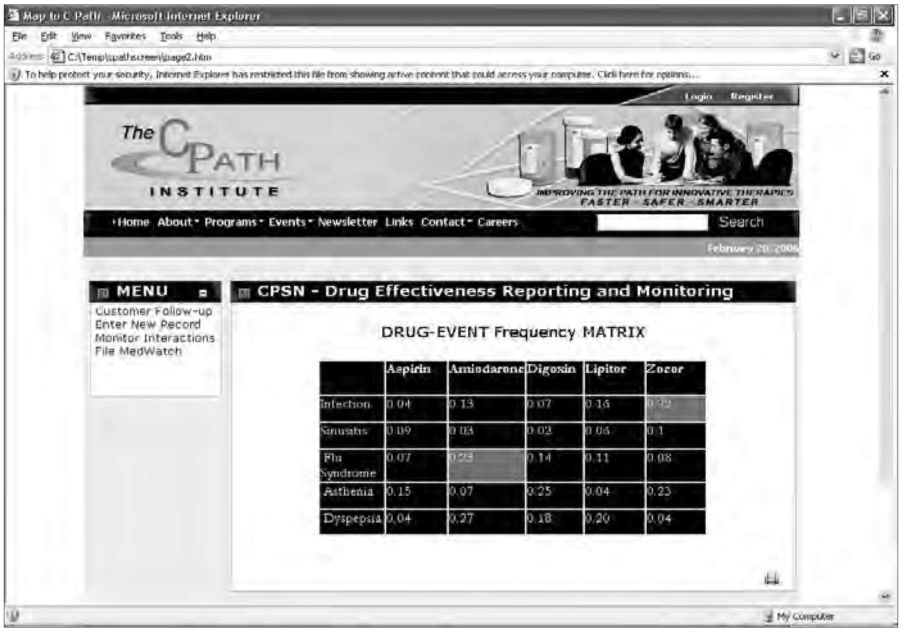


Figure 6. System architecture

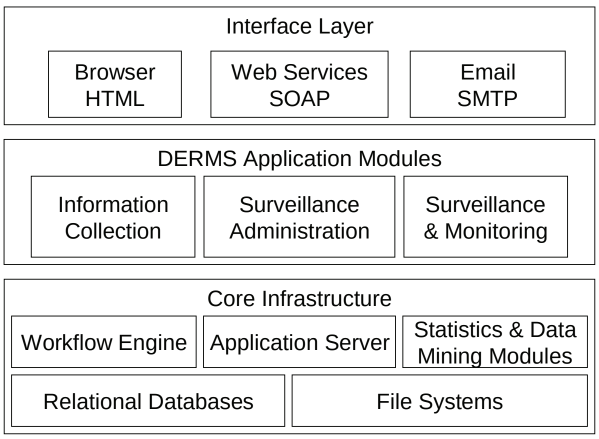

System Architecture

In order to support the above mentioned key processes, we propose a three layer system architecture, as illustrated in Figure 6. It consists of a core infrastructure layer, an application layer, and an interface layer. The core IT infrastructure supporting the drug effectiveness reporting and monitoring system consists of a centralized relational database and file system for storing the surveillance data and associated documents. The core infrastructure also includes an application server, a workflow engine, and a statistics and data-mining module that help execute the business logic implemented in the DERMS modules. Three application modules corresponding to the key processes supported by the DERMS system are included in the application layer. They implement the business logic and processes that support the data collection, administration, and surveillance and monitoring mechanisms.

The interface layer consists of a HTML interface accessible through a Web browser, a Web service interface, and an e-mail interface. The HTML interface is the primary Web-based interface used by the pharmacists to execute the data collection process. The Web service interface can be used to interface with pharmacy information systems to directly retrieve data from pharmacy systems. The Web service interface can also be by researchers to interface with statistical and analysis software. The e-mail interface is used for communication between various entities involved in the data collection, administration, and surveillance and monitoring processes.

Critical Success Factors

The proposed large-scale post marketing surveillance system involves the participation of multiple stakeholders and is influenced by several factors that determine its adoption and successful implementation. We reviewed literature in the area of event reporting systems (Barach & Small, 2000), post-marketing surveillance methods (Fisher et al., 1987), pharmaco-epidemiological studies involving the participation of community pharmacists (Farris, Kumbera, Halterman, & Fang, 2002; Oh, McCombs, Cheng, & Johnson, 2002; Schommer, Pederson, Doucette, Gaither, & Mott, 2002; Weinberger, 2002), and information technology adoption (Menachemi, Burke, & Brooks, 2004) to determine the key factors that influence the successful implementation of such a system.

Barach and Small (2000) draw lessons from an analysis of various nonmedical critical event reporting systems to prescribe a set of guidelines for the design of medical event reporting systems. They identify six different factors as being critical to the successful adoption and high quality of a medical event reporting system: "immunity (as far as practical); confidentiality or data de-identification (making data untraceable to caregivers, patients, institutions, time); independent outsourcing of report collection and analysis by peer experts; rapid meaningful feedback to reporters and all interested parties; ease of reporting; and sustained leadership support." We analyze each of these factors and identify the critical elements of the community pharmacy-based surveillance model to derive the technological requirements of the DERMS model.

Immunity: A key barrier to adoption of an incident reporting system is the fear of reprisal or a lack of trust for an individual and fear of litigation for organizations. As such, immunity to the greatest extent possible is important for successful adoption of an incident reporting system. In the context of the community pharmacy-based adverse event reporting system, this translates into immunity for pharmacists and the community pharmacy participating in the reporting program. From a technical requirements point of view, enabling immunity requires the use of mechanism that provide confidentiality of users, anonymity to the pharmacists and pharmacies, and mechanisms that prevent the traceability of actions by unauthorized users.

Confidentiality: Confidentiality of data is an important element for a successful reporting system. For health care applications, confidentiality implies protecting the privacy rights of the patients by de-identifying patient data. However, de-identification of data sometimes leads to duplication of records. Therefore, data management mechanisms that enable de-duplication of records and the identification of unique individual records while preserving patient privacy need to be developed. Access control mechanisms and data encryption technologies need to be provided in order to ensure the security of data and prevent unauthorized use of the data.

Evaluation: Barach and Small (2000) report that an independent collection of reports and analysis by peer evaluation is an important factor influencing the quality of an incident report-

Table 1. Critical success factors

Success Factor	Implementation	Possible IT Solutions
Immunity	Anonymity of reporters, participants	Data Encryption and de-identification. Access control.
Independent Reporting and Evaluation	Involvement of Community Pharmacies, Quality Improvement Organizations and administrative entity.	Workflow systems, Mediators and Web Services for heterogeneous data and application integration. Access control and relational views.
Confidentiality	Patient Privacy, Data de-identification	Data element identification and Probabilistic de-duplication algorithms.
Feedback	Summary reports and information	Reporting modules and data validation and verification algorithms
Ease of Reporting	Minimal reporting time, Capture of key and minimal data elements	Assistive technologies and intuitive user interfaces.
Leadership	Surveillance Administration, Dashboards, Real-time monitoring of key metrics, problem detection and communication capability.	Communication modules, Monitoring and reporting modules.
Workload Minimization	Financial Incentives, Workload distribution between Pharmacists and Pharmacy Technicians	Integration with pharmacy systems to minimize computer entry.

ing system. In the community pharmacy-based approach, this is achieved by outsourcing the data evaluation to regional quality improvement organizations, data collection to community pharmacies, and monitoring and overview to an independent administrative entity. Providing the above features would require a scalable and flexible mechanism that would enable multiple diverse entities to seamlessly exchange data by integrating heterogeneous applications and data sources and at the same time provide privacy and data security, and prevent unauthorized access. Recent developments in information technology, such as workflow system, Web services, service-oriented architecture (SOA), and grid computing can provide a successful implementation to support the independent collection and evaluation features of the community pharmacy-based system.

Feedback: Feedback to incident reporters and all participating stakeholders is necessary for successful adoption and implementation of an incident reporting system. The reporting and data analysis modules, along with workflow and communication tools, can be used to provide meaningful feedback to the interested participating users.

Reporting: Two major factors need to be considered when designing the data collection process: the ease of reporting the data and the quality of the data being collected. Previous studies (Bates et al., 2003) have shown that typical hospital incident reports and ICD-9 based reporting mechanisms are inadequate for detecting adverse drug events. Reporting mechanisms need to be customized for each drug and drug combinations to collect relevant symptomatic information. While the data fields determine the quality of the data being collected, the design of the report affects the adoption of the reporting system. Complexity and amount of time spent reporting is a major barrier to large scale adoption of a reporting system. The reporting system needs to be designed such that it leverages the users familiarity with other computer-based systems, and minimizes the amount of data to be manually entered and the overall reporting time.

Leadership: Continued leadership is necessary to maintain and manage an incident reporting system and to effectively respond to changing needs. Monitoring and communication capability are key to enabling effective leadership. In the DERMS system, an administrative module is provided to initiate and monitor the surveillance process. Graphical tools, integrated e-mail, and messaging mechanisms can be used to provide this functionality.

Workload Minimization: A key barrier to adoption of the system is the addition to workload because of increased reporting responsibilities. Time and motion studies indicate that pharmacist spend around 6-7% of their time in computer entry activities (Murray, Loos, Tu, Eckert, Zhou, & Tierney, 1998). A study by Oh et al. (2002) estimates that pharmacists need to spend an additional 3 minutes of time for patient consultation and adverse drug effect monitoring. As long as the additional computer order entry time is minimal, resistance to adoption should be minimal.

The introduction of additional workload is a key problem, especially in locations with shortages in pharmacists. However, the following mechanisms can be considered to alleviate the problem. First, the additional workload can be distributed between a pharmacist and a pharmacy technician, such that the computer entry activities are handled by a pharmacy technician while the activities related to the elicitation and identification of adverse events are delegated to a pharmacist. Second, depending on resource constraints, the surveillance mechanism can be limited to patients who are prescribed certain newly introduced drugs, thereby lowering the additional workload.

Incentives: Previous studies have indicated that the provision of financial incentives has had a positive effect on patient counseling activities of pharmacists, resulting in reduced adverse events (Farris et al., 2002). As such, financial incentives can serve an additional factor in promoting the adoption of a community pharmacy-based system. In addition to financial incentives, job satisfaction is a key driver in increased pharmacist involvement in patient counseling and drug therapy reviews. A study by Schommer (2002) concludes that pharmacists prefer to spend more time on patient consultation and drug use management instead of medication dispensing and business management.

Factors Influencing Pharmacy Participation

The successful adoption and continued use of the proposed system by community pharmacies and pharmacists is dependent on several factors. In order to promote the successful adoption of the new surveillance system, the features of the system also need to be aligned with the interests of the community pharmacy and the professional interests of the pharmacists. Based on previous studies on IT adoption, we hypothesize that while organizational buy-in is necessary for initial adoption of a new system, its continued use is dependent on the perceived usefulness of the system and its alignment toward the skill and professional interests of the pharmacists.

Several operational factors also need to be considered for the successful implementation of the proposed surveillance system. For example, an article describing randomized control trials conducted to evaluate the effectiveness of pharmaceutical care programs in Indianapolis (Weinberger, 2002) highlights several operational difficulties that occur in programs involving community pharmacies. The study, initiated at a Revco pharmacy chain, analyzed new pharmaceutical care programs aimed at giving the pharmacists a greater role in providing the patients with better health care. The data were initially transmitted from Revco to the Indianapolis Network for Patient Care (INPC) for purposes of consolidation and analysis. As this experimental study progressed, CVS acquired Revco in a corporate acquisition. Apart from the problems caused by differences in computer systems of the two organizations, there were problems created by major differences in their management policies. For example, CVS required the patients to give their categorical affirmative response before patient data could be utilized in any manner. In order to address this new requirement, a decision was made to offer a sum of $60 as incentive to patients who were willing to let their data be used for purposes of this experimental study. With this incentive, 21% of the patients responded to CVS, with five-sevenths of them agreeing to let the data be used, and the balance two-sevenths declining the offer. In order to increase the response rate, CVS personnel initiated follow-up efforts. Finally, one-fifths of the persons originally contacted agreed to accept the offer of $60 in lieu of data to be utilized for the experimental study.

The above experience emphasizes four critical success factors for achieving progress in this area. First, senior management must accept the need for such studies and be prepared to explicitly support the endeavor through its entire lifestyle; without such close involvement, the effort will fail. Second, pharmacists should view this function as an integral part of their job of dispensing drugs and interacting with patients on issues related to drugs; in order to make this scenario feasible, financial incentives may need to be provided to pharmacists. Third, the policies of major pharmacy chains vary significantly from each other; and discussions need to occur among them in order to generate consensus on this critical issue that impacts human lives. Fourth, new mechanisms need to be developed to share relevant chains across otherwise competing entities in a manner that meets applicable guidelines for information, security, and safety, while simultaneously ensuring that the risks to human lives is minimized.

Limitations

At the beginning of this article, we had identified some of the weaknesses of the current MedWatch system. The concept demonstration prototype described in this article mitigates some of the problems, but several of them still remain and need further research and attention. The areas requiring further attention are discussed in the following paragraphs.

First, the concept demonstration prototype system studied the relevant issues in one city only (Tucson, Arizona). The automated assimilation of the information from diverse information systems, each characterized by its own design and significantly different from others, will require use of advanced concepts from the realm of integration of heterogeneous information systems. Similarly, state-of-the-art ideas related to data mining and knowledge discovery will need to be employed. The scalability of the concept demonstration prototype needs to be examined in detail in order to evaluate the potential feasibility of utilizing the proposed approach over an extended geographic area.

Second, the prototype system tracks drugs that are provided to customers across the counters at retail outlets of major pharmaceutical chains. If this concept is extended to smaller chains and individual shops, it will need to deal with still greater variety of legacy hardware and software. The problem is further complicated by the fact that patients now acquire drugs by mail, both from outlets in the U.S. and abroad, using Web-based and telephone-based mechanisms to place the concerned purchase orders for drugs. No effective mechanism currently exists for tracking the purchase of such drugs.

Third, our approach lacks the ability to track samples of drugs that have been provided by the medical physician to the patient. Such dispensing of drugs by the physicians may need to be monitored, especially for drugs that have been introduced in the recent past. The same Web-based interface could be used to enter the requisite information by personnel in the physician's office. Also, some pharmaceutical companies now provide magnetic cards that can be redeemed at pharmacies for samples of drugs. If this new concept is used for all samples, this limitation will be overcome in terms of monitoring of drug samples.

Fourth, our proposed system relies heavily on pharmacists in terms of their expertise and goodwill in terms of talking with the patients, eliciting requisite information from them, and entering the same using the Web-based interface.

Fifth, patients currently obtain drugs from multiple pharmacy outlets that may belong to different chains. Without a common identifier, it is difficult to track that the medicines were indeed purchased for use by the same patient. The most obvious identifier would be the social security number in the U.S. However, current regulations and concerns for patient privacy prevent such usage. New options need to be explored.

CONCLUSION

In this article, we propose an IT architecture that forms the enabling infrastructure for a new post-marketing surveillance tool for newly introduced drugs called the Drug Effectiveness Reporting and Monitoring System. We briefly define the key characteristics of the DERMS system and propose a system architecture for supporting the key processes implemented in the DERMS system. We then analyze the critical success factors for the DERMS-based post marketing surveillance mechanism and identify supporting IT solutions.

Future work in this area involves further investigation of the critical success factors and development of instruments to validate the hypothesized critical success factors. In addition, large-scale implementation of such as system requires further investigation of the privacy and security issues related to data collection, storage, and sharing processes.

ABSTRACT

Semantic Similarity relates to computing the similarity between conceptually similar but not necessarily lexically similar terms. Typically, semantic similarity is computed by mapping terms to an ontology and by examining their relationships in that ontology. We investigate approaches to computing the semantic similarity between natural language terms (using WordNet as the underlying reference ontology) and between medical terms (using the MeSH ontology of medical and biomedical terms). The most popular semantic similarity methods are implemented and evaluated using WordNet and MeSH. Building upon semantic similarity, we propose the Semantic Similarity based Retrieval Model (SSRM), a novel information retrieval method capable for discovering similarities between documents containing conceptually similar terms. The most effective semantic similarity method is implemented into SSRM. SSRM has been applied in retrieval on OHSUMED (a standard TREC collection available on the Web). The experimental results demonstrated promising performance improvements over classic information retrieval

methods utilizing plain lexical matching (e.g., Vector Space Model) and also over state-of-the-art semantic similarity retrieval methods utilizing ontologies.

INTRODUCTION

Semantic Similarity relates to computing the similarity between concepts, which are not necessarily lexically similar. Semantic similarity aims at providing robust tools for standardizing the content and delivery of information across communicating information sources. This has long been recognized as a central problem in Semantic Web where related sources need to be linked and communicate information to each other. Semantic Web will also enable users to retrieve information in a more natural and intuitive way (as in a "query-answering" interaction).

In the existing Web, information is acquired from several disparate sources in several formats (mostly text) using different language terminologies. Interpreting the meaning of this information is left to the users. This task can be highly subjective and time consuming. To relate concepts or entities between different sources (the same as for answering user queries involving such concepts or entities), the concepts extracted from each source must be compared in terms of their meaning (i.e., semantically). Semantic similarity offers the means by which this goal can be realized.

This article deals with a certain aspect of Semantic Web and semantics, that of semantic text association, and text semantics respectively. We demonstrate that it is possible to approximate algorithmically the human notion of similarity using semantic similarity and to develop methods capable of detecting similarities between conceptually similar documents even when they don't contain lexically similar terms. The lack of common terms in two documents does not necessarily mean that the documents are not related. Computing text similarity by classical information retrieval models (e.g., Vector Space, Probabilistic, Boolean (Yates & Neto, 1999)) is based on lexical term matching. However, two terms can be semantically similar (e.g., can be synonyms or have similar meaning) although they are lexically different. Therefore, classical retrieval methods will fail to associate documents with semantically similar but lexically different terms.

In the context of the multimedia semantic Web, this article permits informal textual descriptions of multimedia content to be effectively used in retrieval, and obviates the need for generating structured metadata. Informal descriptions require significantly less human labor than structured descriptions.

In the first part of this article, we present a critical evaluation of several semantic similarity approaches for computing the semantic similarity between terms using two well-known taxonomic hierarchies namely WordNet[1] and MeSH[2]. WordNet is a controlled vocabulary and thesaurus offering a taxonomic hierarchy of natural language terms developed at Princeton University. MeSH (Medical Subject Heading) is a controlled vocabulary and a thesaurus developed by the U.S. National Library of Medicine (NLM)[3] offering a hierarchical categorization of medical terms. Similar results for MeSH haven't been reported before in the literature. All methods are implemented and integrated into a semantic similarity system, which is accessible on the Web.

In the second part of this article, we propose the "Semantic Similarity Retrieval Model" (*SSRM*). *SSRM* suggests discovering semantically similar terms in documents (e.g., between documents and queries) using general or application specific term taxonomies (e.g., WordNet or MeSH) and by associating such terms using semantic similarity methods. Initially, *SSRM* computes *tf·idf* weights to term representations of documents. These representations are then augmented by semantically similar terms (which are discovered from WordNet or MeSH by applying a range query in the neighborhood of each term in the taxonomy) and by re-computing weights to all new and pre-existing terms. Finally, document similarity is computed by associating semantically similar terms in the documents and in the queries respectively and by accumulating their similarities.

SSRM together with the term-based Vector Space Model (Salton, 1989) (the classic document retrieval method utilizing plain lexical similarity) as well as the most popular semantic information retrieval methods in the literature (Richardson & Smeaton, 1995; Salton, 1989; Voorhees, 1994) are all implemented and evaluated on OHSUMED (Hersh, Buckley, Leone, & Hickam, 1994), a standard TREC collection with 293,856 medical articles, and on a crawl of the Web with more than 1.5 million Web pages with images. *SSRM* demonstrated promising performance achieving better precision and recall than its competitors.

RELATED WORK

Query expansion with potentially related (e.g., similar) terms has long been considered a means for resolving term ambiguities and for revealing the hidden meaning in user queries. A recent contribution by Collins-Thomson and Callan (2005) proposed a framework for combining multiple knowledge sources for revealing term associations and for determining promising terms for query expansion. Given a query, a term network is constructed representing the relationships between query and potentially related terms obtained by multiple knowledge sources such as synonym dictionaries, general word association scores, co-occurrence relationships in corpus or in retrieved documents. In the case of query expansion, the source terms are the query terms and the target terms are potential expansion terms connected with the query terms by labels representing probabilities of relevance. The likelihood of relevance between such terms is computed using random walks and by estimating the probability of the various aspects of the query that can be inferred from potential expansion terms. *SSRM* is complementary to this approach: It shows how to handle more relationship types (e.g., hyponyms, hypernyms in an ontology) and how to compute good relevance weights given the *tf·idf* weights of the initial query terms. *SSRM* focuses on semantic relationships; a specific aspect of term relationships not considered in Collins-Thomson et al. (2005) and demonstrates that it is possible to enhance the performance of retrievals using this information alone.

SSRM is also complementary to Voorhees (1994) as well as to Richardson and Smeaton (1995). Voorhees proposed expanding query terms with synonyms, hyponyms, and hypernyms in WordNet but did not propose an analytic method for setting the weights of these terms. Voorhees reported some improvement for short queries, but little or no improvement for long queries. Richardson and Smeaton proposed taking the summation of the semantic similarities between all possible combinations of document and query terms. They ignored the relative significance of terms (as captured by *tf·idf* weights) and they considered neither term expansion nor re-weighting. Our proposed method takes term weights into account, introduces an analytic and intuitive term expansion and re-weighting method, and suggests a document similarity formula that takes the previous information into account. Similarly to *SSRM*, the text retrieval method (Mihalcea, Corley, & Strapparava, 2006) works by associating only the most semantically similar terms in two documents and by summing up their semantic similarities (weighted by the inverse document frequency *idf*). Query terms are neither expanded nor re-weighted as in *SSRM*. Notice that *SSRM* associates all terms in the two documents and accumulates their semantic similarities.

The methods previously referred to allow for ordering the retrieved documents by decreasing similarity to the query taking into account that two documents may match only partially (i.e., a retrieved document need not contain all query terms). Similarly, to classic retrieval models like VSM, *SSRM* allows for non-binary weights in queries and in documents (initial weights are computed using the standard *tf idf* formula). The experimental results in this article demonstrate that *SSRM* performs better (achieving better precision and recall) than its competitors like Salton (1989) and ontology-based methods (Richardson & Smeaton, 1995; Voorhees, 1994).

Query expansion and the term re-weighting in *SSRM* resemble also earlier approaches, which attempt to improve the query with terms obtained from a similarity thesaurus (e.g., based on term to term relationships (Mandala, Takenobu, & Hozumi, 1998; Qiu & Frei, 1993)). This thesaurus is usually computed by automatic or semi-automatic corpus analysis (global analysis) and would not only add new terms to *SSRM* but also reveal new relationships not existing in a taxonomy of terms. Along the same lines, Possas, Ziviani, Meira, and Neto (2005) exploit the intuition that co-occurring terms occur close to each other and propose a method for extracting patterns of co-occurring terms and their weights by data mining. These approaches depend on the corpus.

SSRM is independent of the corpus and works by discovering term associations based on their conceptual similarity in a lexical ontology specific to the application domain at hand (i.e., WordNet or MeSH in this article). The proposed query expansion scheme is complementary to methods, which expand the query with co-occurring terms (e.g., "railway," "station") in retrieved documents (Attar & Fraenkel, 1977) (local analysis). Expansion with co-occurring terms (the same as a thesaurus like expansion) can be introduced as additional expansion step in the method. Along the same lines, *SSRM* needs to be extended to work with phrases (Liu, Liu, Yu, & Meng, 2004).

SEMANTIC SIMILARITY

Issues related to semantic similarity algorithms along with issues related to computing semantic similarity on WordNet and MeSH are discussed next.

WordNet

WordNet[4] is an online lexical reference system developed at Princeton University. WordNet attempts to model the lexical knowledge of a native speaker of English. WordNet can also be seen as ontology for natural language terms. It contains around 100,000 terms, organized into taxonomic hierarchies. Nouns, verbs, adjectives, and adverbs are grouped into synonym sets (synsets). The synsets are also organized into senses (i.e., corresponding to different meanings of the same term or concept). The synsets (or concepts) are related to other synsets higher or lower in the hierarchy defined by different types of relationships. The most common relationships are the *Hyponym/Hypernym* (i.e., Is-A relationships), and the *Meronym/Holonym* (i.e., Part-Of relationships). There are nine noun and several verb Is-A hierarchies (adjectives and adverbs are not organized into Is-A hierarchies). Figure 1 illustrates a fragment of the WordNet Is-A hierarchy.

MeSH

MeSH[5] (Medical Subject Headings) is a taxonomic hierarchy (ontology) of medical and biological terms (or concepts) suggested by the U.S. National Library of Medicine (NLM). MeSH terms are organized in Is-A taxonomies with more general terms (e.g., "chemicals and drugs") higher in a taxonomy than more specific terms (e.g., "aspirin"). There are 15 taxonomies with more than 22,000 terms. A term may appear in more than one taxonomy. Each MeSH term is described by several properties the most important of them being the *MeSH Heading* (MH) (i.e., term name

Figure 1. A fragment of the WordNet Is-A hierarchy

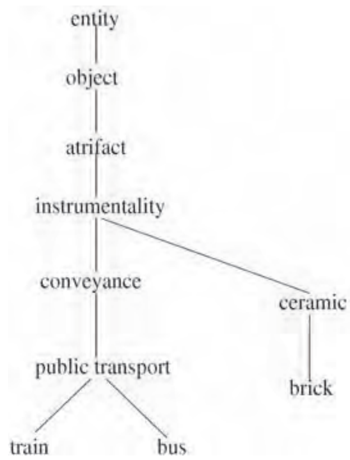

Figure 2. A fragment of the MeSH Is-A hierarchy

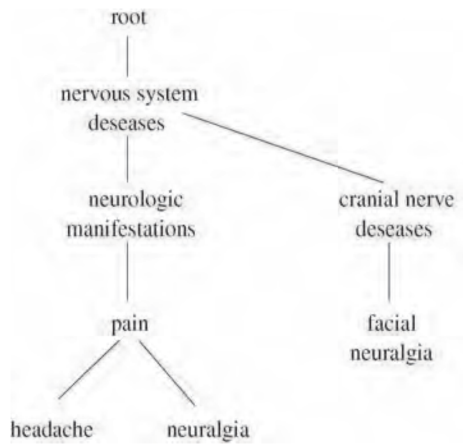


or identifier), *Scope Note* (i.e., a text description of the term) and *Entry Terms* (i.e., mostly synonym terms to the MH). Entry terms also include stemmed MH terms and are sometimes referred to as quasi-synonyms (they are not always exactly synonyms). Each MeSH terms is also characterized by its MeSH tree number (or code name) indicating the exact position of the term in the MeSH tree taxonomy (e.g., "D01,029" is the code name of term "Chemical and drugs"). Figure 2 illustrates a fragment of the MeSH Is-A hierarchy.

Semantic Similarity Methods

Several methods for determining semantic similarity between terms have been proposed in the literature and most of them have been tested on WordNet[6]. Similar results on MeSH haven't been reported in the literature.

Semantic similarity methods are classified into four main categories:

1. Edge Counting Methods: Measure the similarity between two terms (concepts) as a function of the length of the path linking the terms and on the position of the terms in the taxonomy (Leacok & Chodorov, 1998; Li, Bandar, & McLean, 2003; Rada, Mili, Bicknell, & Blettner, 1989; Richardson, Smeaton, & Murphy, 1994; Wu & Palmer, 1994).
2. Information Content Methods: Measure the difference in information content of the two terms as a function of their probability of occurrence in a corpus (Lin, 1993; Lord, Stevens, Brass, & Goble, 2003; Jiang & Conrath, 1998; Resnik, 1999). In this article, information content is computed according to Seco, Veale, and Hayes (2004). The taxonomy (WordNet or MeSH in this article) is used as a statistical resource for computing the probabilities of occurrence of terms. More general concepts (higher in the hierarchy) with many hyponyms convey less information content than more specific terms (lower in the hierarchy) with less hyponyms. This approach is independent of the corpus and also guarantees that the information content of each term is less than the information content of its subsumed terms. This constraint is common to all methods of this category. Computing information content from a corpus does not always guarantee this requirement. The same method is also applied for computing the information content of terms.

3. Feature Based Methods: Measure the similarity between two terms as a function of their properties (e.g., their definitions or "glosses" in WordNet or "scope notes" in MeSH) or based on their relationships to other similar terms in the taxonomy. Common features tend to increase the similarity and (conversely) non-common features tend to diminish the similarity of two concepts (Tversky, 1977).
4. Hybrid methods combine the previous ideas (Rodriguez & Egenhofer, 2003). Term similarity is computed by matching synonyms, term neighborhoods, and term features. Term features are further distinguished into parts, functions, and attributes and are matched similarly to (Tversky, 1977).

Semantic similarity methods can also be distinguished between:

1. Single Ontology similarity methods, which assume that the terms which are compared are from the same ontology (e.g., MeSH).
2. Cross Ontology similarity methods, which compare terms from two different ontologies (e.g., WordNet and MeSH).

An important observation and a desirable property of most semantic similarity methods is that they assign higher similarity to terms which are close together (in terms of path length) and lower in the hierarchy (more specific terms), than to terms which are equally close together but higher in the hierarchy (more general terms).

Edge counting and information content methods work by exploiting structure information (i.e., position of terms) and information content of terms in a hierarchy and are best suited for comparing terms from the same ontology. Because the structure and information content of different ontologies are not directly comparable, cross ontology similarity methods usually call for hybrid or feature based approaches. The focus of this work is on single ontology methods. For details on the methods used in the work, please refer to Varelas (2005).

Additional properties of the similarity methods previously referred to are summarized in Table 1. It shows method type, whether similarity affected by the common characteristics of the concepts which are compared, whether it decreases with their differences, whether the similarity is a symmetric property, whether its value is normalized in [0,1] and, finally, whether it is affected by the position of the terms in the taxonomy.

Semantic Similarity System

All methods previously stated are implemented and integrated into a semantic similarity system which is accessible on the Web[7]. Figure 3 illustrates the architecture of this system. The system communicates with WordNet and MeSH. Each term is represented by its tree hierarchy (corresponding to an XML file, which is stored in the XML repository. The tree hierarchy of a term represents the relationships of the term with its hyponyms and hypernyms. These XML files are created by the XML generator using the WordNet XML Web-Service[8]. The purpose of this structure is to facilitate access to terms stored in the XML repository by indexing the terms by their name of identifier (otherwise accessing a term would require exhaustive searching through the entire WordNet or MeSH files). The information content of all terms is also computed in advance and stored separately in the information content database. The user is provided with several options at the user interface (e.g., sense selection, method selection).

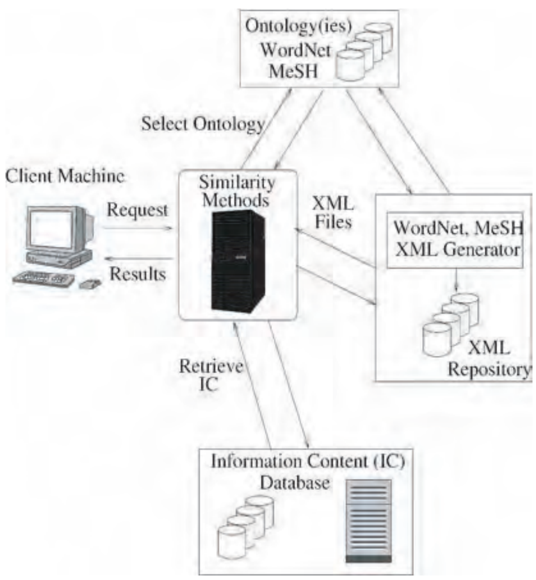
Evaluation of Semantic Similarity Methods

In the following, we present a comparative evaluation of the similarity methods referred to previously.

Table 1. Summary of semantic similarity methods

Method	Method Type	Increases with Commonality	Decreases with Difference	Symmetric Property	Normalized in [0,1]	Position in Hierarchy
(Rada et al., 1989)	Edge Counting	yes	yes	yes	yes	no
(Wu & Palmer, 1994)	Edge Counting	yes	yes	yes	yes	yes
(Li et al., 2003)	Edge Counting	yes	yes	yes	yes	yes
(Leacok & Chodorov, 1998)	Edge Counting	no	yes	yes	no	yes
(Richardson et al., 1994)	Edge Counting	yes	yes	yes	yes	yes
(Resnik, 1999)	Info Content	yes	no	yes	no	yes
(Lin,1993)	Info Content	yes	yes	yes	yes	yes
(Lord et al., 2003)	Info Content	yes	no	yes	yes	yes
(Jiang & Conrath, 1998)	Info Content	yes	yes	yes	no	yes
(Tversky, 1977)	Feature	yes	yes	no	yes	no
(Rodriguez & Egenhofer, 2003)	Hybrid	yes	yes	no	yes	no

Figure 3. Semantic similarity system



Semantic Similarity on WordNet

In accordance with previous research (Resnik, 1999), we evaluated the results obtained by applying the semantic similarity methods presented in this work to the same pairs used in the experiment by Miller and Charles (1991): 38 undergraduate students were given 30 pairs of nouns and were asked to rate the similarity of each pair on a scale from 0 (not similar) through 4 (perfect synonymy). The average rating of each pair represents a good estimate of how similar the two words are.

We compared the computed similarity scores for the same terms as in Miller and Charles with the human relevance results reported there. The similarity values obtained by all competitive computational methods (all senses of the first term are compared with all senses of the second term) are correlated with the average scores obtained by the humans in Miller and Charles (1991). The higher the correlation of a method the better the method is (i.e., the more it approaches the results of human judgments).

Table 2 shows the correlation obtained by each method. Jiang et al. (1998) suggested removing one of the pairs from the evaluation. This increased the correlation of their method to 0.87. The method by Li et al. (2003) is among the best and it is also the fastest. These results lead to the following observations:

1. Information Content methods perform very well and close to the upper bound suggested by (Resnik, 1999).
2. Methods that consider the positions of the terms in the hierarchy (e.g., Li et al., 2003) perform better than plain path length methods (e.g., Rada et al., 1989).

Table 2. Evaluation of semantic similarity methods on WordNet

Method	Method Type	Correlation
(Rada et al., 1989)	Edge Counting	0.59
(Wu & Palmer, 1994)	Edge Counting	0.74
(Li et al., 2003)	Edge Counting	0.82
(Leacok & Chodorov, 1998)	Edge Counting	0.82
(Richardson et al., 1994)	Edge Counting	0.63
(Resnik, 1999)	Info Content	0.79
(Lin, 1993)	Info Content	0.82
(Lord et al., 2003)	Info Content	0.79
(Jiang & Conrath, 1998)	Info Content	0.83
(Tversky, 1977)	Feature	0.73
(Rodriguez & Egenhofer, 2003)	Hybrid	0.71

3. Methods exploiting the properties (i.e., structure and information content) of the underlying hierarchy perform better than Hybrid and Feature based methods, which do not fully exploit this information. However, Hybrid and feature based methods (e.g., Rodriguez et al., 2003), are mainly targeted towards cross ontology similarity applications where edge counting and information content methods do not apply.

Semantic Similarity on MeSH

An evaluation of Semantic Similarity methods on MeSH haven't been reported in the literature before. For the evaluation, we designed an experiment similar to that by Miller and Charles (1991) for WordNet: We asked a medical expert to compile a set of MeSH term pairs. A set of 49 pairs was proposed, together with an estimate of similarity between 0 (not similar) and 4 (perfect similarity) for each pair. To reduce the subjectivity of similarity estimates, we created a form-based interface with all pairs on the Web[9] and we invited other medical experts to enter their evaluation (the interface is still accepting results by experts worldwide). So far, we received estimates from 12 experts.

The analysis of the results revealed that: (a) Some medical terms are more involved or ambiguous leading to ambiguous evaluation by many users. For each pair, the standard deviation of their similarity (over all users) was computed. Pairs with standard deviation higher than a user defined threshold t=0.8 were excluded from the evaluation. (b) Medical experts were not at the same level of expertise and (in some cases) gave unreliable results. For each user we computed the standard deviation of their evaluation (over all pairs). We excluded users who gave significantly different results from the majority of other users. Overall, 13 out of the 49 pairs and 4 out of the 12 users were excluded from the evaluation.

Following the same procedure as in the WordNet experiments, the similarity values obtained by each method (all senses of the first term are compared with all senses of the second term) are correlated with the average scores obtained by the humans.

The correlation results are summarized in Table 3. These results lead to similar observations with the previous experiment:

1. Edge counting and information content methods perform about equally well. However, methods that consider the positions of the

Table 3. Evaluation of semantic similarity methods on MeSH

Method	Method Type	Correlation
(Rada et al., 1989)	Edge Counting	0.50
(Wu & Palmer, 1994)	Edge Counting	0.67
(Li, et al., 2003)	Edge Counting	0.70
(Leacok & Chodorov, 1998)	Edge Counting	0.74
(Richardson, et al., 1994)	Edge Counting	0.64
(Resnik, 1999)	Info Content	0.71
(Lin, 1993)	Info Content	0.72
(Lord et al., 2003)	Info Content	0.70
(Jiang & Conrath, 1998)	Info Content	0.71
(Tversky, 1977)	Feature	0.67
(Rodriguez & Egenhofer, 2003)	Hybrid	0.71

terms (lower or higher) in the hierarchy (e.g., Li et al., 2003) perform better than plain path length methods (e.g., Rada et al., 1989).

2. Hybrid and feature based methods exploiting properties of terms (e.g., scope notes, entry terms) perform at least as well as information content and edge counting methods (exploiting information relating to the structure and information content of the underlying taxonomy), implying that term annotations in MeSH represent significant information by themselves and that it is possible to design even more effective methods by combining information from all the sources listed previously (term annotations, structure information and information content).

SEMANTIC SIMILARITY RETRIEVAL MODEL (*SSRM*)

Traditionally, the similarity between two documents (e.g., a query q and a document d) is computed according to the Vector Space Model (VSM) (Salton, 1989) as the cosine of the inner product between their document vectors:

$$Sim(q,d) = \frac{\sum_i q_i d_i}{\sqrt{\sum_i q_i^2 \sum_i d_i^2}} \qquad (1)$$

where q_i and d_i are the weights in the two vector representations. Given a query, all documents are ranked according to their similarity with the query. This model is also known as the “bag of words model” for document retrieval.

The lack of common terms in two documents does not necessarily mean that the documents are unrelated. Semantically similar concepts may be expressed in different words in the documents and the queries, and direct comparison by word-based VSM is not effective. For example, VSM will not recognize synonyms or semantically similar terms (e.g., “car,” “automobile”).

SSRM suggests discovering semantically similar terms using term taxonomies like WordNet or MeSH. Query expansion is also applied as a means for capturing similarities between terms of different degrees of generality in documents and queries (e.g., “human,” “man”). Queries are augmented with conceptually similar terms, which are retrieved by applying a range query in the neighborhood of each term in an ontology. Each query term is expanded by synonyms, hyponyms, and hypernyms. The degree of expansion is controlled by the user (i.e., so that each query term may introduce new terms more than one level higher or lower in an ontology). *SSRM* can work with any general or application specific ontology.

The selection of ontology depends on the application domain (e.g., WordNet for image retrieval on the Web (Varelas, Voutsakis, Raftopoulou, Petrakis, & Milios, 2005), MeSH for retrieval in medical document collections (Hliaoutakis, Varelas, Petrakis, & Milios, 2006)).

Query expansion by *SSRM* resembles the idea by Voorhees (1994). However, Voorhees did not show how to compute good weights for the new terms introduced into the query after expansion nor it showed how to control the degree of expansion. Notice that, high degree of expansion results in topic drift. *SSRM* solves this problem and implements an intuitive and analytic method for setting the weights of the new query terms.

Voorhees relied on the Vector Space Model (VSM) and therefore on lexical term matching for computing document similarity. Therefore, it is not possible for this method to retrieve documents with conceptually similar but lexically different terms. *SSRM* solves this problem by taking all possible term associations between two documents into account and by accumulating their similarities.

Similarly to VSM, queries and documents are first syntactically analyzed and reduced into term vectors. Very infrequent or very frequent terms are eliminated. Each term in this vector is represented by its weight. The weight of a term is computed as a function of its frequency of occurrence in the document collection and can be defined in many different ways. The term frequency-inverse document frequency model (Salton, 1989) is used for computing the weight: The weight d_i of a term *i* in a document is computed as $d_i = tf_i \cdot idf_i$, where tf_i is the frequency of term *i* in the document and idf_i is the inverse document frequency of *i* in the whole document collection.

Then SSRM works in three steps:

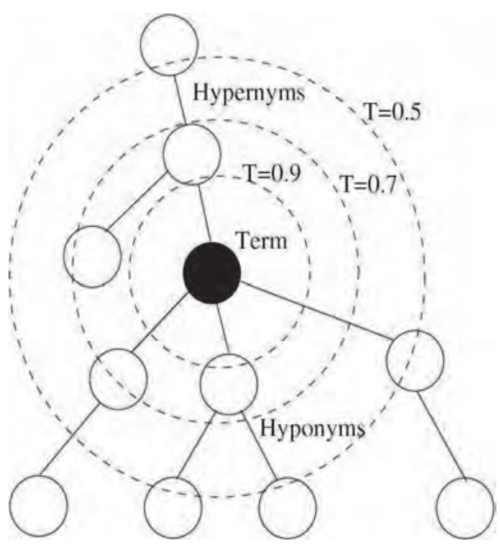
Query Re-Weighting: The weight q_i of each query term *i* is adjusted based on its relationships with other semantically similar terms *j* within the same vector:

$$q_i' = q_i + \sum_{sim(i,j) \geq t}^{j \neq i} q_j sim(i,j) \qquad (2)$$

where *t* is a user defined threshold (*t*=0.8 in this article). Multiple related terms in the same query reinforce each other (e.g., "railway," "train," and "metro"). The weights of non-similar terms remain unchanged (e.g., "train," "house"). For short queries specifying only a few terms the weights are initialized to 1 and are adjusted according to the formula in Equation 2.

Query Expansion: First, the query is augmented by synonym terms, using the most common sense of each query term. Then, the query is augmented by terms higher or lower in the tree hierarchy (i.e., hypernyms and hyponyms) which are semantically similar to terms already in the query. Figure 4 illustrates this process: Each query term is represented by its tree hierarchy. The neighborhood of the term is examined and all terms with similarity greater than threshold *T* are also included in the query vector. This expansion may include terms more than one level higher or lower than the original term. Then, each query

Figure 4. Term expansion



term i is assigned a weight as follows:

$$q_i' = \begin{cases} q_i + \sum\limits_{sim(i,j) \geq T}^{i \neq j} \frac{1}{n} q_j \, sim(i,j), & i \text{ had weight } q_i \\ \sum\limits_{sim(i,j) \geq T}^{i \neq j} \frac{1}{n} q_j \, sim(i,j), & i \text{ is a new term} \end{cases} \quad (3)$$

where n is the number of hyponyms of each expanded term j. For hypernyms $n=1$. The summation is taken over all terms j introducing terms to the query. It is possible for a term to introduce terms that already existed in the query. It is also possible that the same term is introduced by more than one other terms. Equation 2, suggests taking the weights of the original query terms into account and that the contribution of each term in assigning weights to query terms is normalized by the number n of its hyponyms. After expansion and re-weighting, the query vector is normalized by document length, like each document vector.

Document Similarity: The similarity between an expanded and re-weighted query q and a document d is computed as:

$$Sim(q,d) = \frac{\sum_i \sum_j q_i q_j \, sim(i,j)}{\sum_i \sum_j q_i q_j} \quad (4)$$

where i and j are terms in the query and the document respectively. Query terms are expanded and re-weighted according to the previous steps while document terms d_j are computed as *tf idf* terms (they are neither expanded nor re-weighted). The similarity measure in Equation 4 is normalized in the range [0,1]. Figure 5 presents a summary of *SSRM*.

Discussion

SSRM relaxes the requirement of classical retrieval models that conceptually similar terms be mutually independent (known also as "synonymy problem"). It takes into account dependencies between terms during its expansion and re-weighting steps. Their dependence is expressed quantitatively by virtue of their semantic similarity and this information is taken explicitly into account in the computation of document similarity. Notice however the quadratic time complexity of *SSRM* due to Equation 3 as opposed to the linear time complexity of Equation 1 of VSM. To speed up similarity computations, the semantic similarities

Figure 5. SSRM algorithm

Input: Query q, Document d, Semantic Similarity function *sim()*, Thresholds t, T, Ontology.
Output: Document similarity value $Sim(d,q)$.

1. **Compute query term vector**: $q=(q_1,q_2,...)$ using *tf idf* weighting scheme.
2. **Compute document term vector**: $d=(d_1,d_2,...)$ using *tf idf* weighting scheme.
3. **Query re-weighting**: For all term i in q computer new weight based on other semantically similar terms j in q as $q_i' = q_i + \sum\limits_{sim(i,j) \geq t}^{j \neq i} q_j \, sim(i,j)$.
4. **Query expansion**: For all terms j in q retrieve terms i from ontology satisfying $sim(i,j) \geq T$.
5. **Term re-weighting**: For all terms i in q compute new weight as
$$q_i' = \begin{cases} q_i + \sum\limits_{sim(i,j) \geq T}^{i \neq j} \frac{1}{n} q_j \, sim(i,j), & i \text{ had weight } q_i \\ \sum\limits_{sim(i,j) \geq T}^{i \neq j} \frac{1}{n} q_j \, sim(i,j), & i \text{ is a new term} \end{cases}$$
6. **Query Normalization**: Normalize query by length.
7. **Compute document similarity**: $Sim(q,d) = \frac{\sum_i \sum_j q_i q_j \, sim(i,j)}{\sum_i \sum_j q_i q_j}$.

between pairs of MeSH or WordNet terms are stored in a hash table. To reduce space only pairs with similarity greater than 0.3 are stored.

SSRM approximates VSM in the case of non-semantically similar terms: If $sim(i,j)=0$ for all $i \neq j$ then Equation 3 is reduced to Equation 1. In this case, the similarity between two documents is computed as a function of weight similarities between identical terms (as in VSM).

Expanding and re-weighting is fast for queries, which are typically short, consisting of only a few terms, but not for documents with many terms. The method suggests expansion of the query only. However, the similarity function will take into account the relationships between all semantically similar terms between the document and the query (something that VSM cannot do).

The expansion step attempts to automate the manual or semi-automatic query re-formulation process based on feedback information from the user (Rochio, 1971). Expanding the query with a threshold T will introduce new terms depending also on the position of the terms in the taxonomy: More specific terms (lower in the taxonomy) are more likely to expand than more general terms (higher in the taxonomy). Notice that expansion with low threshold values T (e.g., T=0.5) is likely to introduce many new terms and diffuse the topic of the query (topic drift). The specification of threshold T may also depend on query scope or user uncertainty. A low value of T might be desirable for broad scope queries or for initially resolving uncertainty as to what the user is really looking for. The query is then repeated with higher threshold. High values of threshold are desirable for very specific queries: Users with high degree of certainty might prefer to expand with a high threshold or not to expand at all.

The specification of T in Equation 2 requires further investigation. Appropriate threshold values can be learned by training or relevance feedback (Rui, Huang, Ortega, & Mechrota, 1998). Word sense disambiguation (Patwardhan, Banerjee, & Petersen, 2003) can also be applied to detect the correct sense to expand rather than expanding the most common sense of each term. *SSRM* also makes use of a second threshold t for expressing the desired similarity between terms within the query (Equation 1). Our experiments with several values of t revealed that the method is rather insensitive to the selection of this threshold. Throughout this article we set t = 0.8.

Evaluation of *SSRM*

SSRM has been tested on two different applications and two data sets respectively. The first application is retrieval of medical documents using MeSH and the second application is image retrieval on the Web using WordNet.

The experimental results illustrate that it is possible to enhance the quality of classic information retrieval methods by incorporating semantic similarity within the retrieval method.

SSRM outperforms classic and state-of-the-art semantic information retrieval methods (Richardson et al., 1995; Salton, 1989; Voorhees, 1994). The retrieval system is built upon Lucene[10], a full-featured text search engine library written in Java. All retrieval methods are implemented on top of Lucene.

The following methods are implemented and evaluated:

1. Semantic Similarity Retrieval Model (SSRM): Queries are expanded with semantically similar terms in the neighborhood of each term. The results that follow correspond to two different thresholds T=0.9 (i.e. the query is expanded only with very similar terms) and T=0.5 (i.e., the query is expanded with terms which are not necessarily conceptually similar). In WordNet, each query term is also expanded with synonyms. Because no synonymy relation is defined in MeSH we did not apply expansion to Mesh terms in the query with Entry Terms. Semantic similarity in SSRM is computed by Li et al., 2003).

2. Vector Space Model (VSM) (Salton, 1989): Text queries can also be augmented by synonyms.
3. Term expansion (Voorhees, 1994): The query terms are expanded always with hyponyms one level higher or lower in the taxonomy and synonyms. The method did not propose an analytic method for computing the weights of these terms.
4. Semantic similarity accumulation (Richardson et al., 1995): Accumulates the semantic similarities between all pairs of document and query terms. It ignores the relative significance of terms (as it is captured by *tf idf*). Query terms are not expanded nor re-weighted as in SSRM.

In the experiments that follow, each method is represented by a *precision/recall* curve. For each query, the best 50 answers were retrieved (the *precision/recall* plot of each method contains exactly 50 points). Precision and recall values are computed from each answer set and therefore, each plot contains exactly 50 points. The top-left point of a precision/recall curve corresponds to the *precision/recall* values for the best answer or best match (which has rank 1) while the bottom right point corresponds to the *precision/recall* values for the entire answer set. A method is better than another if it achieves better precision and better recall. As we shall see in the experiments, it is possible for two precision-recall curves to crossover. This means that one of the two methods performs better for small answer sets (containing less answers than the number of points up to the cross-section), while the other performs better for larger answer sets. The method achieving higher precision and recall for the first few answers is considered to be the better method (based on the assumption that typical users focus their attention on the first few answers).

Information Retrieval on OHSUMED

SSRM has been tested on OHSUMED[11] (a standard TREC collection with 293,856 medical articles from Medline published between 1988-1991) using MeSH as the underlying ontology. All OHSUMED documents are indexed by title, abstract and MeSH terms (MeSH Headings). These descriptions are syntactically analyzed and reduced into separate vectors of MeSH terms which are matched against the queries according to Equation 3 (as similarity between expanded and re-weighted vectors). The weights of all MeSH terms are initialized to one while the weights of titles and abstracts are initialized by *tf idf*. The similarity between a query and a document is computed as:

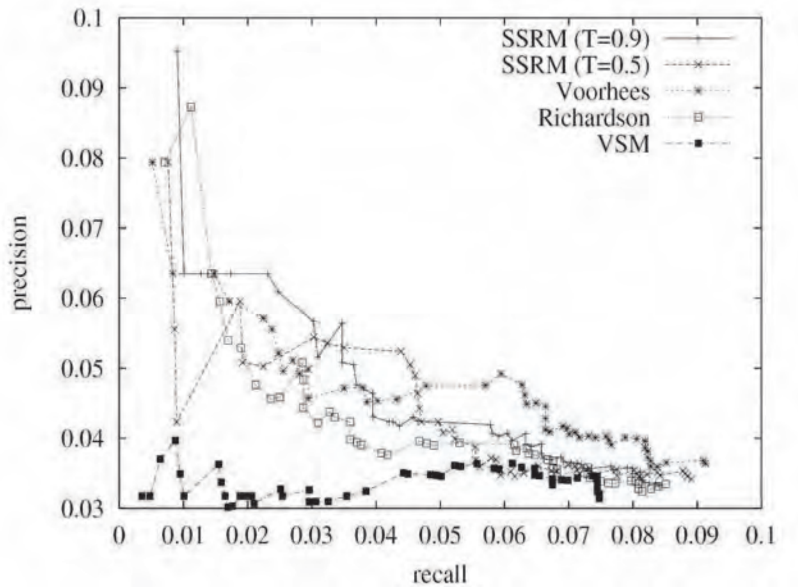
$$Sim(q,d) = Sim(q,d_{MeSH-terms}) + Sim(q,d_{title}) + Sim(q,d_{abstract}) \qquad (5)$$

where $d_{MeSH\text{-}terms}$, d_{title} and $d_{abstract}$ are the representations of the document MeSH terms, title and abstract respectively. This formula suggests that a document is similar to a query if its components are similar to the query. Each similarity component can be computed either by VSM or by *SSRM*.

For the evaluations, we applied the subset of 63 queries of the original query set developed by Hersh et al. (1994). The correct answers to these queries were compiled by the editors of OHSUMED and are also available on the Web along with the queries. A document is considered similar to a query if the query terms are included in the document. OHSUMED provides the means for comparing the performance of different methods. However, it is not particularly well suited for semantic information retrieval with *SSRM*. A better criterion would be to judge whether a document is on the topic of the query (even if it contains lexically different terms).

The results in Figure 6 demonstrate that *SSRM* with expansion with very similar terms T=0.9 and for small answer sets (i.e., with less than eight an-

Figure 6. Precision-recall diagram for retrievals on OHSUMED using MeSH



swers) outperforms all other methods (Richardson et al., 1995; Salton, 1989; Voorhees, 1994). For larger answer sets, Voorhees (1994) is the best method. For answer sets with 50 documents all methods (except VSM) perform about the same. *SSRM* with expansion threshold *T*=0.5 performed worse than *SSRM* with *T*=0.9. An explanation may be that it introduced many new terms and not all of them are conceptually similar with the original query terms.

Image Retrieval on the Web

Searching for effective methods to retrieve information from the Web has been in the center of many research efforts during the last few years. The relevant technology evolved rapidly thanks to advances in Web systems technology (Arasu, Cho, Garcia-Molina, Paepke, & Raghavan, 2002) and information retrieval research (Yates et al., 1999). Image retrieval on the Web, in particular, is a very important problem in itself (Kherfi, Ziou, & Bernardi, 2004). The relevant technology has also evolved significantly propelled by advances in image database research (Smeulders, Worring, Santini, Gupta, & Jain, 2000).

Image retrieval on the Web requires that content descriptions be extracted from Web pages and used to determine which Web pages contain images that satisfy the query selection criteria. Several approaches to the problem of content-based image retrieval on the Web have been proposed and some have been implemented on research prototypes, for example, ImageRover (Taycher, Cascia, & Sclaroff, 1997), WebSEEK (Smith & Chang, 1997), Diogenis (Aslandongan & Yu, 2000), and commercial systems, Google Image Search[12], Yahoo[13], and Altavista[14]. Because, methods for extracting reliable and meaningful image content from Web pages by automated image analysis are not yet available images on the Web are typically described by text or attributes associated with images in html tags (e.g., filename, caption, alternate text etc.). These are automatically extracted from the Web pages and are used in retrievals. Google, Yahoo, and AltaVista are example systems of this category.

We choose the problem of image retrieval based on surrounding text as a case study for this evaluation. *SSRM* has been evaluated through *IntelliSearch*[15], a prototype Web retrieval system for Web pages and images in Web pages. An earlier system we built supported retrievals using only VSM (Voutsakis, Petrakis, & Milios, 2005). In this article, the system has been extended to support retrievals using *SSRM* with WordNet as the underlying reference ontology. The retrieval system of *IntelliSearch* is built upon Lucene and the database stores more than 1.5 million Web pages with images.

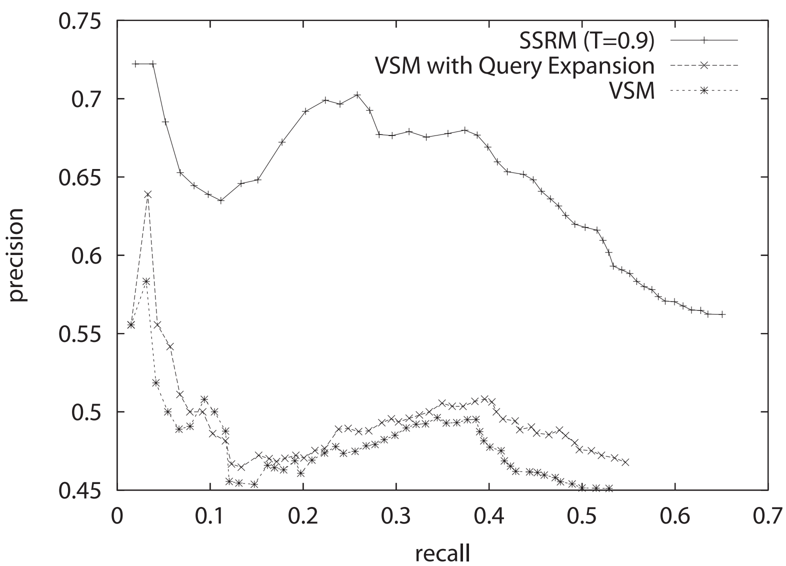
As it is typical in the literature (Petrakis, Kontis, Voutakis, & Milios, 2005; Shen, Ooi, & Tan, 2000; Voutsakis et al., 2005), the problem of image retrieval on the Web is treated as one of text retrieval as follows: Images are described by the text surrounding them in the Web pages (i.e., captions, alternate text, image file names, page title). These descriptions are syntactically analyzed and reduced into term vectors, which are matched against the queries. Similarly, to the previous experiment, the similarity between a query and a document (image) is computed as:

$$Sim(q,d) = Sim(q,d_{image-file-name}) + Sim(q,d_{caption}) + Sim(q,d_{page-title}) + Sim(q,d_{alternate-text}) \quad (6)$$

For the evaluations, 20 queries were selected from the list of the most frequent Google image queries. These are short queries containing between 1 and 4 terms. The evaluation is based on human relevance judgments by five human referees. Each referee evaluated a subset of four queries for both methods.

Figure 7 indicates that *SSRM* is far more effective than VSM achieving up to 30% better precision and up to 20% better recall. A closer look into the results reveals that the efficiency of *SSRM* is mostly due to the contribution of non-identical but semantically similar terms. VSM (like most classical retrieval models relying on lexical term matching) ignore this information. In VSM, query terms may also be expanded with synonyms. Experiments with and without expansion by synonyms are presented. Notice that VSM with query expansion by synonyms improved the results of plain VSM only marginally, indicating that the performance gain of *SSRM* is not due to

Figure 7. Precision-recall diagram for retrievals on the Web using WordNet



the expansion by synonyms but rather due to the contribution of semantically similar terms.

CONCLUSION

This article makes two contributions. The first contribution is to experiment with several semantic similarity methods for computing the conceptual similarity between natural language terms using WordNet and MeSH. To our knowledge, similar experiments with MeSH have not been reported elsewhere. The experimental results indicate that it is possible for these methods to approximate algorithmically the human notion of similarity reaching correlation (with human judgment of similarity) up to 83% for WordNet and up to 74% for MeSH. The second contribution is SSRM, information retrieval method that takes advantage of this result. *SSRM* outperforms VSM, the classic information retrieval method and demonstrates promising performance improvements over other semantic information retrieval methods in retrieval on OHSUMED, a standard TREC collection with medical documents, which is available on the Web. Additional experiments have demonstrated the utility of SSRM in Web image retrieval based on text image descriptions extracted automatically. *SSRM* has been also tested on Medline[16], the premier bibliographic database of the U.S. National Library of Medicine (NLM) (Hliaoutakis et al., 2006). All experiments confirmed the promise of SSRM over classic retrieval models. SSRM can work in conjunction with any taxonomic ontology like MeSH or WordNet and any associated document corpus. Current research is directed towards extending *SSRM* to work with compound terms (phrases), and more term relationships (in addition to the Is-A relationships).

ACKNOWLEDGMENT

Dr Qiufen Qi of Dalhousie University for prepared the MeSH terms and the queries for the experiments with MeSH and evaluated the results of retrievals on Medline. We thank Nikos Hurdakis, and Paraskevi Raftopoulou for valuable contributions into this article. The U.S. National Library of Medicine provided us with the complete data sets of MeSH and Medline. This article was funded by project MedSearch/BIOPATTERN (Fp6, Project No 508803) of the European Union (EU), the Natural Sciences and Engineering Research Council of Canada, and IT Interactive Services Inc.

Chapter 2.22
A Distributed Patient Identification Protocol Based on Control Numbers with Semantic Annotation

ABSTRACT

One important problem of information systems in health care is the localisation and access to electronic patient records across health care institute boundaries, especially in an international setting. The complexity of the problem is increased by the absence of a globally accepted standard for electronic health care records, the absence of unique patient identifiers in most countries, and the strict data protection requirements that apply to clinical documents. This article describes a protocol that allows the identification of locations of patient records for a given patient and provides access to these records, if granted, under consideration of the legal and technical requirements. The protocol combines cryptographic techniques with semantic annotation and mediation and presents a simple Web-service-based access to clinical documents.

INTRODUCTION

Information technology used in the health care sector is most often characterised by heterogeneity of systems, longevity of data and devices, and high availability requirements. While the heterogeneity and longevity of systems is a consequence of the fact that expensive special-purpose devices such as MRI (magnetic resonance imaging) scanners are produced by only a few vendors and need to be integrated with the existing IT infrastructure, the longevity and availability requirements of medical data such as images and diagnostic reports are related directly to the care process. Since patient treatment needs to continue, even if some part of the IT infrastructure is off-line, a distributed data storage with loose message-based coupling between devices is used most often. This implies that data inconsistencies between systems are not unusual and need to be accounted for. These properties of IT systems in health care explain the pressing need for interface standardisation and interoperability in this field, reflected by comprehensive interface standards like DICOM (NEMA, 2004) and HL7 (2003). According to the CEN/ISSS eHealth Standardization Focus Group (2004), a study currently being performed at the request of the European Commission, the key strategic aims for applications of information and communication technology to health services include improving access to clinical records and enabling patient mobility and cross-border access to health care. While much work has been devoted to developing standard system interfaces for applications within a single health care enterprise (i.e., hospital or private practice), the digital cross-enterprise exchange of clinical records is certainly the exception rather than the norm today, particularly in the case of cross-border communication. A key issue in this field is the absence of a unique identifier that could be used to unambiguously identify records pertaining to a particular patient. In this article, we discuss requirements for locating and accessing clinical records across enterprise and country borders under consideration of data protection and propose a protocol based on control numbers and semantic annotation that addresses these requirements. This protocol is being developed within the framework of the ARTEMIS project, which is introduced in the following section.

THE ARTEMIS PROJECT

The ARTEMIS project (ARTEMIS Consortium, 2004; Dogac et al., in press), funded by the European Union, aims to improve the interoperability of clinical information systems among different organisations, based on Semantic Web Services and suitable domain ontologies. A health care organisation can join the ARTEMIS peer-to-peer (P2P) network and advertise electronic services, such as the provision of access to a patient's electronic health care record (given suitable authorisation) and access to different subsystems (e.g., patient admission or laboratory information systems). Within the ARTEMIS network, further services might be invoked dynamically, for example, in order to translate and map among different representations of health care information. In ARTEMIS, all participating health care organisations (peers) are coupled loosely via the ARTEMIS P2P network. Groups of participating organisations are coupled via so-called Super Peers, which are connected among each other. The project is carried out with partners from Turkey, Germany, Greece, and the United Kingdom.

THE PATIENT IDENTIFICATION PROTOCOL

While a number of projects currently are attempting to establish central electronic health record (EHR) archives for certain regions or countries, most clinical records are still kept and maintained at the place of their creation. This means that, given a patient with a disease requiring long-term treatment (such as diabetes), related clinical records may be located at one or more family doctors' practices, several specialists, labs, and a number of hospitals. In particular, the patient may not even be aware of all the locations where records relevant to a particular medical problem may be kept. Any protocol that attempts to make relevant clinical documents available in digital form needs to take this distributed nature of document storage into account. The advent of wide area networks such as the Internet, along with various VPN (virtual private network) technologies provides a solution to the underlying problem of a digital transport connection between document requestor and document provider, but it does not solve the problem of how to *locate* the relevant records.

The task of locating relevant medical records is complicated by the fact that there is no unique patient identifier that could be broadcast as a query in order to locate information pertaining to one patient. While countries such as Turkey, Norway, and Sweden maintain a national person identifier that commonly is used as the index key for medical records, no such unique identifier is available in most other countries either for historic reasons or due to data protection regulations. This means that a query applicable to cross-border health care delivery only can be based on the patient demographics that are commonly available, including the patient's name, date and place of birth, sex, nationality, and postal address.

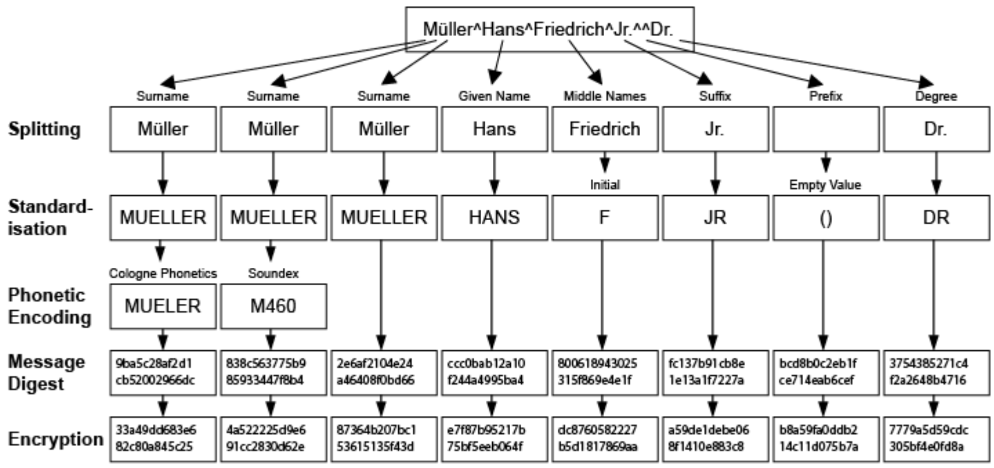
It should be noted that the set of demographics available may depend on the location (i.e., a national patient identifier certainly would be included in any query *within* a country in which it is valid) and on the patient's health condition (i.e., whether the patient is able to provide the doctor with additional information not contained in the passport or driver's license, which may be the only source of information available for an emergency patient). It also should be noted that spelling errors in medical record archives are not uncommon and may need to be accounted for, using, for example, phonetic encoding techniques. An additional challenge for cross-border application is the different character sets used in different European countries. For example, names of patients of Turkish origin are certainly common in German hospital information systems, since this group accounts for more than 2% of the population. However, Turkish names may contain characters not present in the Latin-1 alphabet (ISO, 1999b) commonly used by information systems in Germany, since the Turkish language requires the Latin-9 alphabet (ISO, 1999a), which means that the spelling of one name may differ, depending on the character set supported by the information system.

Since medical records generally are considered to be sensitive personal information, it would neither be appropriate (or legal) for a health care enterprise to allow third parties to browse through the demographics of the local record archive, nor would it be appropriate if a request of the form *Hospital X is looking for prior psychiatry records for patient Hans Friedrich Müller, born 12-24-1960 in Hamburg* were made available widely (i.e., broadcast) to all health care institutes in the network that might possibly have such records available. Clearly, the query already communicates information to the recipient that needs to be protected under the applicable data protection rules; namely, the facts that Mr.Müller currently receives treatment at Hospital X and may have had a prior psychiatric treatment. We propose the use of control numbers along with semantic annotation and a probabilistic record linkage as a way of addressing the possible fuzziness of demographic data and at the same time preventing an inappropriate (i.e., premature and unlimited) communication of personal data.

Control Numbers and Record Linkage

Control numbers is a concept that is used in the epidemiological cancer registries in Germany to allow record linkage of anonymised records that describe cancer cases and are collected independently of multiple sources, as described by Thoben, Appelrath, and Sauer (1994). The patient identification protocol makes use of this concept in a modified form. The generation of a set of control numbers from a set of demographic values is performed through the following series of five processing steps, as shown in Figure 1:

Figure 1. Creation of control numbers



- **Splitting.** This first step initialises the process. The available demographics are split into fields that later are converted into different control numbers. For example, the date of birth typically would be split into different components for year, month, and day.
- **Standardisation.** This step addresses character set issues. Each component is standardised according to a set of rules that needs to be known to all parties participating in the protocol. Standardisation typically would involve conversion of names to upper-case ASCII characters, zero-padding of numbers such as day and month of birth, and the initialisation of unknown and empty fields with well known constants representing the concept of an unknown or empty value. The standardisation process certainly could be extended to Unicode to also cover multi-byte character sets such as Chinese or Japanese Kanji, for which a conversion of names to ASCII may not be appropriate, but this topic is not discussed further within the scope of this article.
- **Phonetic encoding.** Optionally, name components may be encoded with a phonetic encoding, such as the Soundex coding system used by the United States Census Bureau, the Metaphone algorithm or the Cologne phonetics for the German language (Postel, 1969). It should be noted that phonetic encoding is highly language-specific, and therefore, different encodings are likely to be used in different countries. For this reason, a name component always would be converted to at least two different control numbers, one with and one without phonetic encoding.
- **Message digest.** Each standardised and possibly phonetically encoded field in the set of demographics is subjected to a cryptographic message digest algorithm such as MD5, SHA-1, or RIPEMD-160 in this step. Due to the cryptographic properties of this class of algorithms, it is not possible to efficiently construct a matching input string to a given message digest; that is, the digest function is not reversible. It should be noted, however, that the set of possible input values for a patient's sex, year, month and day of birth, and so forth is rather limited. A dictionary-based attack, therefore, would quickly re-identify the plain-text source for these fields, along with most of the given names and family names that also could

be determined by means of a dictionary attack.

- **Encryption.** In the final step, each message digest is encrypted with a secret encryption key that needs to be known by all parties in the protocol that generate control numbers to be compared with each other. Each encrypted message digest is called a control number, and the complete set of control numbers describes the patient demographics in a form that does not allow for the reproduction of any plain-text field by any party that does not have access to the encryption key, but it allows for a comparison of two different sets of control numbers without the need for access to the encryption key.

Given a set of control numbers describing a query and a larger number of sets of control numbers describing all patients in a record repository, matches in the repository can be identified using *record linkage*, defined by Winkler (1999) as "the methodology of bringing together corresponding records from two or more files or finding duplicates within files." We propose the use of a probabilistic rather than a deterministic record linkage algorithm, as described by Jaro (1989) as well as Blakely and Salmond (2002). This class of algorithms not only compares each pair of control numbers for equality, but it also considers the significance of each control number, based on an estimation of the true positive rate and the false positive rate; that is, the probabilities of a pair of identical control numbers of representing the same or different patients. The probabilistic record linkage also allows one to compensate to a certain degree for missing data (control numbers that are not available at the record repository), typing errors, and so forth. Basically, the algorithm allows a person to identify the most promising matches from a larger set. The final choice of records that would be treated as definitive matches depends on a threshold and possibly on human choice. Further issues in record linkage, such as array comparison, are discussed in Aden, Eichelberg, and Thoben (2004).

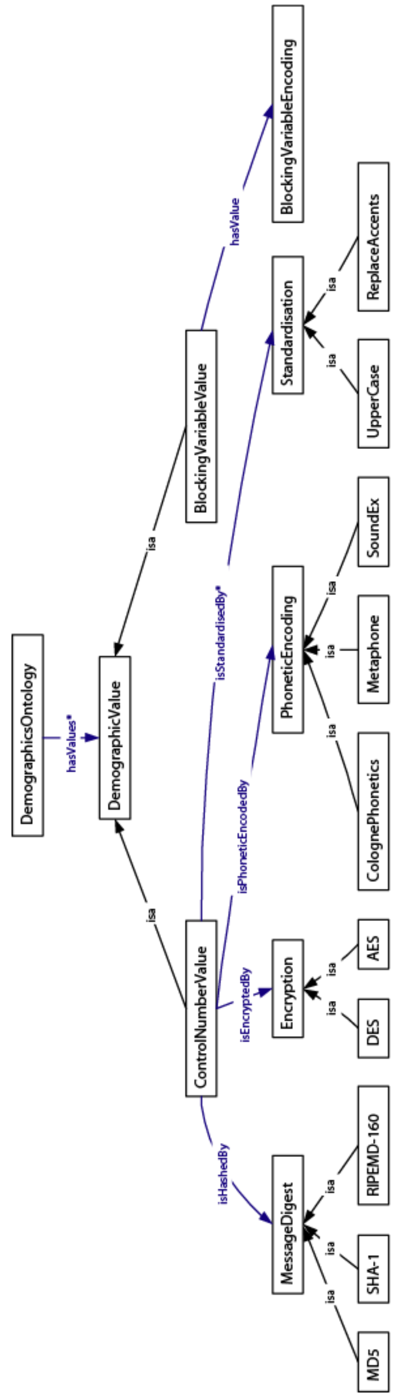
Blocking Variables

The protocol as previously described would require every record repository to create a set of control numbers for each patient in the repository and to repeat this for each incoming query because of the encryption key, which would change with each request. This, of course, is not practical for a large number of patients. Therefore, the protocol uses the concept of so-called *blocking variables* to reduce the number of possible candidate records for which control numbers have to be computed and evaluated. Blocking variables are simply plain-text demographics that are transmitted in unencrypted form (a transport level encryption can be used, of course, but the blocking variables are available to the record repository in plain-text form). Blocking variables must be chosen carefully to make sure that a patient cannot be identified from the blocking variables alone. As an example, the day of birth (not including month and year) certainly would not be sufficient to identify any specific patient but would reduce the number of candidates for which control numbers would have to be computed by a factor of up to 30. Similarly, a postal code of the place of residence or the place of birth would not be sufficient to identify a patient, even when combined with the day of birth, but would reduce significantly the number of candidates in most record repositories (except for hospitals actually located at the given place, where a large number of patients may have the same place of birth or residence). The set of blocking variables needs to be chosen carefully in order to reduce the number of candidate records as much as possible while avoiding the risk of exposing the patient's identity.

Semantic Annotation

As previously described, we can expect different countries to use different, though certainly overlapping, sets of control numbers accounting for country- or region-specific aspects such as phonetic encoding or national unique patient identifiers. Since control numbers only can be compared for binary equality but not evaluated in any other way, it is of prime importance for all parties participating in the protocol to understand exactly what each control number (and each blocking variable) means and which control number is supported by which party. The use of ontology-based semantic annotation allows one to introduce the amount of flexibility into the protocol that is needed to make it work in an international setting, where different sets of control numbers might be supported by different actors. Each request or response dataset consisting of a list of control numbers and blocking variables is encoded as a Web ontology language (OWL) (Dean & Schreiber, 2004) instance that describes the demographics from which each entry was generated, as well as the processing steps that were applied to the entry. Figure 2 shows the core demographics ontology defined for this purpose. A *DemographicsOntology* used by a health care enterprise to describe the supported set of control numbers and blocking variables consists of a set of *DemographicsValue* entities that are either control numbers or blocking variables (the asterisk in the *hasValues* relationship type denotes a one-to-many relationship). For control numbers, the processing steps are described through properties; for blocking variables, the *BlockVariable Encoding* describes the standardisation process or value range. Since different countries typically will use different sets of control numbers, more than one *DemographicsOntology* might exist. The country-, region-, or hospital-specific demographics ontologies (called local ontologies) are defined as extensions to the core ontology. Figure 3 shows a subset of such a local ontology, describing a

Figure 2. Demographics ontology describing control numbers and blocking variables

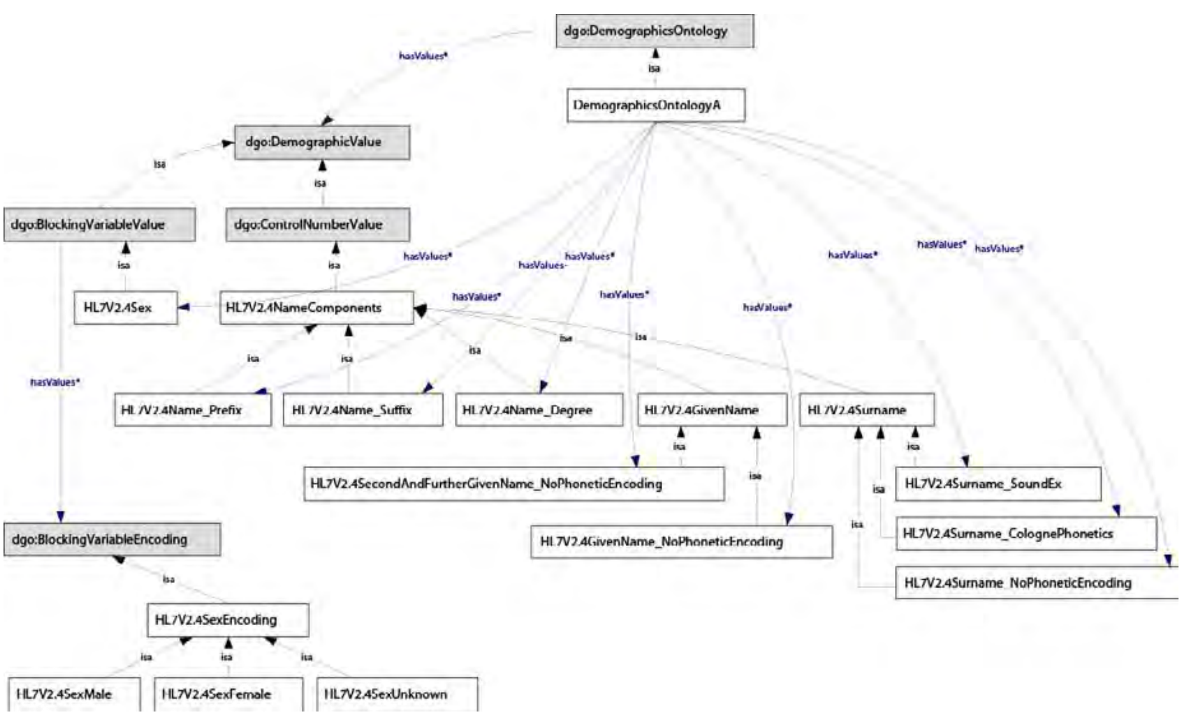


single blocking variable (the patient's sex) and a set of control numbers for the name components as defined in HL7. All ontology classes shown in grey with the prefix *dgo:* in their name refer to the core ontology. OWL restrictions on properties that are not shown in this figure define the algorithms used in the local ontology for standardisation, phonetic encoding, message digest, and encryption. Also not shown is a binary property *isUnique* defined for each subclass of *DemographicValue* that denotes control numbers that guarantee a unique identification of the patient for a match. These properties are used to initialise the weights of the record linkage process accordingly. If the requestor and a record repository in the protocol use different local ontologies, then a direct or indirect mapping between these ontologies is used, which is available both to the record repository (for the purpose of interpreting the blocking variables) and the record linkage server, which is introduced next. A mapping would be defined as an ontology describing *owl:equivalentClass* relationships between ontology classes in the different ontologies, allowing for a reconciliation between the ontology instances using rather simple inference rules. Instance nodes (i.e., individual control numbers or blocking variables) for which no equivalence in the other local ontology can be found simply are omitted from the record linkage process.

Knowledge Distribution

As described, the security of the control numbers is based on the combination of a message digest algorithm followed by an encryption with a session key. The session key, which is randomly generated for each query, guarantees that responses from different queries cannot be compared in order to derive information from the evaluation of a large

Figure 3. Local ontology describing control numbers and blocking variables for one country or institute



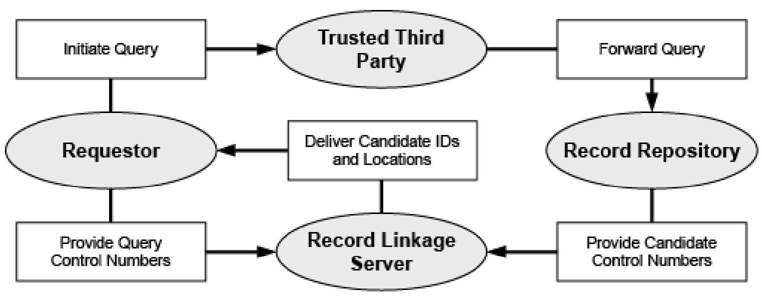
set of queries. However, the problem of dictionary attacks still remains: Any entity that has access to both a set of control numbers and the session key could attempt to decrypt the control numbers and use a dictionary of names, dates, and so forth to re-identify the patient described by the control numbers. In order to prevent this, the following simple policy needs to be established:

Any entity in the network that has access to the session key must not be granted access to any set of control numbers except the control numbers generated by this entity itself.

This means that the initiator of a query for a specific patient (called the *requestor*) cannot receive the control numbers generated by the record repositories responding to the query. The record repositories, on the other hand, cannot be given access to the control numbers in the query, because they need to access the session key in order to generate their own sets of control numbers for all patients matching the blocking variables. Fortunately, the record linkage process does not require access to the session key — only to the control numbers in the query and the responses that were pre-filtered by the record repositories using the blocking variables. Therefore, the protocol needs to introduce additional actors between requestor and record repositories in order to guarantee that no patient-related information is leaked through the protocol before explicit authorisation has been granted. The actors and their transactions in a slightly simplified form are shown in Figure 4. The complete protocol is detailed in Eichelberg, Aden, and Riesmeier (2004). Figure 4 shows the actors involved in the protocols as ovals and the transactions (i.e., message exchange between them) as boxes with an arrow indicating the direction of the information flow. Only a single record repository is shown in the diagram; however, the protocol is designed to work with a potentially large number of record repositories and possibly with more than one instance of the other actors involved. The two additional actors involved are as follows:

- **Record Linkage Server (RLS).** An entity in the network that receives a set of control numbers from the requestor describing the patient to be identified and a possibly large number of sets of control numbers generated by the record repositories, based on the blocking variables and the session key. The RLS performs the probabilistic record linkage and identifies a number of candidates; that is, patient records in the record repositories that have a high probability of referring to the same patient described by the query control numbers. Once the RLS has completed its work and authorisation has been given by the record repositories (see discussion that follows), the set of best matches (based on a threshold value) is reported back to the requestor completing the patient identification process. Since the RLS

Figure 4. Actors and transactions in the Patient Identification Protocol (simplified)



does not have access to the session key, it cannot re-identify the patient demographics from the control numbers it receives. The RLS must be a trusted component in the network in the sense that both requestor and record repositories have to rely on the RLS to never give away any control numbers it receives and never trying to obtain a session key in order to perform a re-identification of patient demographics.

- **Trusted Third Party (TTP).** An entity in the network that enables distribution of the query containing the session key and blocking variables among the record repositories in the network, preventing any direct communication between requestor and record repositories at this stage. The TTP also can act as a gatekeeper to the network in the sense that only requestors accepted by the TTP are able to initiate patient identification queries, and only repositories accepted by the TTP are able to provide information to the RLS. Each match retrieved by the requestor from the RLS consists of a resource identifier (e.g., URL), under which the record repository that has provided this matching record can be contacted, a set of flags indicating for each of the control numbers in the query whether or not they matched or were missing in the response, and a candidate identifier, a simple numeric identifier generated by the record repository as an alias to the local patient ID that identifies a specific patient in the context of the current query transaction and can be used to request medical records for this specific patient.

Medical Record Access

Once a requestor has identified one or more record repositories that have clinical documents pertaining to the current patient available, the appropriate documents have to be selected, requested, retrieved and displayed. This comprises the second phase of the protocol described in this article. Since no global standard for electronic health care records exists at this time that could be used to provide record access in the cross-border scenario previously described, we suggest using the Retrieve Information for Display (RID) (IHE, 2004) protocol defined by the Integrating the Healthcare Enterprise (IHE) initiative (Eichelberg, Poiseau, Wein & Riesmeier, 2003) for this purpose. IHE is a non-profit initiative addressing the issue of system integration in health care with strong participation from industry, science, and medical professional societies in North America, Europe and Japan. While IHE does not develop standards as such, it selects and recommends appropriate standards for specific use cases and develops restrictions (application profiles) for these standards that allow for a simplified system integration. The result of this technical work is published as the *IHE Technical Framework* and revised annually. The *IHE Technical Framework for IT Infrastructure* (IHE, 2004) gives the following short overview about the purpose of the RID integration profile:

The Retrieve Information for Display Integration Profile (RID) provides simple and rapid read-only access to patient-centric clinical information that is located outside the user's current application but is important for better patient care (for example, access to lab reports from radiology department). It supports access to existing persistent documents in well-known presentation formats such as HL7 CDA (Level 1), PDF, JPEG, etc. It also supports access to specific key patient-centric information such as allergies, current medications, summary of reports, etc. for presentation to a clinician.

IHE interface definitions are based on actors (the IT systems involved in the protocol) and transactions (interfaces between actors). In the case of RID, the actors are called *information source* and *display*. The information source, which corresponds to the record repository in the previous discussion, is a system that maintains a database of persistent clinical documents and specific key patient-centric information such as allergies, current medications, summary of reports, and so forth. The display, which corresponds to the requestor, is a system that accesses the information source, retrieves patient-centric information or persistent documents, and displays them to a human observer. The focus of the integration is visual presentation, not a complete integration of the structured databases on which the actors might be based. Documents are exchanged in well-known presentation formats. Communication between display and information source is always initiated by the display and implemented as a Web Service using the Web Services description language (WSDL) with a binding to HTTP GET.

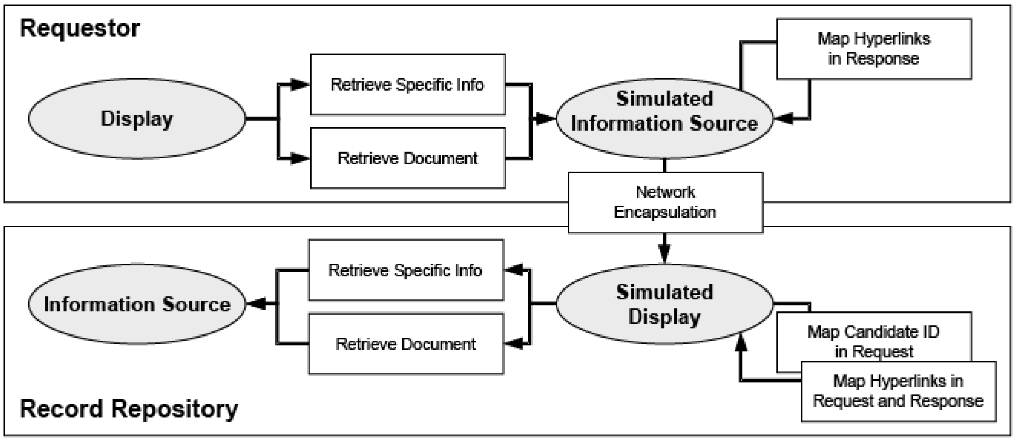
The RID protocol is ideal for integration with the patient identification process described before, because the only *a priori* information that the display needs when accessing a record repository is the patient identifier. This identifier is provided by the patient identification protocol in the form of the candidate identifier, which describes a single patient and is only valid in the context of a single query transaction. Figure 5 shows how an existing RID information source at the record repository site and an existing RID display system at the requestor site can be combined with an additional layer of middleware to provide medical record access in combination with the patient identification protocol.

On the repository site, a simulated display receives the incoming requests from the requestor, replaces the candidate ID generated during the patient identification process by the real patient ID locally used in the hospital, and forwards the request to the existing information source, to which this actor looks like any local display actor. Before forwarding the response to the requestor, all hyperlinks in the response have to be replaced with links pointing to the simulated display, because these hyperlinks typically will refer to resources that cannot be reached directly from the outside world (due to firewall protection and network address translation). Subsequent requests for these mapped hyperlinks simply would be redirected from the simulated display to the original resource. In a similar manner, a hyperlink lookup scheme can be implemented on the requestor site inside the simulated information source to address firewall and network address translation issues. As a side effect, the two simulated actors can provide a secure tunneling of the request and response message, which is usually transmitted in clear text form within a hospital, using any available transport level security protocol. Figure 6 shows the combined sequence of transactions for the patient identification protocol and the following medical record access. In this figure, the PID requestor from Figure 4 and the RID display from Figure 5 have been grouped into a single system providing the user interface to the end user. This is the typical use case and also reflects the ARTEMIS implementation. The scalability aspect of the protocol (i.e., involvement of multiple TTPs and repositories) is not shown for reasons of clarity. The grouped requestor/display actor and the simulated information source are part of the IT infrastructure of the user's site. The TTP and the RLS are central components provided by the network, and all other actors are located at the repository site.

Data Protection and Patient Consent

The EU data protection directive (Council of the European Communities, 1995) and the recommendation of the Council of Europe on the protection of medical data (Council of Europe, 1997) determine that neither person identifying data nor medical records are allowed to be exchanged between different organisations unless either the patient agrees on the exchange of the identifying data and medical records for a specific purpose or the vital interests of the patient are touched.

Figure 5. Access to medical records based on IHE retrieve information for display



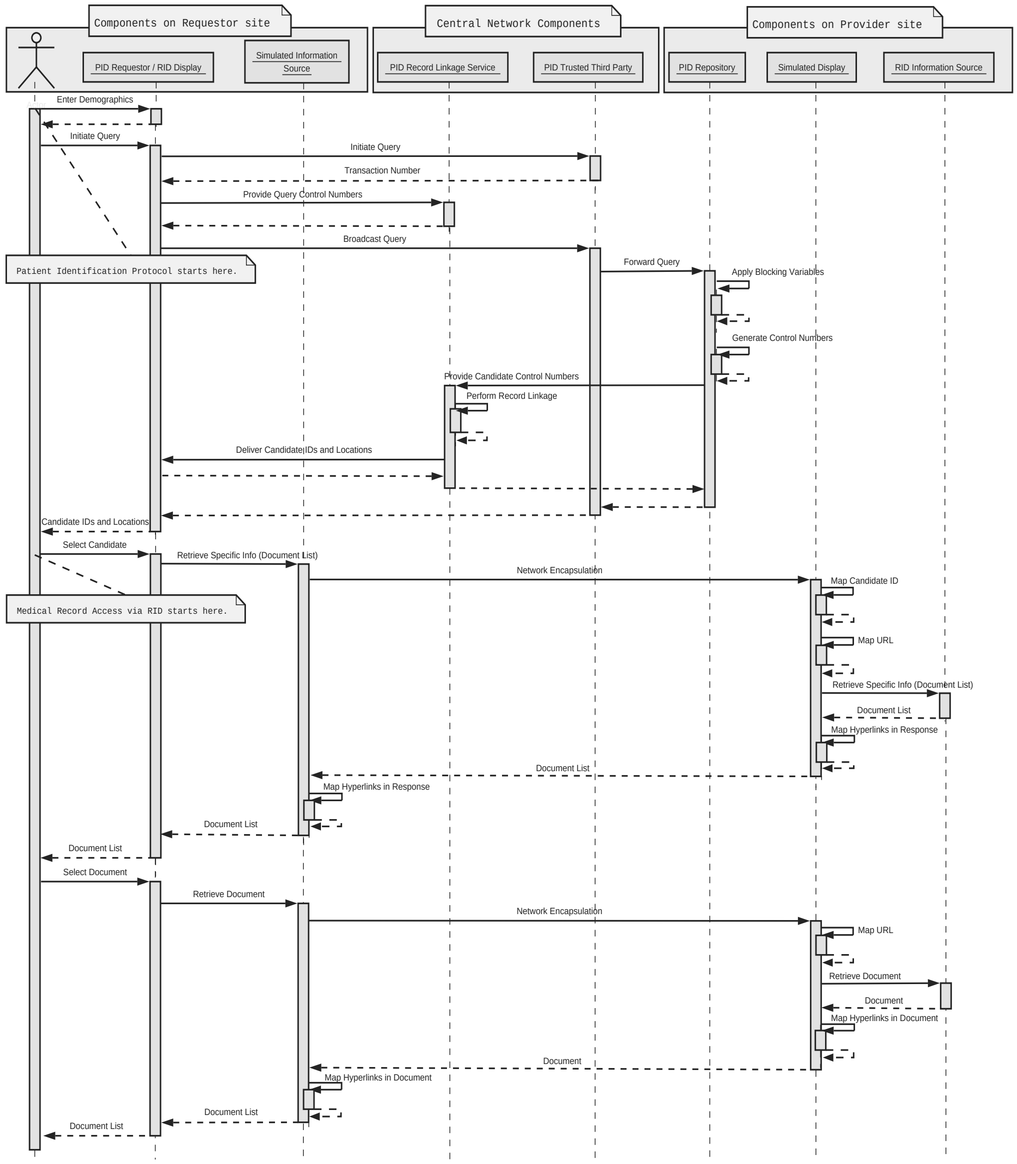
Therefore, in most cases, an explicit patient consent will be a prerequisite to an exchange of medical records.

Since the patient is most likely to be at the health care institute searching for and requesting to access clinical records (i.e., the requestor), the question arises how the patient consent can be demonstrated to the record repository; in particular, if the exact location of the repository is unknown. It should be noted that no information that would allow one to identify a patient or derive any information about a patient is exchanged in the patient identification protocol, until the RLS provides a list of matches to the requestor that is in the last step of the first phase of the protocol depicted in Figure 4. This list of matches enables the requestor to identify resources (i.e., health care institutes) that have clinical documents for the given patient available with a certain probability. The second more significant exchange of information takes place during the second phase of the protocol when the requestor uses the modified Retrieve Information for Display protocol to request and access clinical documents for a specific patient. Correspondingly, there are two places at which additional barriers can be installed in the protocol, barriers that will be opened automatically or manually once the patient consent has been demonstrated to the record repository:

- The requestor may deposit a proof of the patient consent at the RLS when initiating the query. The RLS would make this document available only to those record repositories that have been identified as matches in the record linkage and request permission to report them back to the requestor. Only repositories granting this permission would ever be reported to the requestor.
- The RID access to clinical documents for a specific candidate may require additional authorisation at the repository site requiring a prior communication of the proof of patient consent. It also would be possible to restrict access within the RID protocol to specific documents or document types (e.g., radiology reports).

Two different approaches for demonstrating patient consent are conceivable — the use of a public-key infrastructure (PKI) for patients or a conventional out-of-band communication using possibly digitised letters, telephone, mail, or fax conversation. A PKI for patients would allow for a solution of the issue of patient consent in a fully digital manner by providing a digital signature of the patient authorising the request. This, however, would require that certificates and security

Figure 6. Sequence of transactions for patient identification and medical record access



tokens for the private key, such as smartcards, be issued for all patients. While a few countries, including Belgium, Taiwan, and Germany, have plans for a PKI for the health care sector (Dietzel & Riepe, 2004), there are no such plans in many other countries, and there is no sign of a global or at least a European-wide harmonisation of these PKIs (the European health insurance card does not include PKI functionality).

Since a PKI-based solution will not be available in the foreseeable future for cross-border communication, a conventional approach needs to be supported. As an example, the patient may be asked to sign a letter of consent at the requesting health care institute, and a digitised copy of this letter could be deposited with the RLS and made available to the record repositories for which matches were found during the record linkage process. The data protection officer at each health care institute operating a record repository would check the letter of consent and, if appropriate, give permission to the RLS to report the location of the record repository back to the requestor and grant access to certain clinical documents. In cases where an original handwritten signature is legally required, the digitised document could be accompanied by a contact address at the requesting health care institute where a delivery of an original document (e.g., by express service) could be requested. While it is not realistic to assume a working PKI for patients as a prerequisite to a digital cross-border exchange of clinical records, a working PKI for the health care institutes connected to the network could be implemented rather easily, again utilising the gatekeeper role of the TTP entity in the network. This would assure that only authenticated entities could participate in the protocol either as a requestor or as a record repository and, therefore, would provide a minimum level of quality control of the data communicated within the network.

RESULTS

The patient identification protocol establishes a concept that, to our knowledge, has not been available in the health care sector before — an undirected search for patient records (i.e., a search that does not require *a priori* information about the location of the records) that does not violate data protection requirements. The concept matches well with the peer-to-peer network structure established in the context of the ARTEMIS project, where many health care institutes may form a network of services in a very dynamic manner. The use of semantic annotation allows one to cope with the fact that different institutes identify patients with different demographics and that no globally unique identifier for patients will be available for the foreseeable future. The possibility of including national extensions allows one to maximise the specificity of the search algorithm in environments that can make use of such extensions, while the inclusion of phonetic encoding allows one to improve sensitivity by gracefully handling spelling errors. The integration of the Retrieve Information for Display protocol for the second phase (i.e., the request and transmission of clinical documents once their location has been identified) provides a simple read-only access to clinical documents that easily can be integrated with the existing legacy systems.

An implementation of the patient identification protocol is currently under development in the context of the ARTEMIS project. The implementation is based on the ARTEMIS middleware, which provides for the peer-to-peer infrastructure required by the protocol; that is, message transmission and broadcast facilities based on the JXTA peer-to-peer communication platform (Gong, 2002), a policy-based security architecture for a secure communication over unsecured networks and a pre-selection of record repositories that participate in a query based on geographical location (e.g., "we are looking for records located in Germany only"). Pilot applications that will evaluate the protocol in a clinical setting are planned in the UK and in Turkey. From these prototypes, we expect practical experience about use patterns, performance, and scalability of the protocol. Krieg, Hense, Lehnert, & Mattauch (2001) report about an evaluation of the probabilistic record linkage based on control numbers, which is used in the Münster Cancer Registry in Germany. They use a set of 19 control numbers computed from the patient's name (including name of birth, prior name, and phonetic encoding of the name components) and the day of birth. The clear-text blocking variables comprise the month and year of birth, the patient's sex, and place of residence. They evaluated 27,262 record linkage processes performed in the year 1998 for a database of 101,880 patients. In this case, the record linkage provided a false positive rate (i.e., patients that were incorrectly selected as a match) of 0.36% and a false negative rate (i.e., matches in the database that were not found) of 1.81%. Krieg et al. (2001) emphasise that these figures depend significantly on the size of the database. Nevertheless, the figures indicate that the patient identification protocol provides good results even with a rather limited set of demographics available. It should be noted that in countries that have a national patient identifier available, the record linkage process would be able to provide 0% false positive and false negative rate in repositories that support the national patient ID while still providing results in the order of magnitude shown above for other repositories (i.e., other countries). Additional work will be needed to improve the internationalisation of the splitting and standardisation algorithms for control number generation, which currently are based mainly on German experiences with epidemiological cancer registries. Fine-tuning may be needed for the parameters of the record linkage process in order to maximise specificity and sensitivity of the record linkage process.

CONCLUSION

The patient identification protocol described in this article provides a solution for a common problem in the health care sector that is likely to become very important with the increasing mobility of the workforce in Europe—locating and accessing prior clinical records for the continuity of care. The solution combines techniques from different domains—control numbers, blocking variables, and record linkage procedures as used in epidemiological registries, knowledge distribution, and TTP services from cryptographic communication protocols, semantic annotation, and ontology-based mediation, core technologies of the Semantic Web. The protocol reflects the way clinical records typically are stored, indexed, and accessed in today's health care information systems. While the advent of a universally accepted standard for electronic health care records possibly could render the patient identification protocol obsolete in the future, there is no indication at the moment that such a standard is going to be established in the foreseeable future, and even then, the issue of historical records would remain for a number of years. Therefore, the authors believe that the patient identification protocol can be a significant help in improving access to clinical information while safeguarding data protection rules and protecting the patient's right of self-determination regarding his or her clinical records.

Chapter 2.23
Image Mining for the Construction of Semantic-Inference Rules and for the Development of Automatic Image Diagnosis Systems

Petra Perner
Institute of Computer Vision and Applied Computer Sciences (IBal), Germany

ABSTRACT

This chapter introduces image mining as a method to discover implicit, previously unknown and potentially useful information from digital image and video repositories. It argues that image mining is a special discipline because of the special type of data and therefore, image-mining methods that consider the special data representation and the different aspects of image mining have to be developed. Furthermore, a bridge has to be established between image mining and image processing, feature extraction and image understanding since the later topics are concerned with the development of methods for the automatic extraction of higher-level image representations. We introduce our methodology, the developed methods and the system for image mining which we successfully applied to several medical image-diagnostic tasks.

INTRODUCTION

The increasing number of digital-image and video repositories have made image mining an important task. Image mining means a process of nontrivial extraction of implicit, previously unknown and potentially useful information from image databases. The application of image mining will help to get some additional knowledge about specific features of different classes and the way in which they are expressed in the image. This method can elicit nonformalized expert knowledge; it can automatically create effective models for decision-making, and can help to find some inherent non-evident links between classes and their imaging in the picture. It can help to get some nontrivial conclusions and predictions on the basis of image analysis. The new knowledge obtained as a result of data analysis in the database can enhance the professional knowledge of the expert or the user of the image-database. This knowledge can also be used for teaching novices or can support image analysis and diagnosis by the expert. It can be used for semantic annotation of digital visual content to enable sophisticated semantic querying of the media in terms familiar to the user's domain, whilst also ensuring that the information and knowledge have a much greater chance of being discovered and exploited by services, agents and applications on the Web.

An additional advantage of image-mining application in decision-making of medical or other tasks is on the long-run the opportunity of creating fully automatic image-diagnosis systems that could be very important and useful in the case of lacking knowledge for decision-making.

In this chapter we present our methods and methodology for performing image mining. We describe the recent state of the art in image mining, the questions that can be answered by applying image-mining methods to image databases, and the problems concerned with image mining. A design of image-mining tools is considered followed by a presentation of our methods and the developed tool for image mining. A methodology for image mining that was created and tested in the task of Hep-2 cell analysis is described. Finally, we summarize our experience in applications of image-mining methodology in different medical tasks, such as pre-clinical diagnosis of peripheral lung cancer on the basis of lung tomograms, lymph-node diagnosis and investigation of breast diseases in MRI and the inspection of microscopic images of cell-based assays. Conclusions and plans for future work are given at the end of this chapter.

BACKGROUND

As in data mining, we can classify image mining into two main problem types: prediction and knowledge discovery. While prediction is the strongest goal, knowledge discovery is the weaker approach and usually occurs prior to prediction. In prediction we want to discover a model that allows us, based on the model, to predict new data in the respective classes. In knowledge discovery we want to discover similar groups of database entries, frequent patterns, and deviations from a normal status or just relations among the database entries.

Image mining differs from data mining in respect of the data and the nature of the data. The raw image is of 2-dimensional or 3-dimensional numerical data type. Videos are temporal sequences of numerous 2-d images. The image information can be represented by the 2-d or 3-d image matrix itself, by low-level features such as edges, blobs and regions, or by high-level features that allow a human to semantically understand the image content. The different data types in which an image or an image sequence can be represented and the resulting need for special methods and techniques offer a data-type dimension to data mining and make image mining a specific field.

Consequently, image mining can be applied to all the different data representations of an image. Which of the data representations is used, usually depends on the question under study. If we mine our images for knowledge that can be used to construct a fully automatic image-interpretation system, we have different questions to answer: We have to mine the images for regions-of-interest and separate them from the background of the image. Once we have found these regions we need to mine them for distinguishing features and later on we are interested in discovering rules that allow us to classify these regions into different patterns. Based on all this information discovered we might be able to build an automatic image-interpretation system.

In video mining it is of interest to detect scenes, group them into similar groups or detect events. These three main tasks require a specific image-mining procedure applicable to videos.

Unlike in other fields we can only do this automatically if we have proper automatic information-extracting methods. This brings us to the topics of image processing, feature extraction and image understanding. Image mining is closely related to these topics and will only succeed if a bridge can be established between image mining and these topics.

All the above mentioned questions can inherently suffice in other applications. The problem of searching the regions of special visual attention or interesting patterns in a large set of images has been studied for medical CT and MRI image sets in Megalooikonomou, Davatzki, and Herskovits (1999) and Eklund, You, and Deer (2000) or in satellite images (Burl & Lucchetti, 2000). Usually, experienced experts have discovered this information. However, the amount of images, which is being created by modern sensors, makes the development of methods necessary that can tackle this task for the expert. Therefore, standard primitive features able to describe the visual changes in the image background are being extracted from the images, and the significance of these features is being tested by a sound statistical test (Burl & Lucchetti, 2000; Megalooikonomou, Davatzki, & Herskovits, 1999).

Clustering is applied in order to explore the images seeking similar groups of spatial connected components (Zaiane & Han, 2000) or similar groups of objects (Eklund, You, & Deer, 2000). Association rules are used for finding significant patterns in the images (Burl & Lucchetti, 2000). A method for obtaining the principal objects, characters and scenes in a video by measuring the reoccurrence of spatial configurations of viewpoint invariant features is described in Sivic and Zisserman (2004). How to discover the editing patterns of videos from different editors with data mining and to use the discovered rules for editing new video material is described in Matsuo, Amano, and Uehara (2002). Multilevel sequential association mining is applied to explore associations among the audio and visual cues in Zhu, Wu, Elmagardmid, Feng, and Wu (2005). The associations are classified by assigning each of them with a class label. Their appearances in the video is recognized and used to construct video indices. A method for unsupervised classification of events in multi-camera indoors surveillance video by applying self-organizing map (SOM) is described in Petrushin (2005).

The measurement of image features in these regions or patterns provides the basis for pattern recognition and image classification. Computer-vision researches are conducted to create proper models of objects and scenes, to obtain image features and to develop decision rules that allow one to analyze and interpret the observed images. Computer-assisted diagnosis methods of image processing, segmentation, and feature measurements are successfully used for this purpose (Kehoe & Parker, 1991; Perner, 1998; Schröder, Niemann, & Sagerer, 1988).

The basic research of image mining and machine learning in pattern recognition deals with a wide spectrum of different problems that need to be solved for image mining. The developed methods reach from learning local structural features by a multiscale relevance function (Palenichka & Volgin, 1999) to the construction of artificial neural nets for estimating the local mean grey value for image processing (Jahn, 1999) or for model selection and fitting if the models are linear manifolds and data points distribute to the union of a finite number of linear data points (Imiya & Oatani, 2001). Multiple classifier systems and case-based reasoning (Perner, 1998, 2005; Schmidt & Gierl, 2001) are further approaches for prediction models. Case-based reasoning methods for image segmentation (Perner, 1999) as well as for the recognition of similar video scenes (Zhu, Wu, Elmagardmid, Feng, & Wu, 2005) have been developed. Multiple classifier systems can be designed by applying unsupervised learning to ensure that the multiple classifiers works efficiently by making independent errors (Giacinto & Roli, 1999). First-order rule induction (Malerba, Esposito, Lanza, & Lisi, 2001) is applied for the recognition of morphological patterns based on symbolic terms in topographic maps. Methods for clustering with relevance feedback (Bhanu & Dong, 2001) have been developed to overcome the gap between low-level visual features and human high-level concepts and rule-based ensembles are applied to solve regression problems (Indurkhya & Weiss, 2001). The incremental appearance of most media is now considered by incremental clustering techniques (Bougila & Ziou, 2005; Jänichen & Perner, 2005). Sampling schedules for face recognition and finger print recognition based on neural nets that are adaptive to the data and allow using only a portion of data from a huge dataset for the development of recognition models are developed in Satyanarayana and Davidson (2005). These few examples show that image mining is still a basic research topic with a lot of different subtopics, but on the other hand systems for image mining are needed that can be used in practice.

The mining process is often done bottom-up. As many numerical features as possible are extracted from the images, in order to achieve the final goal—the classification of the objects (Fischer & Bunke, 2001; Perner, Zscherpel, & Jacobsen, 2001). However, such a numerical approach usually does not allow the user to understand the way in which the reasoning process has been achieved.

The second approach to pattern recognition and image classification is an approach based on the symbolic description of images made by the expert (Perner, 2000). This approach can present to the expert in an explicit form the way in which the image has been interpreted. The experts having the domain knowledge usually prefer the second approach.

Normally simple numerical features are not able to give a description of complex objects and scenes. They can be described by an expert with the help of non-formalized symbolic descriptions, which reflect some gestalt in the expert domain knowledge. This task of semantic tagging becomes more popular since such descriptions enable sophisticated semantic querying of the media in terms familiar to the user's domain, whilst also ensuring that the information and knowledge have a much greater chance of being discovered and exploited by services, agents and applications on the Web. In contrast to that it is also the basis for the development of automatic image interpretation systems.

One problem is how to find out the relevant descriptions of the object (or the scene) for its interpretation and how to construct a proper procedure for the extraction of these features. This top-down approach is the more practical approach for most applications. However, the symbolic description of images and feature estimation face numerous difficulties:

1. A skilled expert knows how to interpret the image, but often has no well-defined vocabulary to describe the objects, visual patterns and gestalt variances, which are standing behind the expert's diagnostic decisions. When the expert is asked to make this knowledge explicit, the expert usually cannot specify and verbalize it.
2. Although numerous efforts are going on to develop such a vocabulary for specific medical tasks (for example, the ACR-BIRADS-code has been constructed for image analysis in mammography) and MPEG-7 standard (Martinez, 2001) is used for ontology-based annotations of natural images, the problem of the difference between "displaying and naming" still exists.

3. A developed description language will differ for example from medical school to medical school and as a result the obtained symbolical description of image features by a human will be expert-dependent and subjective.
4. Besides this, the developed vocabulary usually consists of a large number of different symbolic features (image attributes) and feature values. It is not clear a-priori whether all the attributes included into the vocabulary are necessary for the diagnostic reasoning process. To select the necessary and relevant features would make the reasoning process more effective.

We propose a methodology of image mining that allows one to learn a compact vocabulary for the description of objects and to understand how this vocabulary is used for diagnostic reasoning or in semantic-inference rules of semantic tagging. Besides that we also use basic image features that have been calculated from the image. This methodology can be used for a wide range of image-diagnostic tasks and semantic annotations.

Developed methodology takes into account the recent status of the art in image analysis and feature extraction and combines it with new methods of data mining. It allows us to extract quantitative information from the image and when possible combine it with subjectively determined diagnostic features, and then to mine this information for the relevant diagnostic knowledge acquisition by objective methods such as data mining.

Our methodology should help to solve some cognitive, theoretical and practical problems:

1. It will reproduce and display a decision model of an expert for specific task solutions.
2. It will show the pathway of human reasoning and classification. Image features will be discovered which are basic for correct decision-making by the expert.
3. A developed model will be used as a tool to support the decision-making of a human who is not an expert in a specific field of knowledge. It can be used for teaching novices, as well as for semantic image retrieval.

The application of data mining will help to get some additional knowledge about specific features of different classes and the way in which they are expressed in the image. It could help to find some inherent non-evident links between classes and their imaging in the picture that could be used to make some nontrivial conclusions and predictions on the basis of elicited knowledge.

DESIGN CONSIDERATIONS

Besides the development of new methods for image mining, there is a need for systems that can support a user at all steps of an image-mining task. We developed a tool for data mining which was to meet several requirements:

1. The tool had to be applicable for a wide range of image-diagnostic tasks and image modalities that occur for example in medical practice. It was to be used for semantic annotation of large image contents for image retrieval.
2. It should allow the users to develop their own symbolic descriptions of images in the terms which are appropriate to the specific diagnostic task.
3. Users should have a possibility for updating or adding features according to new images or a diagnostic problem.
4. It should support the user in the analysis and interpretation of images; for example, in the evaluation of new imaging devices and radiographic materials.
5. It should assist the user in learning a proper prediction model based on different methods that are applicable for different data-type characteristics.

6. It should support the user in finding groups of features, objects or relations by proper clustering methods.

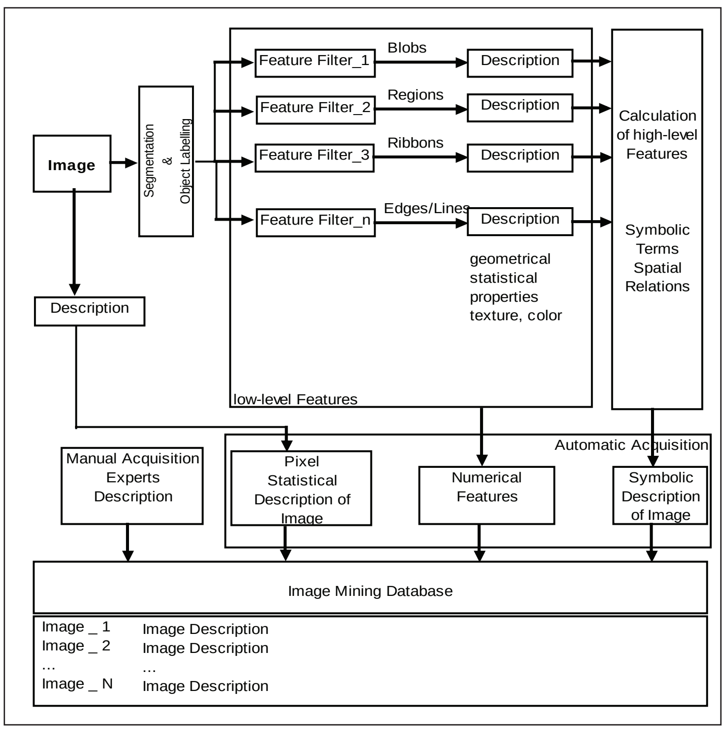
Taking into account these criteria and the recent state-of-the-art in image analysis, we provided an opportunity for semiautomatic image processing and analysis to enhance imaging of diagnostically important details in the image and measure some image features directly in the image and by this way to support the user by the analysis of images. The user has to have the possibility to interact with the system in order to adapt the results of image processing.

This image-processing unit should provide extraction of such low-level features as blobs, regions, ribbons, lines and edges. On the basis of these low-level features we are able to calculate then some high-level features to describe the image. Besides that, the image-processing unit should allow evaluation of some statistical image properties, which might give valuable information for the image description.

However, some diagnostically important features, such as "irregular structure inside the nodule," "tumor" are not so-called low-level features. They present some gestalts of expert domain knowledge. Development of an algorithm for extraction of such image features can be a complex or even unsolvable problem. So we identify different ways of representing the contents of an image that belongs to different abstraction levels (see Figure 1). We can describe an image:

- By statistical properties (i.e., that is, the lowest abstraction level)
- By low-level features and their statistical properties such as regions, blobs, ribbons, edges and lines (this is the next higher abstraction level)
- By high-level or symbolic features that can be obtained from the low-level features

Figure 1. Overview on image descriptions based on different abstraction levels



- By an expert's symbolic description, which is the highest abstraction level

The image-processing unit combined with the data-evaluation unit should allow a user to learn the relevant diagnostic features and effective models for the image interpretation. Therefore, the system as a whole should meet the following criteria:

1. Support the medical person as much as possible by the extraction of the necessary image details (region of interest).
2. Fulfill measurement of the feature values directly in the image when possible.
3. Display the interesting image details to the expert.
4. Store in a database the measured feature values as well as the subjective description of images by the expert.
5. Import these data from the database into the data-mining unit.

SYSTEM DESCRIPTION

Overall System Architecture

Figure 2 shows a scheme of the tool *ImageMiner Version 2.1*. There are two main parts in the tool:

- The online part that is comprised of the image analysis (Figure 3) and the image interpretation part
- The off-line part that is comprised of the database and the data-mining and knowledge discovery part (Figure 4)

The tool is written in C++ and runs under Windows NT. These two units communicate over a database of image descriptions which is created in the frame of the image-processing unit. This database is the basis for the image-mining unit.

The online part can automatically detect the objects, extract image features from the objects and classify the recognized objects into the respective classes based on the previously stored decision rules. The interface between the offline and the online part is the database where images and calculated image features are stored. The off-line part can mine the images for a prediction

Figure 2. Architecture of an image mining tool

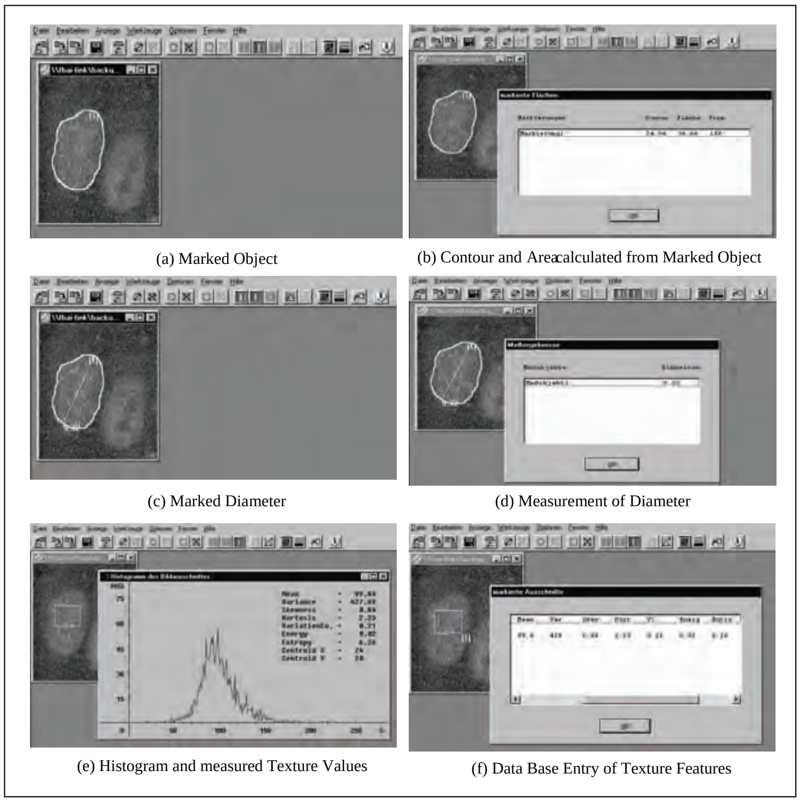

Figure 4. Tool ImageMiner Version 2.1

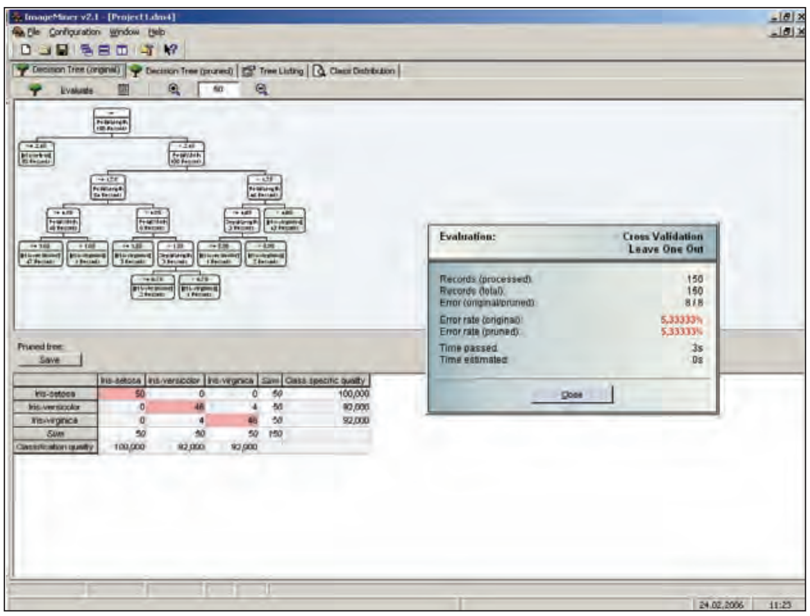

model or discover new groups of objects, features or relations. These similar groups can be used for learning the classification model or just for understanding the domain. In the latter case the discovered information is displayed to the user on the terminal of the system. Once a new prediction model has been learnt, the rules are inserted into the image interpretation part for further automatic interpretation after approval of the user.

Besides that there is an archiving and management part that controls the whole system and stores information for long-term archiving.

Images can be processed automatically or semi-automatically. In the first case a set of images specified by the expert is automatically segmented into the background and objects of interest and for all these objects features based on the feature-extracting procedures installed in the system are automatically calculated. In this way as many features as possible are calculated, regardless of whether they make sense for a specific application or not. This requires feature-subset selection methods later on. In the second case, an image from the image archive is selected by the expert and then displayed on the monitor (Figure 3). In order to perform image processing an expert communicates with a computer. In this mode he has the option to calculate features based on the feature-extracting procedures and/or insert symbolic features based on his expert knowledge. In both modes the features are stored into the database.

CBR Image Segmentation

To ensure that the system is as flexible as possible we have installed a case-based image-segmentation procedure (Perner, 1999) into our image-analysis part.

The CBR-based image segmentation consists of a case base in which formerly processed cases are stored. A case comprises image information, non-image information (e.g., image acquisition parameters, object characteristics, and so on), and image-segmentation parameters. The task is now to find the best segmentation for the current image by looking in the case base for similar cases. Similarity determination is based on both non-image information and image information. The evaluation unit will take the case with the highest similarity score for further processing. If there are two or more cases with the same similarity score, the case that appear first will be taken. After the closest case has been chosen, the image-segmentation parameters associated with the selected case will be given to the image-segmentation unit, and the current image will be segmented. Images having similar image characteristics will show similar good segmentation results when the same segmentation parameters are applied to these images.

This procedure finds the objects-of-interest in the image and labels them. In the automatic mode the labeled objects are automatically calculated and given to the image-interpretation part, whilst in the off-line mode the found object is displayed on a monitor to the user.

Feature Extraction

The expert can calculate image features for the labeled objects. These features are composed of statistical gray level features, the object contour, square, diameter, shape (Zamperoni, 1996) and a novel texture feature that is flexible enough to describe different textures on objects (Perner, Perner, & Müller, 2002). The expert evaluates or calculates image features and stores their values in a database of image features. Each entry in the database presents features of the object of interest. These features can be numerical (calculated on the image) and symbolical (determined by the expert as a result of image reading by the expert). In the latter case the expert evaluates object features according to the attribute list, which has to be specified in advance for object description, or is based on a visual ontology available for visual content description. Then the expert feeds these values into the database.

When the expert has evaluated a sufficient number of images, the resulting database can be used for the mining process.

Decision Tree Induction Unit

The stored database can easily be loaded into the image mining tool (Figure 4).

The tool fulfills a decision-tree induction as well as case-based reasoning and clustering. Decision-tree induction allows one to learn a set of rules and basic features necessary for decision-making in a specified diagnostic task. The induction process does not only act as a knowledge-discovery process, it also works as a feature selector, discovering a subset of features that is the most relevant to the problem solution.

Decision trees partition decision space recursively into sub-regions based on the sample set. By this way the decision trees recursively break down the complexity of the decision space. The outcome has a format which naturally presents the cognitive strategy that can be used for the human decision-making process.

For any tree all paths lead to a terminal node, corresponding to a decision rule that is a conjunction (AND) of various tests. If there are multiple paths for a given class, then the paths represent disjunctions (ORs).

The developed tool allows choosing different kinds of methods for feature selection, feature discretization, pruning of the decision tree and evaluation of the error rate. It provides an entropy-based measure, a gini-index, gain-ratio and chi square method for feature selection (Perner, 2002).

The following methods for feature discretization are provided: cut-point strategy, chi-merge discretization, minimum description-length-principal based discretization method and lvq-based method (Perner, 2002). These methods allow one to make discretization of the feature values into two and more intervals during the process of decision-tree building. Depending on the chosen method for attribute discretization, the result will be a binary or n-ary tree, which will lead to more accurate and compact trees.

The *ImageMiner* allows one to chose between cost-complexity pruning, error-reduction-based methods and pruning by confidence-interval prediction. The tool also provides functions for outlier detections.

To evaluate the obtained error rate one can choose test-and-train and n-fold cross validation. Missed values can be handled by different strategies (Perner, 2002).

The user selects the preferred method for each step of the decision tree induction process. After that the induction experiment can start on the acquired database. A resulting decision tree will be displayed to the user. The user can evaluate the tree by checking the features used in each node of the tree and comparing them with his/her domain knowledge.

Once the diagnosis knowledge has been learnt, the rules are provided either in txt-format or XML format for further use in the image-interpretation system or the expert can use the diagnosis component of the *ImageMiner tool* for interactive work. It has a user-friendly interface and is set up in such a way that non-computer specialists can handle it very easily.

Case-Based Reasoning Unit

Decision trees are difficult to utilize in domains where generalized knowledge is lacking. But often there is a need for a prediction system even though there is not enough generalized knowledge. Such a system should (a) solve problems using the already stored knowledge and (b) capture new knowledge making it immediately available to solve the next problem. To accomplish these tasks case-based reasoning is useful. Case-based reasoning explicitly uses past cases from the domain expert's successful or failing experiences.

Therefore, case-based reasoning can be seen as a method for problem solving as well as a method to capture new experience in incremental fashion and make it immediately available for problem solving. It can be seen as a learning and knowledge-discovery approach, since it can capture from new experience some general knowledge such as case classes, prototypes and some higher level concept. We find these methods especially applicable for inspection and diagnosis tasks (Perner, 2006). In the case of these applications people rather store prototypical images into a digital image catalogues than a large set of different images.

We have developed a unit for our *ImageMiner* that can perform similarity determination between cases, as well as prototype selection and feature weighting [Cheng, 1974]. We call $x_n^{`} \in \{x_1, x_2, ..., x_n\}$ a nearest-neighbor to x if $\min d(x_i, x) = d(x_n', x)$, where i=1,2,...,n. The instance x is classified into category C_n, if x_n is the nearest neighbor to x and x_n belongs to class C_n.

In the case of the k-nearest neighbor we require k-samples of the same class to fulfil the decision rule. As a distance measure we use the Euclidean distance. Prototype Selection from a set of samples is done by Cheng's algorithm (Cheng, 1974). Suppose a training set T is given as $T = \{t^1, ..., t^m\}$. The idea of the algorithm is as follows: We start with every point in T as a prototype. We then successively merge any two closest prototypes p^1 andm p^2 of the same class by a new prototype p if the merging will not downgrade the classification of is patterns in T. The new prototype p may simply be the average vector of p^1 and p^2. We continue the merging process until the number of incorrect classifications of patterns in T starts to increase.

The wrapper approach (Wetterschererk & Aha, 1995) is used for selecting a feature subset from the whole set of features. This approach conducts a search for a good feature subset by using the k-NN classifier itself as an evaluation function. The 1-fold cross validation method is used for estimating the classification accuracy and the best-first search strategy is used for the search over the state space of possible feature combination. The algorithm terminates if we have not found an improved accuracy over the last k search states. The feature combination that gave the best classification accuracy is the remaining feature subset. After we have found the best feature subset for our problem, we try to further improve our classifier by applying a feature weighting technique.

The weights of each feature w_i are changed by a constant value δ:w_i:=w_i±δ. If the new weight causes an improvement of the classification accuracy, then the weight will be updated accordingly; if not, the weight will remain as it is. After the last weight has been tested the constant δ will be divided into half and the procedure repeats. The procedure terminates if the difference between the classification accuracy of two iterations is less than a predefined threshold.

Conceptual Clustering

The intention of clustering is to find groups of similar cases among the data according to the observation. This can be done based on one feature or a feature combination. The resulting groups give an idea how data fit together and how they can be classified into interesting categories.

Classical clustering methods only create clusters but do not explain why a cluster has been established. Conceptual clustering methods build clusters and explain why a set of objects forms a cluster. Thus, conceptual clustering is a type of learning by observations and it is a way of summarizing data in an understandable manner (Fisher, 1987; Gennari, Langley, & Fisher, 1989). In contrast to hierarchical clustering methods, conceptual clustering methods build the classification hierarchy not only based on merging two groups. The algorithmic properties are flexible enough to dynamically fit the hierarchy to the data. This allows incremental incorporation of new instances into the existing hierarchy and updating this hierarchy according to the new instance.

A concept hierarchy is a directed graph in which the root node represents the set of all input instances and the terminal nodes represent individual instances. Internal nodes stand for sets of instances attached to the nodes and represent a super-concept. The super-concept can be represented by a generalized representation of this set of instances such as the prototype, the mediod or a user-selected instance. Therefore a concept C, called a class, in the concept hierarchy is represented by an abstract concept description and a list of pointers to each child concept $M(C)=\{C_1, C_2, ..., C_i, ..., C_n\}$, where C_i is the child concept, called subclass of concept C.

Our conceptual clustering algorithm presented here is based on similarities (Jänichen & Perner, 2006; Perner, 2003). Due to its concept description, it explicitly supplies for each cluster a generalized shape case which represents this group and a measure for the degree of its generalization. The result will be a sequence of partitions (concept hierarchy), where the root node contains the complete set of input cases and hence it follows that this node is represented by the most generalized case. The nodes in lower hierarchy levels are comprised of fewer cases (at least one) and are more specific.

In addition to *create* and *add*, we also introduced the operators *split* and *merge* into the algorithm. We prefer to apply these local operators because they preserve the incremental fashion of the algorithm. Order dependency also becomes decreased sufficiently, even it is not guaranteed that the local changes have a sufficiently strong effect on the global data.

The algorithm implements a top-down method. Initially the concept hierarchy only consists of an empty root node. A new case is placed into the actual concept hierarchy level by level, beginning with the root node until a terminal node is reached. In each hierarchy level one of these four different kinds of operations is performed:

- The new case is incorporated into an existing child node.
- A new empty child node is created where the new case is incorporated.
- Two existing nodes are merged to form a single node where the new case is incorporated.
- An existing node is split into its child nodes.

The new case is tentatively placed into the next hierarchy level by applying all of these operations. Finally that operation is performed which gives the best score to the partition according to the evaluation criteria. A proper utility function prefers compact and well- separated clusters. These are clusters with small inner-cluster variances and high inter-class variances. Thus we calculate the score of a partition comprised of the clusters $\{X_1, X_2, \ldots X_m\}$ by: $SCORE = \frac{1}{m}\sum_{i=1}^{m} p_i\ (SB_i - SW_i)$, where m is the number of clusters in this partition, p_i is the relative frequency of the i-th cluster, SB_i is the inter-cluster variance and SW_i is the inner-cluster variance of the i-th cluster. The normalization according to m is necessary to compare partitions of different size. The relative frequency p_i of the i-th cluster is: $p_i = \frac{n_i}{n}$, where n_i is the number of cases in the i-th cluster and n is the number of cases in the parent node. The inter-cluster variance of a cluster X is calculated by: $SB_X = \frac{1}{n_x}\sum_{i=1}^{n_x} d(x_i, \bar{\mu}_P)^2$, where $\bar{\mu}_P$ is the cluster centre of the parent node and x_i are the instances in all child nodes.

The output of our algorithm for applying eight exemplary shape cases of fungal strain *Ulocladium Botrytis* is shown in Figure 5. On the top level the root node is shown which comprises of all input cases. Successively the tree is partitioned into nodes until each input case forms its own cluster.

The main advantage of our conceptual clustering algorithm is that it brings along a concept description. Thus, in comparison to agglomerative clustering methods, it is easy to understand why a set of cases forms a cluster. During the clustering process the representative case, and also the variances and maximum distances in relation to this representative case are calculated, since they are part of the concept description. The algorithm is of incremental fashion, because it is possible to incorporate new cases into the existing learnt hierarchy.

THE OVERALL IMAGE MINING PROCEDURE

The whole procedure for image mining is summarized in Figure 6. It is partially based on our developed methodology for image-knowledge engineering (Perner, 1994). The process can be divided into five major steps: (1) brain storming, (2) interviewing process, (3) collection of image descriptions into the data base, (4) mining experiment and (5) review.

Brain storming is the process of understanding the problem domain and identifying the important knowledge pieces on which the knowledge-engineering process will focus.

For the interviewing process we used our developed methodology for image-knowledge engineering described in Perner (1994) in order to elicit the basic attributes as well as their attribute values. Then the proper image processing and feature-extraction algorithms are identified for the automatic extraction of the features and their values.

Based on these results we then collected into the data base image readings done by the expert and done by the automatic image-analysis and feature-extraction tool. The resulting data base is the basis for our mining experiment. The error rate of the mining result was then determined based on sound statistical methods such as cross validation. The error rate as well as the rules were then reviewed together with the expert and depending on the quality of the results the mining process stops or goes into a second trail, starting either at the top with eliciting new attributes or at a deeper level, for example with reading new images or

Figure 5. Concept hierachy for 2-D forms of biological objects

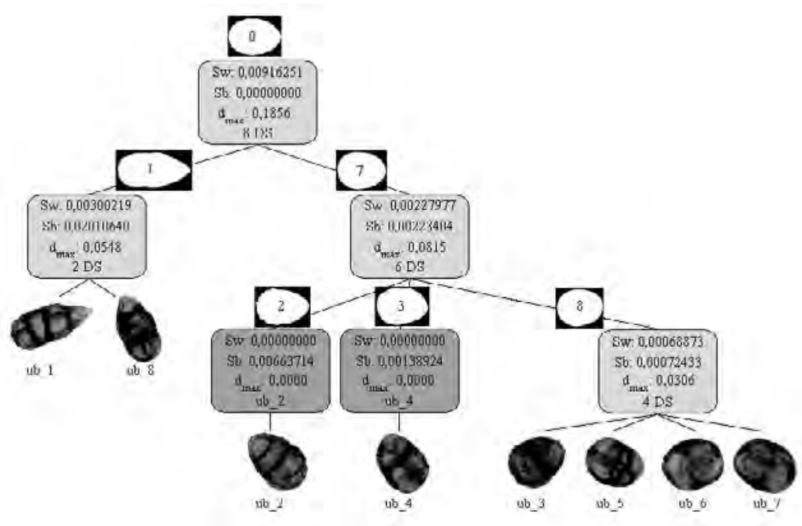

Figure 6. Procedure of the image mining process

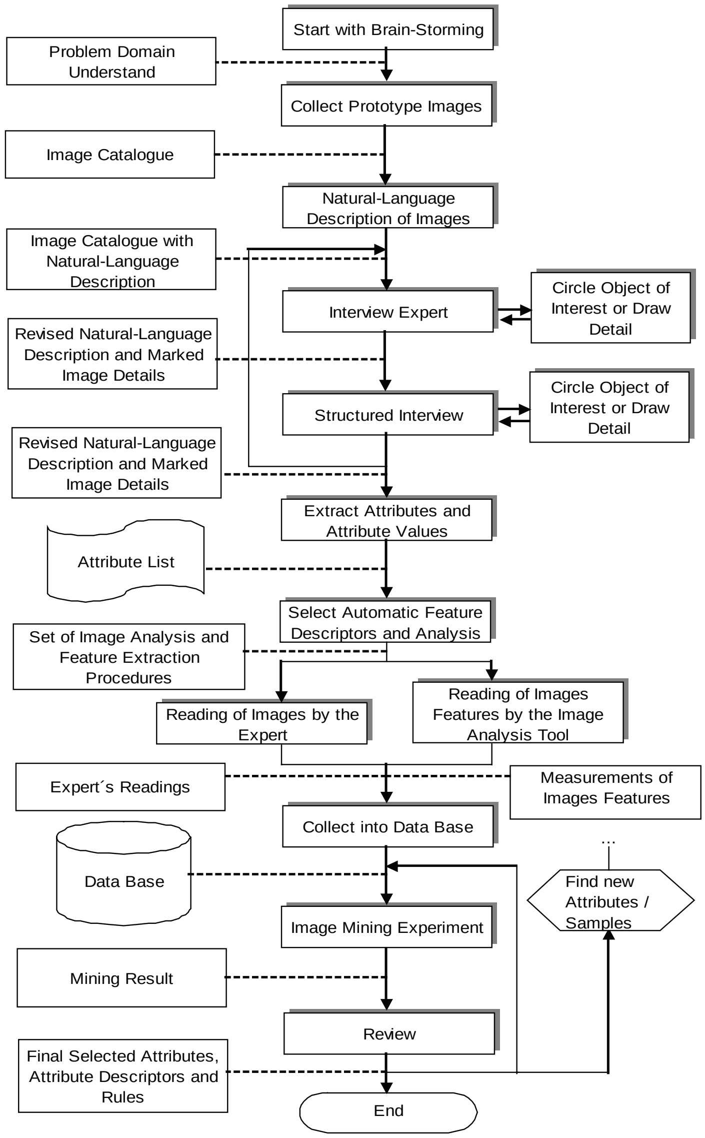

incorporating new image-analysis and feature-extraction procedures. The incorporation of new image-analysis and feature-extraction procedures seems to be an interactive and iterative process at the moment, since it is not possible to provide ad-hoc sufficient image-analysis procedures for all image features and details appearing in the real world. The mining procedure stops as soon as the expert is satisfied with the results.

A CASE STUDY

The Application

We will describe the usage of the image-mining tool based on the task of HEp-2 cell classification. HEp-2 cells are used for the identification of antinuclear autoantibodies (ANA). They allow the recognition of over 30 different nuclear and cytoplasmic patterns which are given by upwards of 100 different autoantibodies. The identification of these patterns has up to now been done manually by a human inspecting the slides with the help of a microscope. The lacking automation of this technique has resulted in the development of alternative techniques based on chemical reactions, which do not have the discrimination power of the ANA testing. An automatic system would pave the way for a wider use of ANA testing.

Recently, the various HEp-2 cell images occurring in medical practice are being collected into a data base at the university hospital of Leipzig. The images were taken by a digital image-acquisition unit consisting of a microscope AXIOSKOP 2 from Carl Zeiss Jena, coupled with a color CCD camera Polariod DPC. The digitized images were of 8-bit photometric resolution for each color channel with a per pixel spatial resolution of 0.25 µm. Each image was stored as a color image on the hard disk of the PC but is transformed into a gray-level image before being used for automatic image analysis.

The scope of our work was to mine these images for proper classification knowledge, so that it can be used in medical practice for diagnosis or for teaching novices. Besides that it should give us the basis for the development of an automatic image-diagnosis system.

Our experiment was supported by an immunologist who is an expert in the field and acts as a specialist to other laboratories in case of diagnostically complex cases.

Figure 7. Image catalogue and expert's description

Class	Image	Description
Fine Speckled 200 000		Smooth and uniform fluorescence of the nuclei Nuclei sometimes dark Chromosomes fluoresced weak up to extreme intensive
Fine dotted (speckled) nuclei fluorescence 320 200		Dense fine speckled fluorescence Background diffuse fluorescent
Homogeneous Nuclear 100 000		A uniform diffuse fluorescence of the entire nucleus of interphase cells. The surrounding cytoplasm is negative.
...	...	...
Centromere 500 000		Nuclei weak uniform or fine granular, poor distinction from background

Brainstorming and Image Catalogue

First, we started with a brain storming process that helped us to understand the expert's domain and to identify the basic pieces of knowledge. We could identify mainly four pieces of knowledge: Hep-2 cell atlas, the expert, slide preparation and a book describing the basic parts of a cell and their appearance.

Table 1. Attribute list

Attribute	Code	Attribute Values
Interphase Cells	0	Undefined
	1	Fine speckled
	2	homogeneous
	3	Coarse Speckled
	4	Dense fine speckled Fluorescence
Nucleoli	0	Undefined
	1	Dark area
	2	fluoresce
Background	0	Undefined
	1	Dark
	2	Fluorescence
Chromosomes	0	Undefined
	1	Fluorescence
	2	Dark
Cytoplasm	0	Undefined
	1	Speckled Fluorescence
Classes	100 000	Homogeneous
	100 320	Homogeneous fine speckled
	200 000	Nuclear
	320 000 320 200	Fine speckled Fine speckled nuclear

Then the expert collected prototype images for each of the six classes appearing most frequently in his daily practice. The expert wrote down a natural-language description for each of these images. As a result we obtained an image catalogue having a prototype image for each class and associated to each image is a natural-language description of the expert (see Figure 7).

Interviewing Process

Based on these image descriptions we started our interviewing process. First, we only tried to understand the meaning of the expert description in terms of image features. We let the individual circle the interesting object in the image to understand the meaning of the description. After having done this, we went into a structured interviewing process asking for specific details such as: "Why do you think this object is *fine-speckled* and the other one is not. Please describe the difference between these two." It helped us to verify the expert description and to make the object features more distinct.

Finally, we could extract from the natural-language description the basic vocabulary (attributes and attribute values, see Table 1) and associate the meaning to each attribute.

In a last step we reviewed the chosen attributes and the attribute values with the expert and found a common agreement on the chosen terms. The result was an attribute list which is the basis for the description of object details in the images. Furthermore, we identified from the whole set of feature descriptors the set of a feature descriptors which might be useful for the objective measurement of image features. In our case we found that describing the cells by their boundary and calculating the size and the contour of the cell might be appropriate. The different descriptors of the nuclei of the cells might be sufficiently described by the texture descriptor of our image-analysis tool.

Collection of Image Descriptions into the Data Base

Now we could start to collect a data base of image descriptions based on these attributes and attribute values as well as on feature measurements calculated with the help of the image-analysis tool. For our experiment we used a dataset of 110 images. The dataset contained 6 classes, each equally distributed. For each class we had 20 images. The expert used the image-analysis tool shown in Figure 3 and displayed one after another each image from our data base. He watched the images on display and described the image content on the basis of our attribute list and fed the attribute values into the data base. Besides that he marked the objects of interest in the image on display and used the necessary feature descriptors selected during the interviewing process and provided by the image-analysis unit to measure the image features such as size, contour, and texture. The resulting values for these features are automatically fed into the data base and stored together with the expert's image description into the data base (see Figure 8).

The Image Mining Experiment

The collected dataset was then given to the tool *ImageMiner*. The decision-tree induction algorithm that showed the best results on this dataset is based on the entropy-criterion for the attribute selection, cut-point strategy for the attribute discretization and minimal error-reduction pruning. We carried out three experiments. First, we learnt a decision tree only based on the image reading by the expert, then learnt a decision tree only based on the automatic calculated images features, and finally, we learnt a decision tree based on a data base containing both feature descriptions. The resulting decision tree for the expert's reading is shown in Figure 9 and the resulting decision tree for the expert's reading together with the measured image features is shown in Figure 10. We do not show the tree for the measured image features, since the tree is too complex. The error rate was evaluated by leave-one-out cross-validation.

The error rate of the decision trees from the first two experiments is higher than the error rate made by the expert (see Table 2). None of the trees, whether based on the expert's reading or based on the measured image features, give a sufficiently low error rate. Only the combined data base from the expert's reading and measured image features gives us an error rate that comes close to an expert's error rate.

Review

The tree created based on the image readings from the expert has an error rate of 27.9% (see Table 2). Under the assumption that the class labels represent the true class (gold standard), we can only conclude that there is a knowledge gap.

Figure 8. Excerpt from database

Class	Contour (Kontur)	Area	Shape Factor (Form)	MEAN	VAR	SKEW	CURT	VC	ENERGY	...	NUCLEOLI	CHROMO	CYTOPLA (Zytopla)	Background (Hintergrund)	
100000	14,3734	14,3189	144,2812	87,1507	244,3043	1,1233	7,5139	0,1793	0,0209	...	1	1	0	1	
100320	10,3675	7,2986	147,2687	144,6974	282,0444	-0,6999	2,4243	0,1161	0,0238	...	1	0	0	0

Figure 9. Decision tree obtained from expert's readings

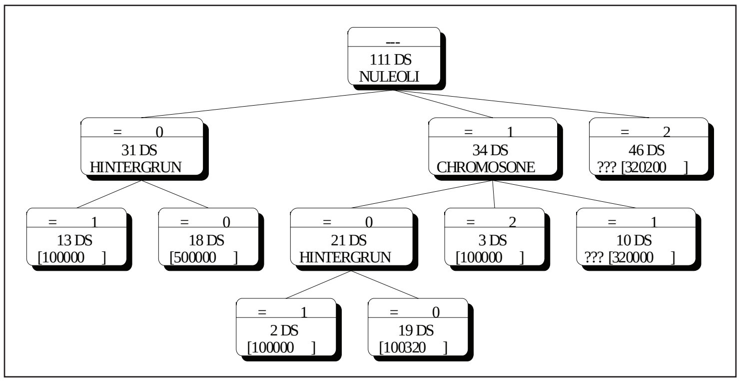

Figure 10. Decision tree obtained from expert's readings and image readings

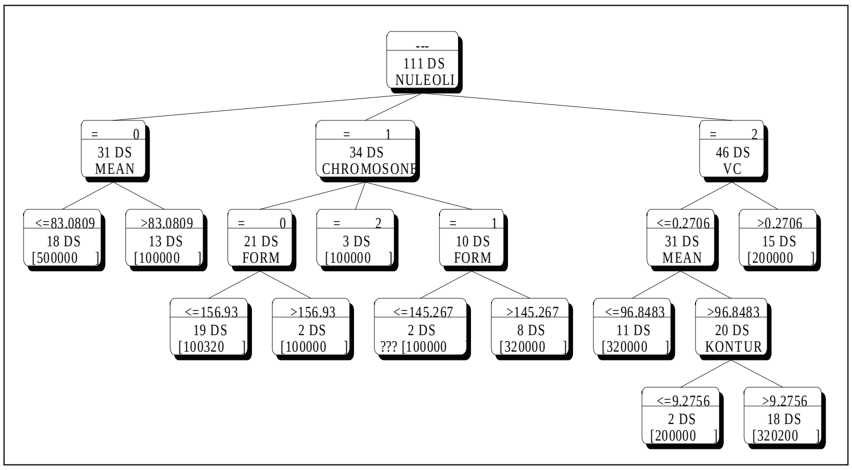

Table 2. Error rate for decision trees obtained from the different databases

	Error Rate		
Data Set	**Expert**	**Unpruned Tree**	**Pruned Tree**
Original Data Set	25 %		
Expert Readings		27 %	27 %
Automatic Feature Analysis		27 %	27 %
Combined Data Set		6,9 %	6,9 %

There must be some hidden knowledge which the expert is using during decision making, but the expert could not make this knowledge explicit during the interviewing process. Here we have an example for the problem "difference between showing and naming" mentioned in the second section. However, the expert's error rate is also high.

Our first objection was: Is the assumption that the class label is the true class label true or not? As far as we know the chemical investigation of the serum which was used to determine the gold standard does not so accurately discriminate between the different classes.

The experiment based on the features automatically measured in the images gives us no better results. The resulting tree is very bushy and deep and uses almost all attributes.

Only the combination between the expert's readings and the readings by the image-analysis unit shows us reasonable results. The feature nucleoli is the most important feature and the correct description of the nucleoli will improve the results dramatically. During the image-analysis phase we did not describe this object separately. The hope was that the texture descriptor for the whole cell is sensitive enough to model the different visual appearances of the different cells. The experiment shows that only the combination of basic image descriptors from the image analysis with expert reading gave sufficient results. Therefore, we believe that our first objection concerning the true class label does not hold any more. We rather think that in order to improve the accuracy of the classifier we must find a good feature descriptor for the different appearances of the object nucleoli.

LESSONS LEARNED

We have found out that our methodology of data mining allows a user to learn the decision model and the relevant diagnostic features. A user can independently use such a methodology of data mining in practice. The user can easily perform different experiments until the user is satisfied with the result. By practicing this, the user can explore the application and find out the connection between different knowledge pieces.

However, some problems should be taken into account for the future system design.

As we have already pointed out in a previous experiment (Perner, 2000), an expert tends to specify symbolic attributes by means of a large number of attribute values. For example in this experiment the expert specified for the attribute "margin" 15 attribute values such as "non-sharp," "sharp," "non-smooth," smooth," and so on. A large number of attribute values will result in small sub-sample sets soon after the tree-building process started. It will result in a fast termination of the tree-building process. This is also true for small sample sets that are usual in medicine. Therefore, a careful analysis of the attribute list should be done after the physician has specified it.

During the process of building the tree, the algorithm picks the attribute with the best attribute-selection criteria. If two attributes have both the same value, the one that appears first in the attribute list will be chosen. That might not always be the attribute the expert himself would choose. In order to avoid this problem, we think that in this case we should allow the expert to choose manually the attribute that the expert prefers. We expect that this procedure will bring the resulting decision model closer to the expert's ones.

The developed image-analysis tool allows extracting image features (see the fourth section). It supported the analysis and exploration of other image-diagnosis tasks, such as the analysis of sheep follicle and lymph nodule analysis. It proved to be very useful for the analysis of microscopic images of different cell-based assays. New applications might require further feature descriptors. Therefore the image-analysis tool must have an open architecture that allows incorporating new feature descriptors into the tool.

The described method of image mining had been applied to a wide range of applications. This includes the analysis of sheep follicle based on a texture descriptor, evaluation of imaging effects of radiopaque material for lymph-nodule analysis, mining knowledge for IVF therapy, transplantation medicine, and inspection of microscopic images of cell-based assays and for the diagnosis of breast carcinoma in MR images. In all these tasks we did not have a well-trained expert. These were new tasks and reliable decision knowledge had not been built up in practice yet. The physicians did the experiments by themselves. They were very happy with the obtained results, since the learnt rules gave them deeper understanding of their problems and helped to predict new cases. It helped the physicians to explore their data and inspired them to think about new improved ways of diagnosis. In some of the tasks we were able to build an automatic image-interpretation system based on the discovered visual features and knowledge.

Compared to our first version of the image-mining tool the new features of case-based image segmentation, case-based reasoning and clustering gave a new flexibility to the image mining process depending on the characteristics of the data of the particular application. The clustering method allowed discovering new groups according to the considered observation(s) that could be used further for the construction of the prediction model. Case-based image segmentation gave the flexibility needed to discover objects of interest in different image modalities and qualities. In the case of rare data or image catalogues case-based reasoning was the right method to construct a decision model and acquire new images in incremental fashion.

CONCLUSION AND FURTHER WORK

In this chapter we have presented our methods and the methodology for image mining. Based on that, we built our system *ImageMiner Version 2.1*. This tool has shown excellent performance for a wide range of image-mining tasks. The basis for the image mining experiment is a sufficiently large database with images, feature description and/or expert descriptions. Such databases result for example from the broad use of image databases in many fields.

We were able to learn the important attributes needed for image interpretation and to understand the way in which these attributes were used for decision-making by applying data- mining methods to the database of image descriptions. We showed how the domain vocabulary should be set up to get good results and which techniques should be used in order to check the reliability of the chosen features.

The explanation capability of the induced tree was reasonable. The attributes included into the tree represented the expert knowledge. Finally, we can say that image-archiving systems in a combination with image-mining methods open a possibility for advanced computer-assisted diagnosis-system development.

We have recently been going on to apply the system to video microscopy and develop more feature extractions and image-mining procedures that can further support the image-mining process.

Chapter 2.24
Efficient Method for Image Indexing in Medical Application

Richard Chbeir
University of Bourgogne, France

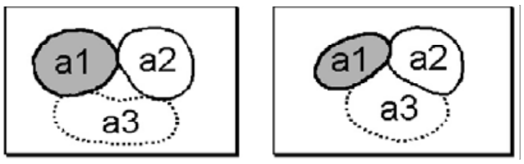
INTRODUCTION

In last two decades, image retrieval has seen a growth of interests in several domains. As a result, a lot of work has been done in order to integrate it in the standard data processing environments (Rui, Huang, & Chang, 1999; Smeulders, Gevers, & Kersten, 1998; Yoshitaka & Ichikawa, 1999). To retrieve images, different methods have been proposed in the literature (Chang & Jungert, 1997; Guttman, 1984; Lin, Jagadish, & Faloutsos, 1994). These methods can be grouped into two major approaches: metadata-based and content-based approaches. The metadata-based approach uses alphanumeric attributes and traditional techniques to describe the context and/or the content of the image such as title, author name, date, and so on. The content-based approach uses image processing algorithms to extract low-level features of images such as colors, textures, and shapes. Image retrieval using these features is done by methods of similarity and hence is a non-exact matching.

The requirement of each method depends on the application domain. In this paper, we address the domain of medicine where image retrieval in particular is very complex and should consider:

- Both content-based and metadata representations of images and salient objects. This guarantees a pertinent integration of all the aspects of image in order to capture pertinent information and to assure the relevance of all query types (Chbeir, Atnafu, & Brunie, 2002).
- High-precision description of images. For example, the spatial data in surgical or radiation therapy of brain tumors is decisive because the location of a tumor has profound implications on a therapeutic decision (Chbeir, Amghar, & Flory, 2001; Chbeir et al., 2002). Furthermore, it is crucial to distinguish between similar situations. Figure 1 shows two different images of three salient objects that are traditionally described by the same spatial relations in both cases: topological relations: a1 Touch a2, a1 Touch

Figure 1. Two different spatial situations

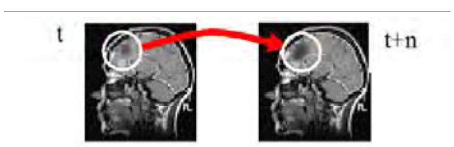


a3, a2 Touch a3; and directional relations: a1 Above a3, a2 Above a3, a1 Left a2.

- The evolutionary aspect of image content (Chbeir, Amghar, Flory, & Brunie, 2001) such as tumor development in brain (Figure 2), virus changes, and so on. The detection of the evolutionary aspects of objects (displacement, deformation, contraction, rotation, etc.) can significantly help physicians to establish an appropriate diagnosis or to make a therapeutic or surgical decision. An example for such a query is: "Find treatments of lesion detected inside brain images where a size increasing has been observed at every examination between time t and t+n".

In this article, we address the spatial and evolutionary issues of images. We propose a novel method that considers different types of relations. This method allows providing a highly expressive and powerful mechanism for indexing images.

Figure 2. Tumor growth inside the brain



The rest of this article is organized as follows: the next section is devoted to detail the related work. In the following section, we define our method of computing the different relations and we show how image indexing can be done. The subsequent section demonstrates how our method can adequately index medical images. Finally, we conclude and give future work orientations.

RELATED WORK

The problem of image retrieval is strongly related to image representation. Computing relations between either salient objects, shapes, points of interests, etc. have been widely used in image representation such as R-tree and its variants (Beckmann, 1990; Guttman, 1984), hB-tree (Lomet & Salzberg, 1990), ss-tree (White & Jain, 1996), TV-tree (Lin et al., 1994), 2D-String and its variants (Chang & Jungert, 1997; Chang & Jungert, 1991; Chang, Shi, & Yan, 1987), and so on. Spatial relations are mostly used for indexing and retrieval purposes for its automatic detection capability.

Three major types of spatial relations are generally proposed in image representation (Egenhofer, Frank, & Jackson, 1989):

- Metric relations measure the distance between salient objects (Peuquet, 1986). For instance, the metric relation "far" between two objects A and B indicates that each pair of points A_i and B_j has a distance grater than a certain value d.
- Directional relations describe the order between two salient objects according to a direction, or the localisation of salient object inside images (El-kwae & Kabuka, 1999). In the literature, fourteen directional relations are considered:
  - **Strict:** north, south, east, and west.
  - **Mixture:** north-east, north-west, south-east, and south-west.

- **Positional:** left, right, up, down, front and behind.

Directional relations are rotation variant and there is a need to have referential base. Furthermore, directional relations do not exist in certain configurations.

- Topological relations describe the intersection and the incidence between objects. Egenhofer and Herring (1991) have identified six basic relations: disjoint, meet, overlap, cover, contain, and equal. Topological relations present several characteristics that are exclusive to two objects (i.e., there is one and only one topological relation between two objects). Furthermore, topological relations have absolute value because of their constant existence between objects. Another interesting characteristic of topological relations is that they are transformation, translation, and scaling invariant.

In spite of all proposed work to represent complex visual situations, several shortcomings exist in the methods of spatial relation computations. Particularly, traditional methods do not have the required expressive power to distinguish between similar situations in critical domains such as in medicine.

On the other hand, the evolution of image content needs to be taken into consideration in several domains. Any evolution needs to consider time and thus temporal relations. For that reason, two paradigms are proposed in the literature in order to compute temporal relations:

- The first paradigm consists of representing the time as a set of instants: $t_1,..t_i,..t_n$. Traditionally, only three temporal relations are possible between two objects: before, its symmetric relation after, and equal.
- The second paradigm considers the time as a set of intervals $[t_i, t_j]$. Allen relations (Allen, 1983) are often used to represent temporal relations between intervals. Allen proposes 13 temporal relations (Figure 3), in which six are symmetrical.

For instance, in geographic applications, spatio-temporal queries (Bonhomme, Trepied, Aufaure, & Laurini, 1999) are used more and more to study the translation of a mobile object, the evolution of spatial objects, and so on. In the medical domain, images are evolutionary in nature. Their content evolution description can provide an important support for the treatment of diseases. To the best of our knowledge, the evolutionary content of medical images was only studied by Cárdenas, Ieong, Taira, Barker, and Breant, (1993); Chu, Hsu, Cárdenas et al. (1998). In Cardenas et al. (1993), the authors study the development of bones structures. They define a temporal evolutionary data model (TEDM). It extends traditional constructs. However, several evolutionary situations (such as deformation, expansion, contraction, etc.) are not considered.

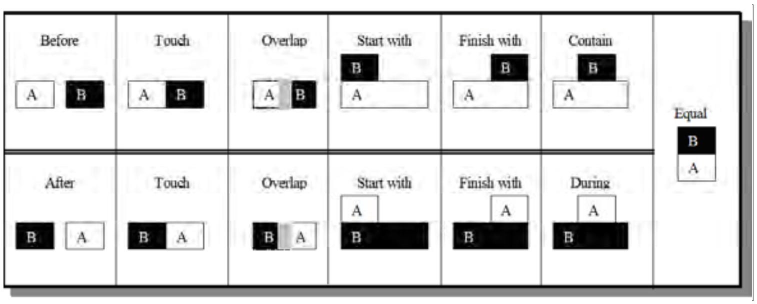
In this paper, we present our indexing method that is capable to represent spatial relations in highly expressive manner and to provide efficient technique to detect evolutionary content of images.

META-MODEL OF RELATIONS

Our proposal represents a generalized extension of the 9-Intersection model and its variants (Egenhofer & Franzosa, 1991). It provides a method for computing not only topological relations but also other types of relations with higher precision.

The idea is to identify relations of two values (or instances) on the basis of the same feature (such as shape, position, time, etc.). For example, the shape feature expresses spatial relations, the time feature provides temporal relations, and so on. To identify a relation between two feature values, we use an intersection matrix between several sets defined below.

Figure 3. Allen relations



Definition of Intersection Sets

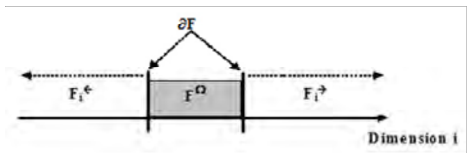
Let us first consider a feature F. We define its intersection sets as follows:

- The interior F^{Ω} contains all elements that cover the interior or the core of F. In particular, it contains the barycentre of F. The definition of this set has a great impact on the other sets. F^{Ω} may be empty ($\emptyset$).
- The boundary ∂F contains all elements that allow determining the frontier of F. ∂F is never empty ($\neg\emptyset$).
- The exterior F^{-} is the complement of $F^{\Omega}\cup\partial F$. It contains at least two elements: the minimum value and the maximum value. F^{-} can be divided into several disjoint exterior subsets. This decomposition depends on the number of the feature dimensions.

If the feature has only one dimension i (such as the acquisition time of a frame in a video), two exterior intersection subsets are defined (Figure 4):

- $F_i^{\leftarrow}$ (or inferior) contains elements of F^{-} that do not belong to any other intersection set and inferior to ∂F elements on the basis of i dimension.
- $F_i^{\rightarrow}$ (or superior) contains elements of F^{-} that do not belong to any other intersection set and superior to ∂F elements on the basis of i dimension.

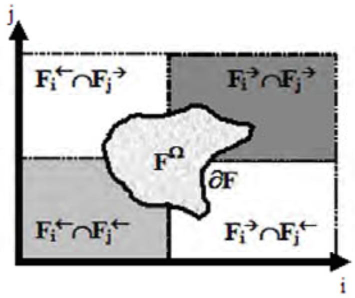
Figure 4. Intersection sets of one-dimensional feature



If we consider a feature of two dimensions i and j (as the 2D shape of a salient object in Figure 5), we then define four exterior intersection subsets:

- $F_i^{\leftarrow}\cap F_j^{\leftarrow}$ (or inferior) contains elements of F^{-} that do not belong to any other intersection set and inferior to F^{Ω} and ∂F elements on the basis of i and j dimensions.
- $F_i^{\rightarrow}\cap F_j^{\rightarrow}$ (or superior) contains elements of F^{-} that do not belong to any other intersection set and superior to F^{Ω} and ∂F elements on the basis of i and j dimensions.
- $F_i^{\leftarrow}\cap F_j^{\rightarrow}$ contains elements of F^{-} that do not belong to any other intersection set and inferior to F^{Ω} and ∂F elements on the basis of i dimension, and superior to F^{Ω} and ∂F elements on the basis of j dimension.
- $F_i^{\rightarrow}\cap F_j^{\leftarrow}$ contains elements of F^{-} that do not belong to any other intersection set and superior to F^{Ω} and ∂F elements on the basis of i dimension, and inferior to F^{Ω} and ∂F elements on the basis of j dimension.

Figure 5. Intersection sets of polygonal shape



More generally and using the same reasoning, we are able to determine intersection sets (2n) of n dimensional feature.

In addition, we use a tolerance degree in the feature intersection sets definition in order to represent separations between sets and to provide a simple flexibility parameter for the computing process. For this purpose, we use two tolerance thresholds:

- Internal threshold ε^i: defines the distance between F^{Ω} and ∂F,
- External threshold ε^e: defines the distance between subsets of F^-.

Relations Computing Via Intersection Matrix

To calculate relation between two feature values, we establish an intersection matrix of their corresponding feature intersection sets. Matrix cells have binary values:

- 0 whenever intersection between sets is empty
- 1 otherwise

For two-dimensional feature (such as the shape) of two values A and B, we obtain the following intersection matrix.

The indexing relation between two values is expressed then by a binary value which is the juxtaposition of each raw of the corresponding intersection matrix. This is very important for indexing purposes.

Indexing Images

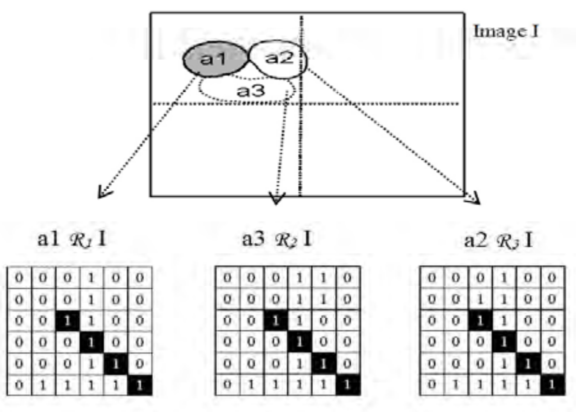
To index an image, we proceed as follows. First, we identify the spatial relations between the whole image and its salient objects. This allows determining the relative position of each object inside the image. In this case, the shape is used as a feature. The image is considered as a special object[1] that encloses all salient objects. We compute the intersection matrix of each pair of Image/Salient object. Figure 7 shows the result of this step on a 2D image I: three different spatial relations between the image I and its salient objects (a1, a2, and a3) are identified. It is important to mention that these relations are traditionally described by only one expression (i.e. northwest). We can see that, even at this level, our method provides a higher expression capability.

The second step consists of computing spatial relations between each pair of salient objects. Our

Figure 6. Intersection matrix of two values A and B on the basis of two-dimensional feature

$A^{\Omega}\cap B^{\Omega}$	$A^{\Omega}\cap\partial B$	$A^{\Omega}\cap B_1^{\leftarrow}\cap B_2^{\leftarrow}$	$A^{\Omega}\cap B_1^{\leftarrow}\cap B_2^{\rightarrow}$	$A^{\Omega}\cap B_1^{\rightarrow}\cap B_2^{\rightarrow}$	$A^{\Omega}\cap B_1^{\rightarrow}\cap B_2^{\leftarrow}$
$\partial A\cap B^{\Omega}$	$\partial A\cap\partial B$	$\partial A\cap B_1^{\leftarrow}\cap B_2^{\leftarrow}$	$\partial A\cap B_1^{\leftarrow}\cap B_2^{\rightarrow}$	$\partial A\cap B_1^{\rightarrow}\cap B_2^{\rightarrow}$	$\partial A\cap B_1^{\rightarrow}\cap B_2^{\leftarrow}$
$A_1^{\leftarrow}\cap A_2^{\leftarrow}\cap B^{\Omega}$	$A_1^{\leftarrow}\cap A_2^{\leftarrow}\cap\partial B$	$A_1^{\leftarrow}\cap A_2^{\leftarrow}\cap B_1^{\leftarrow}\cap B_2^{\leftarrow}$	$A_1^{\leftarrow}\cap A_2^{\leftarrow}\cap B_1^{\leftarrow}\cap B_2^{\rightarrow}$	$A_1^{\leftarrow}\cap A_2^{\leftarrow}\cap B_1^{\rightarrow}\cap B_2^{\rightarrow}$	$A_1^{\leftarrow}\cap A_2^{\leftarrow}\cap B_1^{\rightarrow}\cap B_2^{\leftarrow}$
$A_1^{\leftarrow}\cap A_2^{\rightarrow}\cap B^{\Omega}$	$A_1^{\leftarrow}\cap A_2^{\rightarrow}\cap\partial B$	$A_1^{\leftarrow}\cap A_2^{\rightarrow}\cap B_1^{\leftarrow}\cap B_2^{\leftarrow}$	$A_1^{\leftarrow}\cap A_2^{\rightarrow}\cap B_1^{\leftarrow}\cap B_2^{\rightarrow}$	$A_1^{\leftarrow}\cap A_2^{\rightarrow}\cap B_1^{\rightarrow}\cap B_2^{\rightarrow}$	$A_1^{\leftarrow}\cap A_2^{\rightarrow}\cap B_1^{\rightarrow}\cap B_2^{\leftarrow}$
$A_1^{\rightarrow}\cap A_2^{\rightarrow}\cap B^{\Omega}$	$A_1^{\rightarrow}\cap A_2^{\rightarrow}\cap\partial B$	$A_1^{\rightarrow}\cap A_2^{\rightarrow}\cap B_1^{\leftarrow}\cap B_2^{\leftarrow}$	$A_1^{\rightarrow}\cap A_2^{\rightarrow}\cap B_1^{\leftarrow}\cap B_2^{\rightarrow}$	$A_1^{\rightarrow}\cap A_2^{\rightarrow}\cap B_1^{\rightarrow}\cap B_2^{\rightarrow}$	$A_1^{\rightarrow}\cap A_2^{\rightarrow}\cap B_1^{\rightarrow}\cap B_2^{\leftarrow}$
$A_1^{\rightarrow}\cap A_2^{\leftarrow}\cap B^{\Omega}$	$A_1^{\rightarrow}\cap A_2^{\leftarrow}\cap\partial B$	$A_1^{\rightarrow}\cap A_2^{\leftarrow}\cap B_1^{\leftarrow}\cap B_2^{\leftarrow}$	$A_1^{\rightarrow}\cap A_2^{\leftarrow}\cap B_1^{\leftarrow}\cap B_2^{\rightarrow}$	$A_1^{\rightarrow}\cap A_2^{\leftarrow}\cap B_1^{\rightarrow}\cap B_2^{\rightarrow}$	$A_1^{\rightarrow}\cap A_2^{\leftarrow}\cap B_1^{\rightarrow}\cap B_2^{\leftarrow}$

Figure 7. The spatial relations between the image and its 3 salient objects



method allows combining both directional and topological relation into one binary relation. The directional and topological relations are replaced by an expressive binary spatial relation between two salient objects. Figure 8 shows the result of this step where a distinguished[2] spatial relation is identified for each pair of salient objects of the image I.

As a result, the image I is indexed as:

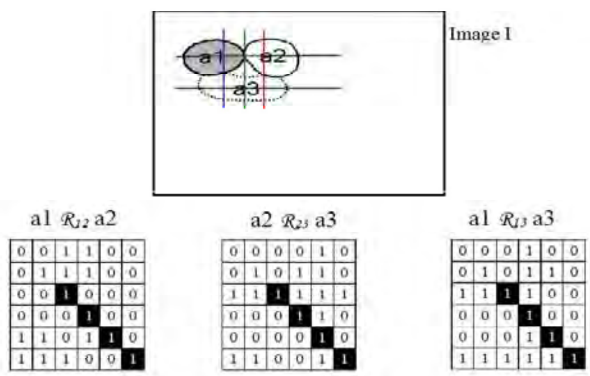
$$(a1\ R_1\ I + a2\ R_2\ I + a3\ R_3\ I) +$$
$$(a1\ R_{12}\ a2 + a2\ R_{23}\ a3 + a1\ R_{13}\ a3)$$

Indexing Evolutionary Content

To index evolutionary content of images, we compare some of their features values. We consider that calibrating techniques are already applied before comparing. In Chbeir et al. (2001b), we identified several types of evolutionary possibilities in the medical domain. In this paper, we address only two major possibilities: the displacement and the transformation of salient object.

The displacement represents the evolution of salient object position between two images. For example, the displacement of a fibrinocruorique clot through a deep vein of the lower limb is very common in medicine. The displacement of a salient object can be captured by comparing its relative spatial relations with images, and then its spatial relations with other salient objects. Using our method, even similar and complex spatial situations are detected (see following below).

Figure 8. The spatial relations between salient objects



The transformation represents the evolution of an object shape between two images. For example, the expansion of tumor size inside the left lobe of a brain is an example of this type of evolution. The transformation can be expressed as deformation, contraction, stability, and so on. To detect salient object transformation, we consider the surface as a feature. In this case, the exterior set F^- is considered as indivisible. We determine then the relation between the surface changes of the same salient object detected in two images. In the medical domain, it is obvious that the two images must belong to the same patient. Figure 9 snapshots some of the possible evolutionary relations that can be detected.

APPLICATION EXAMPLE

Let us consider a medical image with three salient objects a1, a2, and a3 (Figure 10) where shapes have changed during a period of time. These two situations resemble similar but actually different. The distinction between them must be well expressed especially in the application domains that require precision (such as in medicine). As shown in Figure 10, our method is capable to distinguish the different situations that are traditionally impossible to detect. The relations R_{12} and R'_{12} are equal but both relations R_{23} / R'_{23}, and R_{13} / R'_{13} are clearly distinguished.

Furthermore, our indexing method allows detecting the salient objects transformations: the deformation of a3, and the contraction of both a1 and a2.

CONCLUSION

We presented the domain of spatio-temporal image indexing and an original method capable of considering different types of relations in image representation. With our method, it is possible to homogenize, reduce and optimize the relations in

Figure 9. Several evolutionary relations detected

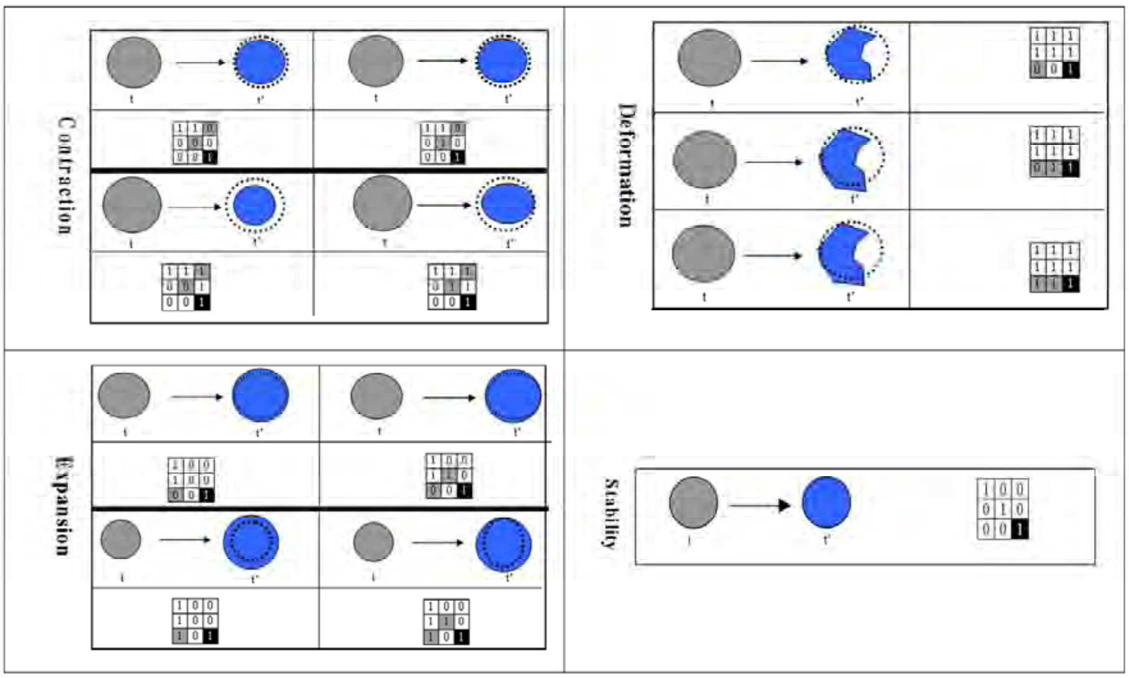


Figure 10. Using our method, the identification of similar spatial situations is possible

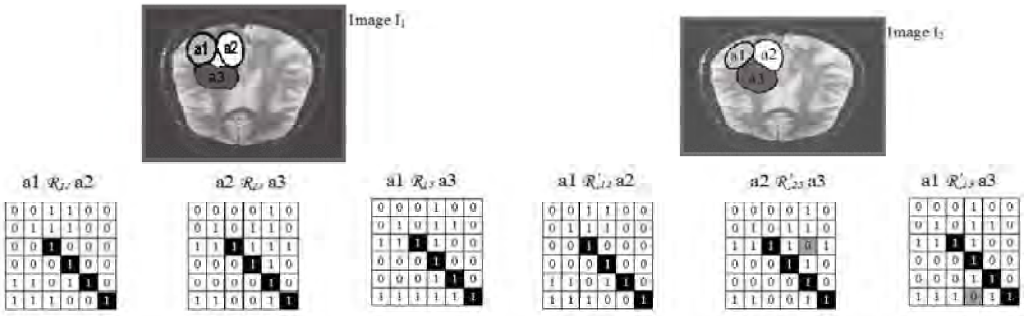

image description models (Chbeir et al., 2002). In this article, we showed how to provide a highly expressive power to spatial relations that can be applied to describe images and then to formulate complex visual queries. We also showed how to detect evolutionary content of images. The example in medical domain demonstrates how image indexing can be improved.

Currently, we are working on integrating such indexing method in our prototype EMIMS (Chbeir et al., 2001a; Chbeir et al., 2002). Future work includes considering indexing of low-level features (color, texture, etc.) and more intense experiments in complex environment where large number of feature dimensions (2,5D[3] and 3D images) and salient objects exist. Our method will also be studied to see if it can used in datagrid computing.

KEY TERMS

Directional Relation: Describes the order between two salient objects according to a direction, or the localization of salient object inside images. In the literature, 14 directional relations are considered:

- **Strict:** north, south, east, and west.
- **Mixture:** north-east, north-west, south-east, and south-west.
- **Positional:** left, right, up, down, front and behind.

Image Indexing: Consists of assigning concise and significant descriptors to an image. Objects shapes and positions are used in several indexing approaches where image is represented as a graph or tree (R-tree, B-tree, etc.).

Metric Relation: Measures the distance between salient objects. For instance, the metric relation "far" between two objects A and B indicates that each pair of points A_i and B_j has a distance grater than a certain value d.

Multimedia Document: Represents a document containing not only textual data but also multimedia ones such as images, videos, songs, and so on.

Salient Object: Interesting or significant object in an image (sun, mountain, boat, etc.). Its computing changes in function of the application domain.

Spatio-Temporal Relation: A combination of two spatial and temporal relations into one relation used to index video-documents and objects evolution between two images (e.g., tumor evolution).

Topological Relation: Describes the intersection and the incidence between objects. Six basic relations have been identified in the literature: *disjoint, meet, overlap, cover, contain, and equal*.

ENDNOTES

1. Where the interior set is empty, the boundary set is the barycentre, and the exterior is divided into four sets.
2. Traditionally, the three salient objects are described by non expressive spatial relations (same topological and directional relations).
3. Sequence of 2D images in medical applications (i.e., scanner).

Section III
Tools and Technologies

This section presents extensive coverage of the interaction between healthcare and the various technologies that both derive from and support the research of practitioners, students, and patients alike. These chapters provide an in-depth analysis of mobile technologies and their use in healthcare, while also providing insight into new and upcoming technologies, theories, and instruments that will soon be commonplace. Within these rigorously researched chapters, readers are presented with countless examples of the tools that facilitate and support medical innovations. In addition, the successful implementation and resulting impact of these various tools and technologies are discussed within this collection of chapters.

Chapter 3.1
Application of Mobile Technologies in Healthcare Diagnostics and Administration

Ketan Vanjara
Microsoft Corporation, India

ABSTRACT

This chapter explores various advancements in mobile devices and corresponding software applications that enhance diagnostics and administration in the healthcare domain. This chapter further proposes networking and integration of these devices with the existing networks and devices as further development in healthcare.

A ROAD ACCIDENT SCENARIO

In 1992, a colleague of mine was traveling from our offices in western India to our manufacturing facilities about 50 kilometers away. He had worked late the previous night and again come to the office early in the morning. We had our lunch together and he left for the manufacturing facilities (factory) around noon, driving his own car. Even after two hours, he had not reached our factory and, increasingly, the office and the factory administrators were panicking, trying to locate this employee of ours. Around 6:30 p.m. we received a call from the general hospital of the city that a semi-conscious accident patient had been admitted to the hospital. In short, my colleague had met with an accident around 1 p.m., and he was admitted to the hospital only around 6 p.m. The treatment could not begin before 8 p.m. The end result was that he became paraplegic. Based on the information provided by the doctor on duty, had he been treated within three hours of the accident, paraplegia could have been avoided. Did mobile devices—or their lack of—have a role to play in this incident? The answer has to be a 'yes'.

Though just a little over a decade ago, this era was devoid of any mobile devices in India. My colleague did not have a cell phone, nor did his family (it took a while to contact them). His car did not have a Global Positioning System (GPS). The hospital and doctors too did not have any mobile devices. Finally, even after arriving at the hospital, the doctors had to wait for the family before starting treatment, as they needed medical information of the patient such as existing diseases, allergies, sensitivities, and so on. Overall, the above scenario shows the lack of our ability to manage emergency medical situations without immediate communication. Today, though, with the advancement of mobile technologies, such events are better managed. However, there is still a need to provide integration of various mobile tools with the existing devices, technologies, and networks in order to reap full benefits of mobility in the healthcare sector in general and emergency medical situations in particular.

This chapter explains how mobile technologies are shaping the face of healthcare today. This chapter also discusses the potential for improved healthcare through mobility in the future. The primary focus of this chapter is on the integration of mobile devices/gadgets in diagnostics, healthcare administration, and healthcare information systems. Finally, this chapter also proceeds to identify issues and challenges involved in such integrations and how to handle them.

THE HEALTHCARE LANDSCAPE

Healthcare is one of the major domains in life that is full of amazing advancements. However, it also comes with its ever evolving challenges. For example, of late this domain has been mired in controversies on ethical issues like cloning and stem cell research. While medical science still continues to struggle with challenges like eradication of malaria and treatment of cancer and AIDS, its achievements have not been mean by any standards.

The progress made in the last 20 years (is) amazing if one looks at it now. In short, the advances made in the last 10-15 years are equal or even surpass the advances made in the last 100 years. (Majeed, 2005)

Medical science has discovered new diseases and invented new treatments and therapies. In fact, a number of medical scientific disciplines like Pharmacogenomics that allows creation of personalized medicine, toxicokinetics, proteomics, therapeutic vaccines, stem cell research, bioinformatics, and telemedicine, to name a few, evolved in the last 20 years.

Complex diagnostics, short-duration intensive care, acute medicines, and micro-surgeries are all becoming common in today's healthcare.

Another major contributor to advancements in medical sciences has been the developments in digital technologies. Be it bioinformatics or telemedicine, the need for modern healthcare to offer the best treatment for complex diseases in the fastest possible manner with resource constraints makes it highly dependent on digital technologies. Data-intensive areas like bioinformatics also need to depend heavily on high-end computing devices.

Thus, today's healthcare is characterized by the following:

- **Multiplicity and Complexity of Diseases and Treatments:** The breadth and depth of knowledge on various medical disciplines, diseases, their symptoms, causes, and various alternatives of treatment have been growing exponentially in the last couple of decades. This has led to increased complexity in the fields of diagnostics and therapies. So much has been the growth in knowledge and complexity that it is almost impossible for a medical practitioner to function effectively without supporting devices like computers and PDAs.
  An indicator of this fact is the vast amount of literature available on all the medical disciplines—a simple search on Google (2005) returns thousands of medical journals, 1,440 of which are free. Hundreds of viruses and their mutations have been identified for something as simple as the common cold (Health-Cares, 2005).
- **Quick Response:** Given that the number of accidents is increasing every day, the demand for quick response from medical services is growing too. Continuous efforts

are on to reduce the interval between the time a person needs medical attention to the time when treatment is provided to her. This has led to provisioning of preliminary treatment as soon as the patient is contacted—at the accident site, at the patient's home, or even in the ambulance taking the patient to a clinic or hospital. Mobile clinics and surgery ambulances are quite common nowadays to meet this need of quick response.

- **Quick Cure:** Quick response alone is not enough. A typical patient today expects to get cured much faster so that he can get back to work and his normal life. This need drives the entire industry, especially pharmaceutical companies, to constantly research and produce better drugs and come up with drug delivery systems that offer faster cure (Howard, 2004).
- **Mobility and Remote Assistance:** Mankind is more mobile today than it has ever been before. This increase in mobility has given rise to the need for remote medical assistance. Despite their mobility, a patient and a doctor need to stay in touch with each other to get/provide remote assistance. Such remote assistance can take various forms, ranging from simple things like monitoring a patient's progress and response to treatment, to more complex and technology-intensive issues like telemedicine or tele-surgery.
- **Cost-Price Paradox:** While it is quite obvious that the emerging nature of medical services as well as demands on them result in increased costs, there is constant pressure to drive the price of healthcare southwards. Besides providing better value for money to patients, reduced price also makes healthcare affordable to many more people. Thus, it is imperative upon various players in the healthcare sector to provide superior and continuously improving products and services at continuously reducing costs. This requires a lot of automation and innovation.
- **Resource Constraint:** Increase in multiplicity and complexity of medical disciplines, diseases, and therapies requires specialized skills. Thus, we have specialists in every branch and sub-branch of medicine. By their very nature, specialist skills are scarce. However, the demand on such specialist skills keeps on rising. This creates a resource constraint and a need to be able to utilize the same resources effectively across different locations or geographies.
- **Data Driven:** Given the plethora of variables that need to be considered and evaluated to provide effective treatment, the medical profession has become highly data driven. Besides supporting research, such data actually influences, if not drives, treatment. Such dependence on volumes of data necessitates use of digital devices.
- **Return of Alternative Therapies:** These include medical disciplines like the age old ayurveda, naturopathy, homeopathy, and so on. While their acceptance is growing among many people all over the globe, technology has not made as many inroads into these branches of medicine as others. This presents a huge opportunity. We shall discuss one such potential in this chapter.

THE MOBILE TECHNOLOGY LANDSCAPE

After surveying the healthcare landscape, let us take a look at the mobile technology landscape as well. The handheld devices of today, like cell phones and PDAs, are far more powerful than the large supercomputers of yesteryears that occupied large space. In addition to this shrinking of sizes, there are quite a few other significant developments taking place in this arena. Some of the recent developments that help us understand the mobile technology landscape are as follows:

- **Nanotechnology—Miniaturization Shift:** Handheld devices and various other gadgets related to mobile technologies are getting smaller and smaller. The scale is moving from micro to nano. Nanotechnology, considered to be one of the foundations of future technology revolutions, enables many unthinkable things like storing several gigabytes of data on a millipede nanodrive of the size of a postage stamp (Global Change, 2005). We already get 60 GB of storage in an iPod (http://www.apple.com/ipod/). PDA PC watches and pocket-sized holographic projectors are on their way to the market. One of the constraints of adopting mobile technologies has been smaller output interfaces in the form of display screens. Hologram projectors resolve this problem effectively (http://www.lightblueoptics. com/index.html; Howard, 2004).
- **Software Power:** While hardware devices are offering more (functionality) in less (smaller devices), software is not to be left behind. There are thousands of applications created for these small devices that have larger functionality and very small footprint. Be it Win CE operating system, various MS Office applications, or entertainment software like iTunes_all of them provide extensive functionality while occupying much less space on the devices (Microsoft, 2005).
- **Convergence:** The world talked a lot about convergence of information and communication technologies in late nineties. However, such convergence is an ongoing process that is still continuing. What we are seeing today is convergence of various advanced technologies like computing, mobile telephony (cell phones), and connectivity (Internet) on a single handheld device like the HP iPAQ 6315 (2005) Pocket PC–Phone Edition. Pretty soon, positioning (GPS) too will be integrated. Handheld GPS receivers are already available in the market. Microsoft's product *Streets & Trips 2005* with handheld GPS locator combines Streets & Trips software with a GPS plug-n-play receiver hardware component, to create a planning and driving tool that turns a laptop into a real-time GPS tracking device (Microsoft Streets & Trips 2005 GPS, 2005). Very soon we may see all these features available on nano devices, resulting in the handheld devices having more processing power, superior features, larger storage, longer battery life, and becoming more universally accessible than the tablet PC of today. Such convergence of technologies will empower and enable users to work far more efficiently and effectively than ever_and from wherever.
- **Natural Interfaces.** Another major area of advancement in technologies is natural interfaces. These include voice recognition, handwriting recognition, and visual recognition. One of the greatest hindrances to adoption of mobile devices has been the input interfaces in the form of the keyboard or mouse. The smaller keypads of handheld devices make it difficult to input large content. Voice and handwriting recognition address this issue. Visual recognition addresses issues related to security. Very soon we will also see interactive surfaces like floors, tables, walls, and so on (http://www.naturalinteraction.org, http://www.hcirn.com/, http://nooface.net).
- **Function-Specific Handheld or Nano Devices.** While information and communication technology industries are creating newer, smaller, and smarter versions of technology-driven handheld devices like cell phones, pocket PCs, and PDAs, industries like healthcare are creating and continuously improving functionality-driven handheld devices to perform specific functions related to healthcare. These include diagnostic devices like Smart Pill from Smart Pill

Diagnostics and Amplichip from Roche (Medgadget, 2005a).

- **Mobility and Wireless:** With mobility comes the need of wireless. One cannot be truly mobile with wired devices. In addition to wireless devices, we are also seeing the creation of connectivity infrastructure in the form of cellular and Wi-Fi networks.

  A cellular radio network is a radio network made up of a number of radio cells (or just cells) each served by a fixed transmitter, normally known as a base station. These cells are used to cover different areas in order to provide radio coverage over a wider area than the area of one cell. (Cellular Network, 2005)

  Wi-Fi networks (also known as wireless LAN) use radio technologies called IEEE 802.11b or 802.11a to provide a secure, fast, and reliable wireless connection. Wi-Fi functions through a transmitting antenna which is usually linked to a DSL or high-speed land-based Internet connection and uses radio waves to beam signals. Another antenna, which is in the laptop or PC, catches the signal. The signal, usually, has a range of about 300 feet for most home connections. The farther the user is from the signal, the slower the connection speed. (Shaheen, 2005)

  Our cell phones work on a cellular network, while mobile computers use various other wireless technologies to network, like infrared, Wi-Fi, radio-frequency, Bluetooth, and so on. Recently, cell phones that can work on both cellular and Wi-Fi networks, and also seamlessly switch between the two, have also arrived (Computerworld, 2004).
- **Cost Paradox:** The cost paradox in the technology landscape is quite opposite of that in the healthcare space. In technology areas, the normal trend is to get more for less. From memory to storage to functionality—hardware or software—we either get the same product cheaper or a better product at the same price with passing time. This puts technology in an enviable position where it can be and it is complementary to all other industries or needs.
- **Business Intelligence:** Due to increasing specialization and complexity in various domains today, decision making in today's world is a function of a multitude of variables. This has necessitated creation of huge databases. These databases need to be analyzed almost real time to support decision making. Data mining and business intelligence come in handy here.

APPLYING MOBILE TECHNOLOGIES IN HEALTHCARE

Having surveyed the healthcare and mobile technologies landscape, we now move on to explore the possibilities of convergence of both. Though the possibilities are endless, we will keep our exploration limited to:

- **Diagnostics:** With the exception of certain alternate medical sciences, treatment of therapy nowadays is seldom provided without diagnosing the symptoms through a plethora of tests in the areas of pathology and radiology, as well as physical examination. The field of diagnostics, therefore, offers many challenges—in other words opportunities—for mobile technologies.
- **Healthcare Administration:** Healthcare administration includes the complete cycle of healthcare provisioning from the moment a patient seeks the service until the patient is cured or no more needs the service. This includes activities like consulting, symptom recording, diagnostics, analysis and interpretation of test reports, prescription of treatment, therapy or surgery, drug delivery, post-operative support, and so on. Due to

various characteristics of the healthcare sector mentioned earlier, mobile devices can make a lot of contribution in this area as well.

- **Healthcare Information Management Systems:** This includes creation, maintenance, and global provisioning of all healthcare-related information like medical records, test reports, receipts, payments, service levels, and so on. Not all information is critical such that it needs to be provided anytime, anywhere. However, information like medical records, test reports, service levels, and so forth do need to be universally available.

MOBILE TECHNOLOGIES IN DIAGNOSTICS

Among all the applications of mobile technologies in the healthcare space, diagnostics is the most challenging as it involves integration of multiple technologies. A patient has to go through a series of diagnostic tests to enable a doctor to provide appropriate treatment. There are two major bottlenecks around this: (1) in urban areas, where the diagnostic labs are normally located, the patient population is very mobile and also adversely affected by traffic conditions of modern urban areas; and (2) in rural areas, where the patients are not that mobile and rarely have a diagnostic lab. Mobile technologies can resolve both these problems. In addition, mobile technologies can also assist in cases of emergencies, like accidents or elderly patients that cannot travel much.

Conventional diagnostics can be broadly classified into four areas: pathology, radiology,

scans (MRI, CT, etc.), and pulse (ECG, physical pulse examination, etc.).

The good news is that today we have miniature devices that are useful in all types of diagnostics. In the beginning, personal wellness monitoring meant the bathroom scale and the mercury thermometer. Then they went electronic, and home blood-pressure devices became common. Today, it would not be shocking to see a home cardiac defibrillator sitting in the corner (HealthDay, 2005). However, only some of the diagnostics devices have become popular so far. Others are at various stages of development, clinical trial, or market deployment.

Let us briefly look at some of the handheld or miniature devices for diagnostics that are already being used or about to be deployed in the healthcare market. A brief description is given on the functionality of each device (http://www.medgadget.com/archives/diagnostics/index.html).

- **Blood Glucose Monitor Systems/Diabetes Systems:** These devices help in monitoring/determining the glucose levels in blood. They have become quite sophisticated over a period of time, and the latest models have many features like no strip handling, 250-test memory, and so on.
- **Wrist BP Monitors:** They look very similar to electronic wrist watches and are used in determining the systolic and diastolic blood pressure of a patient. The advanced versions can store up to 90 readings and are very lightweight, operating on AA or AAA batteries.
- **Oximeter:** These devices determine the degree to which hemoglobin on the red blood cell is loaded with oxygen ("oxygen saturation"). Sophisticated models have additional features like measurement of pulse rate and SpO2, verification of endotracheal tube placement, and changes in carbon dioxide level with the help of a CO_2 sensor.
- **Automatic External Defibrillators/Pacemakers/CHF Monitor/Fluid Status Monitoring:** These are electrical devices used to counteract fibrillation of the heart muscle and restore normal heartbeat by applying a brief electric shock. In addition, they have built-in monitors that track the problem to

prevent crisis. The fluid status monitoring device sits under the patient's left collarbone and sends out electrical impulses to monitor liquid levels; whenever the level is near critical, the device alerts the patient to get help before the problem turns critical. Doctors also can check the monitors by phone, using computerized hookups in their patients' homes.

- **iPod:** The iPod is not just for music any more. Radiologists in the United States, Europe, and Australia are now using iPod devices to store medical images. "This is what we call using off the shelf, consumer market technology," says Osman Ratib, MD, PhD, professor and vice-chairman of radiologic services at UCLA. "Technology coming from the consumer market is changing the way we do things in the radiology department" (Ratib, 2004). A software (OsiriX) has also been developed to automatically recognize and search for medical images on the iPod. When it detects the images, they automatically appear on the list of image data available—similar to the way music files are accessible by the iTunes music application.
- **Portable Patient Monitors:** These devices monitor and provide digital display of mean and diastolic blood pressures, heart rate and respiratory rate, temperature (a, b, or differential A-B) based on two temperature inputs, blood pressure, and ECG trace. Several alarms can also be set in these monitors based on over/under pulse rate, pressure, or temperature (http://www.pemed.com/pmonitor/pmon.htm).
- **GI Monitoring System:** A patient swallows this slightly larger-than-multi-vitamin-sized capsule containing two subminiature radio transmitters. The capsule's transmissions are received by a small, patient-worn mobile receiver/controller. Site-specific data is captured in real time as the capsule passes through the GI tract. It also measures pH, temperature, and pressure. The capsule is not absorbed, nor does it interact with the GI tract in any way other than its propulsion via peristalsis, eventually exiting through the colon. The future-generation systems are expected to enable real-time, site-specific tracking of the capsule's position within the GI tract, transmit pictures, and also facilitate drug delivery.
- **Handheld MRI:** The primary reason for the large size of conventional MRI scanners is the use of large magnets that have to be chilled by complicated cooling systems. Igor Savukov and Michael Romalis of Princeton University have shown that a device called an atomic magnetometer can detect magnetic signals from water without giant magnets or complicated cooling systems. This has given rise to a distinct possibility of handheld MRI scanners in the future that would image tissues inside the body as easily as a digital camera takes a photo.
- **Wireless/Handheld X-Ray Sensor:** A company has developed a wireless direct digital radiography system for dental x-ray examinations that communicates images it captures with a dentist's computer. There are quite a few models of handheld or portable x-ray instruments available now. They provide greater flexibility, are optimal for remote uses, capture high-quality images, transfer them digitally to computers, and reduce radiation exposure.
- **Oral Swab Kit:** Various organizations are prototyping oral swab kits or similar devices for saliva-based diagnostics that can detect exposure to a variety of substances, from narcotics to anthrax to common bacteria and viruses including those of HIV. These will be quantum enhancements to rapid saliva tests that are already in use. These devices would increase ease of detection and accelerate response time whether they are used

in the middle of a public health incident or in a busy doctor's office. The devices are expected to communicate captured data in digital form as

- **Wireless Miniature Devices for CHF Patients:** These are technologies integrated into minute implants, requiring no antenna, wires, or connecting leads, that allow a tiny device implanted deep inside the body to communicate wirelessly with other implanted devices and external systems. Such devices include a device that offers on-demand, non-invasive means to monitor intra-aneurysm pressures following endovascular graft procedures and a device for measurement of pulmonary artery pressure, which is the most important hemodynamic indicator in heart failure. A one-time, minimally invasive catheter-based procedure allows unlimited, non-invasive home-based monitoring of a CHF patient's hemodynamic status.
- **Other Handheld Wireless Diagnostic Devices:** These include holographic sensors, PathoTester (a wireless handheld system that can detect growth of microbial pathogens using nanocartridge-based technology that contains microbe-specific sensor holograms), non-invasive glucometer (that measures blood sugar in the body based on the amount of heat released from the tip of the finger—metabolic heat conformation), Glucose Monitoring Watch (which continuously displays blood glucose through use of photo acoustic waves originating in the blood vessels), and Wireless Objective Hearing Assessment Systems.
- **Pulse Meter for Ayurveda:** Ayurveda, the science of life and longevity, is an ancient Indian system of holistic medicine, which has re-emerged as an important form of holistic therapy throughout the world. Its essence is the conjunction of the body and the mind, and their coordination that achieves optimal health and happiness. This science is heavily dependent on pulse examination for diagnostics *Nadi Pariksha*. This involves determining *Prakriti* and *Vikriti* in pulse, understanding the seven levels of pulse, and integrating qualities of the pulse with signs and symptoms in clinical assessment. Future enhancements of pulse meters are expected to fulfill the needs of Ayurveda as well.

There are tele-healthcare gadgets galore, and the list can go on and on. Take for instance an all-in-one device that helps patients do the following: measure blood pressure, blood sugar, blood oxygen (SpO_2), measure temperature and weight, record peak flow, record stethoscope sounds, and take ECGs.

As of now many of these devices are not network ready for communication with other wireless devices like cell phones or PDAs, nor are all of them following any common communication standard. However, very soon they will be getting linked wirelessly to home computers and cell phones, as a health revolution is creeping quietly into our lives.

Where it is going to take us is anyone's guess, just as whether new age health monitoring will make us live longer. But the IBM Corp., for example, has developed a little electronic pillbox that may come in handy as the Baby Boomers edge into the years of forgetfulness. The box sends a signal to a mobile phone every time a pill is removed. If patients forget a pill, or take too many pills from the box, they get a friendly reminder phone call. For patients who need frequent monitoring of vital signs, an IBM wristband device measures blood pressure and heart rate at the push of a button, and these are transmitted automatically to medical personnel.

Sun Microsystems and MedicTouch have introduced the Pulse Meter, which they call the 'ideal health monitoring solution for sport enthusiasts, the elderly, rehabilitation outpatients and health-

care providers; providing health-monitoring anytime, anywhere.' A Pulse Meter user connects the sensor to a hand, starts the program on a mobile phone and the pulse is displayed within seconds on the phone screen, archived, customized for user, and transmitted. (HealthDay, 2005)

Medical monitoring and treatment are going wireless and Internet based, both at home and at the hospital. HealthDay (2005) reports about tele-healthcare gadgets designed for initial, basic in-home diagnostics.

NEXT STEPS

We are at the crossroads of mobile technologies and healthcare diagnostics today. While both of them converge here coming from two different directions, the convergence itself is expected to advance in two different directions simultaneously. These two directions are as follows:

1. **Integration of all the handheld diagnostic devices or their functionality** into a single device that is connected to the wired and wireless networks. Eventually, they would be interconnected with healthcare networks and databases (generic as well as medical records). This model would look somewhat similar to that in Figure 1.
   In fact, European researchers have just completed something very similar—the Wearable Health Care System project, otherwise known as WEALTHY (2005). In addition to being fashionable and slimming, the body suit will measure all manner

Figure 1. Network of all handheld devices (diagnostic and others) providing healthcare administration and healthcare information management systems-related services to doctors and patients. A single handheld diagnostic device with all the diagnostic functionality enables the patient to get desired healthcare services.

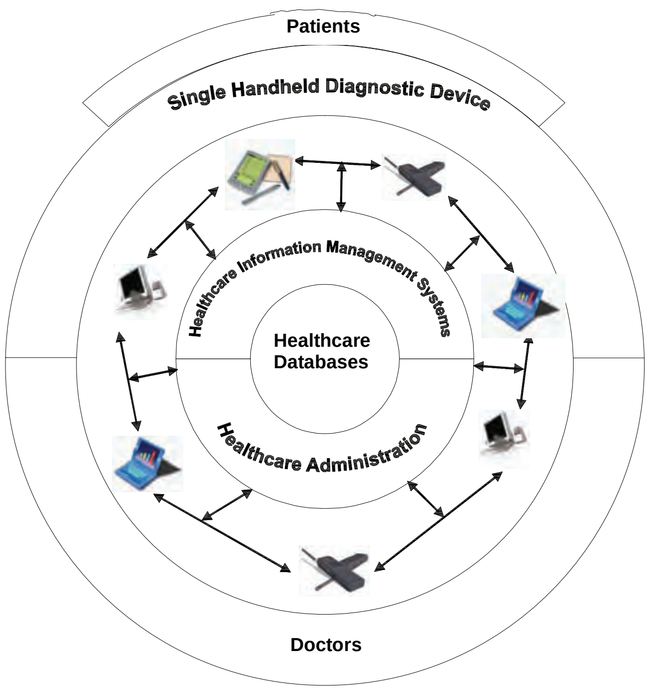

Figure 2. A representative diagram of WEALTHY

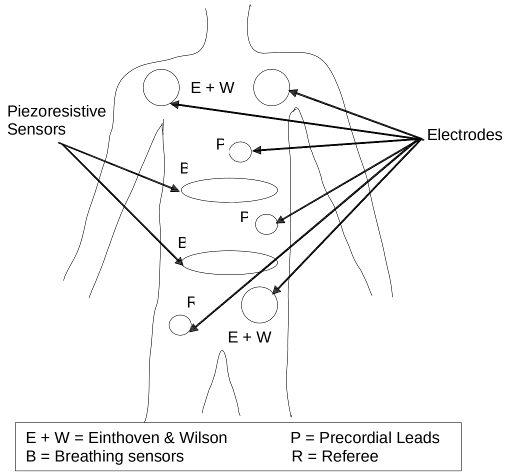

Figure 3. Network of all handheld devices (diagnostic and others) providing healthcare administration and healthcare information management systems-related services to doctors and patients. HDD = a network of handheld diagnostic devices that is integrated with wired and wireless networks. This entire network is accessible to doctors and patients.

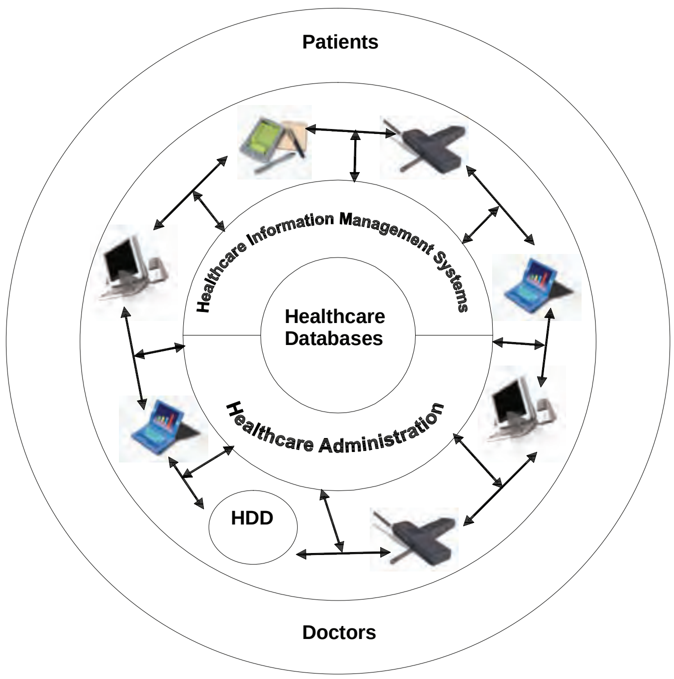

of bodily processes, including respiration, core and surface skin temperature, position, and movement. It will also transmit all this data over the mobile phone network thanks to a miniaturized GPRS transmitter hidden in the suit. The transmitter can also alert emergency services if the wearer stops responding or shows alarming vital signs. WEALTHY is depicted in Figure 2.

2. **Networking of individual handheld diagnostic devices** amongst themselves and to wired and wireless networks. Eventually, they would also be interconnected with healthcare networks and databases (generic as well as medical records). This model would look somewhat similar to that shown in Figure 3.

MOBILE TECHNOLOGIES IN HEALTHCARE ADMINISTRATION

Healthcare administration consists of all the activities undertaken to provide healthcare services to patients. Broadly, these activities are:

- **Consultation**
  - Patient visits the doctor
  - Patient provides details of their ailment to the doctor
  - Doctor carries out physical examination for symptoms
  - Doctor may suggest further diagnostic tests—the probability of this is much higher today with the advancement of medical science
- **Diagnosis**
  - Patient visits various laboratories for diagnostic tests
  - Patient visits the laboratories again to collect the diagnostic test reports
  - Patient visits the doctor again with the diagnostic test reports
- **Treatment**
  - Doctor prescribes medication to the patient or recommends a surgery
  - Patient visits the pharmacy to buy the medication
  - If recommended, patient registers for the surgery at a hospital
- **Payment**
  - Patient makes payment to the doctor
  - Patient makes payment to the pharmacy
  - Patient approaches the insurance company or concerned agency for reimbursement of medical expenses.
  - Alternatively, the medical agencies (like the physician) approach the insurance company for reimbursement

What we need to explore now is how many of these steps can be performed effectively using mobile devices like cell phones or PDAs. I would not be overstating if I mentioned that most of the activities related to healthcare administration can be performed using various handheld devices. Table 1 shows how.

ADDITIONAL THOUGHTS

In addition to the normal healthcare administration process, there are many more things that can be achieved using handheld technologies. Some of them are:

- *Embedding important patient data on the smart cards* of mobile phones or PDAs. In cases of emergency like accidents, war, and so forth, quite often the patient is unable to provide any basic information about himself that is important for the doctor to initiate treatment. All such information, starting from the blood group of the patient, his address, contact details of his immediate relatives, his allergies, a brief medical

Table 1.

Activity	How to perform it using handheld device/s – there could be multiple options
Consultation • Patient visits the doctor • Patient provides details of their ailment to the doctor • Doctor carries out physical examination for symptoms • Doctor may suggest further diagnostic tests	• A personal visit by the patient to the doctor may not be required in many cases. Patient can talk to the doctor using cell phones and provide details of their ailment. • If needed, patient can also have a video conference with the doctor using cell phones with cameras & multi-media capabilities or smart phones – this would enable the doctor to observe the physical symptoms of the patient's ailment. • If a meeting with the doctor is absolutely necessary, a patient can access the doctor's calendar through their cell phone or PDA and take an appointment. Similarly doctors too can maintain and access their calendar through their cell phones or PDAs. • Having understood the ailment as well as symptoms, doctors can send a recommendation or prescription for diagnostics to the patient. Such a prescription can be created quickly using a pre-loaded form on the handheld device and then sent to the handheld device of patient as well as to the relevant laboratories.
Diagnosis • Patient visits various laboratories for diagnostic tests • Patient visits the laboratories again to collect the diagnostic test reports • Patient visits the doctor again with the diagnostic test reports	• As discussed at length in the previous section, most of the diagnostics can now be done through handheld devices. A patient in this case would have 3 choices – 1. If he is suffering from chronic ailment, he may have his own diagnostic device/s that he can use for the test and then send the result to the doctor, through a mobile device. 2. Patient can visit a laboratory to get the tests done. The laboratory, in turn, can flash the results to the handhelds of the doctor as well as the patient as soon as they are ready, saving the patient of a second visit. 3. With so many small handheld devices available, there is a good possibility of a doctor having them. Thus, patient can just pay one visit to the doctor and complete consultation, physical examination of symptoms as well as diagnostics – all at a time. In all the cases, the patient and doctor can achieve a lot with more convenience using handheld devices.
Treatment • The doctor prescribes medication to the patient or recommends a surgery • Patient visits the pharmacy to buy the medication • If recommended, patient registers for the surgery at a hospital	• After studying diagnostic reports, doctor can prescribe medication and therapies to the patient. This too can be done using their respective handheld devices. • A doctor can also take help from a lot of references (medical guides, reference, encyclopedia, etc.) preloaded on the handheld or accessible on the net through the handheld. • The prescription of medication and therapies duly signed by doctor can be transmitted to the patient's handheld device. • Patient can visit any pharmacy with the preloaded prescription from the doctor on the handheld device and buy the medicines by providing the prescription to the pharmacy. • If a surgery is recommended, the patient can take an appointment with the concerned doctor and surgery by accessing their calendar through the handheld. • In the surgery, if needed, the doctor/s can get medical advice / expertise from various resources on the net using their handheld devices or even having real-time interaction with experts around the world.
Payment • Patient makes payment to the doctor • Patient makes payment to the pharmacy • Patient approaches the insurance company or concerned agency for reimbursement of medical expenses. • Alternatively, the medical agencies (like the physician) approach the insurance company for reimbursement.	• Patient can pay the doctor / pharmacy using preloaded cash or credit/debit cards on the handheld device. • Patient can similarly receive all the invoices on his handheld and forward them to the insurance company along with a filled in prescribed form for reimbursement. • In case, the doctor has to approach the insurance agencies, they too can forward the relevant forms and documents in digital format from their handheld devices.

history consisting of all major healthcare-related events in the patient's life, and so on can be embedded on the smart card so that it is accessible at the click of a button. This can enable much faster treatment of the patient.
- *GPS enabling of handheld devices.* This also helps in tracking a patient during emergencies. On the diagnostics front, there are already devices that can keep track of a patient's health on certain key parameters and notify the doctor if a negative trend is building on any of them. An integration of these devices with GPS-enabled handheld devices would add a lot more value to provide proactive healthcare to patients.

Thus, a large part of healthcare administration can actually be carried out using handheld devices. One of the primary enablers for this is that the latest models of handheld devices are turning out to be as capable as desktops and laptops of not so long ago—virtually any task that one could complete on a desktop or laptop 3-5 years ago can now be accomplished through a handheld device. In fact, almost all the technologies are already available. All that is required is their integration or convergence.

MOBILE TECHNOLOGIES IN HEALTHCARE INFORMATION SYSTEMS

Having discussed how mobile technologies facilitate healthcare administration, which is essentially interactions between a healthcare service provider—a doctor or a clinic—and a patient for providing healthcare services to the patient, let us now see how these technologies can be useful in healthcare information systems.

Healthcare administration results in the generation of a lot of data that needs to be maintained and managed for future reference. Such data includes, but is not limited to, EMRs (electronic medical records), diagnostic reports, and patients' medical history. Healthcare service providers like doctors, clinics, and hospitals also need to maintain a lot of additional information on schedules of doctors (for appointments) and resources (like operation theatre, etc.), information related to finances and inventories, references on the latest developments in the healthcare industry through subscription to various databases, and so on. Such information needs to be readily accessible, anytime, anywhere. Such information also needs to be available for research studies, study of trends and patterns, and so forth.

Healthcare information systems consist of creation, maintenance, provisioning, and retirement of all such information related to healthcare. Typically this would mean maintaining a healthcare information management system (HIMS) in a clinic or hospital. While this is true in today's world, Vanjara (2005) has suggested a geography-time-person agnostic solution. The solution consists of creating networked virtual healthcare communities that have access to relevant information anytime, anywhere.

In both the scenarios, information can be created, maintained, accessed, and retired through handheld devices. Natural interfaces have further removed one of the major constraints in using handheld devices through the use of keyboards or mice. In addition, there are thousands of software applications and utilities, many of them available as freeware on various handheld platforms that enable mobile healthcare information systems.

Healthcare information can be broadly classified into two types:

1. **Medical Information:** This consists of all information pertaining to a patient's health and includes EMRs (electronic medical records), test reports with images as applicable, history of ailments, diagnostics and treatment, patterns and profile of a patient's health, and so on.

2. **Non-Medical Information:** This consists mostly of all commercial information like receivables and payables, accounts, inventory, and so on. In case of hospitals, such information would be much vaster, including data around various administrative and support functions like laundry, kitchen, and so on.

Currently, only mid-sized to large clinics or hospitals maintain comprehensive real-time healthcare information management systems. This scenario has two constraints: (1) the smaller entities do not have any system for HIMS, and therefore data/information related to patients' interactions with them is never maintained; and (2) even the HIMS in mid-sized or large clinics and hospitals is unable to capture and maintain medical information of patients from different sources. Imagine test reports from four different places being compiled in a single central database of a hospital! Sounds quite difficult.

Mobile devices enable HIMS in both cases. In case of smaller entities, they do not have to make large investments in infrastructure to have a comprehensive HIMS. They can actually subscribe to such infrastructure and Web-based applications, and then access them to maintain their information using handheld devices. The HIMS of mid-sized and large clinics and hospitals can be easily fed with all data from multiple sources almost on a real-time basis using handheld devices. Even voice-based interactions/transactions can be captured using the voice recognition feature of mobile devices. The primary idea behind handheld devices is to capture as much data as possible in digital format right from the point of origin. Manipulation and transfer of data after that becomes quite easy and fast.

Though maintaining all types of information—medical or non-medical—is possible using handheld devices, medical information is a primary candidate because it addresses more issues around mobility than non-medical information, which is to a large extent organization or location specific.

ISSUES AND CHALLENGES

Having read and heard so much about the potential and capabilities of mobile/handheld devices, the first obvious question that comes to mind is, why then are they not used so commonly in these areas of healthcare? Growth of mobile technology advancements in the entertainment and consumer sectors has been much higher than in business. Given the fact that it is business that actually contributes to the economy, and in case of healthcare, also to the fitness and well-being of people, this is quite unfortunate.

However, there are some reasons for these as well—in the form of issues and challenges of mobile technologies:

- **Integration of Devices, Applications, and Platforms:** As of now, most of the devices, applications, and platforms work independently. Even mobile phones of two different manufacturers at times cannot communicate with each other. At most, they exchange some data via IR or Internet; however, there is absence of tight integration in terms of features, functionality, and so on. A robust, standard-based integration of multiple devices, applications, and platforms would go a long way in facilitating wider use of mobile devices in the business of healthcare.
- **Investments and Infrastructure:** A lot of investments need to be made in the non-telecom space, including creation of application infrastructure to popularize the use of mobile devices. This would also entail creation of a lot of enterprise-scale application software that can expose selected services to multiple clients. To work at a global scale, at each level or tier the data will have to be transparent to devices and technologies. This again

will require investment in technologies and standards.

- **Common Standards:** Handheld devices, software applications and platforms, and the healthcare industry also need to have common standards of communication amongst themselves, like the MICS—the Medical Implant Communications Service, HL7, and so on. Such standards would enable multiple devices to talk to multiple software/services on different platforms.
- **Privacy and Security:** While handheld device space is not as rampant with these issues today as is the personal computer space, it will not be long before it catches up. Some cases of viruses on mobile phones and PDAs or data pilferage or snooping have already been reported. Privacy and security become of paramount importance in the healthcare space due to two primary reasons: (1) we are constantly dealing with individuals' personal information, and (2) the impact of security breach can cost a human life. Imagine a software virus that keeps on manipulating prescriptions or for that matter diagnostic reports while spreading itself.
- **Laws:** Laws related to the conduct of various industries like healthcare are also widely different in various countries. These too need to be aligned at a broad level for a universal solution to work. While this is very difficult and far fetched, if all the countries in the world can sign charters and conventions on pollution control, IPRs, and many such issues, creation of a common legal framework at a higher level for the benefit of mankind—for instance in the area of healthcare—can certainly be made possible in the long term.
- **Language:** A global solution also has to address the need of multiplicity of languages. This, though, is the least of problems, as quite a few solutions—Microsoft Windows to small accounting packages like QuickBooks and MYOB—have already addressed this issue. Unicode-based solutions can also be considered to address this issue (http://www.unicode.org
- **Need for Social Interaction:** Most of the technological advancements have resulted into lesser human-to-human interactions. This is creating a large gap in the social needs of people. Quite often, at a sub-conscious level, people express resistance to new technologies due to their adverse impact on the fulfillment of their social need.

CONCLUSION

This chapter reviews the healthcare and mobile technologies landscape as it exists today. It then suggests integration of both these technologies—already happening to some extent—for provisioning of superior healthcare services in a flexible manner from anywhere. It discusses how various mobile healthcare gadgets and communication devices can be networked and connected to healthcare administration and information systems. Having proposed a healthcare solution that is a few quantum jumps from where it exists today, the chapter also discusses some issues and challenges in making this happen. It also makes a few suggestions on how some of these issues and challenges can be taken care of.

Chapter 3.2
Use of Telemedicine Systems and Devices for Patient Monitoring

ABSTRACT

Today's health standards demand a high quality and efficiency as a major characteristic of every health service provided to the public, even in cases where patients have to be treated from a distance. The combination of medicine and information technology (telecommunications) led to the introduction of the term telemedicine. Telemedicine services are used in assisting remote patients. Interaction and feedback through patient monitoring systems and devices allow the health providers interfere when necessary, so medical maintenance can be guaranteed. This chapter deals with the different kinds of such systems and devices. The contribution of old and new telecommunication technologies is currently being discussed. The individual needs of every remote patient are taken into account, thus, several devices and systems are used for telemonitoring. This chapter indicates characteristics and features of the various kinds of patient monitoring systems and devices.

INTRODUCTION

Due to the technological revolution and the entry of informatics in our everyday lives, the expansion of telecommunications became a reality. Challenging telecommunication applications such as cellular telephony, communications through the intervention of satellites, the Internet, and so forth, support the extensive exchange of information. Several scientific areas have become related to telecommunication applications, including the field of health in which the term telemedicine was first introduced.

Telemedicine involves the transfer of medical information for use in diagnosis, treatment, and education over distances and brings medical services directly to the point of need.

A monitoring system adapts to the needs of each and every patient, care unit, and hospital equipped with hardware and software designed to give maximum functionality, flexibility, and responsiveness. Concerning the monitoring devices, severall types are available, including pulse oximeters, spirometers, glucose monitors, and so forth (Demiris, 2004).

TELEMEDICINE SYSTEMS FOR PATIENT MONITORING

There was a big demand for devices for patient monitoring, especially for people who are far away from health providers. The population is growing old, and the high health standards of nowadays claim that patients should be cared for and rehabilitated at their homes. Several telemonitoring systems were developed. The primary aim of such systems is to maintain the autonomy, independence, and quality of life for the frail elderly, disabled persons, remote patients, and their informal family careers by the application of telematic technology. For example, home health tele-assistance systems could provide a large range of services that would permit the user or patient to remain in his or her normal environment:

- Emergency alarm systems (tele-alarms),
- Post-hospital treatment monitoring,
- Social assistance (24-hour tele-assistance) and so forth (Linkous, 2003).

Remote medical services can also be used in other areas as medical care is provided to prisons, on board commercial aircraft and ships, in the military, and even at the South Pole.

TELEMEDICINE SYSTEMS AND TELEHOMECARE

The most common utilization of telemedicine for patients' monitoring is telehomecare. With more technologies moving into home care, and more and sicker patients being treated outside of the hospital environment, the home-care approach to health care is here to stay. Telehomecare is viewed as a method that uses telecommunication and videoconferencing technologies to enable a health-care provider at the clinical site to communicate with patients at their homes. It is one of the brightest examples of the new frontier of health care. These telehomecare solutions are low cost compared to the classic way of monitoring (Linkous, 2003).

TELEMEDICINE SYSTEMS AND INTERACTION

The telemedicine systems permit monitoring devices to interact with doctors' displaying systems. Such an interaction is called a virtual visit. These devices collect information and signs from the patient, and the resulting data can then be transferred through telephone lines (regular, ISDN, DSL, or T1), the Internet, or the wires of a LAN (local area network) or WAN (wide area network) to the doctor or other health scientists (Kyriacou, Voskarides, Pattichis, Istepanian, Pattichis, & Schizas, 2002). Recent technologies such as Bluetooth might also be used (Roke Manor Research Limited, http://www.roke.co.uk). The diffused data, in many cases, has the potential of updating the doctor's displaying devices in real time. Whenever there is a need (urgent case), the medical personnel might immediately interfere and get in contact with the patient.

There are several types of telemonitoring system applications; their purposes differ in proportion to the concerning situation. Examples of telemonitoring systems are provided in the following sections.

Systems for Monitoring Heart Function and Circulation

a. **Systems for Monitoring Cardiac-Rehabilitation Patients:** The first applications that were evaluated concerned systems that monitor cardiac-rehabilitation patients unable to return to a hospital-based program. Devices for these patients could detect arrhythmia and were found to be more effective than ambulatory electrocardiography. The most recent systems are much more complicated and sophisticated.

b. **Systems for Hypertensive Patients:** Other disease-management applications support hypertensive patients, enabling them to control their blood pressure, and are found to be efficient at the evaluation process.

c. **Systems for Chronic Heart Failure:** Studies for home monitoring of chronic heart failure revealed that there is a need for further investigation (Demiris, 2004).

Systems for Pulmonary Function

a. **Systems for Asthma Patients:** Telemonitoring systems for asthma patients provide assistance in daily routines; the systems alert health-care providers when necessary.

b. **Systems for Lung-Transplant Patients:** Systems for the monitoring of pulmonary function in lung-transplant recipients via the Internet are feasible and accurate.

Systems for the Management of Insulin-Dependent Diabetes

Distributed computer-based systems for the management of insulin-dependent diabetes were developed utilizing Internet technology and monitoring devices to support the normal activities of physicians and diabetic patients by providing a set of automated services enabling data collection, transmission, and analysis, and decision support (Demiris, 2004).

Systems to Assist Post-Transplant Patients

Other Web-based telemonitoring systems were developed to assist post-transplant patients; for example, for lung-transplant recipients, regular spirometry monitoring can be used for the early detection of acute infection and rejection of the allograft. A Web-based telemonitoring system, for these cases, provides direct transmission of home spirometry to the hospital (Demiris, 2004).

Systems for Emergency Response

Telemonitoring systems have also been introduced to provide emergency response to disaster situations. The goal is to offer quality health-care services to persons who are victims of a disaster. Portable telemedicine instrumentation packages can provide a compact, integrated suite of tools such as data-acquisition devices for ear, nose, throat, and skin imaging, lung sound auscultation, and so forth (Demiris, 2004).

Similar system projects were developed in many countries for several purposes.

- **United Kingdom:** In Oxford, a remote physiological-monitoring network was established to evaluate cardiorespiratory function during sleep in a number of infants in their homes for research purposes. The center designed and developed portable monitors for the continuous measurement of vital signs, which allowed downloading data from monitor memory to the hospital. This information was then further analyzed.

- **Israel:** A program was developed to gain access to cardiac patients. In the process of a typical patient call, a health professional collects descriptive information about the patient's condition while simultaneously receiving and recording the 12-lead electrocardiograph (ECG) transmitted by the client-managed portable ECG device. The ECG results are displayed and analyzed, and compared with previous ECGs using proprietary transtelephonic ECG-management software.
- **The Netherlands:** One of the areas that seem to be exceptionally well developed in the Netherlands is the use of handheld computers for electronic case management. After data are collected, they can be immediately transferred, using dial-up networking capacity, from the point of care to the central home-care database. Records are regularly updated and are available to different health professionals within the continuum of care.
- **Germany:** A telemonitoring project was designed in Germany and included extensive home monitoring of the vital parameters of infants at risk for sudden infant death syndrome (SIDS). The project monitored breathing movements, ECG, heart rate, and oxygen saturation. All sensors were noninvasive and integrated with the babies' pajamas. The parents were trained in assessing the physiological status of the children and in emergency intervention measures. Information was also transmitted to the test and research telemedical laboratory for further analysis.
- **A Four-Country Project (Greece, Great Britain, France, Germany):** This project was related to patients with renal failure requiring home hemodialysis. The goal of the project was to develop, apply, and evaluate telematics monitoring and consultation services for enabling the supervision of each hemodialysis session and possible intervention (Demiris, 2004).

TELEMEDICINE DEVICES FOR PATIENT MONITORING

Portable Monitoring Devices

There are several commercially available portable monitoring devices that are approved by the FDA, including pulse oximeters, blood-pressure monitors, weight scales, and glucose monitors. In some cases, data are stored in the device and retrieved at a later point or are displayed on a monitor at the completion of the test session (Demiris, 2004).

Wearable Sensors

There are three kinds of wearable sensors: physical, chemical, and biological. These sensors produce a signal in response to an event, which is then transferred to a circuit and becomes digitised. A physical sensor measures physical parameters such as temperature or pressure, whereas a biological or chemical sensor involves a receptor that binds with an analyte. The resulting digital data can be stored and/or displayed.

The concept of wearable sensors is based on the incorporation of sensors into watches, items of clothing, and eye glasses. Thus, one could argue that wearable sensors can function as noninvasive, in vitro diagnostic tools as they are capable of analyzing, among others, human sweat, tears, stress, strain, and pH increases.

There exists a knee-wearable sensor that is also known as the intelligent knee sleeve, and it was first designed for football players. It monitors knee strain or injury. Originally, this device was strapped to the knees, and its sleeve provided feedback to users by emitting an audio tone. It can be a useful application for home-care patients with mobility impairments or for those at the rehabilitation phase.

Another example of a wearable sensor is a small, portable detector in the form of a wristwatch that provides test results for cystic fibrosis in minutes, rather than the 24 hours that is the typical response time for a laboratory. Another wristwatch device uses an electric field to push pilocarpine nitrate into the skin, thereby dilating the pores. Sweat is absorbed and stored in a duct in the watch. The sample is analyzed by a sensor, and the levels of sodium, chloride, and potassium ions are recorded. Other devices in the form of wristwatches include glucose meters that measure glucose in the interstitial fluid as a low electric current pulls glucose through the skin, and a blood oxygen monitor.

In the last few years, the Smart Shirt was introduced that incorporates technology into the design of clothing to monitor the wearer's heart rate, ECG, respiration, temperature, and vital functions, alerting the wearer or physician if there is a problem. The Smart Shirt also can be used to monitor the vital signs of military personnel, chronically ill patients, firemen, and frail elderly persons living alone (Demiris, 2004).

Also, for military purposes, the U.S. military is developing innovative applications for advanced sensors and smart materials. Devices resembling wristwatches will be worn by all soldiers as part of the combat uniform. These devices will monitor the soldier's vital signs continuously by monitoring parameters such as noninvasive blood pressure, pulse oximetry, and medical imaging (Garshnek & Burkle, 1999).

Robots

It is impressive that robots have started claiming doctors' duties. At present, these robots are navigated by an operator using a joystick at a control station and can perform rounds within the hospital. A camera and microphone are mounted above the computer screen, allowing the operator to see and hear. A similar camera and microphone at the control station transmit the operator's face and voice. It is surprising that a number of doctors perform rounds on their patients with these robots, particularly from their homes. The full potential of robots is beginning to be explored. Future generations of control stations are expected to be portable and operational from virtually anywhere in the world (Norris, 2004).

ADVANTAGES OF TELEMEDICINE

The categories of telemedicine are the following:

- Teleconsultation
- Telediagnosis
- Telecare
- Remote clinical sessions and tele-education
- Remote data access
- Teleradiology
- Home care
- Telemonitoring (Mantas & Hasman, 2002)

Telemedicine's objective is to provide users with an integrated health-information service through an expert system, which gives access to existing information related to health, social care, and other general issues that is now distributed in dispersed databases. After achieving this objective, we expect the following advantages.

1. **Advantages in Monitoring the Patient:** The use of telemedicine is followed by an improvement of the quality of the monitoring of patients and an increase in the number of

patients being monitored. Moreover, tools are provided for medical decision support and guided monitoring work is allowed.

2. **Advantages in the Management of Treatment and Training:** Telemedicine improves the communication between doctor and patient, promotes patients' self-management and training, and decreases the response time in the treatment.
3. **Advantages in Telecare:** Telecare reduces the number of visits to hospitals, facilitates patients in finding information regarding their illnesses, allows the patients autonomy, and decreases short-term as well as long-term complications (Mantas, Aguilera, del Pozo Guerrero, Arredondo Waldmeyer, & Martínez Fernández, 2000).

In general, telemedicine offers the following:

- Reduction of health-care costs
- Access to health services in previously unserved or underserved areas
- Easy cooperation between health professionals
- Improved quality of care

CONCLUSION

The development of information-systems technology has led us to an increased number of telemonitoring applications to help with patient health care. These applications enable health professionals to carry out home health visits (virtual visits). Such applications and systems complete the management of data collection and reinforce data analysis. Telemedicine services can be shared among patients and several regional hospitals and other specialized health centers. Thus, patients are allowed to ask for advice, and, as a response, health professionals may interfere when necessary. It appears that the use of telemonitoring systems can cut the cost of medical care for rural and urban areas.

Interesting research and implementations have been developed to evaluate systems delivering assistance to different scientific health fields, contributing to cardiology, neurology, surgery, orthopedics, pediatrics, and so forth. A lot of them were found to be accurate and efficient enough, although the future promises more potent and sophisticated systems for patient monitoring.

However, there are still barriers to the wider adoption of telemedicine, affecting both healthcare professionals and their patients. The general public is not mature enough to get involved in such procedures due to the fact that it is not well acquainted with the subject. In the future, a lot of these difficulties will be overcome, and we expect that the public will accept the challenges of telemedicine and telemonitoring.

KEY TERMS

Home-Care Technology: Any technology used to implement home-care telemedicine services. It can also incorporate any device or instrument for patient monitoring, therapy, or environmental control (Mantas & Hasman, 2002).

Telecare: The use of telecommunication systems to provide remote assistance in therapy to patients (Mantas & Hasman, 2002).

Teleconsultation: Remote access to a specialist's knowledge. This type of service is seen as a particular case of cooperative work or cooperative diagnosis (Mantas & Hasman, 2002).

Telediagnosis: Diagnosis of a patient by a remote physician. This kind of service does not operate directly between the patient and remote doctor (Mantas & Hasman, 2002).

Telehomecare: Uses telecommunication and videoconferencing technologies to enable a healthcare provider at the clinical site to communicate with patients at their homes (Demiris, 2004).

Telemedicine: The use of electronic information and communication technologies to provide and support health care when distance separates the participant. It emphasizes applications that link clinician to patient or one clinician to another (Gantenbein, 1992).

Telemonitoring: Remote monitoring of patients' physiological value. This kind of service is used with chronic and/or high-risk patients (Mantas & Hasman, 2002).

Chapter 3.3
Mobility in Healthcare for Remote Intensive Care Unit Clinical Management

Carolyn McGregor
University of Western Sydney, Australia

ABSTRACT

This chapter reviews current research directions in healthcare mobility and assesses its impact on the provision of remote intensive care unit (ICU) clinical management. Intensive care units boast a range of state of the art medical monitoring devices to monitor a patient's physiological parameters. They also have devices such as ventilators to offer mechanical life support. Computing and IT support within ICUs has focused on monitoring the patients and delivering corresponding alarms to care providers. However many intensive care unit admissions are via intra and inter health care facility transfer, requiring receiving care providers to have access to patient information prior to the patient's arrival. This indicates that opportunities exist for mobile gadgets, such as personal digital assistants (PDAs) to substantially increase the efficiency and effectiveness of processes surrounding healthcare in the ICUs. The challenge is to transcend the use of these mobile devices beyond the current usage for personal information management and static medical applications; also to overcome the challenges of screen size and memory limitations. Finally, the deployment of mobile-enabled solutions within the healthcare domain is hindered by privacy, cost and security considerations and a lack of standards. These are some of the significant topics discussed in this chapter.

INTRODUCTION

Intensive care units (ICUs) worldwide offer support for patients in need of critical care. The research, development, and adoption of new information technologies (ITs) and information systems (ISs) within ICUs, and particularly neonatal intensive care units (NICUs) to support patient and care provider mobility, is currently lagging behind other industries and other areas of healthcare (McGregor, Heath, & Wei, 2005a; McGregor, Kneale, & Tracy, 2005b; Wu, Wang, & Lin, 2005). In order to understand and improve upon this lag, we need to understand the current healthcare scenario within the context of intensive care.

To start with, mobile clinical management solutions within the context of intensive care units need to consider not only the mobility of the patient, but equally importantly, the mobility of the care provider. When an incident requiring critical care occurs, patients may already be located in the care provider's ICU. However, the patient may also be located elsewhere in the care provider's hospital, in another hospital, in their home, or in another location outside the hospital of the care provider. Patients may also be in transit between any of these locations via an ambulance, helicopter, or inter-hospital transport.

Care providers can be understood in this chapter as any physician, clinician, or nursing specialist responsible for some aspect of the clinical management of the ICU patient. In daily routines, physicians, clinicians, nurses, and other staff of the hospital have to be reached and updated of new incidents and information while they are commuting in their work environments (Kafeza, Chiu, Cheung, & Kafeza, 2004). However, similar to the patients, care providers may also be located within the ICU, their office, elsewhere within their hospital, in their home, or in another location outside their hospital (e.g., attending an off-site meeting or conference).

Ammenwerth, Buchauer, Bludau, and Haux (2000) report that one of the major clinical management issues that mobile technologies can help with within the hospital is communication and reachability of care providers. This clinical management issue has the additional challenge of determining to whom the message should be sent (Kafeza et al., 2004). Both of these issues are particularly relevant within the ICU setting.

When critical care clinical management is required, the sooner the patient/care provider(s) information exchange can commence, the faster the clinical management can commence. In the case where the patient and care provider(s) are not located together within the ICU, critical care can still commence, provided there is adequate clinical management support to facilitate clinical decision making and execution.

Mobile healthcare systems (MHSs) have been defined by Wu et al. (2005) as the use of IS/IT to exchange healthcare information and services via mobile devices anytime and anywhere, providing patients and care providers with easy access to resources whether stationary or moving.

Recent research directions for computing and IT support within ICUs has focused on the delivery of alarms/alerts to care providers (Catley & Frize, 2003; Catley, Frize, Walker, & St. Germain, 2003; Shabot, LoBue, & Chen, 2000; Sukuvaara, Makivirta, Kari, & Koski, 1989; van der Kouwe & Burgess, 2003). However these approaches do not enable mobility in healthcare and neither do they exploit the substantial benefits possible by proper application of mobility. Furthermore, many intensive care unit admissions are via intra- and inter-healthcare facility transfer, requiring receiving care providers to have access to patient information, prior to the patient's arrival and often while the care provider is also in transit. These are some interesting challenges in terms of communication and reachability of care providers.

Recent surveys show that between 25-35% of physicians, as distinct from care providers in general, use personal digital assistants (PDAs) (Carroll & Christakis, 2004; Fontelo, Kim, & Locatis, 2003). However, Carroll et al. (2003) further note that these PDAs are mainly for personal information management and static medical applications. Opportunities exist for PDAs and similar handheld devices to enhance and effectively deliver services within the ICU clinical management sector. However, PDA screen size and memory are seen as crucial factors in the development of PDA applications. In addition, deployment of mobile-enabled solutions within the healthcare domain is impacted by privacy, confidentiality, cost, and security considerations in addition to a current lack of standards.

This chapter reviews current research directions in healthcare mobility and assesses its impact on the provision of remote intensive care unit clinical management. A background to intensive care unit clinical management is first introduced. Recent computing and IT-related research to support ICUs is then presented. Hardware and associated research to support ICU clinical management mobility is then described. A comparison of recent ICU research within the context of its ability to support mobility is presented. Issues impacting the implementation of mobile ICU clinical management solutions are then detailed. Finally, the conclusion and future directions are presented.

BACKGROUND TO ICU CLINICAL MANAGEMENT

Clinical management systems are designed to assist care providers in diagnosis and treatment using existing, already established methods of diagnosis and accepted treatments (Gross-Portney & Watkins, 2000). Hence, mobility in clinical management must support mobility in relation to diagnosis and treatment. Tasks such as medication monitoring, emergency hospitalization of patients, laboratory examination results, ordering and shipment of drugs, and exchange of information relating the patient clinical management occur frequently (Kafeza et al., 2004). Within the ICU context, clinical management systems must respond actively and very timely to the patient's needs, which can be life critical.

One of the most prominent objectives within the modern hospital is the need for accurate, safe, and continuous communications among departments and highly specialized medical staff. In addition, the need for flexible communications to enable communication with other hospitals is also dominant. As a result there has been a great demand among the care providers for a mobile alert management system that is robust, efficient, cost effective, simple, and user friendly (Kafeza et al., 2004).

Intensive care units (ICUs) worldwide offer support for patients in need of critical care. They boast a range of state-of-the-art medical monitoring devices to monitor a patient's physiological parameters such as blood oxygen, blood pressure, and heart rate. Other devices such as ventilators offer mechanical life support.

Broadly, there are three types of intensive care, namely, adult, pediatric, and neonatal. While the age of the patient is the differentiator between adult and pediatric ICUs, the clinical management differs greatly from these ICUs to the neonatal ICUs (NICUs)—where gestational age greatly impacts clinical management.

Approximately 18% of babies born in New South Wales (NSW), Australia, require special care or neonatal intensive care admission (NSW Health Department, 1994). Premature babies can be up to 17 weeks early and may only weigh 450 grams; they can spend three or four months in intensive care and have dozens of specific diseases before discharge. In addition, 15% of neonatal intensive care admissions are transferred after delivery from smaller remote hospitals without intensive care facilities. Similar conditions apply elsewhere within Australia and internationally, where small remote hospitals are spread throughout a given country supported by centrally located referral hospitals with NICUs.

Remote hospitals have equipment to provide limited NICU support within 'special care nurseries'; but without the ability for a neonatologist to receive information from this equipment, the baby must be moved to a referral hospital with neonatologist support. Given the critical requirement to maintain a consistent environment, moving a baby at this time can be life threatening. Critically ill, term and pre-term babies that have to be transferred have higher mortality rates and much higher rates of long-term disability than similar babies born in hospitals with intensive care facilities (McGregor, Bryan, Curry, & Tracy, 2002). A major limitation is that the attending care provider at the remote hospital must contact a neonatal specialist (neonatologist) via telephone, or in some instances the provider—who may or may not be located at the NICU at that time—must describe via e-mail (Deodhar, 2002) the baby's symptoms and, where possible, relay any physiological information verbally, or narratively in the context of an e-mail. The consulting neonatologist must then make decisions based on this verbal or textual exchange.

It is very common for critically ill babies to have significantly abnormal variation in the measured parameters minute by minute, and not all these variations are made available to the consulting neonatologist. Frequent transient falls in blood pressure and blood oxygen content, often with swings into the high range, may be of critical importance in survival and quality of survival, free of significant disability (Lister, Bryan, & Tracy, 2000).

Hence the neonatologists located at referral hospitals require the ability to obtain information from the monitors attached to babies. Similarly, a neonatologist need not be located at a PC within the hospital to view patient data, but should be free to view this information through any device offering a secure Internet/intranet connection. These scenarios open up opportunities for application of mobility in ICU management, as discussed in this chapter.

RECENT COMPUTING AND IT RESEARCH TO SUPPORT ICU CLINICAL MANAGEMENT

Much of the recent computing and IT related research to support intensive care units (ICUs) has focused on clinical alerts (Catley & Frize, 2003; Catley et al., 2003; Shabot et al., 2000; Sukuvaara et al., 1989; van der Kouwe & Burgess, 2003). The information made available to these systems is limited to a small set of physiological data and/or clinical data from patients located within their ICUs. In addition, care provider access to these systems is limited to the receipt of alerts, with minimal content via e-mail and in some cases pagers.

An integrated XML-based healthcare framework for NICU clinical alerts is described by Catley and Frize (2003) and Catley et al. (2003). The alerting is based on the individual device alarms, and predicts mortality and ventilation requirement probability and estimated length of stay. In the implementation as presented, only e-mail alerts and Java GUI alerts are generated. They indicate that future directions for this research are a WML-based alert using Java Servlet technology running on a Web server connected to a WAP Gateway. The WAP Gateway would transmit alerts via WML to mobile devices.

Shabot et al. (2000) describe a software system which extracts clinical information from clinical information systems on a continuous basis and sends it through event detection algorithms. Alerts for detected events are forwarded through a commercial paging system to designated care providers and pharmacists.

InCare was a rule-based alarming system prototype to support clinical management within ICUs (Sukuvaara et al., 1989) that detected four important patient pathological conditions, which develop gradually during postoperative recovery of cardiac patients, namely: (1) hyperdynamic state, (2) hypoventilation, (3) hypovolemia and left ventricular failure. User interface to the alarms was via a PC.

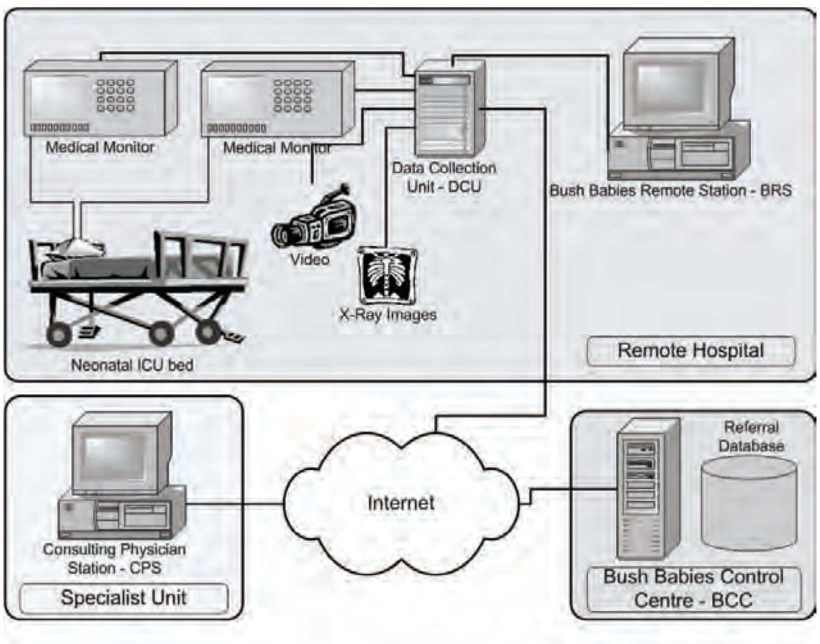
Van der Kouwe and Burgess (2003) present an architecture for continuous electrophysiological monitoring within a neurointensive care unit. While this information is available in real time through Web-based interface, access is limited to PCs via the hospital's secure intranet.

Shin, Huh, Lee, and Kim (2003) have developed Web-based real time for checking temperature and humidity within infant incubators in NICUs. However the access to this information was limited to the NICU central monitoring station PC, with the information delivered via the hospital intranet.

The Bush Babies Broadband research project (McGregor, Kneale, & Tracy, 2005b), supported by the Telstra Broadband Fund, aims to significantly improve the quality of treatment for babies born in regional and remote areas by providing the first on-demand virtual neonatal intensive care unit architecture in Australia. The Bush Babies architecture is shown in Figure 1. Real-time data collected from medical monitors and ventilators attached to the baby, audiovisual streams, and static physiological data such as x-ray images are transmitted from the data collection unit (DCU) to the consulting neonatologist to gain a better picture of the patient's condition than is currently available. The Bush Babies Remote Station enables the remote care provider to initiate a bush babies session. The BRS uses a centralised Bush Babies Control Centre database to select a neonatologist from a NICU where space for the baby would be available if transport was required. A limitation of that research is that the only consulting physician station (CPS) device that neonatologists can use to view this patient condition information is via the screen of a PC or laptop. Given that consulting neonatologists are not always located in their offices within their NICU when there services are required, alternate and more portable technologies to deliver the information need to be investigated.

In association with the Bush Babies project, McGregor et al. (2005a) and McGregor, Purdy, and Kneale (2005c) propose a Web service-based framework for the transmission of XML-encoded physiological data output by medical monitoring and life support devices. That research, together with the previously mentioned Bush Babies, are portions of the "e-Baby" research collaboration (McGregor et al., 2002, 2005a, 2005b, 2005c) that

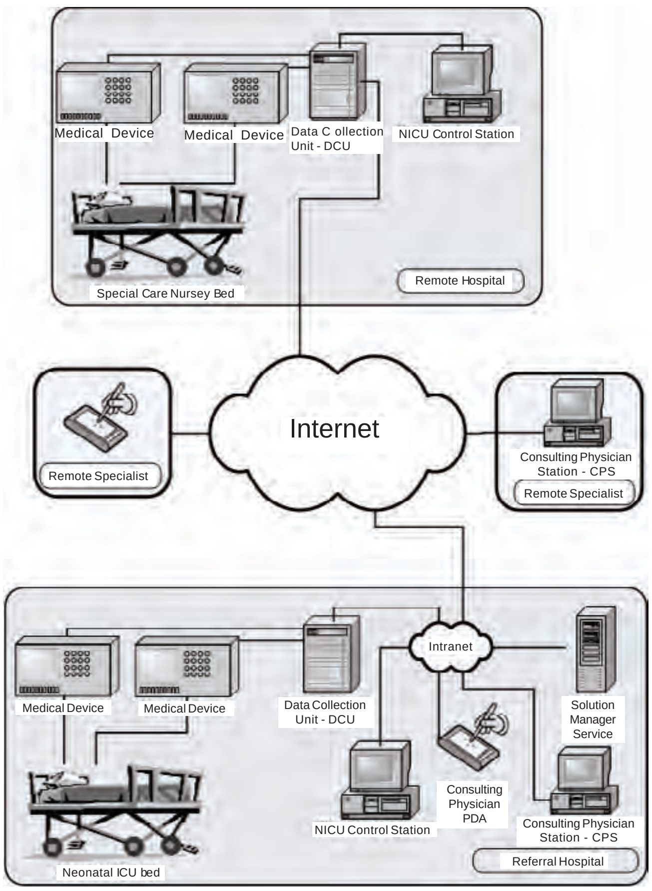
Figure 1. Bush Babies architecture (McGregor et al., 2004)



is researching new approaches to the application of computing and information technology to support mobility in healthcare through local and remote neonatal intensive care. The high level e-Baby architecture is shown in Figure 2.

The Web service-based framework for the transmission of XML-encoded physiological data forms part of the solution manager service (SMS). The SMS is situated in the referral hospital NICU and receives and stores data collected by the data collection units via the *physiological log Web service* for near-real-time analysis and trend detection. The consulting physician station is used by the neonatologists to access the physiological data located in SMS via a set of *analyse Web services* or via a direct link to the data as it is streamed through the *physiological log Web service.* That research enables patient and care provider mobility, as a result of the Web service-based data transmission. However, the prototype as presented only tests transmission of data from patients located either within the NICUs or remote hospital and care providers located within the hospital with the NICU. In addition, care provider access is only available through the PC-based CPS, though future research indicates the forwarding of data to consulting physician PDAs.

Figure 2. e-Baby architecture (McGregor et al., 2005a)



HARDWARE TO SUPPORT ICU CLINICAL MANAGEMENT MOBILITY

The variety of mobile devices available for use to support clinical management within ICUs include: PDAs, laptops, notebooks, GPSs, and smartphones. Recent surveys show that approximately 25% or more of physicians use PDAs, although mainly for personal information management and static medical applications. A PDA provides many advantages. It starts quickly at the push of a button. It is convenient to carry around, fitting easily into a shirt pocket or handbag. Some devices can function for weeks of regular use after a quick battery recharge. However, PDA screen size and memory are seen as crucial factors in the development of PDA applications (Fontelo et al., 2003).

Carroll and Christakis (2004) recently surveyed pediatricians in relation to their use of PDAs and found that 35% currently use PDAs at work; the most common uses were for drug reference (80%), personal scheduling (67%), and medical calculations (61%).

A plethora of software packages are available for PDAs to support clinical management in the broad areas of medical handheld software collections, medical publishers, university medical handheld resources, document readers, access to medical literature, pharmacopoeias, specialty specific, and patient tracking. Patient tracker (www.handheldmed.com) gives the user the option to enter patient records, including demographics, laboratory results, medication,/allergy lists, test results, and radiology reports. Wardwatch (www.torlesse.com) was designed to aid medical staff in ward rounds. Medical Pocket Chart (www.gemedicalsystems.com) is an electronic medical record keeper (Fischer, Mehta, Wax, & Lapinsky, 2003).

Providing care providers with the ability to perform research at the bedside via PDA access to PubMed and clinical trial Internet sites was described by Fontelo et al. (2003).

Carroll (2001, 2002) and Carroll, Tarczy-Hornoch, O'Reilly, and Christakis (2004) describe the implementation of a PDA-based patient record and charting system for an NICU; however, the charting component relies on the care providers completing patient flowsheets manually into the PDA, rather then having the physiological data streaming to the PDA.

A PDA-based approach for managing patient data is defined by Lapinsky et al. (2001). Patient data was entered into the Memopad using a customized template. This data was transferred between care providers using the PDAs' infrared ability. Daily paper notes were generated via infrared link to a HP LaserJet printer, as the hospital policy required paper records.

NICU Notes (Schulman, 2003) enables care providers to collect data at the point of care and utilizes synchronization to move the patient data from the PDA via an ODBC DSN to a secure Microsoft Access application.

A critical PDA issue as defined by Carroll (2002) is the asynchronous nature of hot syncing. Information on the PC and PDA only match immediately after hot syncing. The sheer volume of data being passed during the hot sync process caused the hot sync process to fail intermittently, resulting in incomplete or duplicated information.

COMPARISON OF RECENT RESEARCH

Having discussed the routine usage of mobility in healthcare thus far, we now focus our attention on comparing the previously presented computing and IT research to support ICU clinical management—with an aim to assess the ability of that research to support mobility.

The comparison is broadly categorized into the areas of broad functionality, patient and care provider mobility, and finally architecture mobility. Within the context of broad functionality, three areas were considered: the clinical management

Table 1. Broad functionality

Research Identifier	**Clinical Management Function(s) Supported**	**Decision Time**	**Decision Quality**
(Catley & Frize, 2003; Catley et al., 2003)	Clinical alerts predicting mortality, ventilation requirements, and length of stay	Non-critical	Not available
(Shabot et al., 2000)	Clinical event detection, laboratory results, and medication alerts	Non-critical and life threatening	High
(Sukuvaara et al., 1989)	Alarms relating to postoperative recovery of cardiac patients	Life threatening	High
(van der Kouwe & Burgess, 2003)	Samples electro physiological data	Life threatening	High
(Shin et al., 2003)	Infant humidicrib temperature and humidity monitoring	Life threatening	High
(McGregor et al., 2005b)	Video, image, and physiological data stream monitoring	Life threatening	High
(McGregor et al., 2005a, 2005c)	Physiological data stream monitoring	Life threatening	High
(Carroll, 2002; Carroll et al., 2004)	Patient record charting system	Non-critical	Medium
(Lapinsky et al., 2001)	Managing patient data	Non-critical	Medium
(Schulman, 2003)	Managing patient data	Non-critical	Medium

function(s) that was (were) being supported, the time sensitivity of the decision, and the decision quality sensitivity. Time sensitivity was considered important, as Panniers (1999) has stated that only low and medium urgency decisions are suitable for computerization into a decision support system to support clinical management. The comparison based on broad functionality is presented in Table 1.

Secondly, the degree of patient and care provider mobility was assessed, together with the extent of information that was available to the care provider and is summarized in Table 2.

Finally, the extent to which the proposed architectures incorporate mobility is summarized in Table 3.

Contrary to Panniers' (1999) time sensitivity observations, the research indicates that clinical management systems are being developed to support life-threatening conditions by alerting care providers quickly of the development of the situation.

When data is being forwarded directly in a time series stream from medical devices, data quality

Table 2. Degree of patient and care provider mobility

Research Identifier	Extent of Patient Mobility	Extent of Care Provider Mobility	Extent of Information Available to (from) Care Provider
(Catley & Frize, 2003; Catley et al., 2003)	Located within NICU	Accessing PC within hospital (wireless access proposed for future research)	Text-based notification that physiological data values have exceeded threshold
(Shabot et al., 2000)	Located within ICU	Alerts sent to pager	Limited text-based alerts, based on type of alert
(Sukuvaara et al., 1989)	Located within ICU	Accessing PC within ICU	Physiological data streams
(van der Kouwe & Burgess, 2003)	Located within ICU	Accessing PC within hospital	Physiological data streams
(Shin et al., 2003)	Located within NICU	PC located at NICU control station	Data stream
(McGregor et al., 2005b)	Located within local NICU or remote hospital	Accessing PC within hospital	Video, image, and physiological data stream
(McGregor et al., 2005a, 2005c)	Located within local NICU or remote hospital	Accessing PC within hospital	Physiological data stream
(Carroll, 2002; Carroll et al., 2004)	Located within NICU	Located within NICU	(Clinical charts updated by care provider)
(Lapinsky et al., 2001)	Located within ICU	Located within ICU	(Clinical charts updated by care provider)
(Schulman, 2003)	Located within NICU	Located within NICU	(Clinical charts updated by care provider)

Table 3. Extent to which architectures incorporate mobility

Research Identifier	User Interface Device(s)	Networks	S oftware/Middleware
(Catley & Frize, 2003; Catley et al., 2003)	Web-based	Wired hospital intranet	XML-based messaging
(Shabot et al., 2000)	Pager	PageNet network	Pager messaging
(Sukuvaara et al., 1989)	PC GUI	Wired hospital intranet	Not available
(van der Kouwe & Burgess, 2003)	Web-based	Wired hospital secure intranet	Not available
(Shin et al., 2003)	Web-based	Wired hospital secure intranet	HTML document
(McGregor et al., 2005b)	Web based	Wired hospital secure intranet	Simple Medical Data Protocol (SMDP) document
(McGregor et al., 2005a, 2005c)	Web-based	Wired hospital secure intranet	XML document
(Carroll, 2002; Carroll et al., 2004)	PDA	Hotsync to PC	PDA HotSync
(Lapinsky et al., 2001)	PDA	Between PDAs and printer via infrared	PDA infrared
(Schulman, 2003)	PDA	Hotsync	PDA Hotsync

is high. However, when PDAs are used to collect data from care providers, errors still occur.

None of the research reviewed catered to patients located elsewhere within the care provider's hospital, and the only out-of-hospital location that was supported was another special care nursery within McGregor et al.'s (2005b) research.

Only Shabot et al. (2000) enabled care provider communication from outside the hospital, and this was via a pager. Hence, information available to care providers outside the hospital was limited.

While most user interfaces for the delivery of information were Web enabled, the task of delivery to devices other than PCs and notebooks has not been adequately addressed.

Standards for user interfaces and communications have not been developed as part of these research efforts, nor does the research contain references to other standards efforts. This indicates that such standards do not exist within the context of ICU clinical management.

ISSUES IMPACTING IMPLEMENTATION

In addition to considering PDA usage, there are several factors that to date are still issues impacting successful research, development, and implementation of mobile clinical management solutions within the ICU setting. These factors are indeed common to all clinical management solutions and include wireless network interference in ICUs, security, privacy, confidentiality, cost, and a lack of communications standards.

While the adoption of 802.11b wireless networks is increasing, Fontelo et al. (2003) state that security issues may preclude current deployment of wireless devices for medical data access and utilize infrared access stations within their research. This link was restricted to a 15-degree arc on each side of the centre and a maximum distance of 8 feet. They also found that a transient, rapid disruption of the infrared (IR) beam, such as a person walking between the IR point and the PDA, did not disconnect an established link. In addition, the use of devices via wireless networks within ICUs currently interferes with many of the devices used within ICUs for critical care.

Fischer et al. (2003) state that patient confidentiality and costs are the main implementation issues for handheld systems used within clinical management and that consumer interest may be the limiting factor to successful implementation. In addition, the lack of standards and limited bandwidth for data transfer may also impact increased implementation.

However, they conclude that *a growing body of literature supports the use of handheld devices in a variety of medical settings and with the rapid advances in this technology, the mobile computer may well become an essential medical tool.*

While the deployment of mobile clinical management solutions within ICUs offers the potential of improved patient care and service quality and increasing care efficiency, most applications within the broad healthcare context have failed or not been implemented as predicted, with 30% of failures attributed to non-technical factors (Wu et al., 2005).

For mobile IS/IT solutions to significantly impact ICU clinical management and result in a paradigm shift in the approaches to healthcare within this context, several standards need to be developed to support the ICU clinical management functions. These functions include the exchange of information relating to the patient clinical management, medication monitoring, ordering and shipment of drugs, and the examination of laboratory results.

While all monitoring and life support devices used within ICUs to supply physiological data have the ability to output the device readings usually via a serial port, the data formats vary greatly from device to device. As such, efforts to make device data from devices attached to local or remote patients accessible for mobile viewing are hampered by the myriad of formats required for transmission. McGregor et al. (2005a, 2005c) propose a Web service-based framework for the transmission of physiological data output by such devices, proposing an XML format for such data transmission; however, it has not to date resulted in mainstream standards adoption for the transmission of physiological data.

To enable ICU clinical management mobility, standards for physiological data transmission, medication monitoring, laboratory examination results, and the ordering and shipment of drugs are still required.

CONCLUSION AND FUTURE DIRECTION

While the paradigm shift to mobile clinical management for ICUs offers the potential to significantly improve the speed, efficiency, and effectiveness of critical care within ICUs, there are currently several factors impacting its mainstream adoption.

This chapter has presented a review of current healthcare mobility within the context of ICU clinical management. A comparison of recent ICU computing and IT-related research indicates that the issue of both patient and care provider mobility has not been considered a priority within these research efforts.

Several issues continue to impact successful implementation of mobile clinical management solutions for ICUs; these include issues relating to the use of wireless networks, in addition to security, privacy, cost, and a lack of communications for data exchange and user interface standards.

Current computing and IT-related research to design and develop the next-generation IT/IS solutions for ICUs is not adequately incorporating the issue of mobility of patient and care provider.

Traditionally, clinical research is used as the catalyst for providing evidenced-based recommendations for change to clinical management practices. To gain care provider acceptance, changes to clinical management practices proposed through the introduction of computing and IT approaches should consider traditional clinical research approaches to validate findings and gain support and acceptance.

ACKNOWLEDGMENT

The work presented in this chapter is associated with a larger, long-term research effort known as "e-Baby" (McGregor et al., 2002, 2005a, 2005b, 2005c) that is researching new approaches to the application of computing and information technology to support mobility in healthcare through local and remote neonatal intensive care. The researchers wish to thank the staff of the Neonatal Intensive Care Unit, Nepean Hospital, Sydney West Area Health Services, NSW, for their continued support and collaboration in the e-Baby research.

Chapter 3.4
Utilizing Mobile Phones as Patient Terminal in Managing Chronic Diseases

ABSTRACT

Mobile information and communication technologies are advancing rapidly and provide great opportunities for home monitoring applications in particular for outpatients and patients suffering from chronic diseases. Because of the ubiquitous availability of mobile phones, these devices can be considered as patient terminals of choice to provide a telemedical interaction between patients and caregivers. The most challenging part still is the patient terminal, that is, to offer the user a method to enter measured data into a system as well as to receive feedback in a comfortable way. The objective of this chapter is to present and compare solutions for mobile-phone-based patient terminals as developed by us and other authors.

INTRODUCTION

"Telemonitoring is defined as the use of audio, video, and other telecommunications and electronic information processing technologies to monitor patient status at a distance" (Field, 1996, p. 271). This concept may be particularly suitable in the management of chronic diseases where a close partnership as well as collaboration between patient and healthcare provider are essential. New paradigms such as prevention and patient empowerment promote the development of novel care approaches in which outpatient monitoring is a basic aspect.

Rapid advancements of information and communication technologies and the increasing availability of mobile phones open new perspectives in using these devices for tele-monitoring applications to deliver healthcare to people geographically remote from physicians or medical centers. The possibility to use the mobile phone for standard voice communication as well as for the transmission of a variety of multimedia information like text, audio, images, and videos makes it the communication interface of choice for patient-centered tele-monitoring applications.

The basic idea is to track patients' personal health status using the mobile phone as a patient terminal and to send the data to a remote monitoring centre. An automated monitoring process checks the values and gives feedback in order to guide the patient through the self-managing process and to turn the doctor's or other caregiver's attention to the patient when necessary by means of notifications and alerts. The most challenging part in this scenario still is the patient terminal, that is, to offer the user an easy method to enter measured data into a system as well as to get feedback of the current health status in a comfortable way.

This chapter will focus on the usage of mobile phones in the management of chronic diseases and gives an overview of available technologies. Furthermore, it will present and compare already implemented mobile-phone-based home monitoring concepts as developed by us and other authors.

BRIEF HISTORICAL OUTLINE

Basically, tele-monitoring combines topics from the fields of medicine, information and communication technology, and computer science. Particularly, information and communication technologies have undergone rapid advancements over the past decades, driven by the needs of modern information society. Communication devices such as mobile phones or personal digital assistants (PDAs) became smaller and more powerful, and advanced from single-purpose stand-alone devices to multipurpose networked devices that make them usable for tele-monitoring applications indeed.

However, reviewing the literature, the exact date when tele-monitoring was first mentioned in healthcare is still unknown (Brown, 1995). Starting with the first words transmitted by telephone in 1876 by Alexander Graham Bell, communication technology was ready to be used to facilitate healthcare services. For example, William Einthoven, the father of electrocardiography (ECG), transmitted ECG signals over wired telephone lines in 1906 (Barold, 2003).

In the 1930s, when the telephone became standard equipment in households, it also became the mainstay of medical communication and remained a major element until today. Wireless communication technologies were invented at the same time. Around the time of World War I, radio communication was established in a wider area, and, around 1930, it was used in remote areas such as Alaska and Australia to transfer medical information (Zundel, 1996).

Besides pioneering efforts of a few physicians using off-the-shelf commercial equipment to overcome time and distance barriers, current tele-monitoring concepts originated from developments in the manned space-flight program introduced by the National Aeronautics and Space Administration (NASA) in the early 1960s (Brown, 1995). The main intention was to monitor physiological parameters like heart rate, body temperature, ECG, and oxygen and carbon-dioxide concentration of astronauts in space and transmit the data to earth in order to establish an understanding of the health and well-being of the astronauts while they were in orbit.

Nowadays, tele-monitoring is adjudicated an important role in health systems since for a number of indications the cost effectiveness and the medical benefits have been approved (Meystre, 2005). Moreover, there is still a driving force to improve outpatient care by shifting tasks from hospitals to patients' homes, particularly in the management of chronic conditions, which will be discussed in detail in this chapter.

MANAGING CHRONIC DISEASES

Chronic diseases are cited in literature as diseases that have one or more of the following characteristics: They are permanent, leave residual disability, are caused by nonreversible pathological alteration, require special training of the patient for rehabilitation, or may be expected to require a long period of supervision, observation, or care (National Library of Medicine, 2005).

Chronic diseases such as heart failure, hypertension, cancer, diabetes, and asthma were the major cause of death (59% of the 57 million deaths annually) and global burden of disease (46%) in 2004 (World Health Organization [WHO], 2005).

It is also obvious that chronic diseases tend to become more common with age. WHO reported that in 1998, 88% of the population in developed countries over 65 years old suffered from at least one chronic health condition. Since populations are aging worldwide and chronic diseases have a significant impact on healthcare systems, new strategies in prevention, early detection of illness pattern, and long-term treatment are needed.

To address the quality and effectiveness of healthcare services for chronic-disease management, the chronic care model was developed at the MacColl Institute for Healthcare Innovation in 1998 (Wagner, 1998). The model describes the transformation of healthcare from a system that is essentially reactive, responding mainly when a person is sick, to one that is proactive and focused on keeping a person as healthy as possible. Besides strategic and lasting changes in health systems, the model suggests enforcing patients' central role in their care and self-management (Epping-Jordan, Pruitt, Bengoa, & Wagner, 2004).

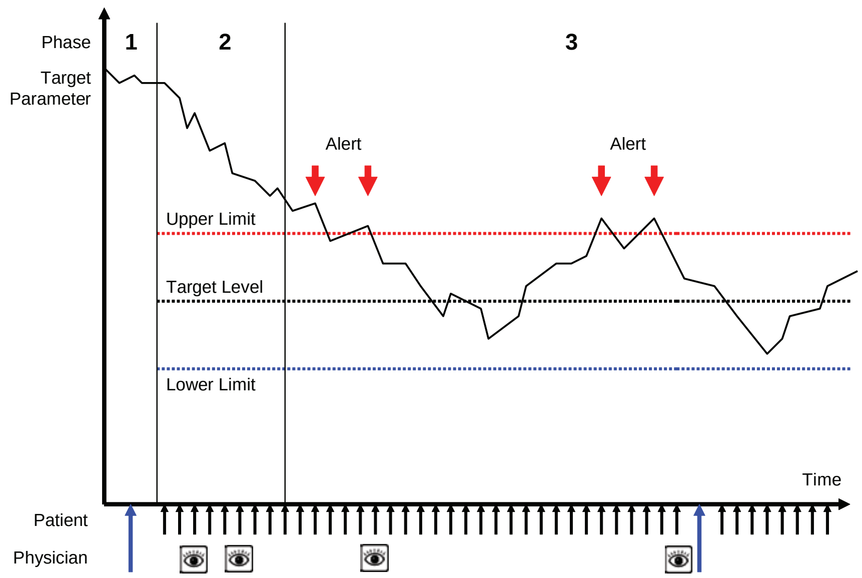
Effective self-management support means more than just telling patients what to do. Because of the fact that neither the chronic condition nor its consequences are static, the process of self-management might be complex and patients are often overstrained. Thus, a close partnership between patients and caregivers is essential in order to guide the patient through the self-management process and to the best possible health status.

It is widely recognized that the monitoring of health-related parameters like blood pressure, blood glucose, or well-being in regular intervals is the central element in the strategy of an effective self-management of chronic conditions. Basically, monitoring is defined as periodic measurements that guide the management of a chronic or recurrent condition. It can have an impact on the improvement of therapy adherence, the better selection of treatments based on individual response, or the better titration of medication (Glasziou, Irwig, & Mant, 2005).

Depending on the target parameter and the phase of treatment, monitoring can be done by clinicians, patients, or both. The strategy of monitoring can be divided mainly into three phases shown in Figure 1. Blue arrows indicate visits at the physician's office. The eye icon indicates tele-monitoring activity. Short, black arrows show the patient's self-monitoring activity.

- **Pretreatment.** Monitoring before treatment is mostly performed at the physician's office by the physician. The main goal is to access the patient's current health status and to verify the need for a medical intervention. Beside standard measurements like the assessment of blood pressure, more complex diagnostic tests like blood tests or urine tests are performed to confirm decisions. At that stage, a person has to be accustomed to his or her new role as a patient in the patient-

Figure 1. Three phases of monitoring (pretreatment, adoption, long-term treatment)



physician relation. Moreover, objectives of treatment, monitoring parameters, target levels, and their upper and lower limits should be well defined.

- **Adoption.** After establishing the target level, application of medication will be started in order to reach the objectives of treatment. Monitoring disease-related parameters, for example, blood pressure in case of hypertension, will show the effect of treatment in a representative way. In case of the necessity to titrate medication, monitoring has to be done very carefully and in shorter intervals to avoid abnormalities or the worsening of the health status.
- **Long-term treatment.** Although the target level has been reached periodically, monitoring is essential because the course of a chronic condition is rarely static. Overstepping or undershooting the predefined target level should be observed carefully. Additionally, alerts could be generated in order to turn the patient's and physician's attention to this special situation. Periods of problems can easily be identified via graphical representation. If noticed problems cannot be solved via tele-medical intervention, the patient has to be ordered to the physician's office for further examination. However, the main objective of tele-monitoring is to detect illness patterns at the earliest possible stage in order to avoid emergency situations and hospitalization.

Today, patients are asked to track their key measures like blood pressure, heart rate, diabetes-relevant data, well-being, or side effects of medication by daily taking notes on a piece of paper, called a health-data diary. The captured data are expected to show trends in the illness patterns and to help the doctor to guide the patient to the best possible health status.

However, patients' motivation for using the conventional method in self-management is often poor. This is hardly surprising since patients are often confronted with complex documents and instructions. On the other hand, paper-based diaries lack proper data representation, feedback, and timely delivery of data. Therefore, an easy-to-use and patient-centered data-acquisition system is essential to guide the patient through data capturing and the complex process of self-management.

USING INFORMATION AND COMMUNICATION TECHNOLOGIES IN HOME MONITORING ENVIRONMENT

The effective management of chronic diseases requires a close partnership between the patient and healthcare provider, which can be supported by contemporary information and communication technologies (Celler, Lovell, & Basilakis, 2003). The timely delivery of data is indispensable to detect an aggravation in illness patterns and to ensure appropriate medical decisions at the earliest possible stage.

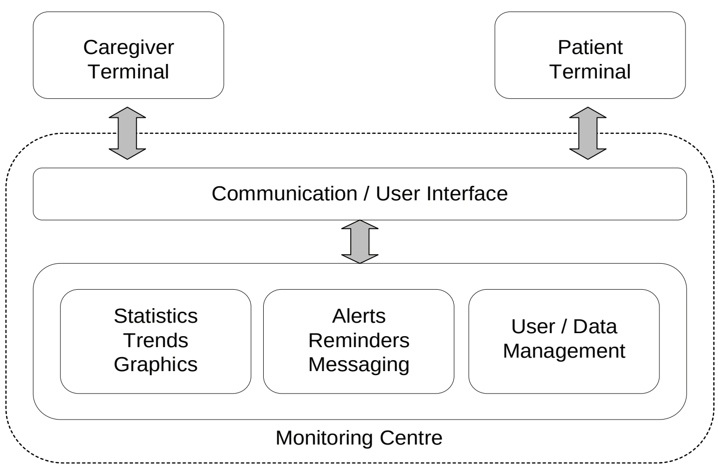
The basic idea is to track the patient's personal health status using a patient terminal, and to transmit the data to a remote monitoring centre where the data are processed and trends, statistics, and graphical representations are generated. An automated monitoring process checks the values and gives feedback. When necessary, the doctor's or other caregivers' attention will be turned to the patient by the means of notifications or alerts.

In our research, we developed a home monitoring platform for regular and home-based measurement and transmission of health parameters like blood pressure, body weight, symptoms, and medication. The system, shown in Figure 2, has been built using mostly standard components and state-of-the-art Internet technology, and it comprises the following.

Monitoring Centre

A 24/7-accessible server system receives, stores, and processes the data. The results are forwarded to the caregivers in a standardized and easily comprehensible format. Central components are user and data management to ensure the security, integrity, and traceability of data. Role-based, hierarchical user management guarantees that only authorized users are able to view, edit, or enter data in the system.

Figure 2. Main components of a home monitoring platform



Patient Terminal

The patient terminal provides the user with an adequate communication interface for entering data into the system as well as to receive feedback or medical advice. Although the availability of PCs (personal computers) with Internet access is already high in developed countries, the use of computers still presents a barrier to the adoption of Web-based solutions, especially by the elderly and technically unskilled people. Hence, different solutions have been developed during the last years to give such users an easy-to-use and intuitive way for entering their health data comfortably using manual, automatic, or semi-automatic methods in conjunction with standard medical measurement devices.

Caregiver Terminal

The Web-based caregiver terminal gives authorized people access to assigned patients and their data via PC or mobile Internet-enabled devices like PDAs or tablet PCs. Specially designed GUI (graphical user interface) components give the physician a quick overview and support straightforward navigation. Transmitted values as well as statistics, trends, and graphical representations can be accessed easily.

Statistics, Trends, and Graphics

An automated process analyses incoming data and generates statistics, trends, and graphical representation. Additionally, the process is able to check for alert conditions (limits given by the responsible physician) or to correlate the values with predefined patterns to identify abnormalities in the course of treatment.

Messaging System

In case of detected aberrance, notification messages will be sent to the physician or the patient via SMS (short-message service) or e-mail immediately in order to initiate further action. Additionally, it turned out that reminder messages are useful for patients and caregivers. The possibility to send interactive messages in several ways enforces communication between patients and caregivers.

Communication and User Interface

Besides the possibility to access or enter data via a Web interface, interfaces to several wireless communication technologies such as WAP (wireless application protocol), SMS, and MMS (multimedia messaging service) are provided in order to send or receive data.

GOING WIRELESS

A current trend in information and communication technologies is the convergence of wireless communication and computer networks as well as a moving from stand–alone, single-purpose devices to multipurpose network devices. Up to now, several studies have demonstrated that tele-monitoring using information and communication technologies on different integration levels - reaching from a simple telephone call to wearable or implantable sensor systems - can effectively assist patients in the management of care. Although the use of older approaches (telephone, fax) is still common, latest innovations in computer and network technologies can be considered for tele-monitoring applications to support the patient with a method to enter and transmit data in a comfortable way.

The Telephone as Communication Interface

Telephone care services represent the oldest method to deliver medical advice to the patients' homes. Nowadays, standard telephone lines are available in almost every household and even technically unskilled people are able to handle the telephone. For monitoring purposes, patients are contacted by a call centre to hand over their key measurements in predefined follow-up intervals. Specially trained personnel check the values against the patient's history and predefined limits and give feedback in order to assist the patient in self-management.

The usage of telephone interventions in the management of outpatients suffering from chronic heart failure was demonstrated in the DIAL(randomised trial of telephone intervention in chronic heart failure) trial (GESICA, 2005): 1,518 patients with stable chronic heart failure and optimal treatment were enrolled in 51 centers in Argentina. The DIAL trial intervention strategy was based on frequent telephone follow-ups provided by nurses trained in heart failure. The purpose of interventions was mainly to educate and monitor the patients as well as to increase the patients' adherence to diet and drug treatments. The results indicate that patients in the usual-care group were more likely to be admitted to the hospital for reasons of worsening and they were also more likely to die than patients in the tele-monitoring group who received telephone intervention. Moreover, patients in the intervention group showed a better quality-of-life score than patients randomized to the usual-care group.

Besides the possibility to use plain old telephone systems (POTS) for voice communication, they can also be used to access the Internet and network-based data services. Medical measurement devices like blood-pressure meters, blood-glucose meters, or scales equipped with modems can be connected to the POTS directly or by the means of a home terminal.

The Trans-European Network Home-Care Management Systems study (TEN-HMS) was the first large-scale, randomized, prospective clinical trial to decide if home-based tele-monitoring services for heart-failure patients are able to reduce hospitalizations and to improve patient well-being while reducing the overall costs of care (Cleland, Louis, Rigby, Janssens, Balk, & TEN-HMS, 2005). In total, 426 patients were randomized to the control group, nurse telephone-support group, or tele-monitoring group. The results indicate that patients randomized to the tele-monitoring group faced a reduced number of days spent in the hospital (minus 26%). Furthermore, it led to an overall cost saving compared to the nurse telephone-support group (minus 10%). Tele-monitoring also significantly improved survival rates relative to the usual-care group and led to high levels of patient satisfaction.

Mobile Phone as Communication Interface

Recent statistics indicate that the number of mobile phones throughout the world exceeded 1.5 billion in 2004 (CellularOnline, n.d.). Moreover, it is estimated that within a few years, about 70% of cell phones in the developed countries will have Internet access. Thus, mobile phones have become potential devices for serving as patient terminals in tele-monitoring applications. Mobile phones as well as communication technologies have undergone incredible changes and advancements during the last years. The amazing employment of mobile phones started in the 1980s when first-generation (1G) cellular systems were introduced. This technology was based on analog circuit-switched technology. Low data rates prevented this technology from being used for data transfer. Up to now, most of the 1G networks have been replaced by second-generation (2G) wireless networks, which are based on digital circuit-switched technologies. Several standards have been developed in different parts of the world: the Global System for Mobile Communication (GSM) technology in Europe, code division multiple access (CDMA) technology in the USA, and personal digital communication (PDC) in Japan. Second-generation wireless networks are digital and expand the range of applications to more advanced voice services and data capabilities such as fax and SMS at a data rate up to 9.6 kbps, which still makes it mostly impractical for extensive Web browsing and multimedia applications.

Through the years, several advanced techniques based on 2G networks were introduced such as general packet radio service (GPRS) and enhanced data rates for global evolution (EDGE). These technologies, also known as 2.5G networks, make it possible to use several time slots simultaneously when sending or receiving data, resulting in a significantly increased data rate (171 kbps for GPRS, 384 kbps for EDGE). The data packages are sent over the network using an IP (Internet protocol) backbone so that mobile users can assess services on the Internet.

The Universal Mobile Telecommunications System (UMTS) presents the third generation (3G) of wireless communication technology. The broadband, packet-switched transmission concept supports the transmission of text, digitized voice, video, and multimedia at data rates up to 2 Mbps. At the moment, users in real networks can expect performances up to 384 kbps for downloading and at least 64 kbps for uploading data. Third-generation systems are expected to have the following features: fixed- and variable-rate bit traffic, bandwidth on demand, asymmetric data rates in the forward and reverse links, multimedia mail storage and forwarding, the capability to determine the geographic position of mobile units and report it to both the network and the mobile terminal, and international interoperability and roaming (Tachakra, Wang, Istepanian, & Song, 2003).

In the course of rapid advances in communication technology and increased data rates, new multimedia services appeared that are the basis for further developments of mobile-phone-based applications for healthcare.

Short-Message Service

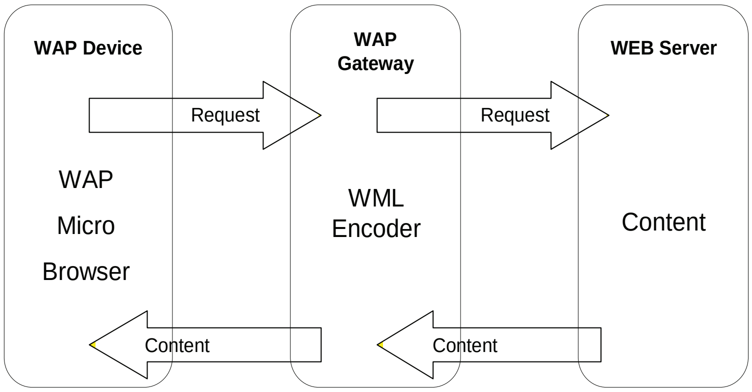
SMS allows sending and receiving text messages of up to 160 characters in length to and from mobile phones as defined within the GSM digital mobile-phone standard (Buckingham, 2000a). The text can comprise words or numbers or an alphanumeric combination. SMS is a store and forward service. This means that SMS messages are not sent directly from sender to recipient. Each mobile telephone network that supports SMS has at least one messaging centre to handle and manage the short messages.

To receive the text message on the server side, a mobile phone is connected to the server via standard interfaces such as RS232. Using the Hayes command set (Attention (AT) commands), the arrived messages can be accessed and stored in the database for further processing.

There are several reports on the use of SMS in medical application areas. SMS has been basically used for patient and appointment reminders. Outpatient clinics that are using SMS-based appointment reminder systems are seeing a reduction in missed appointments or "did not attends" (DNAs). It has been demonstrated that outpatient clinics that deployed SMS patient reminder systems saw DNA rates fall by as much as 30% even though less than 20% of patients chose to use the service (Research and Markets, 2005).

Besides the usage of SMS as a reminder service, SMS has also been applied in several medical application areas to transmit data from patients' homes to a monitoring centre. In 2004, Ferrer-Roca, Cárdenas, Diaz-Cardama, and Pulido presented the use of SMS for diabetes management. Twenty-three diabetic patients (18 to 75 years old) were asked to transmit data such as blood-glucose levels and body weight to a central server. The server automatically answered via SMS with a

Figure 3. WAP programming architecture. The application is stored on the content server and the requested pages are generated dynamically



prerecorded acknowledgement, specific help, or warning messages when data were out of range. During an 8-month study period, an average of 33 SMS messages was sent per patient and month. Unfortunately, no medical benefit was reported. However, they conclude that SMS may provide a simple, fast, efficient, and low-cost adjunct to the management of diabetes at a distance.

On the other hand, medical benefit in asthma monitoring could be demonstrated by Ostojic, Cvoriscec, Ostojic, Reznikoff, Stipic-Markovic, and Tudjman (2005). Sixteen patients (24.6 +/- 6.5 years old) were asked to transfer peak expiratory flow (PEF) measurements at least three times a day during a 16-week study period. Patients randomized to the tele-monitoring group received a weekly adjustment by an asthma specialist based on the values sent to the monitoring centre. They reported that asthma overall was better controlled in the intervention group, according to their findings of reduced PEF variability.

Wireless Application Protocol

WAP is an open global standard for communication between mobile phones or other mobile devices and the Internet (Buckingham, 2000b). WAP-based technology enables the design of advanced, interactive, and online mobile services, such as mobile banking, Internet-based news services, or even tele-monitoring applications.

The WAP standard is based on Internet standards like the hypertext markup language (HTML), extensible markup language (XML), and transmission control protocol/Internet protocol (TCP/IP). Basically, it consists of the wireless markup language (WML) specification, which is a markup language derived from HTML. However, WML is strongly based on XML, so it is much stricter than HTML. WML is used to create Web pages including text, images, user input, and navigation mechanisms that can be displayed on a WAP micro browser.

The WAP architecture consists of a WAP device, a WAP gateway, and a content server (Figure 3). The handheld WAP device communicates with the content server, which stores information and responds to user requests. The gateway in between translates and passes information between the device and the server. To access an application stored at the content server, a connection to the WAP gateway is initialized. Thereafter, the WAP request is converted to HTTP (hypertext transfer protocol) and forwarded to the content server.

Upon handling the request, the requested content is returned to the gateway, transformed into WAP, and sent back to the device to be displayed via the micro browser. The new version of WAP, WAP 2.0, is a reengineering of WAP using a cut-down version of the extensible hypertext markup language (XHTML) with end-to-end HTTP connection. This means that using WAP 2.0, the WAP gateway becomes dispensable.

A couple of authors (Hung & Zhang, 2003; Salvador et al., 2005) have already demonstrated tele-monitoring applications using WAP technology after WAP browsers became a standard feature of mobile phones. It is mentionable that besides demonstrating principal functionality in several pilot trials, only few clinical trials using WAP for patient monitoring have been mentioned in the literature yet.

For example, Italian researchers have shown that aftercare and patient communication might be improved if patients are asked to fill in daily questionnaires using WAP on their mobile phones (Bielli, Carminati, La Capra, Lina, Brunelli, & Tamburini, 2004). They developed the Wireless Health Outcomes Monitoring System (WHOMS), which allows structured questionnaires to be sent to the patient by the medical management team. Each day, an SMS message was sent informing patients of the survey and giving a link to a WAP site accessible through a standard GPRS connection. Users were asked to rate symptoms such as pain, lack of energy, and difficulty sleeping. The collected data were viewable by the doctors in a graphical format that highlighted the patients' states of health.

Although 42% of the patients failed to fill in the questionnaires mainly because of neophobia and unfamiliarity with the technology, the researchers concluded that health-outcome monitoring using mobile phones can be the method of choice for future developments in quality-of-life assessments. They address the need to develop more user-friendly communication terminals supported by upcoming technologies for mobile phones to increase the adoption rate.

In the course of our research, a lot of effort has been done to make WAP technology applicable for the broad usage in home monitoring applications and the management of chronic diseases.

Figure 4. Graphical user interface generated by WML guides the patient through the data-acquisition process

The aim of the Cardio-Memory study (Scherr, Zweiker, Kollman, Kastner, Schreier, & Fruhwald, in press) was to evaluate whether WAP technology would be an acceptable, feasible, and reliable option to provide tele-monitoring for patients with chronic heart failure or hypertension. In the course of a clinical pilot trial, 20 patients (mean age 50 +/- 14 years) were enrolled. Each participant was equipped with a mobile phone, an automatic blood-pressure device, and a digital weight scale. Patients were asked to measure their blood pressure, heart rate, and weight every day. After accessing the system with the micro browser, the menu promptly routed the patients through subsequent entry templates generated by WML syntax (Figure 4). Eventually, all data were sent to the central database at the remote monitoring centre for further processing.

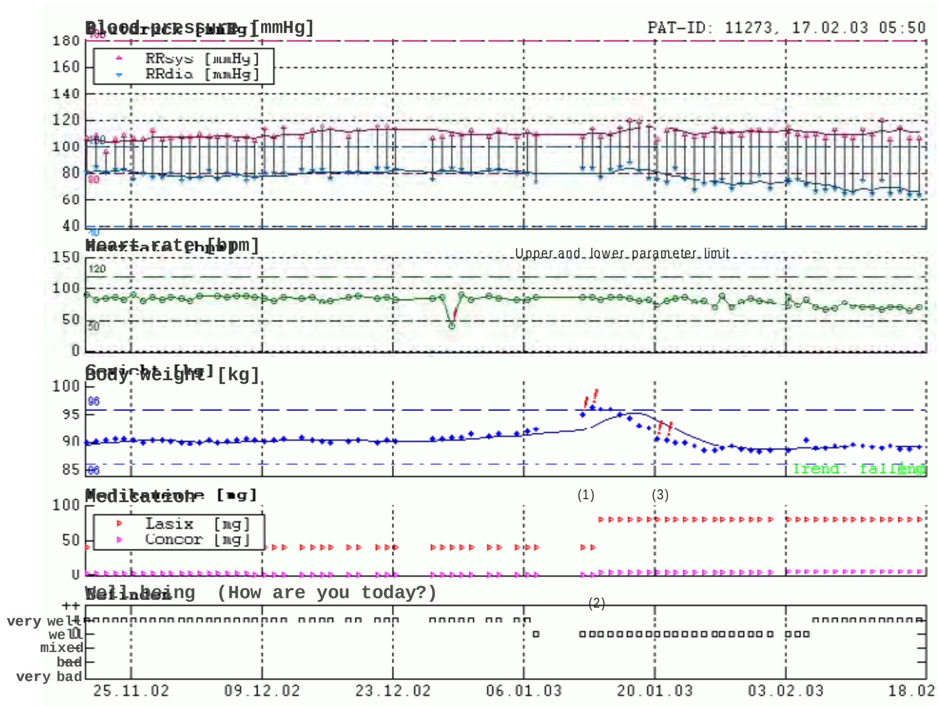
Authorized physicians could access the data via a secure Web site at any time. The Web site provided the data of each patient in numerical format and graphical trend charts, including patient-specific upper and lower parameter limits. Furthermore, it allowed physicians to set automatic reminders: These computer-generated SMS messages reminded patients to take their medications, weigh themselves, measure blood pressure and heart rate, and to transfer the respective data to the secure server at the monitoring centre. Furthermore, the physician could individually configure an automatic warning system for each patient. If the patient's values exceeded individually predefined vital parameter limits, physicians were notified immediately by a computer-generated SMS or e-mail warning. If an intervention (e.g., adjustment of medication dose) was indicated (for example, because a patient exceeded a vital parameter limit), the physician was able to contact the patient directly via mobile phone to confirm the parameters and ask the patient to make an adjustment in medication.

During the 3-month monitoring period, there were 2,040 data-transfer sessions (mean 102 +/- 43 per patient). Only 1 out of 20 patients dropped out after 25 days due to severely impaired vision. The Cardio-Memory system was evaluated through a questionnaire at the end of the study. Eighteen out of 20 patients rated the software as easy to operate, which allows us to conclude that overall patients' acceptance with the system was high. The entire process (measurements and data transfer) took approximately 3 minutes to be completed. Moreover, patients felt that computer-generated reminders about missing data increased their compliance with the treatment regime.

An example of a successful tele-medical intervention of a patient suffering from chronic heart failure is shown in Figure 5. Cardiac decompensation caused a weight gain of more than 2 kg within 3 subsequent measurements and led to a patient alert (1). The physician contacted the patient and increased the diuretic dose (2). Subsequently, the patient lost weight and remained in stable conditions until the end of the observation period (3).

Following the promising results of the Cardio-Memory trail, an advanced study was set up in October 2003 in order to evaluate WAP technology in the management of chronic heart failure (Scherr et al., 2005). In a randomised, prospective, multi-center study, 240 patients who had been admitted to the hospital because of heart failures will be randomised to either pharmacological treatment (control group) or to pharmacological treatment plus tele-medical care (telegroup). Telegroup patients are provided with a mobile telephone, a digital weight scale, and a fully automated blood-pressure device. During the follow-up period of 6 months, patients are asked to send their self-measurements using a WAP application on the mobile phone on a daily basis. Up to now, 65 patients (45 male, 20 female; 64 ± 11 years old) from six centers have been randomised, and 44 patients have completed the study so far. Three patients from the telegroup dropped out due to being not able to handle the monitoring system equipment, in particular, the mobile phone.

Figure 5. Trend chart of a patient monitored with Cardio-Memory



Intermediate results indicate that WAP-based tele-medical surveillance of patients with a recent episode of acute heart failure significantly contributes to an improvement of functional status and may be a promising tool to improve heart-failure therapy and reduce emergency situations and hospitalizations.

Java-Based Software Application Running on Mobile Phones

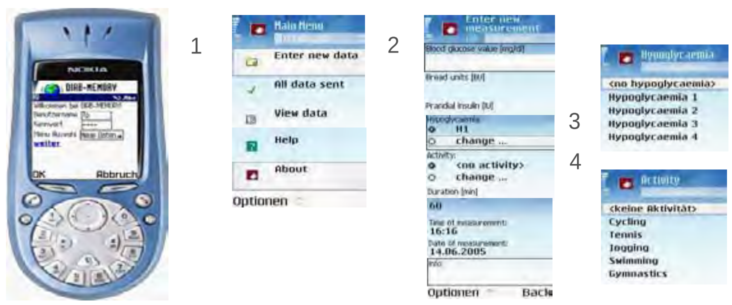
Java 2 Platform, Micro Edition (J2ME), the small footprint version of the Java technology, is optimized to run on memory-constrained devices like mobile phones, PDAs, and TV-set-top boxes. Each device category receives its own profile that includes a set of category-specific application program interfaces (APIs) and a configuration that consists of a minimum set of APIs and a Java virtual machine. In particular, mobile phones support the mobile information device profile (MIDP), which includes APIs covering the user interface, networking, persistent storage (a record-oriented database), security, and messaging (Sun Microsystems, 2002).

The usage of a J2ME-based software application running on mobile phones has been evaluated in a pilot trial concerning the management of diabetes patients (Riedl, Kastner, Kollmann, Schreier, & Ludvik, 2005). The software has been designed to support the user in entering diabetes-related data like blood-glucose level, insulin dose, bread units, well-being, and activities with remote synchronization to the database at the central monitoring centre. The graphical user interface is shown in Figure 6.

After having logged in, the data is entered via the well-designed graphical user interface and stored directly in a local database on the mobile phone. From time to time, the user can initiate a synchronization process via HTTP request and

Figure 6. A Java-based software application running on mobile phones supports the user in home-based data acquisition of diabetes-related key measurements

Flow chart



1 … User authentication
2 … Data entry (Blood glucose, bread units, insulin dose, …)
3 … Hypoglycaemia classification if occurred [1 to 4]
4 … Physical activity if performed

GPRS data transfer. After the uploading of the data to the remote monitoring centre, the user is able to access several graphical representations, statistics, and trends on his or her data through a secure Web interface.

The software has been evaluated in a clinical pilot trial. Ten diabetes mellitus type 1 patients (36.1 ± 11.4 years) were asked to collect diabetes-related data (blood glucose, bread units, insulin dose, well-being, activity, etc.) at least 3 times and up to 10 times a day by using J2ME software application running on a NOKIA 7650 mobile phone. In case of less than 3 transmitted data records a day, an automatic reminder SMS message was sent to the patient. The total number of received messages was 10,053 (1,257 +/- 351 per patient). Average blood-glucose level during the initial and final 14 days was 138.5 +/- 63.7 vs. 137.1 +/- 69.2 mg/dl, and HbA1c values were 7.7 +/- 0.4% vs. 7.6 +/- 0.4%, respectively. Although no tele-medical intervention by the physician was yet established, corresponding parameters decreased due to an advanced adherence to therapy. Additionally, ubiquitous availability and the appealing user interface were well perceived by the patients resulting in a high success rate for data transmission and patient acceptance.

Semiautomatic Methods

Running a J2ME-based software application on mobile phones supports also the possibility to access integrated mobile-phone features like Bluetooth. Bluetooth wireless technology is a short-range radio technology that makes it possible to transmit data over short distances between mobile phones, computers, and other devices. Supporting standard measurement devices like blood-pressure meters or glucose meters with a Bluetooth communication module gives them the possibility to transfer data to the mobile phone in an automated way. The software running on the mobile phone handles data exchange and triggers further data transmission to a central monitoring centre (Husemann & Nidd, 2005).

Multimedia Messaging Service

MMS, an extension to the SMS, defines a way to send and receive wireless messages that may include images, audio, and video clips in addition to text. When the technology will be fully developed, the transmission of streaming videos will be supported as well. A common current application of MMS messaging is picture messaging - the use of camera phones to take photos for immediate delivery to a mobile recipient.

MMS has been used in our research as a unique approach to the human-computer interface challenge based on digital-camera-enabled mobile phones. Values shown on the display of the measurement device were taken by a camera-enabled mobile phone. Special Symbian-based (Symbian, 2005) software, running on the mobile phone, helps the user to handle this data-acquisition process. All necessary configurations are made by the program automatically. If an online connection to the data carrier service (GPRS, UMTS) at a given location and time is not available, the mobile phone repeatedly tries to send the data until the message has been sent successfully. Data acquisition and transmission can be achieved with only two keystrokes.

At the monitoring centre, the MMS arrives as a photo attached to an e-mail. The subject of this e-mail contains the IMEI (international mobile station equipment identity) of the mobile phone. Thus, the photo can unambiguously be assigned to a patient. Other important parameters like capturing date and time are also stored within the e-mail.

Special software, running on the Web server, fetches the e-mail available on the mail server, extracts the photo, and moves it to the local file system. Subsequently, the incoming photo is registered to the database and assigned to the corresponding patient.

Thereafter, a special character-extraction algorithm starts to process the photo in order to extract the numerical values. In case of successful character extraction, the values are stored into the database and the report-processing unit is started.

Figure 7. "MoniCam" principle: A special software application helps the user to take a photo of the display and send it to a central monitoring centre via MMS, where the values are extracted and stored in the database automatically

Graphs and trends are generated and limit checks are performed. Finally, all information is made accessible via the Web interface to authorized users. In case of unsuccessful character extraction or failed plausibility check, the user may receive a message via SMS to repeat the measurement.

This new method has been evaluated in a feasibility study on five users with four different blood-pressure devices and two different camera-enabled mobile phones (Schreier, Kollmann, Kramer, Messmer, Hochgatterer, & Kastner, 2004). The results indicate that the rate of correct value extraction varied considerably with respect to the type of the measurement device but was comparable for the two different types of mobile phone. For two types of blood pressure meters the method was capable of determining the correct values in well above 90% of the cases. The MMS-based transmissions of the taken photos succeeded in all cases.

REQUIREMENTS ON MOBILE-PHONE-BASED TELEMONITORING APPLICATION

Because of the ubiquitous availability of mobile phones, these devices may be considered to be the patient terminal of choice to provide an interface to home monitoring systems. It has to be taken into account, however, that elder patients are often very unskilled and not familiar with the handling of mobile phones. To avoid rejection of this concept as well as to motivate the patients in using such devices, consequentially, an easy-to-learn and easy-to-use system for data acquisition is essential. Based on our experience, the ideal human-computer interface would have the following properties.

High Usability

Usability tells us how well the users can use the system productively, efficiently, and pleasantly to reach the goals in a certain environment. Using mobile phones as home monitoring terminals is limited in terms of input interaction (small buttons to enter data as well as to navigate) and output interaction (small display size and poor resolution). To overcome these limitations, an appealing user interface, well-structured graphical design (metaphoric), and intuitive navigation are essential. The number of buttons to be used as the necessary number of button clicks for navigation and entering data should be reduced to a minimum. Moreover, the data-acquisition process should be easy to learn, intuitive, and well structured to decrease barriers against technical devices and improve users' satisfaction in using the system.

Low Cost

The main driving force for introducing new innovations into healthcare is to reduce costs. Hence, patient terminals for home monitoring applications should ideally be based on off-the-shelf technology available without significant set-up expenses or extra costs.

Error Resistant

User actions as well as data entries should be checked for plausibility on the earliest possible stage. For example, a data-entry plausibility check on the side of the patient will exclude errors at origin. A major aspect in handling errors is to provide the user with well-defined error messages that are also easy to interpret and to understand. Well-structured error handling can guide the user through difficulties without confusing him or her.

Off-Line Data Acquisition

It is a well-known fact that wireless networks especially sometimes lack availability (e.g., in buildings). To provide the user with the possibility to enter data at any time and any location, intermediate local data storage is desirable. When the network is available again, stored data can be synchronized with the central database.

High Flexibility and Adaptability

Patient terminals should provide flexibility in terms of adding or removing parameters to the user interface, corresponding to changing conditions in the treatment of chronic diseases. For meeting the needs of an adjusted, personalized patient terminal, the system should support the possibility to interrogate different parameters depending on the time of day or the patient's history. The user interface for daily use should be configurable to different patients and conditions such as displaying the appropriate drug name to enter the correct dosage. Ideally, user interactions or setup procedures are no longer necessary.

High Security Level

Handling data about the health status of patients, in general, requires a high standard of security. In most countries, end-to-end encryption is compulsory to meet security directives and laws. As a consequence, most standard communication technologies and protocols already provide some sort of data protection to guarantee that data cannot be accessed, stored, or manipulated while they are transmitted via Internet or wireless networks.

Bidirectional Communication

The ideal patient terminal combines the possibility to provide the user with an interface not only for entering data but also for receiving feedback, reminders, or medical advice on the same device.

Device Independency

Currently, numerous models of mobile phones from various manufacturers are available on the market to be used as patient terminals. Therefore, a software application that provides a graphical user interface highly demands independency of device specifications like operating system, display resolution, mobile Internet browser, menu

Table 1. Overview of the properties and technologies (+ means the method complies with the requirement, +/- means it complies only partly, - means does not comply)

	Technology				
Requirement	SMS	WAP	J2ME	MMS	Automatic
Overall usability	-	+/-	+	+	+/-
Low cost	+/-	+/-	+/-	-	-
Error resistant	-	+/-	+	+	+
Off-line data acquisition	+	-	+	+	+/-
High level of flexibility/ adaptability	-	+	+/-	-	-
High security level	-	+	+	+/-	+
Bidirectional communication	+	+/-	+/-	+	+/-
Device independency	+	-	+/-	+	-

navigation, and so forth to ensure high usability for a wide range of mobile phones.

Table 1 gives an overview of the requirements and the degree of compliance of the various technologies as discussed in this chapter and proposes a three-level classification based on our experience and the results of trials of other authors.

SMS

Using SMS technology for data acquisition is not very suitable due to the lack of usability and the fact that a graphical user interface cannot be provided. Basic skills in handling mobile phones as well as knowledge in using the keypad are essential to enter values in a predefined template. SMS for data transmission can be considered when only a single value has to be transmitted (e.g., PEF value in case of monitoring asthma patients; Ostojic et al., 2005). On the other hand, SMS is very suitable for sending messages, automatically generated reminders, or medical advices from the healthcare provider to the patient as an additional way of communication.

WAP

Several studies have been performed utilizing a WAP browser to provide the user with a user interface to enter data. Although a graphical user interface is provided, basic skills in handling a mobile phone and using the numeric keypad are important. Moreover, WAP lacks the possibility of client-side data-entry plausibility checks. The data have to be sent to the server before the values can be processed or checked for plausibility. In case of an error, the user is prompted to the page where the error occurred and asked to reenter the data.

On the other hand, WAP technology provides high flexibility and adaptability because WML scripts are server based and can be generated dynamically depending on user settings and requirements. This fact makes this method seem quite suitable for providing dynamical questionnaires such as quality-of-life assessments or to track medication intake, which is quite different from patient to patient. WAP technology may also be useful were a stepwise data input is required.

A disadvantage of WAP-based systems is that an online connection has to be established during the whole data-entering process. We experienced that this fact can lead to problems. For example, when the data connection is lost, users are confused by the corresponding error message. Thus, incomplete record sets are common and some patients were not able or willing to use the method for daily data acquisition.

Java

Java-based software is less affected by temporary lack of network availability because the data can be stored locally on the mobile phone and the data-transmission process may be postponed until network connectivity is available. Additionally, implementation of checking the plausibility of the entered data is also feasible, resulting in a lower error rate.

Moreover, Java technology allows one to improve usability through the design of user-friendly GUIs by using metaphoric elements. However, updating software applications running on the mobile phones is difficult and requires some additional user experience, although over-the-air application downloading (OAD) simplifies the way applications are delivered to customers.

In addition to standard TCP and HTTP, the Java environment supports the secure hypertext transfer protocol (HTTPS) using standard secure socket layer (SSL) to enable encrypted, secure connections. J2ME is particularly suitable for monitoring applications where frequent data acquisition is necessary (e.g., diabetes) and provides a fast and efficient method to enter, store, and transmit data.

Irrespective of which technology will be used, the most challenging part in developing mobile-phone-based applications for home monitoring is to guarantee interoperability. For example, WAP technology is strongly based on standards but every mobile-phone manufacturer speaks a slightly different WAP language. According to our experience, J2ME applications also change their looks depending on the type of the mobile phone.

MMS

Using a camera-enabled phone for data acquisition by taking a photo of the display provides a really easy and intuitive method for health-data acquisition at home. On the other hand, there is a huge effort on the server side to provide an image-processing algorithm to extract and interpret values correctly. This method lacks also in terms of flexibility and adaptability. Furthermore, costs for the MMS picture transfer are an obstacle for daily usage.

Automatic

Some measurement devices are already equipped with short-range wireless communication technologies like Bluetooth or infrared to transmit data to the mobile phone, which operates as a hub and a gateway to relay those data to a central monitoring centre. Because there is no mass market for such devices yet, they are usually considerably more expensive. Another weak point of this concept, according to our experience, is that it is sometimes not straightforward to establish communication between the mobile phone and the measurement device. Depending on the model, it may be necessary to navigate deep into the menu for setting up the connection. This makes such methods often unusable for technically unskilled people. However, once the system is set up correctly, data acquisition is fairly automated and error resistant. Using the mobile phone as a hub provides a bidirectional communication between patients and healthcare providers; hence, the mobile phone can receive SMS. Therefore, in the long run, automated systems will be the method of choice for elderly and unskilled or handicapped patients to transmit their self-measurements to the monitoring centre.

DEVELOPING MOBILE APPLICATIONS FOR TELEMONITORING APPLICATIONS

Because of small display sizes, limited resolution, and restricted possibilities for user interaction, navigation design and the implementation of software applications for mobile devices is quite different from software developments on other platforms like stationary desktop PCs.

Mobile software applications can be divided into two groups:

1. Highly goal driven.
2. Entertainment focused.

Highly goal-driven services aim at providing fast replies to specific problems, whereas entertainment-focused services enable the user to pass the time, for example, by offering gossip, games, or sports results (Ramsay & Nielsen, 2001). Mobile applications for home monitoring are definitely goal-driven, that is, to provide the users with a method to enter data in the most suitable way. Therefore, a user-centered design process is necessary. This process involves a number of important phases.

Analysis

The initial phase of software development is the most critical one. In this stage, the requirements of the patient terminal should be clearly defined by determining the user-group characteristics and the monitoring scenario. Typical attributes of the user group are age, expertise, experience level, and physical limitations. The definition of the monitoring scenario comprises the parameter to be monitored, the way feedback is given, and the demand in terms of flexibility.

Thereafter, the use case of the specific monitoring scenario should be clearly described in order to define objectives and features that require close cooperation between technician and physician. Once the general use case has been defined, the technology has to be selected that best supports the requirements of the respective application. Table 1 can serve as a guide to get an overview of properties of available technologies. Features as well as limitations of the selected technology should be carefully balanced during the design process.

Design

According to our experience, the typical software application for home monitoring applications comprises the following four stages:

1. **Identification:** The user is asked to log onto the system with a unique user name and password combination to facilitate authentication and access control.
2. **Data acquisition:** Menus and input templates guide the user through the data-acquisition process.
3. **Transmission:** Entered data are either stored locally or are transmitted to a central database in a monitoring centre.
4. **Feedback:** To indicate that data storage or transmission has been executed successfully or the presence of special situations, feedback should be given to the user immediately after data transfer in a representative form.

The development of a consistent, easy-to-use application does not require coding at this stage. On the contrary, ideally, a conceptual framework is established, representing the application and its workflow on a metaphoric level (e.g., a storyboard).

Evaluation

The concept designed in Step 2 should be evaluated by both types of users: patients and physicians. Usability considerations should be made; for example, unnecessary button clicks or confusing workflows should be avoided. There is also the need to identify sources of errors. If significant changes are necessary, an iteration starting with the design step is required.

Implementation

There are several software-development kits (SDKs) available to develop software for mobile devices. However, irrespective of which SDK or programming language is adopted, developing software applications for mobile phones requires substantial experience in programming efficient and reliable software.

Testing

The developed software can be tested and debugged on emulators that are provided by the mobile-phone manufacturers. However, according to our experience, emulators are often error prone and sometimes special features are not supported. Hence, it is essential to test developed software on target devices themselves.

FUTURE TRENDS

Current trends in chronic-disease management enforce shifting tasks from the clinic to patients' homes. This means that self-management and collaboration between patients and caregivers will become more and more important and may benefit from upcoming technologies.

Technical Advancements for Mobile-Phone-Based Patient Terminals

Phones enabled with radio-frequency identification (RFID) and near-field communication (NFC) may soon be used as patient terminals to provide an intuitive and easy-to-use way for health-data acquisition at home.

RFID tags are able to uniquely identify an object, animal, or person, or to store data. They have been introduced in the industry as an alternative to the bar code. Passive RFID tags are powered by the magnetic field generated by the reader. The tag's antenna picks up the magnetic energy, and the tag communicates with the reader in order to retrieve or transmit data.

In a current research project, we developed a scenario where RFID tags are used in a home monitoring environment. Objects to be tracked or identified are equipped with RFID tags. For example, tagging medication boxes with RFID tags provides an easy and intuitive method for the patient to indicate which medication has been taken simply by touching the box with an RFID-reader-enabled phone. Special software running on the mobile phone fetches the information from the tag, adds a time stamp, and initializes a transmission to the monitoring centre automatically. Hence, no cumbersome user interaction and configuration is needed.

Electronic Data Capture in Clinical Trials

The combination of mobile and Web-based technologies will improve clinical-trial efficiencies through increased data accuracy, higher data yield per patient, and real-time access to trial data (Stokes & Paty, 2002) by using mobile phones for timely and patient-centered data acquisition. Patient diaries as well as consequent monitoring of health parameters of interest can add meaningful information about the safety and efficacy of a treatment and can save time and money. Additionally, quality-of-life data will also play a central role in future clinical trials, which can be accessed easily by mobile-phone-based software solutions.

LESSONS LEARNED

Self-management and cooperation between patients and healthcare providers are the basic aspects and strategies of efficient chronic-disease management. An important element in efficient self-management is the monitoring of health-related data reliably. Because of the ubiquitous availability of mobile phones, these devices can be used as patient terminals so as to provide the patient with a method to enter data easily as well as to receive feedback or medical advice from remote healthcare professionals.

The most critical part in this respect is the user interface. Software specifically developed to the needs of the respective patient group is required to guide them through the data-acquisition process. Mobile data services and transmission protocols like SMS, MMS, WAP, and HTTP can be used to exchange data and information between patients and their caregivers. These methods have already been evaluated in several clinical trials and feasibility studies, and medical benefit could be demonstrated as well. However, using mobile phones as patient terminals is limited due to small display, poor resolution, and small buttons for user interaction.

Up to now, there is no method that fulfils all criteria of an ideal patient terminal in terms of high usability, adaptability, flexibility, and low cost. Every method for entering data implies specific advantages and disadvantages. Hence, when designing a mobile-phone-based home monitoring system, the patient terminal that best fits into a particular monitoring application has to be chosen on an individual basis, depending on the requirements, the user group, and the medical demand.

APPENDIX: AUSTRIAN RESEARCH CENTERS GMBH-ARC

Austrian Reseach Center GmbH-ARC (ARC-sr) is Austria's largest centre for applied research and development, employing over 500 highly qualified specialists. The corporation's portfolio is strongly oriented toward national and European-wide research projects and development programs. ARC-sr comprises nine business divisions. The Division of Biomedical Engineering comprises research teams in the fields of e-health systems and smart biomedical systems, and cooperates with all major Austrian medical and technical universities in Vienna, Graz, and Innsbruck as well as a number of additional medical institutions and industrial partners within Austria and abroad.

The E-Health Systems Research Team focuses on e-health-related applications and research and development projects according to its mission: "to provide new connections between patients, physicians and other healthcare partners." Accordingly, we developed several home monitoring solutions utilizing modern information and communication technologies and a 24/7 monitoring service centre to establish these new connections between physicians and patients. The integration of different devices and monitoring indications as well as standardization are major objectives. The ultimate goal of our tele-, home, and health-monitoring concept is to empower physicians and patients with advanced data-acquisition methods for prevention, diagnosis, and therapy management.

This work was previously published in Web Mobile-Based Applications for Healthcare Management, edited by L. Al-Hakim, pp. 227-257, copyright 2007 by IRM Press (an imprint of IGI Global).

Chapter 3.5
Implementation of a Computerized System in an Oncology Unit

Taxiarchis Botsis
Athens Medical School, Greece

Konstantinos Syrigos
Athens Medical School, Greece

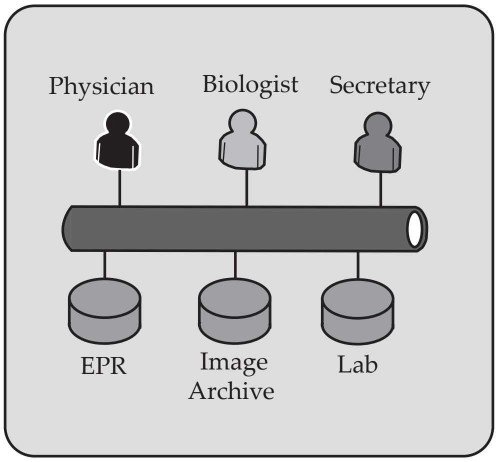
ABSTRACT

Information management is essential for health professionals in order to maintain a level of productivity for health care services management. This is significant when treating cancer patients. The main target of this study was to employ computers to enhance the daily practice of Oncology Unit (Sotiria Hospital, Athens, Greece). Accordingly, a computerized system was developed consisting of three modules: the EPR, the Image Archive, and the Lab Module. The EPR Module is a database application that stores clinical results, physician orders, and several administrative data. The Image Archive Module is used mainly for the reduction of images volume and the Lab Module stores information about the patient blood samples. These two modules interoperate through EPR Module under strict data security policies. Key physicians, biologists, and secretary personnel are involved in data entry and information management, while the system administrator is responsible for the system functioning. Improved health care, user satisfaction, and cost savings were the most important benefits gained with this system. The need of similar systems in oncology is crucial and could involve additional applications, such as quality of life (QoL) systems.

INTRODUCTION

Health Informatics is one of the fastest growing areas of information and communication technology (ICT) (Eysenbach, 2000). It is a multifaceted field concerned with electronic patient records, image processing, computer aided diagnosis, research support, database archival, and hospital

Figure 1. Unit's computerized system



management. Despite the remarkable barriers to adoption there are significant technical, legal, economical, professional, and cultural reasons for the evolution of such systems. In parallel, their use should promote and must certainly not be in conflict with the fundamental principles of medical ethics.

In the clinical work processes, the handling of huge amounts of information is a very important issue. Generally, health care information systems are used to guarantee quality and efficiency of the medical practice. The structured analysis and communication of clinical information are necessary in specific areas of health care (Asp & Petersen, 2003). This is extremely important in the case of caring for cancer patients. The cooperative care for cancer patients (declared as "Shared Care") requires complete, distributed, and summarized clinical records as cancer documentation (Blobel, 2000). Computer-based applications assist crossing specialty boundaries involving members of a multidisciplinary team in an oncology unit (Benghiat, Saunders, & Steele, 1999). Moreover, computer systems support collaboration between patients and health care providers in the area of symptom management (Goldsmith, McDermott & Safran, 2004).

One of the most widely discussed issues among health informatics professionals is the Electronic Patient Record (EPR), also referred to as Electronic Health Record (EHR). EPR is an indicator of the progress in health informatics domain and allows health providers, patients, and payers to interact more efficiently and in life-enhancing ways. It offers new methods of storing, manipulating, and communicating various types of medical information, and is thus characterized as more powerful and flexible compared to paper-based systems. EPR systems are not usually stand-alone, but enhance a variety of add-on components according to the specific requirements of each environment.

In the past, many patient record systems were developed to provide oncology staff with a key infrastructure requirement in information management that is essential to maintain efficient and effective health care (Chamorro, 2000).

In order to embody computers in daily clinical practise and provide qualitative health care to cancer patients, we have developed a computerized system. It consists of three modules: the EPR Module, the Image Archive Module, and the Lab Module. These modules are tightly integrated through the EPR Module that works as the main platform of the system. The system administrator is responsible for the secure system operation and for the users training as well. The system and the users involved are briefly presented in Figure 1.

SYSTEM MODULES

EPR Module

The core of this computerized system is the Electronic Patient Record Module (EPR Module). EPR Module is a relational database, which is accessed by the end users through a friendly interface. EPR data include clinical results (laboratory results, clinical outcome) and physician/patient care orders (orders, requisitions, consultations). It also includes administrative data such as admitting diagnosis, patient location, and follow-up appointments. All EPR data are linked to a unique Patient Record Number (PRN). Data are captured at all stages of patient care, from diagnosis to treatment and follow-up. The EPR Module is used further to produce reports, organize data, and provide immediate feedback.

Data are retrieved from the database using various forms. First of all, there is a welcome screen with a few command buttons that allow users to navigate to the other forms. An example is depicted in Figure 2. In this form, the user is able to navigate through a variety of patients' data (e.g., diagnosis, type of diagnosis) and view the other EPR forms (e.g., "Therapies" form) by clicking on the corresponding button. Additionally, there are search and printing options available.

The Unit secretary is responsible for data entry, under the guidance of the supervising doctor. The data source is the existing paper-based record, which is kept in the Oncology Unit. As shown in Figure 2, the data amount imported in each form is small enough and the included information is well organized. The main idea is that the EPR Module should not be a copy of the paper-based record but a summarized description of patient's status.

Figure 2. Part of EPR module. User is able to enter various data (personal data, diagnosis, type of diagnosis, symptoms, etc.) through a friendly interface.

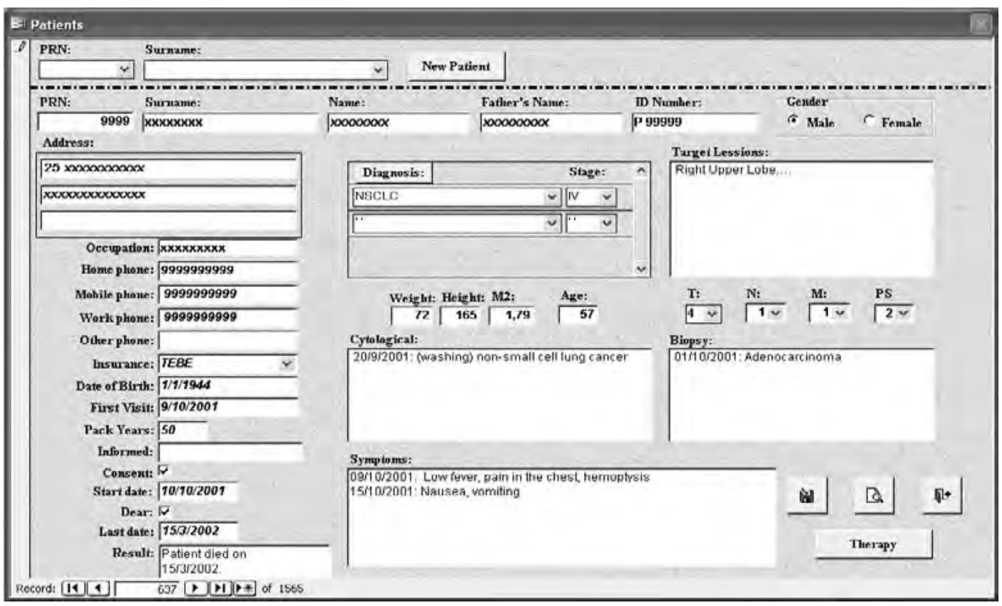


Image Archive Module

The need that led to the development of the Image Archive Module was the reduction in the volume of images, in order to free space in the Unit's archive. This module archives two categories of images, the digital and the film-based ones.

The first category consists of digital images (computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET)) that patients deliver to the Unit immediately after their acquisition. Because there is no need for further process, these images are stored in the archive at once. The film-based have to be digitized and then imported in the Archive Module. For this task a film digitizer (Kodak LS40) is used. The images of each patient are stored according to his PRN and can be accessed through the EPR Module.

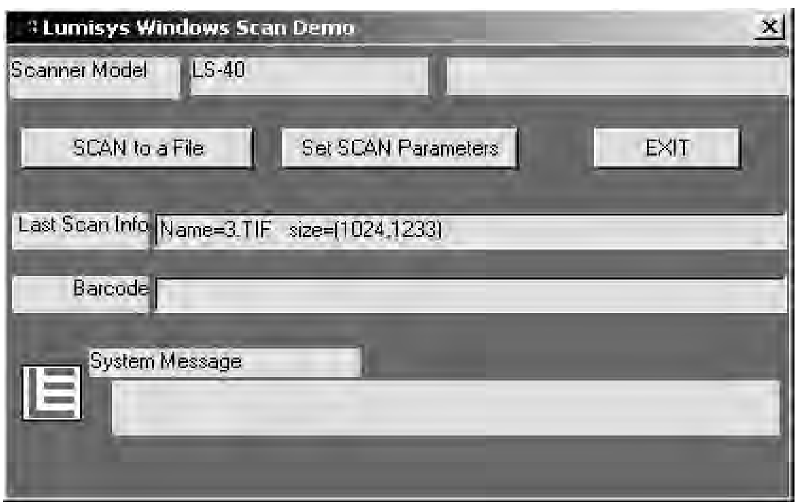
The software program that controls the digitization process is presented in Figure 3. The user sets the scan parameters (image analysis, image format, etc.), selects the archive file, and scans the films. In case of a problem during the scan process, the system produces an error message and the process is interrupted. A success message is produced only after the successful accomplishment of all the appropriate sequences required of an image digitization process. This program produces images in either DICOM or TIFF format. In our study, DICOM format was used. The DICOM images of each patient are further integrated into the EPR Module.

Lab Module

The Lab Module is a simple relational database that stores information about the patient blood samples that are kept in the laboratory. Additionally, it stores data about the patient chemotherapies (cycle, disease, etc.) that need to be kept along with each blood sample. As in the other two modules, all records are stored according to PRN and can be accessed through EPR. Lab Module is very useful, not only for the biologists, but also for the physicians who are in charge of research projects.

The user is able to perform simple and advanced searches for samples, depending on predefined or chosen criteria. Moreover, various reports are produced according to the given criteria.

Figure 3. Image digitizing. User sets the parameters and then scans the film-based images.



Users

Key physicians, biologists, and administrative personnel are involved in data entry and data management in all modules.

Specially trained administrative personnel extract data from paper-based records and subsequently insert them into the EPR Module. Data entry is performed on a daily basis; when a patient leaves the Oncology Unit, his personal record (paper and electronic) is updated the same day or the day after. Physicians verify the extracted data and control the whole process for its reliability. Regarding the Image Archive Module, secretaries perform image digitization using the Kodak LS40 film digitizer. They simply pass the films to the digitizer and save the image files in the archive. Finally, biologists are responsible for data entry in the Lab Module.

The system administrator who is a health informatics specialist is responsible for the flawless functioning of the entire system and is also confronted with the training of the staff.

Security Strategies

Every threat that violates the security of the health care data is carefully controlled using a set of security strategies. The reported strategies could be summarized as follows:

- All modules are password protected.
- There are various levels of authorization corresponding to each kind of user; for example, biologists are not made aware of patient names because all patient data are linked to the PRN.
- The user login and interventions to the system are recorded.

Apart from these strategies, additional actions are taken for other security aspects. The recorded data are backed up at the end of each week and the equipment is locked when it is not in use.

DISCUSSION

In the oncology field, computers may offer great help in data recording and in supporting the clinicians during the therapy process. The collected data are suitable not only for patient care, but also for quality assessment, research, and management. In order to achieve these goals, the best data management should be assured. This need is quite obvious in an Oncology Unit, which is a demanding environment with continuous information overflow and increased pressure for immediate decisions.

Apart from EPR systems, many other computer applications have been developed in the oncology field. A pilot study provided Internet lessons to oncology patients and family members to contribute in a timely fashion to the well being of the patients (Edgar, Greenberg, & Remmer, 2002). Furthermore, various programs attempted either to establish clinical screening programs for the quality of life of cancer patients (Carlson & Bultz, 2003), or to report their psychosocial functioning (Allenby, Matthews, Beresford & McLachlan, 2002).

There are many reasons for using computerized systems in oncology that mainly deal with the quality and efficiency of care. First of all, when using a computer system, voluminous amounts of easily retrievable and analyzed data can be stored. The access to structured and well-organized data offers the health care professionals a better insight into the patient's condition, which leads to improved treatments. Moreover, the data collected in a computerized system can be easily used for research purposes.

However, the paper-based data management is still a reality in clinical practice. Many hospitals retain paper-based records as the main source of patient data. This is also the case for Sotiria General Hospital, where the Oncology Unit is established. As a result and in order to assure the completeness and accuracy of the EPR Module, many data are entered from these paper-based records.

It is true that the modern radiological equipment yields images in digital form, but the time of film-based radiology has not yet come to an end. Additionally, although the application of PACS (Picture Archiving and Communication Systems) is spreading, it is not always possible to access them. Moreover, image procedures (CT, MRI, PET) do not take place at the same radiologist location for all patients. Usually, each patient carries his images when visiting a hospital, then delivers them to his physician and, finally, the images are stored at the clinic's archive.

The situation described above causes the enlargement of image volume and leads to storing and accessing problems. Even though the Oncology Unit had a well-organized film-based image archive, we faced these two problems in a very short period of time. Consequently, the Image Archive Module was developed for two purposes: the reduction of images volume and the ease of access to stored images. Because all images are stored in the Image Archive Module, there is no reason to keep them in both formats (digital and film-based). After their storage, the patient receives the original images and keeps them in his personal record. The

laboratory is one of the first areas in health care where computers were introduced. Computers support the entire process, from sample collection to final report generation and validation. Apart from this process, oncology laboratories perform additional tasks. The most important task is the storage of patient samples at low temperatures (-80 ^{o}C or -20 ^{o}C) for future analysis. The numerous samples have to be well-organized in order to avoid changing or losing them. The Lab Module maintains data about the patient blood samples that are stored in the laboratory. The basic advantage of this module is that it offers the possibility for immediate access to specific samples, by using the search facilities of the module. Moreover, the user is able to categorize samples according to patients' disease or other specific research-targeted criteria.

At this point, it should be mentioned that all users are able to access the modules through the local network. Even though each module serves different purposes, they all work in one. More specifically, through the EPR Module, the user is able to access each patient's images and blood sample information.

Prior to this system development, most of the hospital employees did not have the opportunity to involve computers in their daily practice. Considering this, we used existing technologies to help staff members and offer them the possibility to work and interact with a system based on the Unit's specific needs. Naturally, at the beginning several staff members faced difficulties in using the system, because they were not familiar with computers. This problem was resolved after the daily training and the systematic use of the system modules.

Moreover, user satisfaction is an important aspect and is highly correlated to the system layout (Sittig, Kuerman & Fiskio, 1999). The screen design was based on simple and user-friendly methods governed by the principle that users had to type as less as possible. In order to measure user satisfaction, an evaluation method should be followed, such as the distribution of a well-tested questionnaire. Nevertheless, we decided not to perform a thorough analysis of users' satisfaction, but to briefly evaluate it through the daily practice and the reported problems.

The widespread application of computers increases the accessibility of data, especially when various techniques are applied. Unauthorized use of data is not an illusory danger. Therefore, the access to these data must be regulated. The fact that only authorized users should have access to the data is a logical consequence of the right to privacy. The privacy sensitivity of data is strongly context dependent. Data on various diseases are often considered to be extremely sensitive and oncology data are categorized as such. In our case, data security and patient confidentiality policies were followed to assure the maximum level of system reliability.

In order to reduce the threats concerning data confidentiality, integrity, and availability, some basic methods were used. Regarding confidentiality, all modules are password-protected. The passwords are changed often by the system administrator and are available only to the involved users. Moreover, the equipment (computers, scanner) is under close surveillance and locked when not used, in order to assure physical security. Concerning integrity, data are regularly backed up at the end of the week. Doubtless, database modules enhance various security mechanisms for referential, logical, and entity integrity. For example, each patient receives a unique Patient Record Number (PRN) to avoid duplicate values.

The patients and their families are not actively involved in the system processes, but their role as a data source remains crucial. It is important to note that they are informed that their data are stored in the Unit's system and that it is possible to request a copy for their own use. The data stored in the system are not used for research purposes or published without the patients' permission. It is important to note that extremely sensitive patient data (e.g., DNA), are not stored in the Unit's system in any format. Any sensitive data used for research purposes (research studies, clinical trials) are collected and stored elsewhere as specified per protocol.

Altogether, oncology is often practiced in a quite demanding environment, but not only in the health sector. Doubtless, there are many hospital departments that could benefit from the experience gained using the system described here. For this purpose, the Oncology Unit has already presented its experience to the local staff at Sotiria Hospital and to the public at Med-e-tel Conference (Luxembourg, 5-7 April 2006). The Unit's future plans include close collaboration with organizations or departments eager to share their vision and exchange information with the Unit.

Regarding images, it is obvious that as cost-effective storage media capacity increases, so will the temptation to store all images digitally. Moreover, the extraction of the appropriate data not only improves health care but also saves time in physicians' daily practice. As a result, the Oncology Unit invests the saved working hours in other activities without spending extra funds. Apparently, the economic impact of the described computerized approach is very important.

CONCLUSION

Despite the remarkable barriers to adoption, the use of computers is growing. A variety of health care applications are developed in order to cover the demands of the new era. It is obvious that the Health Informatics field is growing very quickly and some health care areas, such as oncology, may gain important benefits from the implementation of appropriate computerized and digitized systems.

Using the current version of the developed system as an example, we intend to manage patient data in a more beneficial way. Consequently, the collected data could be used in other applications as well. For example, the digitized images could be processed and studied further. Additionally, a quality of life measurement system with immediate feedback of results to clinicians could be developed, as in the Velikova, Brown, Smith, and Selby (2002) study.

Generally, the field of oncology demands new computerized ways of data management. It is clear that computerized systems may open up unexpected paths to new directions in future practice and research.

ACKNOWLEDGMENT

We would like to thank Valsamo Anagnostou, MD, for her assistance in article revision and the helpful comments of the anonymous reviewers to improve the quality of the original version of this article.

Chapter 3.6
Artificial Intelligence Techniques in Medicine and Healthcare

Rezaul Begg
Victoria University, Melbourne, Australia

INTRODUCTION

Now-a-days, researchers are increasingly looking into new and innovative techniques with the help of information technology to overcome the rapid surge in healthcare costs facing the community. Research undertaken in the past has shown that artificial intelligence (AI) tools and techniques can aid in the diagnosis of disease states and assessment of treatment outcomes. This has been demonstrated in a number of areas, including: help with medical decision support system, classification of heart disease from electrocardiogram (ECG) waveforms, identification of epileptic seizure from electroencephalogram (EEG) signals, ophthalmology to detect glaucoma disease, abnormality in movement pattern (gait) recognition for rehabilitation and potential falls risk minimization, assisting functional electrical stimulation (FES) control in rehabilitation setting of spinal cord injured patients, and clustering of medical images (Begg et al., 2003; Garrett et al., 2003; Masulli et al., 1998; Papadourokis et al., 1998; Silva & Silva, 1998).

Recent developments in information technology and AI tools, particularly in neural networks, fuzzy logic and support vector machines, have provided the necessary support to develop highly efficient automated diagnostic systems. Despite plenty of future challenges, these new advances in AI tools hold much promise for future developments in AI-based approaches in solving medical and health-related problems. This article is organized as follows: Following an overview of major AI techniques, a brief review of some of the applications of AI in healthcare is provided. Future challenges and directions in automated diagnostics are discussed in the summary and conclusion sections.

ARTIFICIAL INTELLIGENCE TECHNIQUES

There have been a number of artificial intelligence (AI) tools developed over the past decade or so (cf., Haykin, 1999; Keckman, 2002). Many of these have found their applications in medical and health-related areas. Commonly applied AI techniques can be listed as:

- Neural networks
- Fuzzy logic
- Support vector machines
- Genetic algorithms
- Hybrid systems

In the following, we give a brief overview of neural networks, fuzzy logic and the relatively new support vector machines.

Neural Networks

Artificial neural networks work much like the human brain and have the ability to learn from training data and store knowledge in the network. In the learning phase, it maps relation between inputs and the corresponding expected outputs. During the learning phase, knowledge is acquired and stored in the network in the form of synaptic weights and biases. This knowledge is used to make future predictions in response to new data or inputs during the testing phase. Usually, the network has one input and one output layer, and one or more hidden layers depending on the complexity of the problem. Learning can be supervised; that is, the network is provided with both the inputs and their desired outputs during the leaning process, or it can be unsupervised or self-organizing learning. There are a number of learning algorithms available (Haykin, 1999), and among them back-propagation learning algorithm is the most widely used. In this method, an error signal based on the difference between network-generated output (g_i) and desired output (d_i) is propagated in the backward direction to adjust the synaptic weights according to the error signal. During the learning process, the aim is to minimize an objective function such as the mean-squared error (E),

$$E = \frac{1}{n}\sum_{i=1}^{n}(d_i - g_i)^2$$

Neural networks are frequently used as diagnostics, and therefore it is important to have good generalization ability, that is, good performance in predicting results in response to unseen data. One limitation of neural networks is the possibility of being stuck in local minima during training rather than converging to the global minimum. To overcome this the network is usually trained several times with random initial weights to avoid converging to the local minima. Neural networks have found the majority of their applications in pattern recognition, time-series prediction, signal processing and financial forecasting.

Fuzzy Logic

Fuzzy sets were introduced by Zadeh (1965), and they deal with imprecise and uncertain information or data. Naturally, this has been found suitable for many medical and health-related problems, as it relates to the way humans think. Since the early work of Zadeh, there has been an exponential rise in the number of scientific papers applying fuzzy sets in biology, medicine and psychology areas (Teodorescu et al., 1998).

Support Vector Machines

Support vector machines are a relatively new machine learning tool and have emerged as a powerful technique for learning from data and solving classification and regression problems. This has been particularly effective for binary classification applications. SVMs originate from Vapnik's statistical learning theory (Vapnik, 1995). SVMs perform by nonlinearly mapping the input data into a high dimensional feature space (by means of a kernel function) and then constructing a linear optimal separating hyperplane by maximizing the margin between the two classes in the feature space.

For m training data with input-output pairs $(y_1,\boldsymbol{x}_1),\ldots,(y_m,\boldsymbol{x}_m)$ where each input data $\boldsymbol{x}_i \in \Re^N$ belongs to a class $y_i \in \{-1,+1\}_{i=1,\ldots,m}$, the decision function for a new data ($\boldsymbol{x}_i$) can be given by the sign of the following function (Gunn, 1998):

$$f(x) = sign(\sum_{i \in SVs} \alpha_i y_i K(x_i, x) + b)$$

where, a_i is a nonnegative Lagrange multiplier corresponding to $\boldsymbol{x}_i$, $K(.)$ is a kernel function and b is the bias. The Lagrange multipliers are obtained as the solution of a convex quadratic programming problem. The data points $\mathbf{x}_i$s corresponding to a_i>0 are called support vectors. Such $\boldsymbol{x}_i$s are the only data points in the training set relevant to classification since the decision surface is expressed in terms of these points alone (support vectors, SV). For linearly separable problems, the number of SVs and the hyperplane are determined by a subset of the training set only. For nonlinearly separable problems, a_i in SVs are constrained by an upper bound C, which is regarded as a regularization parameter. This parameter makes a trade-off between margin maximization and minimization of classification errors in the training data set (Gunn, 1998).

Hybrid Systems

Recently, researchers have started looking into ways of combining various AI tools in order to maximize performance of the AI system. The main idea behind this is to offset limitation of one system by cascading with another AI tool. As a result, hybrid systems like Neuro-Fuzzy (neural networks and fuzzy logic), Neuro–SVM (neural networks and support vector machines) and Fuzzy-SVM (fuzzy logic and support vector machines) systems have evolved. Hybrid systems have been applied in many applications, including some biomedical areas (Teodorescu et al., 1998).

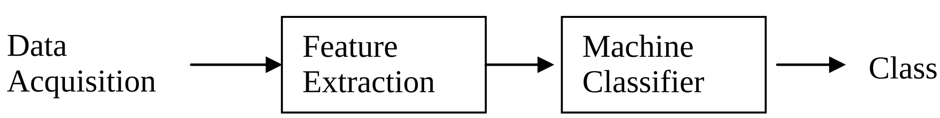
APPLICATIONS IN HEALTHCARE AND MEDICINE

In addition to applications in medical diagnostic systems, AI techniques have been applied in many biomedical signal-processing tasks, including analysis of ECG, EEG and human movement data (Nazeran & Behbehani, 2001). Neural network models have played a dominant role in a majority of these AI-related applications in health and medicine. Many of these applications are for pattern recognition or classification. A typical classification application usually has a number of steps or procedures as shown by the flow diagram (see Figure 1). This involves feature extraction from the input data before feeding these features to the classifier for designing and developing automated classification models, and finally testing the models for generalization.

Medical Decision Support Systems

Medical decision support systems (MDSS) are designed to construct a knowledge database by way of receiving a list of symptoms as input features and their corresponding disease type(s) as the output. Such a developed symptom-to-disease mapping system then facilitates the diagnostic process by generating new responses due to a new set of symptoms. Neural networks have been used to aid MDSS. Silva and Silva (1998) developed such a neural network-based MDSS system for

Figure 1. Stages of a typical pattern recognition task



a relatively small set of 20 randomly selected diseases and reported encouraging results. Disease symptoms in this study were represented as sinusoidal damped waveforms. Hybridization has been shown to improve diagnostic accuracy. For example, Dumitrache et al. (1998) reported an improvement in accuracy (by 28%) for medical diagnosis in cardiac disease using a hybrid decision-making system compared to a classical expert system.

Cardiology

Several studies have applied neural networks in the diagnosis of cardiovascular disease, primarily in the detection and classification of at-risk people from their ECG waveforms (Nazeran & Behbehani, 2001). Celler and Chazal (1998) have applied neural networks to classify normal and abnormal (pathological) ECG waveforms: 500 ECG recordings (155 normal and 345 abnormal) were used to extract features from the QRS complex for training and testing the classifier. The abnormal ECG recordings had six different disease conditions. The classifier was able to recognize these waveforms with 70.9% accuracy.

Electroencephalography

AI tools, including neural networks, fuzzy clustering and SVMs, have been shown to be useful for analyzing electrical activity of the brain, the electroencephalogram (EEG) signals. Features extracted from EEG recordings of the brain have been used with AI tools for improving communication between humans and computers and also for effective diagnosis of brain states and epileptic seizures (Garrett et al., 2003; Geva & Kerem, 1998; Nazeran & Behbehani, 2001).

Opthalmology

Neural networks have been shown to be an effective diagnostic tool to identify glaucoma disease. Glaucoma is more prevalent in older age and can cause loss of vision. Papadourokis et al. (1998) applied backpropagation neural network to classify normal patients and patients with glaucomatic optic nerve damage from perimeter examination. Several neural network models were tested using 715 cases, including 518 glaucoma cases, and they reported 90% recognition accuracy with two hidden layer networks and training with 80% of the input data. In an effort to compare effectiveness of different AI techniques in recognizing glaucoma diagnosis, Chan et al. (2002) used standard automated perimetry data to compare classification performance of several classifiers including multiplayer perceptron and support vector machines (SVM). In-depth analysis of performance of these classifiers was carried out using areas under the receiver operating characteristic (ROC) curves and also sensitivity (true positive rates) and specificity (1 - false positive rates) measures. Machine classifiers were found to perform superiorly in the classification tasks, whereas SVM showed significantly improved performance compared to a multiplayer perceptron. A self-organizing fuzzy structure has also been developed and applied to predict the onset of hypoglycemia for diabetic patients (Hastings et al., 1998).

Gait Analysis and Rehabilitation

Gait is the systematic analysis of human walking. Various instrumentations are available to analyze different aspects of gait (cf. Begg et al., 1989). Among its many applications, gait analysis is being increasingly used to diagnose abnormality in lower limb functions, and also to assess the progress of improvement as a result of treatments and interventions. Recently, neural networks and fuzzy logic techniques have been applied for gait pattern recognition and clustering gait types. Barton and Lees (1997) classified gait patterns based on hip-knee angle diagrams and Holzreiter and Kohle (1993) used neural network models to identify normal and pathological gait patterns from measurements of foot-to-ground reaction forces using force platforms. Wu et al. (1998) applied a back propagation neural network to classify gait patterns of patients with ankle arthrodesis and normal subjects, and reported a superior classification by the neural networks compared to statistical technique (linear discriminant analysis) (98.7% vs. 91.5%). Gait analysis is being increasingly used in rehabilitation settings, and also combining with AI techniques to improve gait control and functionality. Tong and Grant (1998) applied neural networks to optimize sensor sets for control of FES system in people with spinal cord injury and showed improvements in accuracy as a result of neural network aided control. Fuzzy logic has also been recently applied with great success in: clustering children gait with and without neurological disorder (O'Malley, 1997) and also detection of gait events such as the foot contact and take-off during walking in the analysis of paraplegic gait (Skelly & Chizeck, 2001).

Support vector machine (SVM) has recently been applied to classify young and elderly gait patterns (Begg et al., 2003). Gait changes with aging, with potential risks of loss of balance and falls. Recognizing gait patterns with potential falls risks would help to detect at-risk people so that rehabilitation programs could be undertaken to minimize the risk of falls. AI techniques such as neural networks and SVMs have demonstrated their potentials for detecting gait degeneration due to aging and appear to have potential applications in falls prevention in the elderly.

SUMMARY AND FUTURE TRENDS

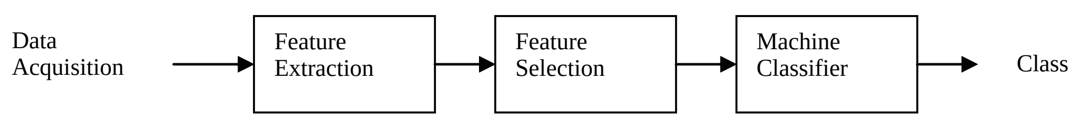
There are plenty of future challenges for AI to be routinely used in medicine and health. The use of automated medical decision support system in routine use in the clinic would make a significant impact on our healthcare system.

One possibility is that healthcare in the future will be built on knowledge networks (Erlandson & Holmer, 2003). Applications of telemedicine and informatics in healthcare can help to provide support to patients in remote areas, and to share expert knowledge or limited resources. Furthermore, effective networking between informatics and biomedical engineering can also help to complement each other's knowledge and to fight in partnership the various challenges faced by the medical and healthcare systems.

One major aim of a classification task is to improve its recognition accuracy or generalization performance. Selecting features that offer the most discriminatory information between the classes or medical groups could help to improve classification accuracy. At the same time, removing redundant features might also improve the medical recognition task. It has been demonstrated in a number of studies that selecting a small number of good features in fact improves the recognition accuracy (Begg et al., 2003; Chan et al., 2002; Yom-Tov & Inbar, 2002), in addition to the added advantages of classifier simplicity and fast processing time. Therefore, a pattern recognition task may be improved by decomposing it into the following stages (see Figure 2).

Recently hybrid systems are emerging, combining various AI tools with improved performance in medical diagnosis and rehabilitation.

Figure 2. Stages of a pattern recognition task involving "feature selection" sub-task



Application of hybrid systems in medical diagnosis has already provided increased efficiency in diagnosis of cardiac disease by as much as 28% compared to classical expert system. This and other applications provide much hope and encouragement for more future applications based on hybridization of AI systems in helping to solve problems in medicine and healthcare.

CONCLUSION

Artificial intelligence, particularly neural networks, fuzzy logic and the recently introduced support vector machines, played a key role over the years for many important developments in medicine and healthcare. Despite such developments there are many future challenges and currently only a few AI-based systems are routinely used in the clinical setting. Continued developments in AI fields are providing much impetus that is needed to tackle the many problems of the healthcare system.

KEY TERMS

ECG: The electrical activity of the heart recorded from the body surface using electrodes as electrical potential is known as electrocardiogram or ECG.

EEG: The electrical activity of the brain recorded from the scalp as electrical potential is known as electroencephalogram or EEG.

Fuzzy Logic: The concept of fuzzy logic is that many classes in the natural environment are fuzzy rather than crisp. It deals with imprecise and uncertain data.

Gait Analysis: Analysis of human walking patterns. It is used to analyze abnormality in lower limb problems and assess treatment or intervention outcomes.

Hybrid Systems: Integration of two or more artificial intelligence tools to improve efficiency or system performance.

Neural Networks: Neural networks resemble the human brain and able to store knowledge during training and use this for decision making during testing phase.

Support Vector Machines: Introduced by Vapnik and capable of learning from data for solving classification and regression problems.

This work was previously published in Encyclopedia of Information Science and Technology, Vol. 1, edited by Mehdi Khosrow-Pour, pp. 157-162, copyright 2005 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).

Chapter 3.7
PDA Usability for Telemedicine Support*

Shirley Ann Becker
Florida Institute of Technology, USA

INTRODUCTION

Telemedicine is broadly defined as the use of information and communications technology to provide medical information and services (Perednia & Allen, 1995). Telemedicine offers an unprecedented means of bringing healthcare to anyone regardless of geographic remoteness. It promotes the use of ICT for healthcare when physical distance separates the provider from the patient (Institute of Medicine, 1996). In addition, it provides for real-time feedback, thus eliminating the waiting time associated with a traditional healthcare visit.

Telemedicine has been pursued for over three decades as researchers, healthcare providers, and clinicians search for a way to reach patients living in remote and isolated areas (Norris, 2001). Early implementation of telemedicine made use of the telephone in order for healthcare providers and patients to interact. Over time, fax machines were introduced along with interactive multimedia, thus supporting teleconferencing among participants. Unfortunately, many of the early telemedicine projects did not survive because of high costs and insurmountable barriers associated with the use of technology.

Telemedicine has been resurrected during the last decade as a means to help rural healthcare facilities. Advances in information and communications technology have initiated partnerships between rural healthcare facilities and larger ones. The Internet in particular has changed the way in which medical consultations can be provided (Coiera, 1997). Personal computers (PCs) and supporting peripherals, acting as clients, can be linked to medical databases residing virtually in any geographic space. Multimedia data types, video, audio, text, imaging, and graphics promote the rapid diagnosis and treatment of casualties and diseases.

Innovations in ICT offer unprecedented healthcare opportunities in remote regions throughout the world. Mobile devices using wireless connectivity are growing in popularity as thin clients that can be linked to centralized or distributed medical-data sources. These devices provide for local data storage of medical data, which can be retrieved and sent back to a centralized source when Internet access becomes available. Those working in nomadic environments are connected to data sources that in the past were inaccessible due to a lack of telephone and cable lines. For the military, paramedics, social workers, and other healthcare providers in the field, ICT advances have removed technology barriers that made mobility difficult if not impossible.

Personal digital assistants (PDAs)[1] are mobile devices that continue to grow in popularity. PDAs are typically considered more usable for multimedia data than smaller wireless devices (e.g., cell phones) because of larger screens, fully functional keyboards, and operating systems that support many desktop features. Over the past several years, PDAs have become far less costly than personal-computing technology. They are portable, lightweight, and mobile when compared to desktop computers. Yet, they offer similar functionality scaled back to accommodate the differences in user-interface designs, data transmission speed, memory, processing power, data storage capacity, and battery life.

BACKGROUND

Computing experts predicted that PDAs would supplant the personal computer as ubiquitous technology (Chen, 1999; Weiser as cited in Kim & Albers, 2001). Though this has not yet happened, PDA usage continues to grow with advances in operating systems, database technology, and add-on features such as digital cameras. They are being used in sales, field engineering, education, healthcare, and other areas that require mobility. In the medical field, for example, they are being used to record and track patient data (Du Bois & McCright, 2000). This mobility is made possible by enterprise servers pushing data onto these devices without user intervention. Enterprise servers are also capable of pulling data from a localized (PDA) database such that centralized data sources are readily updated.

A PDA synchronizes with laptops and desktop computers, making data sharing transparent. This is made possible by a user interface and functionality that are compatible in terms of computing capabilities and input and output devices (Myers, 2001). Compatibility is a major issue in telemedicine given that medical and patient data gathered or stored on a PDA is typically sent to a centralized data source. Nomadic use of PDAs mandates this type of data integration whether it is real-time or batched data when wireless connectivity is temporarily inaccessible (Huston & Huston, 2000). In addition, telemedicine data sharing is typically asymmetric in that the enterprise server transmits a larger volume of medical data to the PDA. In turn, the PDA transmits only a small volume of patient data to the server (Murthy & Krishnamurthy, 2004).

Though PDAs hold great promise in promoting healthcare in remote regions, the usability of these devices continues to be an issue. There are physical constraints that typically do not apply to a laptop or desktop computer (Table 1 describes these constraints). The user interface of a PDA is modeled after a desktop environment with little consideration for physical and environmental differences (Sacher & Loudon, 2002). Yet, these differences are significant in terms of usability given the small screen and keyboard sizes and limited screen resources in terms of memory and power reduction (Brewster, 2002).

There has been important research on PDA usability, primarily in the effective use of its limited screen area. Early research focused primarily on the display of contextual information in order to minimize waste of the screen space while maximizing content (Kamba, Elson, Harpold, Stamper, & Sukariya as cited in Buchanan, Farrant, Jones, Thimbleby, Marsden, & Pazzani, 2001). More recent efforts are taking into account not only screen size, but navigation, download time, scrolling, and input mechanisms (Kaikkonen & Roto, 2003).

Table 1. User-interface design constraints for PDA devices (Paelke, Reimann, & Rosenbach, 2003)

Limited resolution	Typical resolution of a PDA is low (240*320 pixels). This impacts the visibility of content, objects and images.
Small display size	The small screen size of a PDA limits the number of objects and the amount of text on a screen page. This limitation impacts design layout in terms of font size, white space, links, text, images, and graphics, among others.
Navigational structure	Navigation is impacted by the increased number of screen pages required to accommodate text and objects that on a desktop or laptop would fit on one screen page. Design choices include a long page with a flat navigation hierarchy versus the design of multiple short pages with a deeper navigational hierarchy.
Limited use of color	A PDA uses a gray scale or a color palette limited to several thousand color choices (compared to millions of color choices for desktop applications). Readability and comprehension may be impacted when color is used to relay information or color combinations are insufficient in contrast.
Limited processing power	Limited processing power impacts the quality of graphical displays and imaging. It also restricts the use of interactive real-time animation.
Mouse is replaced with stylus pen	A PDA does not use a mouse, which has become a standard peripheral in a desktop environment. As a result, there is a learning curve associated with the use of a stylus pen, which replaces mouse functionality.
Small keyboard size	The PDA keyboard size and layout impacts data entry. As a result, it is more difficult for users to entered lengthy and complex medical data in a real-time environment.

PDA USABILITY AND TELEMEDICINE

An important finding of usability research associated with mobile technology is the need for usability testing beyond a simulated environment. Waterson, Landay, and Matthews (2002), in their study of the usability of a PDA, found that usability testing should include both content and device design. Chittaro and Dal Cin (2002) studied the navigational structures of mobile user interfaces. Their research also identified the need for actual devices to be used in usability testing. Real-world constraints would take into account screen-size and page-design issues, date entry using a built-in keypad, wireless accessibility, data transmission speeds, visual glare, background noise, and battery power, among others.

Our initial findings also reflected the need for usability testing in the telemedical environment in which technology is used. We initiated research on the use of PDAs for monitoring diabetic patients living in remote regions of the United States (Becker, Sugumaran, & Pannu, 2004). Figure 1 illustrates one of our user-interface designs for the Viewsonic® PocketPC. This screen shows part of a foot form completed by a healthcare provider during a home visit. The data entered by the user is stored in a local database that can be transmitted wirelessly to an enterprise server.

The PocketPC is used in this research because of its low cost and its support of relational database technology. It has a built-in digital camera, which is important because of the physical distance between a patient and a healthcare facility. Images of foot sores are taken during a home visit and stored in the local database residing on the PDA. These images become part of the patient's history when transmitted to the enterprise server. Later, the images can be viewed by a clinician for the timely diagnosis and treatment of the sores.

Our research has shown the technical feasibility of using PDA technology to gather data in the

Figure 1. PDA used to gather data about a diabetic patient's foot health

field during a home visit. However, more research is needed to address usability issues uncovered during the use of the PDA during simulated home visits. A significant finding in the use of PDA technology is that usability is tightly integrated with the technological challenges associated with it. One such challenge is the heavy reliance on battery power when PDAs are deployed in the field. When the battery no longer holds a charge, critically stored relational data may be irretrievable due to pull technology used to transmit data from a local source to a central one.

As part of this research, the usability of multimedia data formats is being studied to improve information access in a nomadic environment. For rapid diagnosis and treatment of casualties, multimedia data formats may prove critical. In our work, images are being used to replace textual descriptions that would consume valuable screen space. Figure 1 illustrates this concept of using color codes to represent physical areas of the foot. As such, foot problems can be reported for each area by clicking on the list appearing on the right side of the screen. Audio capabilities are also being explored in providing helpful information that otherwise would be text based. Both of these multimedia capabilities are in the design phase and will be tested in future field studies.

FUTURE TRENDS

Table 2 identifies research opportunities associated with the use of PDAs in telemedicine. Much of what has been done in this area has focused on tracking patient histories. However, there are significant opportunities for real-time data retrieval and transmission using PDA technology. Clinicians could use a PDA, for example, to send prescriptions to pharmacies, receive lab reports, and review medical data for the diagnosis and treatment of patients. These devices could also be used to minimize human error associated with more traditional mechanisms of recording patient data.

There are infrastructure challenges associated with the use of telemedicine in terms of technology acceptance and utilization. Chau and Hu (2004) point out that although telemedicine is experiencing rapid growth, there are organizational issues pertaining to technology and management. It is critical that organizational support is available throughout the implementation stages of tele-

Table 2. Telemedicine research opportunities using PDA technology (Wachter, 2003)

Diagnosis and Treatment	Mobile decision support software would allow for data entry of patient symptoms with output providing a diagnosis and treatment plan.
Patient Tracking	Synchronizing a PDA with a hospital's centralized data source would allow vital signs and other information to be gathered in real-time at the point of care. A clinician would have the capability of obtaining lab reports and test results once they have been entered into the system.
Prescriptions	A PDA would be used by a clinician to send a patient prescription to a pharmacy. This would minimize human error associated with interpreting handwritten prescriptions. It would also provide a centralized tracking system in order to identify drug interactions when multiple prescriptions for a patient are filled.
Medical Information	Clinicians would have access to information on medical research, drug treatments, treatment protocols, and other supporting materials. According to Wachter (2003), a leading clinical PDA technology vendor has converted more than 260 medical texts into PDA formats thus supporting this effort.
Dictation	PDAs support multimedia data including audio, images, and text. As such, clinicians would have an opportunity to record multimedia patient data directly linked to patient history data in a centralized source.
Charge Capture	Data entry into a PDA that is transmitted to a centralized source would provide the means for efficient billing of medical charges to a patient.

medicine. Past experience in the use of ICT with no infrastructural support resulted in failure. The effective management of telemedicine systems and supporting technologies is needed to address barriers to ICT acceptance by healthcare personnel and patients. As such, there are research opportunities in the organizational acceptance and use of PDAs in a telemedical environment.

Security, safety, and social concerns have also been identified by Tarasewich (2003) as research challenges in the use of mobile technology. Though encryption and other security technologies can readily be used during the transmission of data, there remains the issue of security associated with lost or stolen PDAs. Given the memory, data storage, and other technological constraints of a PDA, research is needed on developing security mechanisms for localized data. Research is also needed on ensuring localized data remains private and is accessible only by authorized personnel.

CONCLUSION

The exponential growth of wireless and PDA technologies has brought unprecedented opportunities in providing managed healthcare. For the military and others working in nomadic environments, PDA technology offers the capability for rapid diagnosis and treatment of casualties. Regardless of location, healthcare personnel could be provided with real-time access to reference materials, patient lab reports, and patient history data.

Though there is great promise in the use of PDAs for providing telemedical services, there is research needed in the usability of these devices. Multimedia data formats offer alternative interfaces to accessing data, and research is needed to assess their impact on ease of use and understandability. In addition, technological constraints need to be studied in terms of their impact on device usability. Memory, data storage, transmission speeds, and battery life need to be considered as part of usability testing to assess the impact on rapid medical diagnosis and treatment.

There is a major challenge of moving from traditional medical services and resources to an environment that promotes PDA technology and telemedicine. The potential benefits are great in terms of ubiquitous helth care with no time or space constraints. However, widespread acceptance of PDA technology in a telemedical environment will only become achievable through the design of usable interfaces.

KEY TERMS

Compatibility: The ability to transmit data from one source to another without losses or modifications to the data or additional programming requirements.

Interoperability: The ability of two or more systems or components to exchange information and to use the information that has been exchanged (Institute of Electrical and Electronics Engineers [IEEE], 1990).

Peripheral Devices: Hardware devices, separate from the computer's central processing unit (CPU), which add communication or other capabilities to the computer.

Personal Digital Assistant (PDA): A personal digital assistant is a handheld device that integrates computing, telephone, Internet, and networking technologies.

Telecare: The use of information and communications technology to provide medical services and resources directly to a patient in his or her home.

Telehealth: The use of information and communications technologies to provide a broader set of healthcare services including medical, clinical, administrative, and educational ones.

Telemedicine: The use of information and communications technologies to provide medical services and resources.

Wireless Application Protocol (WAP): The wireless application protocol promotes the interoperability of wireless networks, supporting devices, and applications by using a common set of applications and protocols (http://www.wapforum.org).

Chapter 3.8
Nurses' Perceptions of Using a Pocket PC for Shift Reports and Patient Care

Karen Chang

Jacqueline K. Nielsen
Purdue University, USA

ABSTRACT

Nurses working in hospitals with paper-based systems often face the challenge of inefficiency in providing quality nursing care. Two areas of inefficiency are shift-to-shift communication among nurses and access to information related to patient care. An integrated IT system, consisting of Pocket PCs and a desktop PC interfaced to a hospital's mainframe system, was developed. The goal was to use mobile IT to give nurses easier access to patient information. This paper describes the development of this system and reports the results of a pilot study: a comparison of time spent in taking and giving shift reports before and after the study and nurses' perceptions of the mobile IT system. Results showed significant difference in taking shift reports and no significant difference in giving shift reports. Nurses stated that quick and easy access to updated patient information in the Pocket PC was very helpful, especially during mainframe downtime.

INTRODUCTION AND BACKGROUND

The quality of the American healthcare delivery system has been problematic. The Institute of Medicine (IOM) (2001) identified six dimensions of quality: safe, effective, patient-centered, timely, efficient, and equitable. However, in hospitals with paper-based delivery systems, nurses often face challenges in meeting these expectations. Two areas of inefficiency are communication among nurses and accessing information relevant to patient care.

Paper-based shift reports and patient management can be time-consuming. At the beginning of each shift, nurses take reports of their patients. They use self-designed paper worksheets to write key patient information (e.g., diagnosis, physical or psychosocial status, treatments, tests, etc.) and to organize patient care activities. Audiotaped reports, face-to-face reports, or walking rounds are commonly used for nurses to pass patient information from shift to shift. Face-to-face reports and walking rounds require more time than audiotaped reports. For face-to-face and walking rounds, outgoing nurses and incoming nurses need to be present at the same time and additional communication occurs when both groups are present. Audiotape reports do not require the presence of outgoing nurses and incoming nurses simultaneously. Outgoing nurses give reports by speaking into an audiotape recorder about one hour before the end of the shift. They give reports based on their memory and notes written on self-designed worksheets. Incoming nurses listen to the audiotape reports at the beginning of the shift and take notes on their self-designed paper worksheets. Since the 1990s, audiotaped reports have become prevalent and save about 15 minutes in each shift because outgoing nurses do not need to wait for incoming nurses to give reports (Mason, 2004). However, incoming nurses spend about 30 to 60 minutes taking shift reports from the audiotape reports before starting to take care of their assigned patients. The majority of the time is spent on transcribing key information from audiotape reports to their self-designed paper worksheets. Audiotaped reports continue to limit nurses in providing care in a timely and efficient manner.

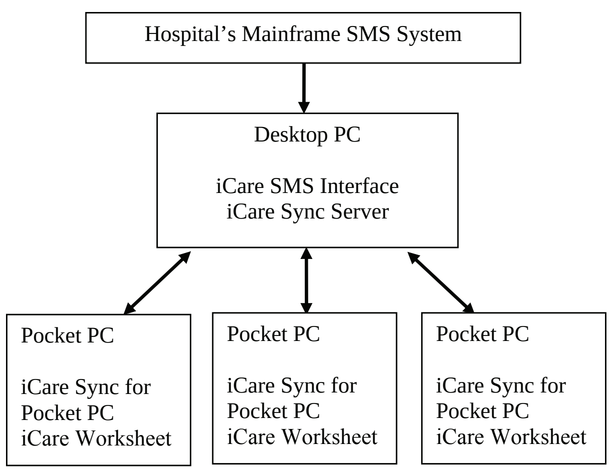
Nurses need to efficiently and effectively communicate information to provide safe, effective, and patient-centered care. When comprehensive patient information is transferred efficiently, nurses can identify patient needs, monitor patient conditions, prevent or detect complications, and implement physician orders safely and accurately. However, accessing all relevant information for patient care in the paper-based delivery system can be difficult and time-consuming. For example, when nurses need to know patient health history and health status, they need to find the patient's paper medical records, which could be misplaced or in use by other healthcare providers. When nurses need to know the results of a patient's most recent laboratory or diagnostic tests that are stored in the hospital's mainframe system, they need to go to a nursing station to log in to the mainframe to obtain the information. When nurses need to give unfamiliar medications, they need to look up the information in a drug reference, which could be misplaced, in use by other nurses, or outdated. If nurses give medications without accurate knowledge of drug information, such as safe dosage, rate of administration, drug interactions, and side effects, medication errors may occur. Thus, paper-based information systems are fraught with inefficiencies that can compromise patient care. Specifically, if nurses do not have pertinent information, they may not detect or prevent complications due to medications, procedures, or treatments or may not provide adequate patient education to help patients care for themselves.

The Institute of Medicine (2001) asserted that information technology (IT) must be used in the 21st century to improve the quality of healthcare. The American Academy of Nursing Technology and Workforce urged the use of IT to support nurses' work and to eliminate waste and redundancy (Sensimeier, Raiford, Taylor, & Weaver, 2002). President Bush announced that electronic medical records (EMR) would be available for residents in the United States in 10 years (iHealth Beat, 2004b). However, there are many barriers to integrating IT in the hospital, such as high cost, lack of support from physicians and administration, and lack of applications that are easy to use (Gillespie, 2002; iHealth Beat, 2004a; Sensimeier et al., 2002). Thus, many hospitals are still using paper-based medical records and mainframe computer systems to store patient information.

To identify studies using Personal Digital Assistants (PDAs) integrated with the hospital mainframe system for nurses to use in shift reports, an extensive search of MEDLINE and CINAHL databases was performed using "Computers, Handheld" as the key word in combination with other key words, such as "Database Management Systems, Hospital Information Systems, Hospital Nursing Staff, or Nursing Information Systems". There is an increasing trend in using PDAs in the healthcare field. For examples, orthopedic surgeons used programs loaded in the PDAs to access patient data in the office and the operating room (Laskin & Davis, 2004); a wireless PDA was developed for patient transport to monitor patient's vital signs (heart rate, three-lead electrocardiography, and SpO2) remotely (Lin, Jan, Ko, Chen, Wong, & Jan, 2004); nurses used PDAs to collect utilization review data that were sent to hospital's mainframe system for quality evaluation (Lanway, 2003); and physicians at Cedars-Sinai Hospital in California used wireless PDAs to access patient EMRs wirelessly and used them during ward rounds or at shift changes (Shabot, 2002). The healthcare providers of Shock Trauma Intensive Care Unit at Intermountain Health Care, Salt Lake City, used EMR and reported that they spent 10 minutes for shift reports (Nelson et al., 2003). However, no studies were found regarding nurses' use of PDAs interfaced with the hospital mainframe system for shift reports.

A collaborative effort among Purdue's School of Nursing, Purdue's Department of Computer Technology, and a local hospital's nursing staff resulted in the development of the iCare system to improve the efficiency and effectiveness of shift reports in the paper-based medical records environment. This paper reports the development of the iCare system and nurses' perceptions of the iCare system for shift reports and patient care. The iCare system consists of handheld computers (Pocket PCs), a desktop personal computer (PC), and a hospital's mainframe system (Figure 1). The goal of the iCare system is to use mobile IT, in the form of Pocket PCs, to give nurses easier access to patient information so that nurses have more time to provide quality patient care. Additionally,

Figure 1. The iCare system architecture



an electronic version of a worksheet, similar to nurses' paper worksheets and audiotape reports, was developed to improve the efficiency of communicating patient information between shifts.

METHOD

Design and Security Considerations

By design, Pocket PCs are small, mobile computing devices and can easily be lost or stolen. Privacy of patient information on the Pocket PCs was a serious concern. To protect this information, several layers of security were used. First, password protection was built into the Pocket PCs, which requires a password each time a Pocket PC was powered on. Second, the custom applications required nurses to log in using a unique user ID and password. And finally, all patient information used by the system was stored in encrypted and obfuscated files on the Pocket PCs and desktop PC (Rosenthal, 2004).

Other considerations were technology-related. Because the hospital did not have a wireless network infrastructure in place, nor would they allow wireless network radios to be installed, the iCare system was not developed to use wireless network access of any kind. Instead, the system required the nurses to send and receive patient information to and from a Pocket PC by periodically synchronizing it with the desktop PC through a sync cable.

In designing the study, a decision was made to limit the impact this research would have on the workload of the hospital IT staff. The project was designed so that no new custom mainframe programs or changes to the existing systems were required. Retrieving patient information from the hospital's mainframe computer system was done using custom software designed by the second author.

System Architecture

After an analysis period and meeting with several of the nursing staff to understand the process of shift reports and the process of accessing the hospital's mainframe system for patient information, four custom software applications were developed. These were named "iCare SMS Interface," "iCare Worksheet for Pocket PCs," "iCare Sync for Pocket PCs," and "iCare Sync Server". An iterative process was used to simulate paper-based worksheets and audiotape shift reports during the development of the iCare worksheet.

A desktop PC was centrally located in a unit of the hospital in which the study was carried out. A program on the central PC periodically accessed patient information from the hospital's mainframe computer systems for all patients in that unit. At the beginning of a shift, each nurse synchronized the Pocket PC by placing it in a cradle connected to the PC. Custom software automatically copied patient information, including data from the mainframe systems and notes from the nurses on previous shifts, to the Pocket PC. During the shift, the nurse recorded new notes about each patient using typed text, handwriting, and/or audio voice recordings. Whenever the nurse wanted to retrieve updated patient information, to send the notes to other nurses, or to give reports at the end of the shift, the nurse connected his or her Pocket PC to the central desktop PC where the software automatically copied any new patient notes.

iCare SMS Interface

The hospital tracked patient information using an information system from Siemens Health Services (SMS) that runs on its mainframe computers. Nurses access this system using dumb terminal hardware, or terminal emulation software running on PCs. To avoid changes to programs running on the mainframe system, the iCare Interface program was written to use a technique called "screen scraping" to gather patient information.

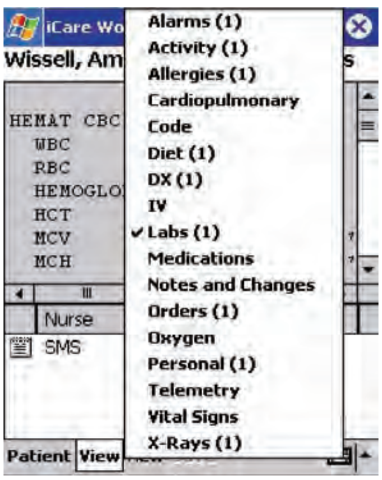
The iCare SMS Interface program functions by communicating with a terminal emulation component running on the same PC. The iCare SMS interface program sends keystrokes to the terminal emulation component that mimics the keystrokes a nurse might use when using the SMS system. When patient information is returned as text to the terminal emulator, the iCare SMS Interface program copies the text from the emulator screen buffer, reformats it, and saves it to encrypted files stored on the PC. Although not efficient by modern IT standards, screen scraping does provide an interface to legacy systems that cannot otherwise be modified to interface with a new system.

The iCare SMS Interface program was developed using Microsoft Visual Basic 6 and a terminal emulation component from Attachmate. These technologies were chosen for this application because it was developed by the authors primarily onsite at the hospital's IT department, and these technologies were already being used by the hospital's IT staff for other projects.

iCare Worksheet for Pocket PCs

The iCare worksheet application is the primary program for nurses to use for shift reports and patient care management. It simulates nurses' self-designed paper worksheets to organize patient information and patient care activities. Nurses can view patient information either gathered from the mainframe system via iCare SMS Interface or recorded notes. They can also record new notes. The user interface allows nurses to see a list of all patients in the unit. After selecting a patient, nurses can see information about the patient. Because of the limited screen space on a Pocket PC, information is grouped into various categories to make finding the information quicker (see Figure 2). The patient information obtained from the mainframe system by the SMS Interface program is automatically sent to the categories of Allergies, Cardiopulmonary (test results), Diet, Lab, Orders (current medications and laboratory orders), Personal (date of admission, room number, physicians), and X-Rays (radiology test results). Nurses can take notes in any of the categories

Figure 2. Categories of the iCare worksheet



Note: Fictitious patient information shown. A number inside of parenthesis indicates the number of notes in that category.

Figure 3. An example of text, audio, and handwriting notes in the iCare worksheet

Note: Fictitious patient information shown. Red, blue, green, and black pen colors can be used when taking handwritten notes.

using either typed text, handwriting, or audio voice recordings (see Figure 3). Alarm features are also built into the iCare worksheet. Nurses can set alarms to remind them to do certain tasks for each patient at a specified time, such as time to give medications or treatments.

This program was written using Microsoft Visual C# .NET and the .NET Compact Framework. These technologies were chosen because the study also included plans to test the effectiveness of Tablet PCs in addition to Pocket PCs for use by nurses. By using Visual C#, the authors hoped that much of the Pocket PC program source code could be ported to the Tablet PC platform easier than other software development tools would allow.

iCare Sync for Pocket PCs and iCare Sync Server

The iCare Sync for Pocket PCs and iCare Sync Server work in tandem to automatically copy patient information to and from the Pocket PCs. When a Pocket PC is connected to the central desktop PC using the sync cable, the iCare Sync for Pocket PCs program running on the Pocket PC establishes a connection to the iCare Sync Server running on the central PC. The list of patient information files on the Pocket PC is compared to the list of patient information files on the central PC. Any note files on the Pocket PC not present on the central PC are copied to the PC. Likewise, any note files on the PC are copied to the Pocket PC.

As with the iCare worksheet application, the iCare Sync programs were developed using Microsoft Visual C# .NET to allow easier porting to the Tablet PC platform.

Study Setting and Participants

This study was conducted in a medical unit of an acute care hospital in the Midwestern United States, where paper-based medical records were used. In addition, key patient information was available using dumb terminals in the nurses' stations. There was no computer access at the bedside. A prospective pre- and post-test design was used to examine the efficiency and effectiveness of the iCare system for shift reports and patient care. Nurses of all shifts who worked during the study period participated in the study.

Procedure

Ten Dell Axim X5 Pocket PCs were used in the study because the maximum number of nurses working at one time on the unit was eight. All Pocket PCs were kept on the unit and maintained by unit secretaries. After the approval from Institutional Review Board, this study was implemented over four weeks (two weeks of learning and two weeks of actual use). In the first week, six one-hour orientation sessions were provided. Nurses were encouraged to practice using the iCare worksheet for shift reports. The purpose and the procedure of the study, confidentiality of collected data, and voluntary nature of participation were explained to participants. After consent was obtained, nurses learned to use Pocket PCs and the iCare worksheet to find patient information, and take notes (text, handwriting, or voice format) in the iCare worksheet. During the second week, nurses continued to practice using the iCare system for shift reports and patient care. In the third week, nurses used both the iCare worksheet and audiotape for all shift reports. In the fourth week, the iCare worksheet was the only means for shift reports and audiotape recorders were removed. Three nursing faculty provided orientation and support for the iCare system. They visited the unit periodically during each shift and talked to every nurse to inquire about concerns or difficulties. They also helped each nurse to use the iCare worksheet.

Questionnaires

To examine efficiency and effectiveness of using the iCare worksheet, Baseline Information and Perceptions of the iCare worksheet questionnaires were used. Nurses were asked to indicate their comfort level using Pocket PC (very uncomfortable, somewhat uncomfortable, somewhat comfortable, and very comfortable) and the number of years working in the hospital and in the unit in the Baseline Information. Nurses were also asked to provide the average time spent in giving and taking shift reports before starting the study.

Perceptions of the iCare worksheet were given to nurses at the end of the study in a self-addressed stamped envelope. Information obtained included: average time spent in giving reports and taking reports using the iCare worksheet, positive and negative experiences in using the iCare worksheet, and suggestions for improvement. In addition, nursing faculty who provided support during the study period took anecdotal notes about nurses' comments and experiences in using the iCare system.

RESULTS

Baseline Information

The response rate was 74.3% (35 received iCare training, 26 responded to questionnaires; 4 of the 26 contained incomplete data). The average years of working in the hospital was 12.62 (range = 1.5 to 36; S.D. = 10.61). The average years of working in this unit was 7.28 (range = 1 to 32, S.D. = 7.57). Most nurses reported that they were comfortable in using Pocket PCs to find information (44% somewhat comfortable; 44% very comfortable).

Efficiency

The results of descriptive statistics showed that on average, nurses using the iCare worksheet method spent 8.54 minutes less in taking reports (24.95 – 16.41 = 8.54) and 2.84 minutes less in giving reports (23.05 – 20.21 = 2.84) than the audiotape method (see Table 1). The average total time spent in giving and taking shift reports using the iCare worksheet method was 11.38 minutes less than the audiotape method.

Paired sample T-Test procedure showed significant differences in taking reports ($t = 3.29$, $p = 0.004$), but no significant differences in giving reports between these two methods (see Table 2).

Table 1. Descriptive statistics of time spent (in minutes) for giving and taking shift reports using audiotape and iCare worksheet methods

		Audiotape		iCare Worksheet	
		Giving Reports	**Taking Reports**	**Giving Reports**	**Taking Reports**
N	Valid	22	22	23	24
	Missing	4	4	3	2
Mean (S.D.)		23.05 (14.25)	24.95 (11.04)	20.21 (14.90)	16.41 (11.52)
Median		20	20	16.25	13
Minimum	7		10	0	3
Maximum	6	0	55	60	55

Table 2. Paired samples statistics: Time spent (in minutes) in giving and taking shift reports — Audiotape vs. iCare worksheet

		Mean	N	SD
Pair 1	Time spent in giving reports per audiotape	23.05	22	14.25
	Time spent in giving reports per iCare worksheet	20.09	22	15.36
Pair 2	Time spent in taking reports per audiotape	25.20	20	11.32
	Time spent in taking reports per iCare worksheet	16.38	20	11.77

		Paired Differences				
		Mean	SD	t	df	Sig. (2-tailed)
Pair 1	Time spent in giving reports per audiotape – Time spent in giving reports per iCare worksheet	2.96	13.45	1.03	21	0.314
Pair 2	Time spent in giving reports per audiotape – Time spent in giving reports per iCare worksheet	8.83	12.01	3.29	19	0.004

** Paired samples statistics (exclude cases analysis by analysis) was performed*

Perceived Benefits

Nurses wrote many positive comments about the accessibility of the iCare worksheet. All respondents (n = 26) stated that quick access to patient information was very helpful. They were glad to see laboratory results, radiology reports, diagnoses, and medications at the beginning of the shift and while providing patient care. Several nurses gave examples to describe how the iCare worksheet helped them provide patient care. For example, one patient had an emergency situation. A nurse responded and did not know this patient. She accessed information in the iCare worksheet (code status and treatment) quickly so that she could provide proper care until support staff arrived. In another example, a nurse answered the call lights of other nurses' patients. She used information in the iCare worksheet to answer patients' requests. A nurse answered physicians' and patients' questions about laboratory and diagnostic tests results promptly by accessing information in the iCare worksheet. Three nurses reported that they were glad to have comprehensive patient information in the Pocket PCs when the hospital's mainframe systems were unavailable.

Eight nurses wrote positive experiences about entering nurses' notes in the iCare worksheet. They also reported that using the iCare worksheet was faster than using audiotape to give reports to the next shift. In addition, being able to see nurses' notes of the previous shift helped them know patients' condition quickly without duplicating work. One nurse liked to use the alarms feature. She set alarms to remind her when to give medications and treatments, to check laboratory results, and to call physicians.

Key Findings from Anecdotal Notes

Anecdotal notes provided further perceived benefits of the iCare system. Initially, nurses stated that they spent more time entering data into the iCare worksheet than they did on their paper-based worksheets. Gradually, they began to voice the benefits of using the iCare worksheet. They could readily access specific patient information in the iCare worksheet without having to leave the patient's room to look up information in dumb terminals during physician rounds.

Taking notes in the iCare worksheet involved a learning curve. Nurses who took notes in the iCare worksheet stated that they became more proficient with repeated use. Some nurses voiced that the time required taking notes and synchronization was far less than the time required to manually abstract updated patient information from patient's medical records.

One nurse reported that an unexpected incident convinced more nurses to use the iCare system. One day, the hospital mainframe systems went down. No new orders or new diagnostic results could be retrieved on the dumb terminals. The only way to find this information was to call various departments. Physician rounding became quite challenging. On this particular day, nurses discovered that they could still access updated patient information in the iCare worksheet if their Pocket PCs were synchronized. Subsequently, whenever there was an indication that hospital's mainframe systems would go down, there was a flurry of activity at the sync station.

Being able to access all patients' data was another significant nurse satisfier. Nurses covered for other nurses during meal breaks or time off the unit. With the iCare worksheet, any nurse could access the most updated information on all patients. Nurses reported that this benefit did not exist with the paper-based worksheet. Some verbalized that they spent less time abstracting information from medical records and the mainframe system and had more time available for patient care.

A train-the-trainer strategy was used to have nurses helping nurses for orientation, training, and support. Many times computer-based training was performed by computer personnel. Nurses with limited computer background tended to become apprehensive because they could not comprehend the information. When the nursing faculty provided the training and were available to help them, they reported feeling less threatened in learning the new technology. Some nurses who began with apprehension due to limited computer skills became enthusiastic participants later.

Areas for Improvement and Suggestions

There was no consistent system to take notes in the iCare worksheet. Some nurses entered useful notes and some nurses who were slow to use the technology did not enter notes. Some nurses worked only once or twice during the study period and were uncomfortable with the technology. To them, talking to the audiotape recorder was faster than entering notes on the Pocket PC. Scribbled handwriting was hard to read sometimes. Voice notes could be hard to hear. Nurses would like to have had all information in one screen instead of going to each category to view. They would like to have had more information from the mainframe systems, such as physician's dictated notes. They would like to print out patient reports and to use the iCare worksheet along with computerized charting and physician-order entry system in the future.

The size of the Pocket PC was identified both as a positive and a negative. The portable size was beneficial for carrying and immediate access. The disadvantage was in reading reports with large amounts of data on a small screen, which necessitated a significant amount of side-to-side and up-and-down scrolling. They would like to have had a larger screen to view reports.

Several suggestions were related to hardware improvement. They would like to hear louder sounds for recorded notes, a lighter weight Pocket PC, a keyboard, and a longer battery life. They would like to have more sync stations, voice translation, faster handwriting recognition program, and a faster sync process. They also voiced a desire to see if the patient call lights system could be integrated with the Pocket PC in the future.

DISCUSSION

The goal of the iCare system is to use an integrated IT system using Pocket PCs to give nurses working in hospitals with paper medical records and mainframe systems quick access to patient information and to improve quality patient care. Most of the nurses in this study were using this mobile technology for the first time. Initially, they were skeptical about using mobile technology. Results indicated that nurses enjoyed the quick access to pertinent patient information at any time and any place without patients' paper medical records or dumb terminals. Their comments and anecdotal notes indicated that the iCare system enabled them to have more time to provide quality patient care.

The iCare system shortens incoming nurses' time taking reports at the beginning of the shift. When the Pocket PC is synchronized with the central PC, pertinent and updated patient information can be viewed in the iCare worksheet. There is less information that nurses need to write down. However, the iCare system does not save nurses' time when giving reports. The discrepancy reflects variations of how each nurse uses the iCare worksheet. One nurse reported spending zero minutes in giving reports while another nurse reported spending 60 minutes in giving reports. The first nurse wrote notes throughout the shift while caring for patients. This nurse used an iCare worksheet the same way as using the paper-based worksheet, in an ongoing fashion throughout the shift. The second nurse tried to enter notes in the iCare worksheet at the end of the shift to give the report. The second nurse did not use this technology the way it was intended and thus took 60 minutes to give her report. IT was often a tough sell to nursing staffs (Gillespie, 2002). Strategies are needed to help nurses embrace the technology to use it in a consistent manner.

The iCare worksheet provides a standard format to record and retrieve patient information. This format decreases variability in transferring and communicating patient information among nurses. In the paper-based worksheet, there is no common ground, each nurse uses his or her own system to transfer and communicate patient information for patient care and shift reports. Variability increases risks for errors. The iCare worksheet has the potential to improve the quality of nursing care by standardizing nurses' information transfer and communication in the hospital with paper-based medical records and the mainframe system.

This project was limited to four weeks, but the impact of this study continues to be experienced. Prior to this study, the hospital's nursing administrators had not considered using Pocket PCs for nurses. After the study, the hospital's nursing administrators saw the benefits of using Pocket PCs to access patient information in the mainframe, but chose not to expand the iCare system hospital-wide because the hospital was going to change the mainframe system to another vendor. An effort to refine the iCare worksheet to interface with the new mainframe system has been sought to continue this technology for nurses as long as the hospital is using the paper-based medical records and the mainframe system.

At the end of this study, it was also identified that nursing students could benefit from using the iCare worksheet to access key patient information instead of looking for paper medical records, which are often used by other healthcare providers. Thus, the hospital allowed the iCare system to be placed in two additional units for students to use during the school year. The iCare worksheet was loaded in both Pocket PCs and Tablet PCs for students to use. Preliminary students' feedback showed the preference of using Tablet PCs rather than Pocket PCs.

CONCLUSION

This study demonstrated that the use of mobile technology, integrated with a hospital's mainframe system, improved the efficiency of communication in shift reports and in accessing information relevant to patient care. Nurses in the study perceived that with quick access to pertinent information in the Pocket PC, they could provide better patient care. This technology provided a standardized means to communicate patient information from shift to shift. However, whether or not the patients perceived an improvement in their care as a result of nurses using this technology was not examined in this study. The future goal of this project is to revise the iCare worksheet to better meet nurses' needs to communicate patient information from shift to shift. A larger and longer study will be conducted in the future.

At the beginning of the study, it was unclear if nurses would be receptive because they had become accustomed to the paper-based system and audiotape reports. However, as they identified the benefits of having quick access to patient information with the mobile technology, they gradually responded positively to the iCare system. At the conclusion of the study, they eagerly offered suggestions for improvement. They even requested to continue using the Pocket PCs after the study ended.

The iCare system has great potential for use in hospitals that use paper-based medical records and mainframe systems. Hospitals face many constraints to fully implement IT for nurses, such as costs, human factors, regulation and standards, technology, and information systems (Androwich, Bickford, Button, Hunter, Murphy, & Sensimeier, 2003; Blair, 2003; iHealth Beat, 2005; Schneider, 1997). As hospitals decide to move away from mainframe systems to EMR systems, the iCare system could be a valuable tool to help nurses during the interim.

In the future, the iCare worksheet could be further improved by engaging nurses in the process of refinement. The iCare system could incorporate advanced technology, such as wireless network infrastructure, to expedite communication, information access, and synchronization. Tablet PCs could be the solution for small-screen issues. Further studies using Tablet PCs in the integrated IT system are warranted and underway by the authors.

ACKNOWLEDGMENTS

This is a collaborative effort between Purdue's School of Nursing, Purdue's Department of Computer Technology, and the Greater Lafayette Health Services, Inc. (GLHSI). This project received supports from Purdue University e-Enterprise center and Microsoft Research.

We would like to acknowledge the following persons from GLHSI for their continuous support and collaborative effort to make this innovative project possible: Sally Lowrey, Vice President, Nursing Services; Cathy Newman, Clinical Director, Nursing Services; Jim Siemers, Director, Information Technology; Lynn Wimberly, Director of 2 PCW at Home Hospital; Elizabeth Bratcher and Heather Askren, education coordinators.

Chapter 3.9
The Evaluation of Wireless Devices Used by Staff at Westmead Hospital

Sandra Synthia Lazarus
University of Sydney, Australia

ABSTRACT

This chapter reports on a study to research and evaluate the use of latest generation wireless devices—typically personal digital assistant devices (PDAs)—by clinical staff at the large Westmead Hospital located in the west of Sydney, Australia. Currently, medical reports in this and other hospitals are primarily recorded on paper supported by personal computers at nursing stations. However, there is very little or no access to medical reports and decision-making tools for medical diagnosis at the patient's bedside—the precise location at which most medical decision-making occurs. Delays in access to essential medical information can result in an increased time taken for accurate diagnosis and commencement of appropriate medical management of patients. This chapter discusses the application of hand held devices into more powerful processing tools connected to a centralised hospital data repository that can support medical applications.

INTRODUCTION

Currently, personal digital assistant (PDA) devices are used by most junior hospital staff to view formulary information. A short survey carried out showed that almost 90% already own a PDA device and use it for drug and medication referencing. Access to drug information databases on PDAs provides a fast and easy way to reference medication details including interactions. Hospital staff members also use PDA devices for day-to-day calendar and appointment notification (Carroll & Cristakis, 2004). But it is just recently, due to the evolution of PDA devices, that it has become possible to take the next step and utilise the full capacity of the PDA devices in a hospital environment.

The study was conducted with a variety of staff members in the hospital; these included senior clinical staff, specialist staff, and junior staff. This was from across the hospital—from general wards, special units, and the emergency department. The duration of this trial was for nine months, with a rotation of staff members. Staff members were assessed before becoming part of the trial as to how long it takes the individual to carry out a particular task without the assistance of a PDA device; these tasks were timed. Then a complete instruction booklet was given to the hospital staff with the PDA device to make use of as they found it necessary in their daily duties.

After a certain period when the staff members were comfortable in using the device, time was again measured for different tasks with and without PDA devices. This set the background for the trial. To evaluate the social accepts of the trial, a survey was conducted to gather the thoughts of the users on the functionality and the useability of the device in a hospital environment.

THE EVOLUTION OF PDA DEVICES

Over the last few years, the PDA has evolved in ways originally unimaginable. One of the first PDAs to enter the market was the Palm Pilot (now more commonly known as the Palm). When first released, the Palm came with a monochrome screen and had a limited amount of onboard memory. Since then the Palm evolved into a PDA that featured expandable slots for additional memory and expandability options (i.e., modems, printers, and other peripherals). In addition, Palm PDAs now feature high-resolution colour screens which are continuously improving. Furthermore, the Palm also comes with built-in wireless access that permits it to connect to various types of devices and networks, allowing it to be truly portable (as originally intended).

Pocket PCs entered the market shortly after Palm PDAs were introduced; however, unlike Palms the Pocket PC is more of a PDA standardisation rather than a brand name. Pocket PCs are made by several companies, for example Dell, Toshiba, and HP/Compaq; however, the core operating system is written by Microsoft. On the other hand, the Palm PDA operating system (Palm OS) is maintained by Palm itself, which ensures that all features of the operating systems are fully functional. Small distinctions such as this have allowed both devices/brands to compete for the same market space and are still considered independent niche markets.

Since Palm has been on the market for a considerably longer period of time, there is a remarkable amount of software support found throughout the Internet. Palm PDAs now have the ability to operate seamlessly with Windows, Linux, UNIX, Novell, Macintosh, and practically any type of network. There is a considerable amount of open source development done within the communities that make featured software available for Palms. Similarly, Pocket PCs are supported through a large number of Internet sites. Since standards are maintained, which include desktop and server operating systems, these have the ability to ensure that their operating systems designed for Pocket PCs will meet the same quality control and compatibility assurance. Nevertheless, with the rivalry between these two PDA vendors, it is possible to see further improvements such as superior screen resolution, improved standard of expandability options, inclusions of newer wireless technology such as 802.11g, and most importantly reduced costs, allowing more people to access such technology. Since their evolution, PDA devices can now interact with the latest available wireless technology and can be used in a hospital environment. The two PDA devices used in this case study are the Palm Tungsten T3 and the Toshiba e800 Pocket PC.

Palm

The Tungsten T3 is selected for this study because of its flexible features. At the time of the study, the T3 was the most highly developed Palm device, with built-in Bluetooth wireless technology, 64 MB memory, and moderate screen resolution. To reduce screen scrolling, the T3 has a stretch screen display as well as portrait and landscape modes.

Figure 1. The Palm Tungsten T3 has the following features: Bluetooth technology synchronisation, 64 MB memory, stretch display, portrait and landscape, moderate resolution 320´480 pixels (Palm One, 2005)

Figure 2. The Toshiba e800 Pocket PC has the following features: Wi-Fi wireless technology—synchronisation, easy configurations for 802.11b wireless environment, 32 MB memory, portrait and landscape, VGA high-resolution screen/480´640 pixels (Toshiba, 2005)

Toshiba e800 Pocket PC

The Toshiba e800 Pocket PC has both Bluetooth and Wi-Fi capabilities, with a memory capacity of 32MB. This has proven to be sufficient memory for the PDA-based medical programs. The e800 has a high-resolution VGA screen, 640 by 480; this improves the images on the Pocket PC and allows medical staff to read data with ease.

AVAILABLE WIRELESS TECHNOLOGIES

Wireless technology has been used for several years in the information technologies area; however, more recently there has been more fascinating development in wireless technology, allowing its useability in a wide range of areas. One such area is medicine: more and more new areas are being developed in which wireless technology is becoming a necessity (Bird, Zarum, & Renzi, 2001). Wireless technology in medicine allows mobility which provides greater advantage when it comes to patient care and patient diagnosis.

Bluetooth technology is an effective radio technology that allows for point-to-point or point-to-multipoint support which connects multiple Bluetooth devices. It has proven to be the most effective cable-free connection for wireless technology.

Some of the features of Bluetooth technology are: the transmission distance is real-world range between 10 and 42 meters, and transmission speed which provides throughput comparable to modems and DSL and security with Bluetooth integrates security mechanisms within several layers of its protocol. Connections are generally configured to use authentication and 128-bit encryption. Applications can build their own security on top of Bluetooth connections to make communications even more secure; radio power output is as little as 1% of the power output of Wi-Fi (Palm One, 2004).

The 802.11x network is more commonly known as Wi-Fi, of which there are three general types: 802.11a, 802.11b, and 802.11g.

The most popular Wi-Fi is 802.11b, which has a throughput capacity of 11 Mbps and an approximate range of 50 meters. Due to bandwidth overheads and congestion, 802.11b will deliver data at about 7 Mbps, which is more than 10 times the performance of Bluetooth (Colin, 2002). The advantage of 802.11a and 802.11g is a five-fold increase in data rate over 802.11b (Colin, 2002).

These are only a few examples of the variety of wireless devices, some of which are being developed for specific use.

Medical Programs on PDA Devices

Apart from the Cerner Pocket Power Chart, other PDA medical software programs were installed on the PDA devices used in the study to assist in decision making and to increase efficiency. This allows medical staff members to access medical information at patient bedsides, reducing the physical load of books and decreasing search time. For example, on a ward round, a staff member may need to enquire about interaction between two drug types. There are two options in this situation: call the pharmacist, or look up the information at the nurse's station on the Internet or in a reference book. With the PDA at the patient bedside, the staff member now has access to the relevant information immediately. These medical programs used on the PDA were selected based on suggestions from medical staff members at the hospital.

iSilo is a program that converts file formats utilising compression for reducing document size. iSilo was used to reduce the size of the Australian Medical Handbook and the Westmead Medical Handbook so that they could be installed on the PDA device.

Medical Calculator is used in performing common calculations useful for clinical decisions or for analysing data in clinical decisions.

Medical Handbook is used by most junior medical staff as a resource to manage common medical and surgical problems.

MIMS (Monthly Index of Medical Specialities) provides medical staff and healthcare professionals with easy access to drug information required for making medical decisions.

Therapeutic Guidelines provides information to support decision making in the prescription of drugs.

HotSync allows programs to be uploaded to PDA devices from desktop computers.

Cerner Pocket Power Chart is a program that provides a mobile solution for hospital results reporting. It enables doctors and other healthcare providers to view patient results such as pathology and radiology reports.

The Cerner Pocket Power Chart has a username and password login as part of its program functions. Each doctor is allocated a username and password that are required for login to view patient lists. All hospital databases are secured behind firewalls, adding to the security of the device. The Cerner client software has built-in security—it is designed to erase all information on a PDA device if that information is not reviewed within 72 hours. This ensures that if a Palm device is lost or stolen, all Cerner Pocket Power Chart patient reports will be erased after 72 hours. This feature protects all patient information and upholds patient confidentiality.

Evaluation Research Method

To evaluate the useability and functionality of the PDA devices in a clinical environment, a survey was conducted. PDA devices were uploaded with medical support programs currently in use by some medical staff, such as MIMS, Therapeutic Guidelines, iSilo, MedCalc, the Westmead and Australian RMOs Handbooks, along with the current available version of Pocket Power Chart Palm OS client from Cerner Corporation, the vendor of the enterprise's results reporting system. The Citrix Client is used to view Cerner patient information and data on the Pocket PC handheld devices.

Doctors from various backgrounds were given PDA devices, complete with necessary programs, a user manual, and surveys to complete. They were allowed to work their way through the different programs in an unstructured way. After a week of using the PDA devices, observations were carried out to determine how often the programs and PDA devices were being used to assess patients and assist with decision making.

Survey

The survey was divided into three sections: the first section contained statements which were answered with agree, strongly agree, disagree, and strongly disagree. The second section consisted of yes and no answers, and the last section was a short, open answer section that allowed the medical staff to express their opinions about the PDA trial. The survey was completed after the trial period.

Statistical Analysis

A statistical analysis was carried out to calculate time utilisation in the clinical trial. Each medical staff member was timed before the clinical trial and during the clinical trial. They were timed on their hospital duties on different hospital shifts, such as ward rounds, overnight shift, patient discharge, and new patient evaluation. This was carried out to determine how long it takes a medical staff member to carry out his or her duties with or without a PDA device. Times were noted and then put into a graph showing the range of time it took to complete, and the average time it will take to complete different duties in different hospital shifts (as outlined in the results).

Method Outline

- A questionnaire was completed by the medical staff before the clinical trial. This determined general knowledge of PDA-type devices.
- Medical staff members were given a PDA device with a complete set of medical software and a user manual for a period of two to three weeks or more if required.
- After the trial period a survey was completed to determine how effective the medical staff found the PDA devices and the PDA-based medical programs.
- Observations were carried out to calculate the average time to access five patients with or without the PDA device.
- How frequently different medical programs were being used was also noted.
- The average time it took to prescribe medication with or without electronic medical databases or PDA-based programs was determined.

Synchronisation of Patient Information

HotSync

HotSync is a Palm-based computerised platform that allows data to be transferred between the Palm devices and the computer. This transfer of data is known as synchronisation and can be carried out through a cable connection or a wireless connection. Palm-based applications and programs are uploaded to the devices using HotSync synchronisation, as shown in Figure 3.

Citrix

Citrix, a revolutionary software, delivers terminal services to a number of operating systems such as Windows, Linux, UNIX, and Macintosh. In addition to these operating systems, Citrix also supports Palm and Pocket PC devices. A Citrix client allows a PDA to connect to a Citrix server, making it compatible to a standard desktop PC or laptop. As a result there are now practically no limitations to portability and compatibility of software restrictions on PDA devices. In addition, there is no longer a need to make a specialised application for both formats—Pocket PC and Palm. Rather, with the power of a terminal session through Citrix, the only requirements would be for the application to run on a desktop such as a Windows operating system.

However, Citrix is not only a medium for reporting applications in terminal sessions, but also a client/server-based application that provides built-in layered security protocols allowing security and confidentiality. A Citrix client can be configured with a wide range of security provisions, including standard authentication using a username and password to extremely high levels of security using EAP (Extensible Authentication Protocol) (Citrix, 2004). Security controls such as certificates, smartcards, or even fingerprint and retinal scans can be used for identification and authentication. A Citrix client can also connect to a Citrix server via the Internet using the World Wide Web, allowing it to be published externally to the Internet, thus allowing ease of use and accessibility worldwide (a handy feature when you are out of the office and require a document stored on a network drive) (Citrix, 2004).

Figure 3. Using HotSync and Bluetooth, wireless technology patient information on Cerner Power Pocket Chart is uploaded to the Palm Tungsten T3

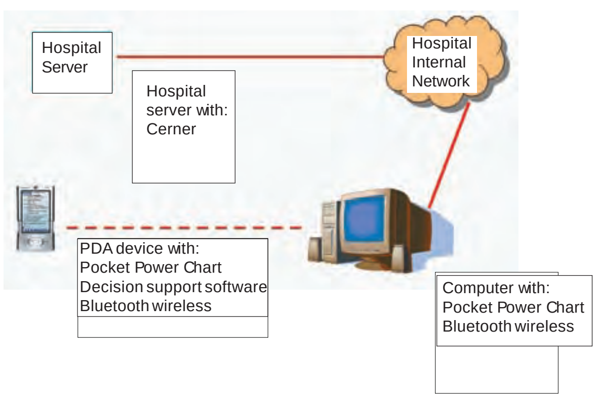

Figure 4. Through Citrix terminal sectioning and Wi-Fi wireless technology patient information on the Cerner program is captured on the Toshiba e800 Pocket PC

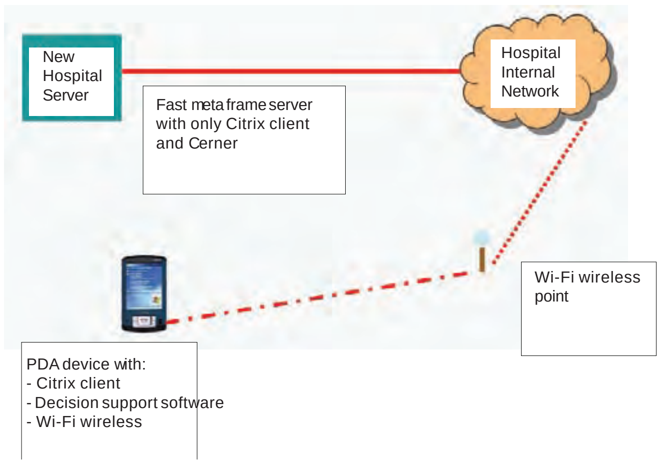


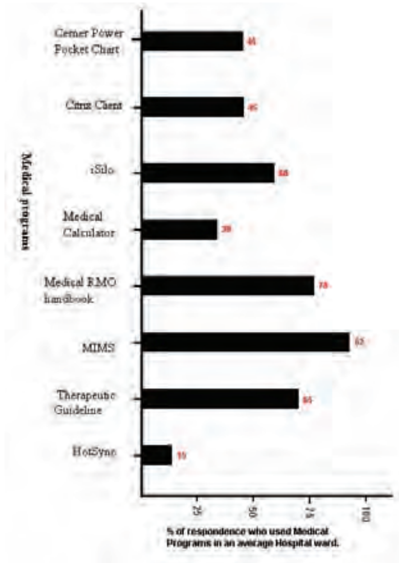
The Use of PDA-Based Medical Programs

Graph 1 outlines the percentage of PDA programs utilised during various hospital ward shifts. Cerner Pocket Power Chart (CPPC) was used by 45% of the doctors; the lower percent was due to a few problems with the CPPC program which includes the time (up to 24 hours) taken to upload and access new patient information and results on a PDA device. The usage may increase if the CPPC program is more efficient in uploading patient information and results. The Citrix client and CPPC had identical usage rates, as CPPC uses Citrix to access patient information. Furthermore, iSilo was used by 60% of the doctors. This was due to medical staff uploading other medical reference programs and using iSilo to convert them into PDA-based programs. The Medical Calculator was mainly used by specialist medical staff to convert and calculate test results when they were required, with approximately 30% reporting use of the application. The Medical RMO handbook was the second most popular program used by 78% of the doctors in a hospital shift. MIMS was the most used application, with 82% of the doctors each shift reporting that they used it, mainly for drug information and drug interactions. Therapeutic Guidelines was found to be the third most popular medical program used by 65% of the trial participants. HotSync had the lowest value of 15%, as its only role is to assist in uploading CPPC from the hospital Cerner desktop program. During an average shift, patient information is only refreshed if a new patient is admitted or new test results are required, meaning that HotSync was not required as often as the other programs.

Time Analysis of PDA Devices While Performing Medical Tasks

Graph 2 illustrates the varying timeframes required for medical activities with or without a PDA device. The graph outlines the average time range taken to carry out a task during different shifts at the hospital. It is evident from the graph

Graph 1. The percentage of respondents who used each medical Palm-based program on an average hospital ward (not to scale)



Graph 2. The range and average time to carry out medical tasks on ward rounds, overnight shift, patient discharge, and new patient assessment (not to scale)

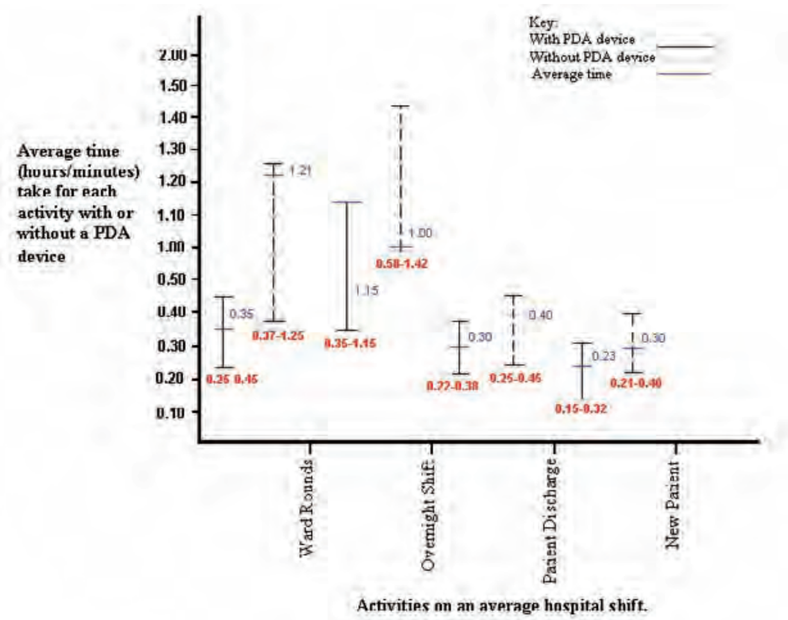


Table 1. Outlines the user percentage on a survey statement

Survey Questions	**Percentage Outcome (%)**			
	Strongly Agree	**Agree**	**Strongly Disagree**	**Disagree**
Did the PDA device improve access to patient information and necessary medical information at the patient's bedside?	23	58 5	1	4
The PDA device with its medical programs assisted in decision making and diagnosis.	18	78 0	4	
Security level in this trial and on PDA application is sufficient.	15	44 1	2	29
Mobile devices such as PDA devices and mobile tailored medical programs can be seen as a daily part of a hospital environment.	21	59 9	1	1

that regardless of the hospital shift or task, the PDA devices and PDA-based programs assisted in reducing time taken to evaluate patients. For example, managing common medical problems and searching for medication for patients requires medical staff members to go back to the nurse station from the patient bedside to look up the necessary information. This can take up to 30 minutes as they go through several book references. But with the PDA devices, the medical staff can stay at the patient's bedside and search for the necessary information in less than a minute (this time is in accordance to observations made during the trial period).

Survey Outcome and Options

The survey conducted outlined the options of the users as well as the productivity of the PDA devices and medical applications and programs. Mobile medical programs and applications were seen as a convenient and essential part of daily duties around the hospital (Tschopp, Lovus, & Geissbuhler, 2002). A larger majority of the users considered the programs a fast and easy tool while making discussions and diagnosis, and approved its use and availability when required at the patient's bedside. The main concern was security of patient information in an event of a theft or lost property; this was secured with the 72-hour limitation on all patient information (Cerner program function) and a complete shutdown of the PDA device if power is not maintained which will erase all stored information in the memory. The security is handled with a user login and server firewalls which maintain the overall security of the hospital wireless system. It was noted that the Palm T3 added functionality of an expandable screen, reduced screen scrolling, and increased visibility. Also the VGA screen on the Pocket PC Toshiba e800 with high resolution provided x-ray images for reference. These increased the potential and further the use of such devices, making them suitable for medical operations.

CONCLUSION AND FUTURE DIRECTIONS

From the above results and feedback from clinical staff at Westmead Hospital, it can be concluded that such trial can be seen as a success and a route to possible implementation of wireless technology. Similar clinical studies have looked at the possibility of PDA devices being introduced into hospitals for clinical use. Previous clinical trials of handheld devices have demonstrated both limitations and benefits to these devices. The PDA clinical trial had a few limitations; these were found in PDA based medical programs. Cerner Power Pocket Chart was found to provide only a limited amount of patient information and patient results. It limited patient results' viewing time to 72 hours and was unable to show previous results for comparison, a major disadvantage in clinical management. This reduced the use of CPPC, as medical staff had to go back to traditional methods to view complete patient details and results. For the CPPC program to be a successful tool in patient evaluation, improvement is required in areas such as patient administration details. However, other PDA medical programs combined together proved to be a very useful collection of reference tools for the medical staff. This also encouraged users to take the initiative and upload other PDA medical programs. To gain a better understanding of the benefits of PDA device usage, it may be important to extend the trial period to allow intermixing periods with and without the staff member having access to a PDA device. This will allow evaluators to measure the effects of PDA devices on hospital staff when the device is used for a longer period.

The main aim of this trial was to evaluate time taken to carry out different medical duties in the hospital setting (Ruland & Cornelia, 2002). Previous trials have concentrated on the functionality of the PDA device or opinion of the medical staff (Carroll, Tarczy-Hornoch, O'Reilly, & Christakis, 2004). This trial considered all three factors: staff option through the use of different medical programs and software, use ability of the PDA device in a hospital environment, and also accessed time during different medical duties. As noted through the results, it is evident that the trial has proven to be successful in determining how effective this method of patient assessment can be, with the correct software environments.

ABSTRACT

This paper presents the results of a study toward generating a wireless environment to provide real-time mobile accessibility to patient information system. A trial system is set up where database, Internet, and wireless personal digital assistants (PDAs) are integrated in such a way that the medical professionals like physicians, nurses, and lab assistants can create, access, and update medical records using wireless PDAs from any location in the hospital, which is covered by wireless LAN. The same services, which can be carried out via fixed terminals with Internet connectivity, can be carried out using wireless PDAs. The implementation has used and integrated many technologies like active server pages (ASP), Visual Basic®, structured query language (SQL) server, ActiveSync®, IEEE802.11 wireless locala area network (WLAN) technology and wireless security concepts. The paper details the architectural aspects of technology integration and the methodology used for setting up the end-to-end system. The proposed architecture, its performance data, and the common implementation barriers are reported.

INTRODUCTION

Medical professionals have already recognized the importance of keeping patient information (medical records) in an electronic format rather than paper-based format because of the sheer size of records generated daily. Due to the extensive size and costly storage requirements, keeping paper-based records became more expensive than keeping records electronically. A study conducted in a 500-bed hospital indicated that a 7-inch stack of paper-based laboratory reports must be filed daily. The informal survey was conducted with medical professionals among the American University of Sharjah medical center staff and a neighboring local hospital in which receptionists, laboratory, and X-ray technicians, nurses, and physicians participated. Most of them liked the idea of using electronic patient record (EPR) technology. Some of them expressed some concerns about the screen size and the resolution limitation of the personal digital assistants (PDAs) used in the trial. Others worried that if such ubiquitous systems are deployed, then medical staff will have to be available all the time even during vacations days. They stated that if such technology is available, they will be liable if they do not answer even during their breaks. "It is a matter of life and death" one of the nurses stated, "I should answer calls anywhere, anytime."

The cost of maintaining paper-based records and filing them in an ordered fashion to keep them accessible is over US$10 per record (Safran & Goldberg, 2000). Keeping records electronically also presented the opportunity of being able to access records over the Internet from anywhere, anytime. Together with the powerful PDAs and wireless connectivity tools, it became feasible to access EPR remotely without being tied to workstations. There are several records in the literature, which mention successful implementations of Web-based access to patient databases (Liu, Long, Li, Tsai, & Kuo, 2001; Garcia et. al., 2002). Others have reported wireless healthcare using wireless local area networks (WLAN) and discussed the electronics home healthcare concepts and challenges (Wang & Hongwei, 2005; Wickramasighe & Misra, 2004). A trial study conducted recently among medical professionals in real hospital settings indicated that medical professionals regard mobile access to the following data highly useful (Ammenwerth, Buchauer, Bludau, & Haux, 2000):

- Medical knowledge like drug data.
- Medical coding references like ICD-10 codes (International Classification of Diseases) and literature databases.
- Patient database and administrative patient data.
- General information like telephone numbers and medical databases.

After using the system for a week, the respondents indicated that mobile communication and mobile information processing power offered by PDAs are very valuable. However, the respondents also reported that they were not satisfied with the 9600-baud rate communication speed offered by the early versions of PDAs and the mobile phones based on the Global System for Mobile (GSM) standard used in the study. During the study, it also became apparent that the messaging ability offered by PDAs was much superior to personal accessibility provided by pagers and mobile phones (Ammenwerth et al., 2000). Since then, the rapid change in the technology provided better connection methods, more durable and faster handheld mobile computing devices. The wireless accessibility provided by nowadays existing WLAN standards such as IEEE802.11g can support 54 Mbits/s data rate and the soon to come IEEE802.11n standard will support 540 Mbits/s data rate. This will clearly satisfy the need to higher access bandwidth required by healthcare providers. Along with the other contemporary software and database tools, this new connectivity method promised better EPR system and motivated many researchers in the healthcare industry to develop integrated wireless applications for use on pocket PC, smart-phone PDAs and other portable device platforms (Lu, Xiao, Sears, & Jacko, 2005).

In this study, we will design a prototype electronic medical database system and evaluate its performance in near-realistic settings. Another aspect of the research conducted is the design of a Web-based database for hospital environment, which could be equally accessed by wireline and wireless networks.

TECHNOLOGY IMPLEMENTATION BARRIERS

As is the case for many newly introduced technologies, even with uncontested technological and economical benefits of the proposed architecture the implementation may be impeded by the perceived steep learning curve for potential users. This fact is especially true for medical professionals who are in general uncomfortable introducing new technology due to the risks involved and required "protected time" to integrate it in their work environment (Van Ginneken, 2002). The flexibility and adaptability to change are regarded as the key factors for medical applications. Standardized and open-vendor systems are also important factors for getting new technology accepted by the user community. Acceptance of EPR by the medical community has improved after an initial hesitation. The technology to access patients' information varies. Literature search indicated that there are several techniques that are currently being used:

- Hybrid architecture using PDAs and wireless GSM modems
- IEEE802.11 WLAN standard
- IEEE802.15 known as Bluetooth standard

Software applications were based on Wireless Application Protocol (WAP). The hybrid system using PDA and GSM modems combination was used in a trial study conducted in real hospital settings (Van Ginneken, 2002). This valuable study was aimed at determining expectations of medical professionals from potential wireless enabled hospital settings. The study indicated many points, which are regarded important by medical professionals. But the study also indicated that the data rate offered by the hybrid solution is far lower than expected to be considered useful. Another connectivity method used in some studies was WAP connectivity, which is used by mobile phones to transfer Web contents to mobile devices. In a successful WAP-based system, patient data was sent successfully from patients monitored to WAP-enabled phone. Information like Electro-Cardiogram (ECG) signal was displayed graphically on the medical professionals WAP enabled phone (Hung & Zhang, 2003). Although the project was successful, the authors reported that the data transfer rate was low. Another major drawback of the system is the limited screen size of the WAP phone. Another similar study used WAP services for connectivity to biological databases (Riikonen, Boberg, Slakoski, & Vihinen, 2002). The Mobile and PDA phones successfully queried the databases and displayed the contents in a browser page on the mobile device. PDA-based client-server architecture is preferred for flexible telemedicine systems (Nazeran, Setty, Haltiwanger, & Gonzalez, 2004). The client uses a Pocket PC platform because of its processing capabilities, low cost, and compact size. The system could be used to transmit audio, still images and vital signs from a remote site to a clinic or a hospital Web-server that implements standard Internet protocols.

Adoption of wireless solutions in the healthcare sector has many advantages but also poses some challenges (Demiris, 2004; Lu et al., 2005). Time and cost saving, mobility and real-time access, reducing medical errors, enhancing productivity, and quality of care are major advantages of using PDA in healthcare (Lu et al., 2005). However, speed, screen size, data entry, maintenance, interoperability issues, patient privacy issues, interference with medical equipment, data security issue, and negative patient perception of delicate devices are notable challenges (Lin & Vassar, 2004; Lu et al., 2005).

DESIGN CONSIDERATIONS FOR THE TRIAL SYSTEM

Literature and informal surveys of medical professionals showed that the designed system should have the following requirements:

- The system should have an EPR database which is user friendly, robust and Web-enabled.
- The system should be secure. Several layers of security should be established at different levels.
- Access speed to the system, data access and update speed should be high; PDA used for the system should have reasonable size and weight.
- The system should use off-the-shelf components and the cost should be reasonable.
- The system should be accessible at any time. Hence, architecture should be robust to provide the needed high availability.

To achieve the previous requirements a client-sever model is designed and constructed. Figure 1 shows the system hardware architecture. A database is designed and managed by SQL-sever, Web site and wireless connectivity via PDA are developed. Figure 2 shows the system software tiers.

Database Design

A database system is designed to serve the requirements of the overall system. Entity relationship diagram (ERD) is used to describe the objects in the hospital database. The objects or entities and the relationship between them were translated into tables. This process helped us identify facts, known as attributes or fields, about these entities. Five entities are used namely; employee, patient, record, department and test. The entity employee consists of doctors, nurses, and lab assistants. For example, each employee is identified by his or her ID number, first name, last name, department ID number, employee designation, address, contact number, and nationality.

Figure 1. System hardware architecture

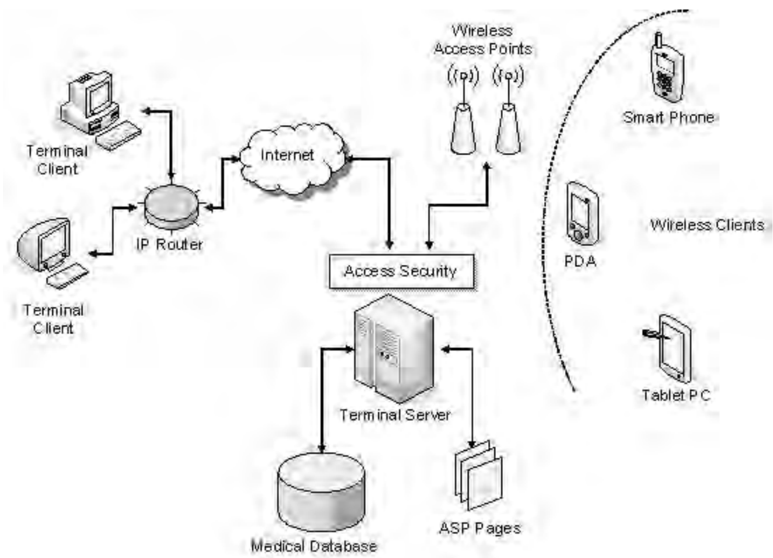

Figure 2. System software tiers

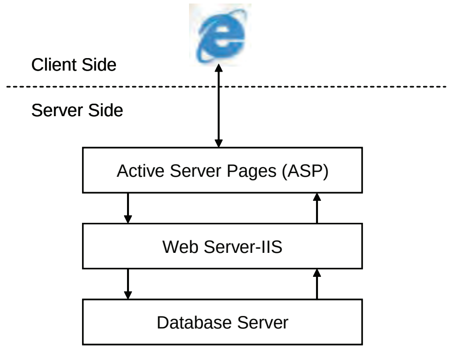

Table 1. Database fileds corresponding to the system entities

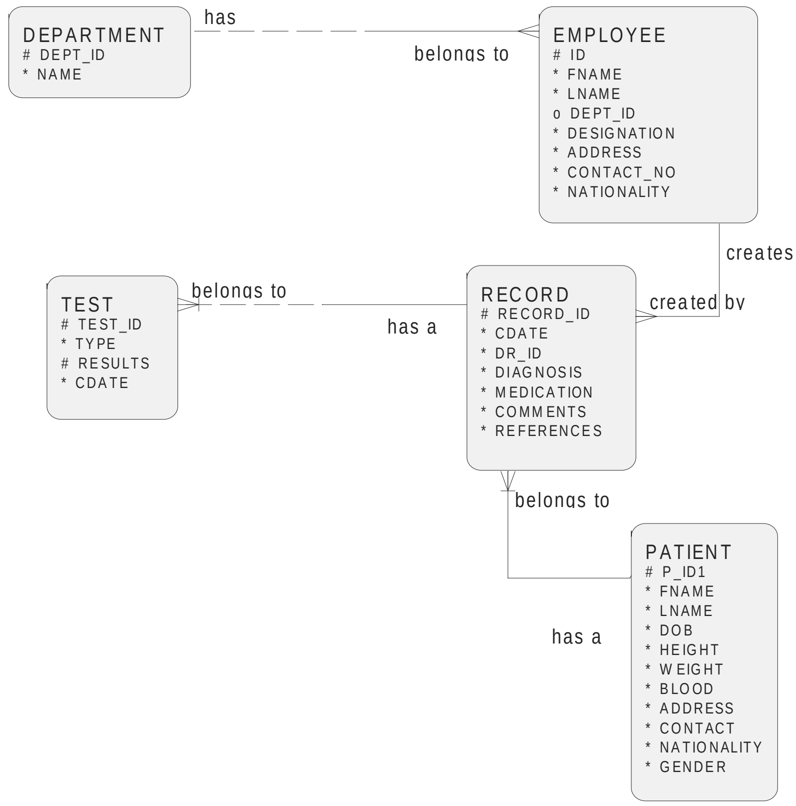
Sr. No	Entity	Attribute	Description
1	**Employee**	ID	Unique identification number of the employee
		FName	First name of the employee
		LName	Last name of the employee
		Dept_ID	Unique department to which the employee belongs
		Designation	Post of the employee in his or her respective department
		Address	Mailing address of the employee
		Contact_no	Contact information
		nationality	Nationality of the employee
2	**Patient**	P_ID1	Unique identification number(patient id) of the patient
		FName	First name of the patient
		LName	Last name of the patient
		DOB	Date of birth of the patient
		Height	Height of the patient
		Weight	Weight of the patient
		Blood	Blood group of the patient
		Address	Mailing address of the employee
		Contact_no	Contact information
		Nationality	Nationality of the employee
3	**Record**	Record_ID	Unique identification of the record along with the P_ID
		CDate	System Date when the record is stored
		Dr_ID	Doctor id
		Diagnosis	Diagnosis of the medical problem
		Medication	Medication prescribed
		Comments	Further comments regarding the record
		References	References to other doctors, medical staff, etc.
4	**Department**	Dept_ID	Unique identification of the department
		Name	Name of the department
5	**Test**	Test_ID	Unique identification of the test in combination with the record id and patient id
		Type	The type of the test
		Result	The results of the test
		CDate	System Date when the record is stored

Figure 3. Entity relationship diagram



A table for each of the entities was constructed and the unique and primary keys for the entities were issued. The final design was implemented in SQL server. The SQL Server technology was chosen because it has enterprise data features, is better in maintaining data integrity, supports triggers and rollbacks, and stores procedures and dynamic data processing. Table 1 describes the entities and the attributes along with a brief description of each. Figure 3 shows the Entity Relationship Diagram.

Web Site Design

A complete functional and interactive Web site for the hospital "Care Well Hospital" medical centre, which is accessible through local intranet and from the Internet, is designed. This site is developed using Active Server Pages (ASP®) and Visual Basic® scripting that was embedded in HTML files. The advantages of using ASP are fast execution, no client-side constraints, ODBC links to any data source and orientation towards Microsoft products. A snapshot of the home page is shown in Figure 4. A dropdown menu helps the users to activate one of the hotlinks to access any of the system functions such as medical services, visiting hours, login, logout, etc. An authorized person can access personal records, patient records, patients table, and add new patients' records. For example, the patients' table link returns a list of all patients who are already registered in the system. Figure 5 shows the existing patients list. Search by a specific key such as "Patient ID" or "Last Name." Figure 6 shows that a patient search by last name "Kumar" returns a list of patients records with matching last name.

PDA INTERFACE AND CONNECTIVITY

System Hardware and Software Description

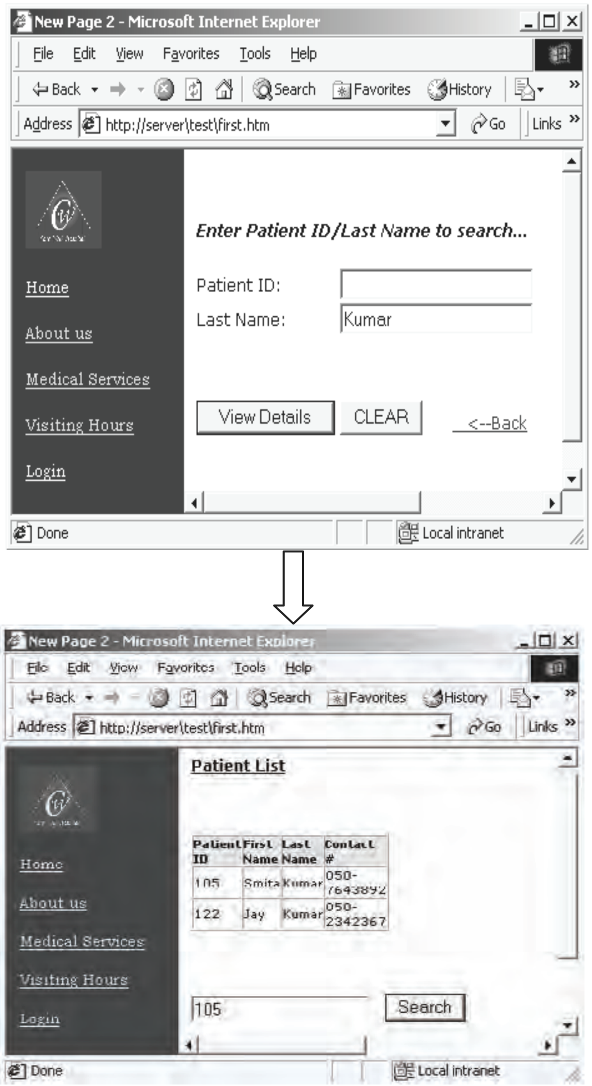
To access the Web site that contains the patient information system via PDA, combination of hardware devices and software drivers are needed.

As shown in Figure 1, the hardware requirements are:

- A Web server along with Internet connection to the service provider.
- PDA with WLAN access interface card.
- Wireless access points.

The software drivers used a set of protocols that provide client utilities such as client manager,

Figure 6. Search by last name output



link status, wireless client login, and encryption manager. The USB connection between the server and the PDA is used to install the above-mentioned software utilities on the PDAs. The USB cable is later removed and the wireless connection became available between the PDA and the LAN via the wireless access point.

The system provides two modes of connectivity, namely server-client model and wireless model. The server-client model uses standard access method to the LAN of the hospitable where doctors, nurses, and lab assistant can create, modify, and access the patient's information system via the Internet Service Provider (ISP) wired conductivity.

In the wireless model, the study used an off-the-shelf Compaq-200 PDA with the following specifications:

- 400MHz processor, Windows CE for Pocket PC operating system, 64-MB SDRAM & 32-MB Flash ROM memory.
- Interfaces: WLAN (IEEE802.11b) and Bluetooth (IEEE802.15) compliant. The distance range of the PDA was 100 meters (class-2 radio).
- TFT liquid crystal display with viewable 64K color image size 2.25 inch wide by 3.02 inch tall.

For wireless access purposes, commercially available wireless access points are used in the study. The access point provides 40-bit and 128-bit wired-equivalent privacy (WEP) encryption security over the 100m coverage area. It is IEEE 802.11b compliant and works at self-adjusted data rates of 11, 5.5, 2, and 1 Megabits/s (Mbps).

Wireless Access Client-Server Synchronization

Synchronizing the wireless access between the Server and the Client is done in two ways:

- Configuration of the wireless access through the Server being connected to the Internet: This was accomplished using a hub through which the server was connected to another network, which was connected to the Internet. The PDA accessed this server through the wireless access point and was able to access sites on the Internet as well.
- Configuration of the wireless access through Terminal Services on LAN: Wireless access through terminal services was introduced as a safety procedure in case Internet access is not available. Terminal services are implemented using Windows 2000® Advanced Server.

SECURITY ISSUES

Two levels of security were implemented, one for the advanced server and the other for the SQL server.

Windows Advanced Server Security

Using the administrative tools, privileges are granted to users and groups. Privileges include restarting the server, modifying certain settings, accessing databases, etc. This is done by creating different profiles for the users and then granting the required privilege. For instance, if an employee is registered under the group "Lab Assistant," upon logging-on to the Windows 2000® system as a Lab Assistant, he or she is given those privileges assigned to the group "Lab Assistant." The privilege denies the lab assistant to reboot the system.

Microsoft SQL Server Security

The SQL Server authentication mode used is "Windows Authentication Only." In other words, SQL Server automatically authenticates users based on their Windows user account names or their group membership. If you've granted the user or the user's group access to a database, the user is automatically granted access to that database.

The SQL Server security model controls access to the database using the server login, permissions and roles.

IMPLEMENTATION AND TESTING

Trial System Implementation

One of the problems encountered during implementation was due to the mismatch of screen resolution of PDA and the Web page. The problem occurred because the contents were being directly viewed from the server's default browser. The problem was solved by using a built-in browser of the PDA. Setting of wireless configurations presented another problem. Initially, a personal LAN was set up using the 3COM wireless access points. Following this, the wireless network card was registered with the Information Technology department of the American University of Sharjah (AUS), so that the PDAs could access the AUS network. Problems such as conflicting devices and security issues had to be dealt with. The solution was to select the auto channel setting when configuring the access point.

Trial System Testing

The designed system has been implemented using AUS infrastructure and tested by doctors, nurses, and lab assistants of AUS healthcare center. AUS infrastructure provided large number of workstations and wireless points distributed throughout the campus. Two wireless PDAs with wireless jackets are used for testing wireless functions.

Each one of the users logs on to network with his or her unique ID and password. The system first validates the ID and password, and then gives access based on the assigned privileges. The following instance shows how the SQL Server database is accessed to retrieve or modify data.

Doctors have the following options and privileges:

- View Personal Records.
- Update Address and Contact Number.
- Search for a Patient using Patient's last name or ID.
- Search for the general record details of a patient using the unique patient ID.
- View the specific record details for a particular record given the record number and Patient ID.
- Create new records for the patient. View a list of all those patients who are under him.
- Can add a new patient to the Patient Database.

The options given to nurses are:

- Update, Create Personal Records.
- Update, Create Patient Records.
- View Patient Table.
- Add New Patient.

The authorized privileges for lab assistants are:

- View Personal Records.
- Can update Address and Contact Number.
- Register Test Results for a patient by entering the patient ID number and the record number view the test results for a patient by entering the patient ID number and the record number.

When the nurse chooses to view the patient table, a list of all the patients is generated. This list contains the Patient ID, First Name, Last Name, and Contact Number of the patient. Figure 7 shows the system response for such a query. It shows the number of record for the patient, data of the visit, visited physician ID and Name, and the diagnosis by each physician.

The ASP Code accesses the database from the SQL Server because the nurse has been authenticated by the login process. Following this, a selected set of columns is retrieved from the database and is displayed to the end user. All of the above activities are tested using wireless PDAs. Also, it is found that they can be carried out and viewed just as it can be done using wired servers.

The ASP Script appends the entered data into the Record Table of the Hospital Database. Furthermore, the ASP Script also stores the Doctor

Figure 7. System output using patient's ID key search

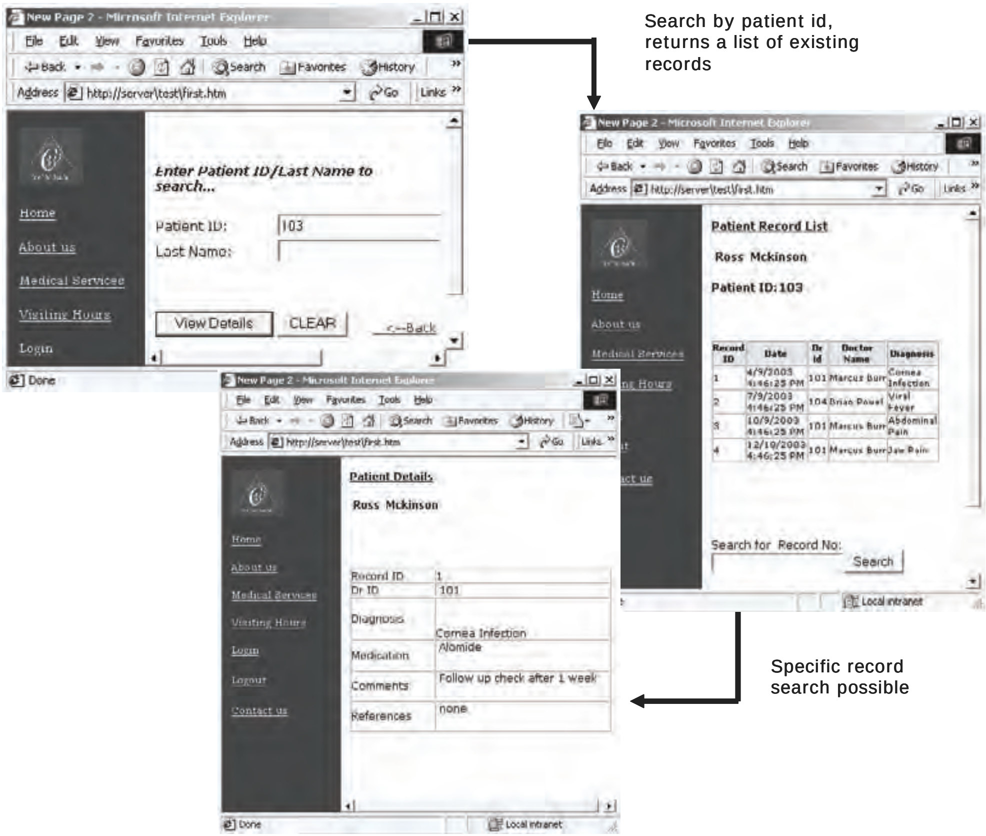


Figure 8. Simultaneous access times through Web-based database using wired and wireless PDA combinations

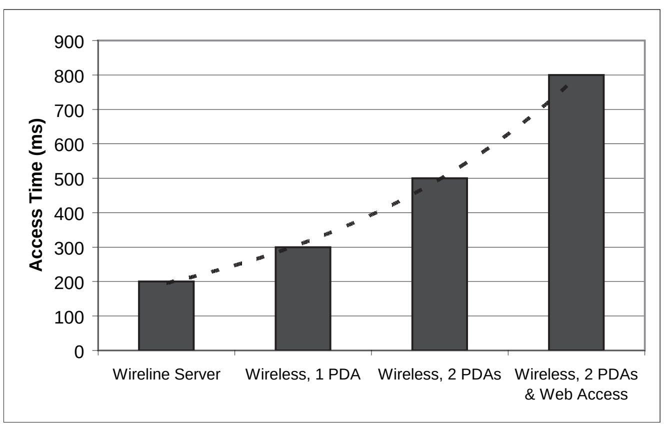

ID (which is a session variable) and the System date into the Record Table. It is worth mentioning that once a patient record is accessed for editing, the database locks the file and it can not be updated by the another user until the current session is finished. However, the stored version of record can be viewed while the update session in progress.

SYSTEM PERFORMANCE ANALYSIS

The system is implemented on AUS network, which covers the entire campus with wired and wireless links. Two wireless PDAs are used for measuring performance of the system. Figure 8 indicates the access time performance values measured during the trial. The access time values were measured while the PDAs were trying to access the server simultaneously. Even though the manufacturer specifications indicate that wireless devices should work with up to 100 meter distance from wireless access points, our tests indicated that the maximum reliable distance from wireless points are around 60 meters.

Our tests also indicated that network traffic over the intranet, which is not related to electronic patient record database increased the previously mentioned access times about 20% as shown in Figure 9.

System access failure rate was studied as a function of PDA-to-access point distance. The results are shown is Figure 10. As it can be seen, the success rate drops drastically as the distance approaches 60 meters.

Figure 10. System access failure rate as a function of distance for different numbers of mobile users

CONCLUSION

A wireless PDA-based patient's information system was designed, implemented, and tested. Hospital personnel can access, create, and update the patient's record using standard Internet browsing method through wireless mobile devices. The system gives the health personnel the mobility feature where they can check their patient's record from anywhere in the hospital using the wireless PDA or using Internet browser from any other location. Limited system performance tests indicated

Figure 9. Impact of concurrent Internet access on the access times through Web-based database

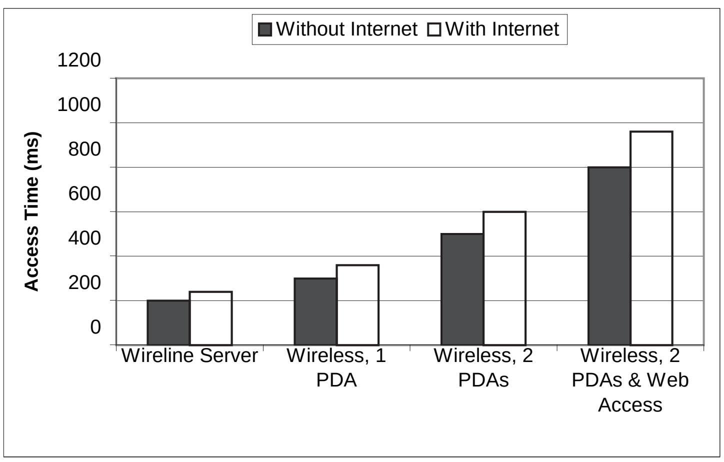

Figure 10. System access failure rate as a function of distance for different numbers of mobile users

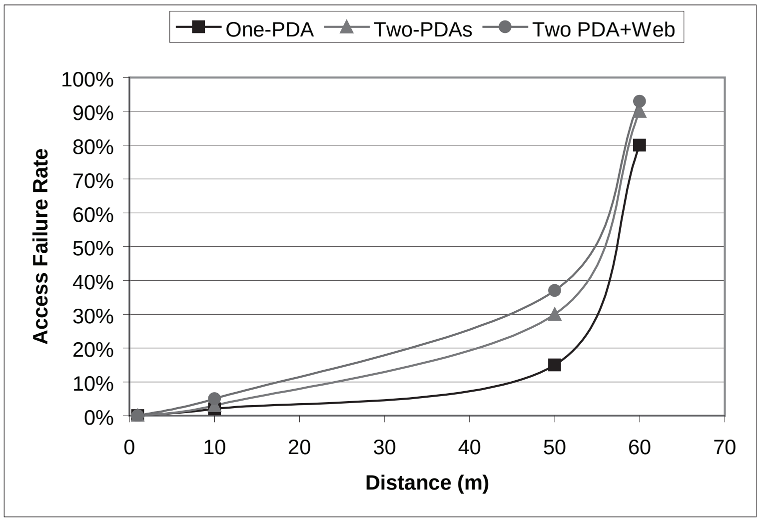

satisfactory performances as long as the hospital's environment is well covered with wireless access points with access distance not exceeding 60 meters. Although it is not implemented in the test system, the users indicated that the inclusion of a practical messaging system similar to pagers will make the system even more useful.

ACKNOWLEDGMENT

The authors would like to express their thanks to Mr. Rahul Saharia, Ms. Sharmila Gupta, Ms. Suvina Singh and Ms. Tara Thomas for their valuable contributions to the project, AUS-IT Center, AUS Medical Center, and local representatives of HP for providing equipment support for the project.

Chapter 3.11
Mobile Clinical Learning Tools Using Networked Personal Digital Assistants (PDAs)

Bernard Mark Garrett
University of British Columbia, Canada

INTRODUCTION

The School of Nursing at the University of British Columbia has more than 300 nursing students engaged in supervised clinical practice in hospital and community settings around Vancouver. Likewise, the Faculty of Medicine has more than 200 medical students undertaking supervised clinical experience locally and remotely in the Prince George and Vancouver Island regions. The management of these clinical experiences and the promotion of learning while in an active clinical setting is a complex process.

BACKGROUND

Supporting the students at a distance while undertaking their clinical experience is particularly resource-intensive. It requires the creation and maintenance of good communication links with the clinical and administrative staff, active management, clinical visits from faculty, and the provision and management of remotely based resources. However, there were few existing resources that helped to contextualize and embed clinical knowledge in the workplace in the practice setting (Landers, 2000). A technological solution was developed and implemented using several clinical applications designed for use on personal digital assistants (PDAs).

MOBILE CLINICAL LEARNING TOOLS

A suite of PDA-based tools were created for a pilot study with the involvement of nursing and medical students during the academic year of 2004-2005 to achieve the following objectives:

- To demonstrate the potential use of mobile networked technologies to support and improve clinical learning.
- To develop and evaluate a range of mobile PDA tools to promote reflective learning in practice and to engage students in the process of knowledge translation.

- To develop and evaluate a suite of pedagogic tools that help contextualize and embed clinical knowledge while in the workplace.
- To evaluate the value of networked PDA resources to help prevent the isolation of students while engaged in clinical practicum.

The tools developed provide a mobile clinical learning environment incorporating an e-portfolio interface for the Pocket PC/Windows Mobile (Microsoft, 2004) operating system. They were implemented on i-mate PDAs equipped with GSM/GPRS (Global System for Mobile Communications/General Packet Radio Service; GSM World, 2002). This platform offered considerable flexibility for the project. It supported the use of cellular telephone connectivity and Pocket Internet Explorer Web browser (which has a full Internet browser with support for HTML, XML/XSL, WML,cHTML, and SSL); the i-mate device had sufficient memory for the storage of text, audio, image, and video data, with a large screen and a user-friendly interface with an integrated digital camera.

The tools included a mobile e-portfolio (with a multimedia interface) designed to promote professional reflection (Chasin, 2001; Fischer et al., 2003; Hochschuler, 2001; Johns, 1995; Kolb, 1984). These mobile learning tools were designed to promote the skills of documentation of clinical learning, active reflection, and also to enable students to immediately access clinical expertise and resources remotely. Community clinical placements are being used for the testing domain, as there are currently no restrictions on using cellular network technology in these areas, whereas this is currently restricted in acute hospital settings in British Columbia and many other parts of the world.

THE PDA INTERFACE DESIGN

The main interface to the clinical tools was based on a clinical e-tools folder on the Pocket PC containing icon-based shortcuts to a number of specific applications (Figure 1).

The clinical e-portfolio tool represented the major focus for the project, allowing the student to access clinical placement information; log clinical hours; achieve clinical competencies; record portfolio entries in the form of text, pictures, or video clips; and record audio memos. This provides the user with a very adaptable interface, allowing them to choose how they input data. For example, a text-based entry describing a clinical procedure may be accompanied by a picture or audio memo.

The e-portfolio tool also incorporates a reflective practice wizard promoting the students to work through the stages of the Gibbs reflective cycle (Gibbs, 1988) when recording their experiences. This wizard also allows students to record their experiences with multimedia, including text, audio, digital images, or video input. Once the data have been recorded in the e-portfolio, they can be synchronized wirelessly (using the built-in GSM/GPRS or Bluetooth connectivity) with a Web-based portfolio. The data then can be reviewed and edited by the student or by clinical tutors.

The other icons represent the following applications:

- The synch portfolio icon initiates synchronization of the content of the student's e-portfolio on the PDA with that of a remote server.
- The University of British Columbia (UBC) library icon presents a shortcut to a Pocket Internet Explorer Web access to the UBC library bibliographic health care database search (CINAHL, Medline, etc.).

Figure 1. Screenshot of the clinical e-tools folder

- The Pocket Explorer icon presents a shortcut to Pocket Internet Explorer for mobile Web access.
- The e-mail icon presents a shortcut to the Pocket PC mobile e-mail application.

The other icons on the screen (Diagnosaurus, ePocrates, etc.) represent third-party clinical software that was purchased and loaded onto the PDAs in order to support the students learning in the clinical area (e.g. a drug reference guide).

FUTURE TRENDS

In the future, the PDA will provide a one-stop resource to support clinical learning. Students also will be able to examine their learning objectives, record their achievements, and record notes/memos attached to specific clinical records for later review. Where students have particular concerns or questions that cannot be answered immediately in the clinical area, they will be able to contact their supervisors or faculty for support using e-mail, cell phone, or multimedia messaging service (MMS) communications.

The use of multimedia in PDA interfaces is likely to become much more widespread as the cost of these devices reduces and they become more accessible to a wider spectrum of the population. This already is occurring with the merging of cell phone and PDA technologies and the uptake of MMS and use of audio and video data entry on mobile devices (deHerra, 2003).

In the long term, multimedia mobile learning tools will encourage a more structured process of professional reflection among students in supervised clinical practice (Conway, 1994; Copa et al., 1999; Palmer et al., 1994; Reid, 1993; Sobral, 2000). When unexpected learning opportunities arise, students will be able to quickly review online materials in a variety of formats and prepare for their experience, record notes, record audio memos or images during their practice, and review materials following their experience.

An expansion in the use of such mobile clinical learning tools is envisaged, and there is considerable scope for the widespread application of such tools into areas where students are engaged in work-based learning. We are likely to see the integration of these technologies into mainstream educational practice in a wide variety of learning environments outside of the classroom.

CONCLUSION

The value of these new tools to students in clinical practice remains to be demonstrated, as the evaluation stage of the project has yet to be completed. The project also has highlighted the necessity of addressing some of the weaknesses of current PDA design, such as the small display screen and the need for more built-in data security. However, initial feedback appears promising, and the interface design appears to promote reflective learning in practice and engage students in the process of knowledge translation.

KEY TERMS

Bluetooth: A short-range wireless radio standard aimed at enabling communications between digital devices. The technology supports data transfer at up to 2Mbps in the 2.45GHz band over a 10m range. It is used primarily for connecting PDAs, cell phones, PCs, and peripherals over short distances.

Digital Camera: A camera that stores images in a digital format rather than recording them on light-sensitive film. Pictures then may be downloaded to a computer system as digital files, where they can be stored, displayed, printed, or further manipulated.

e-Portfolio: An electronic (often Web-based) personal collection of selected evidence from coursework or work experience and reflective commentary related to those experiences. The e-portfolio is focused on personal (and often professional) learning and development and may include artefacts from curricular and extra-curricular activities.

General Packet Radio Service (GPRS): A standard for wireless communications that operates at speeds up to 115 kilobits per second. It is designed for efficiently sending and receiving small packets of data. Therefore, it is suited for wireless Internet connectivity and such applications as e-mail and Web browsing.

Global System for Mobile Communications (GSM): A digital cellular telephone system introduced in 1991 that is the major system in Europe and Asia and is increasing in its use in North America. GSM uses Time Division Multiple Access (TDMA) technology, which allows up to eight simultaneous calls on the same radio frequency.

i-Mate: A PDA device manufactured by Carrier Devices with an integrated GSM cellular phone and digital camera**.** The device also incorporates a built-in microphone and speaker, a Secure Digital (SD) expansion card slot, and Bluetooth wireless connectivity.

Personal Digital Assistant (PDA): A small handheld computing device with data input and display facilities and a range of software applications. Small keyboards and pen-based input systems are commonly used for user input.

Pocket PC: A Microsoft Windows-based operating system (OS) for PDAs and handheld digital devices. Versions have included Windows CE, Pocket PC, Pocket PC Phone Edition, and Windows Mobile. The system itself is not a cut-down version of the Windows PC OS but is a separately coded product designed to give a similar interface.

Wizard: A program within an application that helps the user perform a particular task within the application. For example, a setup wizard helps guide the user through the steps of installing software on his or her PC.

Chapter 3.12
Choosing Technologies for Handheld and Ubiquitous Decision Support

Darren Woollatt
University of South Australia, Australia

Paul Koop
University of South Australia, Australia

Sara Jones
University of South Australia, Australia

Jim Warren
The University of Auckland, New Zealand

ABSTRACT

Wireless, handheld devices are becoming increasingly popular in health care settings, but the full potential of their role in patient-specific decision support remains to be achieved. This article presents a multicriteria framework for choosing technologies apropos to handheld and ubiquitous decision support architecture. This framework is illustrated through architectural middleware choices made in the context of a podiatry and diabetes care network. Performance issues are found to be very important in the handheld space, and minor aspects of connectivity and other constraints drive significant changes in choices of architectural approach. The resulting architecture employs layers, including serialized objects, XML payloads, event notification, Web services, and dynamic class loading, with the mix varying among the system interfaces. The overall recommendation is that organizations wishing to fully exploit mobile technology must use a flexible policy and pursue a process of technology choice that is scenario-based and iterative to take into account discoveries from prototyping and field-test experience.

INTRODUCTION

Handheld computers acting as personal digital assistants (PDAs) are growing in popularity in health care. They are increasingly trusted (particularly as sources for reference material), used, and considered to be efficient (Cimino & Bakken, 2005). A mid 2004 survey (Grasso, Yen, & Mintz, 2005) found 52% of medical students reporting handheld computer use, with drug reference and clinical calculators the major clinical applications of the technology. Characterizing the use and capability of PDAs is an exercise in measuring the position of a moving target, but the dominant trend sees students as a key user group and reference for education as a key application area. PalmCIS (Chen, Mendonca, McKnight, Stetson, Le, & Cimino, 2004) illustrates the less common use of mobile technology as a terminal for viewing patient data. In a nursing context, Chang, Lutes, Braswell, and Nielsen (2006) found that mobile technology integrated with a hospital's mainframe system improves the communications between shifts. Lu, Xiao, Sears, and Jacko (2005) and Fischer, Stewart, Mchta, Wax, and Lapinsky (2003) also have reviewed handheld applications in health care, and Wu and Straus (2006) and Lane, Heddle, Arnold, and Walker (2006) have conducted systematic reviews. Wu and Strauss found limited, but supportive, evidence that handhelds improved documentation taken by physicians. The more functionally ambitious handheld solutions in health care are generally "home-grown" (i.e., purpose-built for a specific application context).

Handheld computing and mobile communications move us closer to a ubiquitous computing environment, where the notions of "a computer" or "the information system" become less central to the attention of the end user and where many often loosely coupled subsystems collaborate to achieve an overall goal. At the University of South Australia (UniSA), we have been following a vision of ubiquitous decision support for chronic disease management with an emphasis on diabetes and foot care that integrates the roles of clinical decision support, provider education, and patient education (Warren, Lundstrom, Osborne, Kempster, Jones, Ma, & Jasiunas, 2004). Two key elements of this vision have been a handheld data collection and decision support application for students at the UniSA Podiatry Clinic (Lundström, Warren, Jones, Chung, & Jasiunas, 2003); and an individualized Web-based consumer diabetes information service (Ma, Warren, Phillips, & Stanck, 2005).

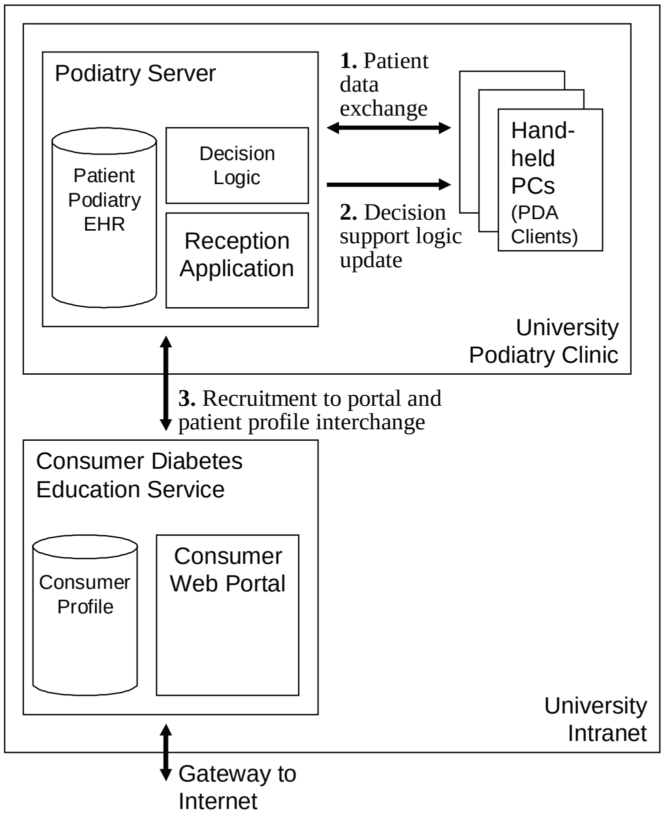
In the context of ongoing iterative development of handheld and ubiquitous decision support, one is faced with a diversity of architectural options in an environment of rapidly changing technology. The remainder of this paper presents a framework for consideration of relevant technology choices, with particular focus on middleware architecture, which is illustrated in terms of a cycle of development in the UniSA podiatry/diabetes management environment. The outcomes highlight the sensitivity of technology appropriateness to existing constraints and the ongoing relevance of performance.

METHODS

Setting

A spiral development lifecycle has been pursued with the UniSA Podiatry Clinic from mid 2002. The objectives of a cycle for calendar year 2005 entailed: (a) achieving a production client-server system in the podiatry clinic, allowing students to undertake podiatry assessments using handheld computers with results logged to a central database; (b) active decision support for the podiatry students on the handheld terminal to critique assessment and plan in terms of recorded observations; and (c) interfacing of the podiatry clinic to a diabetes consumer education service such that the clinic acts as a recruitment point for the education

Figure 1. Podiatry/diabetes care network setting (technology choice scenarios numbered)



service, and podiatry observations lead to tailoring of educational priorities. The environment, with the major communication scenarios addressed in the 2005 cycle, is illustrated in Figure 1.

Aspects of the design were fixed at the commencement of the 2005 cycle, constituting developments, investments, and decisions that were undesirable or infeasible to back away from. These fixed aspects of the design include: (a) use of Hewlett-Packard iPAQ pocket PCs with Microsoft Windows operating system as the podiatry clinic terminals; (b) the elements recorded in the podiatry review, user interface design for data capture, and podiatry clinic server database design (encompassing some 200 specific observations, including some free-hand sketches); (c) the use of Bluetooth for communication within the podiatry clinic (due in part to administrative "turf" problems entangling development on 802.11 standards); and (d) the implementation of the Web portal for the consumer diabetes education service to be impacted minimally.

Outside of these fixed constraints, the outstanding architectural decisions concerned the approach to data interchange at the application level among the major system components, including interchange of decision support logic, a realm that can be termed "middleware architecture." All of these communication interfaces were required to support modification of content in the future, but the decision support content was seen as the most volatile, with plans for active iterative refinement of the logic in a future cycle. Experience with an earlier cycle prototype indicated that the data transmission speed performance of the podiatry server to handheld data exchange link was problematic, although a naïve analysis of Bluetooth bandwidth left the source of the problem unclear.

Procedure

Our procedure was informed by Serain's (2002) "criteria based table model" (p. 211) and the practice of defining scenarios that are to occur within the architecture, as demonstrated by Goedicke and Zdun (2002) and Dobrica and Niemelä (2002).

Major architectural options were identified and each assessed in terms of a number of criteria. It should be noted that the architectural options are not, in general, mutually exclusive, and assessment on criteria is qualitative. The purpose of the resulting option-×-criteria grid is to inform the synthesis of candidate designs, not to support a mechanistic choice of a single option. Each cell of the grid should be populated with an explanation of the qualitative judgement and possibly include a number of unresolved issues. This procedure is iterative. Review of the option-×-criteria grid can result in options being dismissed, merged, or split.

Criteria

The decision criteria group was separated into what classically is called "functional" and "'non-functional" requirements, although we prefer to designate the criteria groups as *case-specific* and *generic*. One case-specific criterion is identified for each major system interfacing scenario. In the current setting, these scenarios are:

1. Distributing and synchronizing patient data (around the podiatry clinic);
2. Ability to transfer decision support logic (from the podiatry server to handheld PCs); and
3. Ability to transfer profiling information (to focus consumer diabetes education, moving data between the podiatry clinic and Web-based consumer education setting).

The generic criteria are fairly standard aspects of systems integrity, but many take on a degree of specific meaning in the health computing context:

- **Security:** Acceptable handling of patient data (notably HIPAA compliance in the United States, although not in demonstration context);
- **Performance:** Chiefly latency, and also reliability;
- **Maintainability:** Outlook for the long-term feasibility of the solution in terms of a continuing user community and availability of technical staff for maintenance;
- **Maturity/vailability:** Presence of standards (de facto or otherwise) to provide stability and practicality of acquisition;
- **Flexibility:** Supporting explicitly expected changes and reasonable estimation of long-term change (A special bonus is if one technology is flexible enough to encompass multiple requirements of the system, making the system simpler overall.); and
- **Feasibility:** To further diffuse "tick-box" thinking, a summative assessment that the technology is actually practical and can fulfil the requirements in question.

RESULTS

Technology Assessment Decisions

Initial brainstorming in the development team (authors Darren Woollatt, Jim Warren, and Paul Koop) revealed seven options for further exploration from among a diverse range of health-specific initiatives, relatively modern generic

Figure 2. Abbreviated option—criteria grid for middleware architecture technology choices

Criterion	HL7	openEHR	iROS	SOAP	CORBA	DCOM	RMI
Scenario 1	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Scenario 2	Yes, Arden	N/A	1, 2	1, 2	1	1	1
Scenario 3	Yes	Yes	Yes	Yes	Yes	3	Yes
Security	Add on	Add on	Add on	Add on	Built in	Built in	Built in
Performance	4	4	4	4	4, well-studied	4, well-studied	4
Maintainability	5	5	OK	Good	OK	3	Good, part of JDK
Maturity/ availability	5, 6	5, 6	6	6	6	3	6
Flexibility	Suits purpose	Suitable for scenario 1 and 3	Very flexible	General	General	General	General
Feasibility	7	7	Good	Good	8	3	Good

[1]*Can transfer guideline representation for interpretation on client*

[2]*Can serialize object with decision logic for execution on client*

[3]*Operating system and language limitations of DCOM (or .NET) are a concern; current Diabetes Consumer Education Service is on Linux*

[4]*A concern for Scenario 1—must be measured in context*

[5]*Steep learning curve and technology is rapidly changing, although adherence to a standard is a plus.*

[6]*Open with freely available implementations and user communities; somewhat more restricted to members for HL7. iROS community rather small but deemed adequate*

[7]*HL7 v3 requires process using RIM to create new messages for our highly specialized application; somewhat better supported and more approachable process using openEHR archetypes*

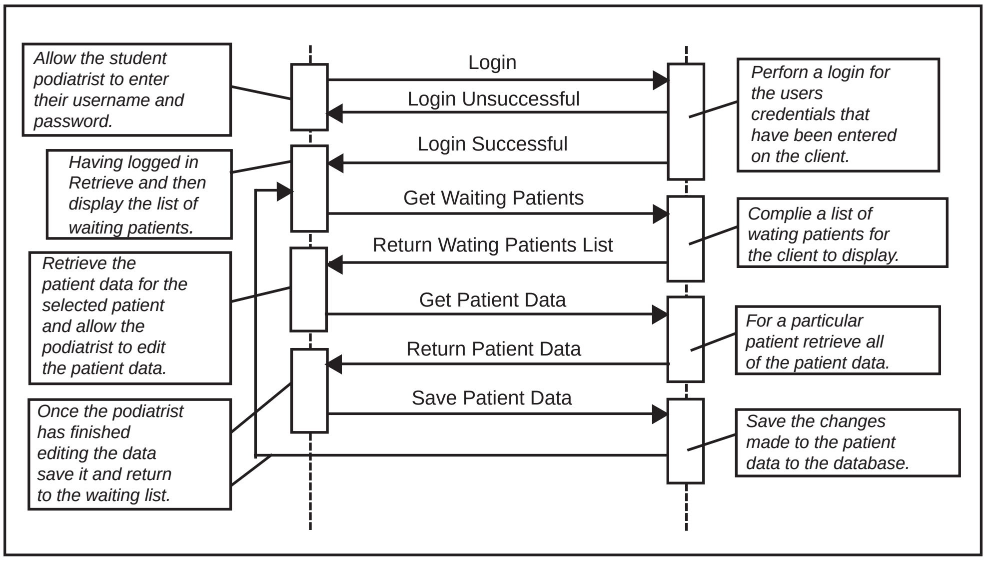
[8]*Possible, but over-spec to needs in absence of multilanguage and legacy system integration motivators of CORBA*

solutions, and solutions of historical interest for comparison. Probably the least generally well-known option under consideration was iROS (Open Source Technology Group, 2006), which had a track record of use for enabling "interactive rooms" through a messaging service and was familiar to the authors. An abbreviated first-cut option-×-criteria grid is shown in Figure 2. The full grid, as used by the development team, occupies a color A3 sheet in 10-point type with 40 footnotes on ancillary pages.

With respect to the first scenario, remote method invocation (RMI) and iROS emerged as strong options based on transfer of serialized objects. Simple object access protocol (SOAP) (W3C, 2004) also had promise. It also had an edge in extensibility, if serialized objects were not used, but required use of XML, which seemed like it might be a performance issue, especially on the client (handheld) side, where computing power for parsing a large XML payload is quite limited. All three options are capable of having XML components to the message, which could then support Health Level Seven (HL7)(2006) or OpenEHR (n.d.) as a further layer.

Performance analysis revealed that a "typical" patient review as a serialized object was 564kB in size and required about 14 seconds to transfer over our BlueTooth connection from the client to server using iROS. However, application of a

Figure 3. Sequence diagram for podiatry application client/server interaction

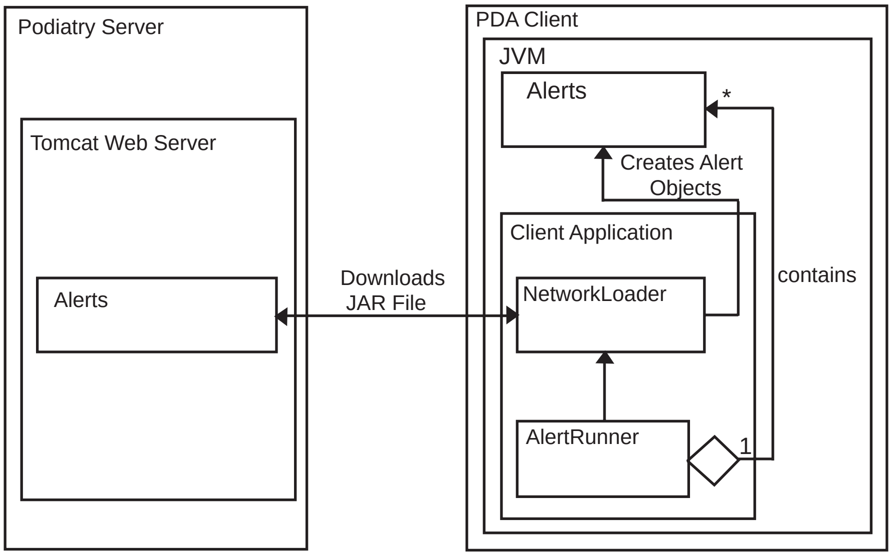


compression routine from the Sun Microsystems Java Development Kit JDK reduced this to 14.5kB and brought the transfer time (with the negligible compression time included) down to an acceptable 0.85 seconds. iROS was compared to SOAP and found to be about 2.5 times faster for the same test object. Encryption of several sensitive fields (again using a JDK routine) also was included with no observable performance impact, yielding an overall acceptable solution to scenario 1. Layering of HL7 or openEHR was not pursued in this scenario, due to performance concerns, availability issues that parallel scenario 2 and 3 as discussed below, and minimal perceived relevance for a system as tightly coupled as the podiatry server and handheld client. The iROS solution was chosen over an RMI solution largely due to developer familiarity.

With respect to scenario 2, SOAP emerges as particularly promising for invocation of decision support methods on the server from the handheld devices. However, a significant constraint in this scenario is that the users may wander outside of BlueTooth range at the time when decision support alert logic must be checked. (This is done interactively in the consulting rooms, whereas scenario 1— completion of the previous patient and start of the next—is done in close physical proximity to Clinic reception desk and the server.) As such, we are restricted to methods that actually transfer the decision support logic to the client at some time between user login and start of processing on the first patient of the user session.

One promising option for transfer of decision support logic was to use a representation scheme, such as the Arden syntax (Jenders, 2006) of HL7. However, this requires the client to interpret logic statements in a high-level specification language, raising issues around performance, as well as the question of availability of such an interpreter to run on a handheld PC. Given the difficulties of an interpreted logic solution, the technology choice taken was to write the decision logic in Java such that all decision alerts shared a common Java interface. Central update of decision logic is achieved by redirecting the handheld client's class loader to the server (see Figure 4), exploiting the compactness of a Java archive (JAR) file to move the logic as Java byte code.

Figure 4. Architecture for updating client decision support logic



In scenario 3, SOAP wins out. While the podiatry server and Diabetes Consumer Education Service currently reside on a common university intranet, the probability of the clinic and Web-education services becoming more widely distributed is high, and hence the ability of the SOAP protocol to cross organizational firewalls provides maximum maintainability of the solution.

The case is strong for layering either HL7 or openEHR onto the SOAP message that transfers the patient profile (observations collected in the podiatry clinic of relevance to diabetes education; some 40 data items in the current data sets). The application fits well with the model of either an HL7 message or an openEHR EHR extract. At the time of implementation, however, neither HL7 v3 nor openEHR were offering a convenient Java toolkit; this situation is changing rapidly (see the Future Research section). The medium-term solution implemented was to provide the profile as an XML payload, but to leave the reconciliation of that payload to the HL7 RIM or an openEHR archetype for future extension of the system. W3C standards of XML signatures (Eastlake & Reagle, 2006) and XML encryption (Reagle, 2006) are applied to meet the security requirements of scenario 3.

Resulting System

With the technology assessment decisions taken as per above, the result is a close coupling of the podiatry server to the PDA clients (handheld PCs) and a looser coupling of the podiatry clinic (through the podiatry server) to the Diabetes Consumer Education Service. The PDA clients communicate to the server over BlueTooth. A sequence of iROS messages, as illustrated in Figure 3, keeps the client up-to-date with the available patients in the waiting room (tracked via a Microsoft .NET application local to the podiatry server) and transfers patient data prereview and postreview. The PDA client implements a common user interface for decision support alerts, the decision logic, which is loaded from the podiatry server when a user logs onto the podiatry application on the PDA (as per Figure 4).

At the end of the podiatry review for patients with diabetes, the PDA client prompts the user to ask whether the patient would like access to the

Consumer Diabetes Education Service. When the podiatry server receives the message to update the patient database and sees the request for an education service account, a SOAP request is issued for an account to be created on the consumer portal. Upon receiving the SOAP result, the server prints a hardcopy invitation letter for the patient with login information, including their specific username and password as provided by the Consumer Diabetes Education Service. Upon login to the portal, the consumer is prompted for consent for the transfer of information from the podiatry clinic, at which time a getProfile method is invoked from the education service to the podiatry server, causing clinical data to be extracted from the patient's podiatry reviews. This data is composed into an XML snippet by the podiatry server and returned to the education service for parsing into its own consumer/patient profile database.

DISCUSSION

We have reached an age that is ripe for innovation in handheld and ubiquitous information technology. It has never been easier to integrate applications across a range of platforms to achieve decentralized behavioral changes, such as improved chronic disease management. Specifically, growing acceptance of handheld computing in the health workplace, ubiquity of short-range radio communications, and the advent of Web services standards are making it feasible and inexpensive to field health data collection and decision support tools. Moreover, it is increasingly easy to "tack on" new avenues for the exploitation of existing functionality (taking an existing application and putting it on the Web, adding a mobile portal, mounting it as a Web Service for other applications, etc.). And many of these integration solutions are well packaged for programmers using common development environments, such as JDK and Microsoft .NET.

The range of available technology choices presents in itself a challenge. An open-minded, explicit and semistructured (but not overstructured) process of technology evaluation is warranted. Mandating a technology choice will cull potential opportunities by making them infeasible for the present, where a more flexible policy could allow them. The process of technology choice must be iterative to take into account discoveries from prototyping and field test experience, even if these emerge uncomfortably late in the project schedule (better late, or even cancelled, than an on-time, on-budget failure). Choices must be scenario based, not just generic criteria based, as subtly different constraints can make major differences in the feasibility or acceptability or particular technology choices.

Performance is a particularly sensitive issue in that technologies can yield surprisingly high latencies and surprising variances in performance among technologies and their implementations, latencies that can render a solution unusable under field conditions. This problem is acute with low-powered mobile devices, especially when using advanced solutions recently ported from mainstream computer systems. While performance of mobile devices will continue to improve, one can expect it to continue to lag the performance of nonmobile counterparts.

The issues of choice are well illustrated in our experiences with middleware architecture. A show stopper emerged on the issue of disconnected operation (for access to decision support alert methods), removing all choices based on remote method invocation from one of our scenarios. Latency was a strong issue in another scenario, driving a technology choice (and also requiring a well positioned use of compression). In addition, we placed a high value on programmer experience and toolkit availability to go ahead with what was known and involved a short learning curve. We found that very different middleware architecture technology choices came through as appropriate for each of our three major system interfacing scenarios.

Many (if not most) experienced developers will disagree with our specific choices. We fully admit to our own biases, idiosyncratic experience levels, and valuation of the features and limitations of certain options. The important message is not in our choices, but the process of choice and acknowledgment of the diversity of outcomes, even within the same development group, in differing scenarios with differing constraints.

An interesting feature of our solutions for the reported development cycle is that we did not use some of the obvious health-specific technology standards. However, we left room for their adoption in the near future.

FUTURE DIRECTIONS

We may be poised for a time where the easy uptake of health informatics standards begins to parallel their mainstream counterparts, such as SOAP and other XML-based methods. The HL7 Java SIG API (Hendler & Schadow, n.d.) indicates the emergence of appropriately usable mechanisms to integrate HL7 with ubiquitous computing applications, such as the one described in this article. In a case, such as integrating the podiatry clinic with a Consumer Diabetes Education Service, this API should prove an excellent fit. Similarly, recent release of the openEHR specification project release 1.0 (OpenEHR, n.d.) should promote further development of Java APIs on this paradigm. Proposal for a Java Compiler for GELLO,an object-oriented query expression language,(Index of /hl7/arden/2005-05-AMS, n.d.) is also timely. As per our decision support scenario, allowing use of the ubiquitous JVM as the decision support interpreter, rather than needing to port (and get adequate performance from) a high-level guideline expression interpreter, is an excellent solution where system capacity and performance are issues.

A question remains as to whether performance of new health informatics packages will be acceptable for use on small devices, including PDAs. We can expect that these devices will remain dependent on application-specific coupling to servers for many scenarios, where more than a few fields of patient data must be exchanged or where the devices must sometimes operate in disconnected mode.

ACKNOWLEDGMENT

The work reported in this article was partly funded by the Co-operative Research Centre (CRC) for Enterprise Distributed Systems Technology (DSTC) through the Australian federal government's CRC Programme (Department of Education, Science, and Training). All authors were employees or students of the University of South Australia at the time the work was conducted. Special thanks to Helen Banwell and all the UniSA Podiatry Clinic staff and students.

ABSTRACT

ECG is one of the most common signals used in medical practice due to its noninvasive nature and the information it contains. Several systems and various automated approaches have been developed that use computer technology to provide ECG diagnosis. These systems detect abnormalities and other features in the ECG signal and produce a decision which helps the physician when performing diagnosis. ECG decision support systems can serve as a diagnostic tool for specific cardiac anomalies such as myocardial ischaemia and arrhythmia.

ELECTROCARDIOGRAM

The electrocardiogram (ECG) is a clinical test that records the electrical activity of the heart.

ECG is used to measure the rate and regularity of heartbeats as well as the size and position of the chambers, the effects of drugs or devices used to regulate the heart, and the presence of any damage to the heart. An ECG is useful in determining whether a person suffers from a heart disease. If a person has chest pain or palpitations, an ECG will determine if the heart is beating normally. If a person is under medications that affect the heart or if the patient is on a pacemaker, an ECG can provide information on the immediate effects of changes in activity or medication levels. An ECG may be included as part of a routine examination in patients over 40 years old.

ECG ANALYSIS

Automated ECG analysis consists of a series of procedures that can be utilized in order to produce useful clinical information to help the physician to reach a diagnosis concerning the pathophysiological condition of the patient's heart faster and safer. ECG analysis consists of four stages: (a) signal acquisition, (b) processing, (c) feature extraction, and (d) diagnosis. Signal acquisition should fulfill certain specifications concerning the sampling frequency (100Hz to 1 KHz), the resolution (number of bits for each sample, 6 to 16), and the sensitivity, which expresses the signal's amplitude range (usually 5 mV or 6 mV). The digital ECG signal is then processed and filtered to suppress noise and enhance the relevant ECG characteristics.

In the feature-extraction stage, all the relevant ECG characteristics are recognized and some of their features are computed. The extracted features vary from simple ones like the duration and amplitude to the more complex like slopes, intervals, frequencies, or other discriminating indices. These are used in the diagnosis stage since the values of certain features are indicators of the existence of an underlying disease. Apparently, the measurement accuracy (Acc) is vital at this stage, and computerized methods are used to address it efficiently.

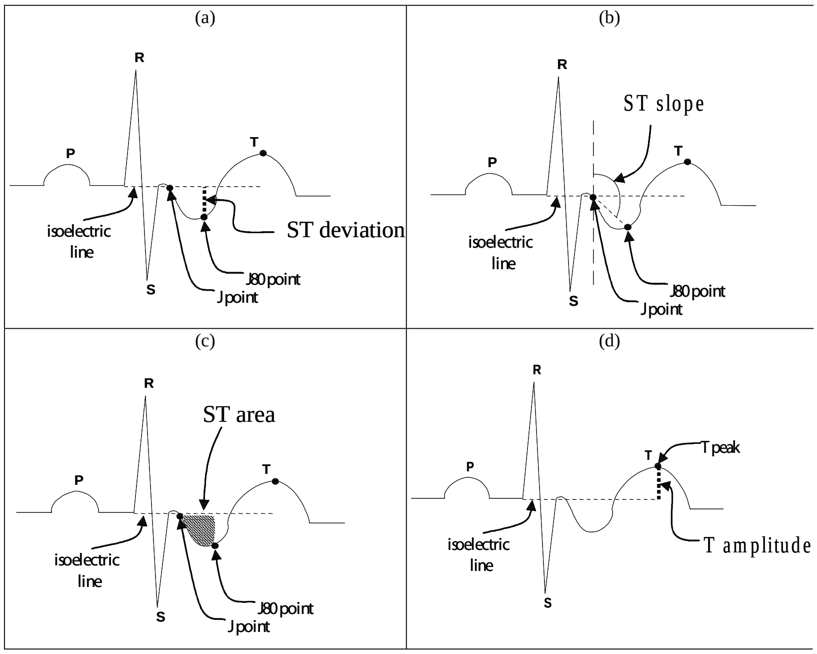
The last stage in the ECG analysis is the diagnosis, where explicit medical knowledge is utilized. Collaboration with medical experts is necessary, and the individual characteristics of each patient complicate the decision-making task. Various automated approaches have been proposed. These systems detect the abnormalities in the ECG and some of them can also produce interpretations for the decisions made. ECG analysis can help diagnose specific cardiac anomalies such as myocardial ischaemia and arrhythmia.

MYOCARDIAL ISCHAEMIA DIAGNOSIS

Myocardial ischaemia is the condition in which oxygen deprivation to the heart muscle is accompanied by the inadequate removal of metabolites due to reduced blood flow or perfusion. This reduced blood supply to the myocardium causes alterations in the ECG signal, such as deviations in the ST segment and changes in the T wave (Goldman, 1982). The detection and assessment of those alterations in long-duration ECGs is a simple and noninvasive method to diagnose ischaemia. In Figure 1, some of the typical ECG features employed for the diagnosis of myocardial ischaemia are shown.

Myocardial-ischaemia diagnosis using the ECG signal can be described as a sequence of two tasks: ischaemic beat detection and ischaemic episode definition. The first is related to the classification of beats as normal or ischaemic. Several techniques have been proposed for ischaemic beat classification, which evaluate the ST-segment changes and the T-wave alterations using different methodological approaches. More specifically, they use parametric modeling (Papaloukas, Fotiadis, Likas, & Michalis, 2002a; Pitas, Strintzis, Grippas, & Xerostylides, 1983), wavelet theory (Senhadji, Carrault, Bellanger, & Passariello,

Figure 1. Typical ECG features extracted for myocardial-ischaemia diagnosis: (a) ST-segment deviation, (b) ST-segment slope, (c) ST-segment area, and (d) T-wave amplitude



1995), a set of rules (Papaloukas, Fotiadis, Liavas, Likas, & Michalis, 2001; Papaloukas, Fotiadis, Likas, Stroumbis, & Michalis, 2002), artificial neural networks (Maglaveras, Stamkopoulos, Pappas, & Strintzis, 1998; Papadimitriou, Mavroudi, Vladutu, & Bezerianos, 2001; Papaloukas, Fotiadis, Likas, & Michalis, 2002b; Stamkopoulos, Diamantaras, Maglaveras, & Stintzis, 1998), multicriteria decision analysis (Goletsis, Papaloukas, Fotiadis, Likas, & Michalis, 2003), genetic algorithms (Goletsis, Papaloukas, Fotiadis, Likas, & Michalis, 2004), and classification using association rules (Exarchos, Papaloukas, Fotiadis, & Michalis, in press).

Cardiac beat detection and classification is a key process in the definition of the ischaemic episodes in the ECG signal. The accuracy of the beat classification influences ischaemic episode definition, in which sequences of ischaemic beats need to be identified. Various methods have been proposed for ischaemic episode detection based on a set of rules (Papaloukas, Fotiadis, Liavas, et al., 2001; Silipo, Taddei, & Marchesi, 1994), artificial neural networks (Papadimitriou et al., 2001; Papaloukas, Fotiadis, Likas, & Michalis, 2002b; Silipo & Marchesi, 1998), fuzzy logic (Vila, Presedo, Delgado, Barro, Ruiz, & Palacios, 1997), and other signal-analysis techniques (Jager, Mark, Moody, & Divjak, 1992; Lemire, Pharand, Rajaonah, Dube, & LeBlanc, 2000; Taddei, Costantino, Silipo, Edmin, & Marchesi, 1995).

The most common techniques for the beat-classification problem are neural- and rule-based approaches. Neural-based approaches have resulted in high performance but exhibit an important drawback due to their inability to provide explanations for the classification decisions. Rule-based approaches exhibit the highly desirable feature of interpreting the decisions, but their performance is not equally satisfactory in terms of accuracy.

A recent knowledge-based system analyzes the ECG signal using a four-stage algorithm (Papaloukas, Fotiadis, Liavas, et al., 2001). The four stages correspond to noise handling and ECG feature extraction, beat classification, window classification, and the identification of ischaemic episode duration. In the first stage, the preprocessing of the ECG recording is performed to achieve noise removal and the extraction of the signal features to be used for beat characterization. In the second stage, each beat is classified as normal, abnormal (ischaemic), or artefact. This information is used in the third stage (the window-characterization stage), where each 30-second ECG window is classified as ischaemic or not. In the fourth stage, the identification of start and end points of each ischaemic episode is performed. The above system is used to detect the overall episodes of ischaemia, but to distinguish also the ST episodes from the T episodes (Papaloukas, Fotiadis, Likas, Stroumbis, et al., 2002). The latter is of great clinical importance since the prognosis of ischaemic episodes with ST-segment changes is worse than those with T-wave alterations only.

Another methodology, which is based on ANNs, has been developed for the detection of ischaemic episodes in long-duration ECG recordings (Papaloukas, Fotiadis, Likas, & Michalis, 2002b). The raw ECG signal containing the ST segment and the T wave of each beat is the input to the beat-classification system, and the output is the classification of the beat. The input to the network is produced using principal component analysis to reduce dimensionality. The network performance in beat classification was tested on a subset of the European Society of Cardiology ST-T Database (*European ST-T Database Directory*, 1991), providing 90% sensitivity (Se) and 90% specificity (Sp). The neural beat classifier is integrated in a four-stage procedure for ischaemic episode detection.

Another technique employs a similar approach as fuzzy logic, multicriteria decision analysis, for ischaemic beat recognition (Goletsis et al., 2003). It deals with assigning objects, namely the cardiac beats, into predefined categories. In order to characterize each beat as ischaemic or not, the beat is compared to already assigned category prototypes. Similarity between each beat and the prototype is computed, and each beat is assigned to the category to which the most similar prototype belongs. The fuzzy pairwise comparison is made for a number of criteria that employ the ST-segment deviation and slope, the T-wave amplitude and polarity, and the patient's age. For each criterion, two parameters are estimated, the similarity and the dissimilarity, while the comparison outcome is aggregated into an indifference index with the use of criterion weights. All the parameters of the method, thresholds and weights, were adjusted using medical experience. A more recent approach uses genetic algorithms for the automatic calculation of the thresholds and the weights (Goletsis et al., 2004).

The latest developed approach for ECG beat classification employs data-mining techniques and especially algorithms that use association rules for the classification (Exarchos et al., in press). A methodology based on a three-stage schema was developed. The three stages correspond to noise handling and ECG feature extraction, feature discretization, rule mining, and beat classification. In the first stage, the preprocessing of the ECG recording is performed to achieve noise removal and the extraction of the signal features that are used for beat characterization. In the second stage, every continuous valued feature is discretized (it is transformed to categorical) in order to be utilized in the next stage. In the third stage, association-rule mining algorithms are applied to generate association rules, which are used to establish the beat-classification model. The methodology was evaluated using data from the European Society of Cardiology ST-T Database, and the obtained sensitivity and specificity were 87% and 93%, respectively.

Other approaches for beat classification are based on the combination of an auto-associative, nonlinear ANN and a radial basis function ANN (Stamkopoulos et al., 1998), ANNs and parametric

Table 1. Comparison of the performance of several methods for myocardial-Ischaemia diagnosis

Method	Se[1] (%)	Sp[2] (%)	Acc[3] (%)
ANN & parametric modelling (Papaloukas et. al., 2002)	81	8 4	
Rule-based (Papaloukas et. al., 2001)	70	63	
Feed forward ANN and nonlinear principal components analysis (Stamkopoulos et. al., 1998).	79	7 5	
Bidirectional associative memories ANN (Maglaveras et. al.,1998)			56
ANN (Classification partitioning-Self organising map) (Papadimitriou et. al., 2001)			74
ANN (Classification partitioning-Self organising map & radial basis function) (Papadimitriou et. al., 2001)			77
ANN (Classification partitioning-Self organising map & support vector machine) (Papadimitriou et. al., 2001)			80
ANN & principal components analysis (Papaloukas et. al., 2002a)	90	90	
Multicriteria decision analysis (Goletsis et. al., 2003)	90	89	
Genetic algorithms & multicriteria decision analysis (Goletsis et. al., 2004)	91	91	
Association rule mining (Exarchos et. al., 2005)	87	93	90

modeling (Papaloukas, Fotiadis, Likas, & Michalis, 2002a), bidirectional associative memories (Maglaveras et al., 1998), and the Kohonen self-organizing map algorithm combined with radial basis functions or support vector machines (Papadimitriou et al., 2001).

In order to evaluate the performance of automated systems for myocardial-ischaemia diagnosis, a standard reference database has been developed: the European Society of Cardiology ST-T Database (*European ST-T Database Directory*, 1991).

In Table 1, we can see the performance of several systems designed for beat classification.

ARRHYTHMIA DIAGNOSIS

Arrhythmia can be defined as either an irregular single heartbeat (arrhythmic beat), or as an irregular group of heartbeats (arrhythmic episode). Arrhythmias can affect the heart rate, causing irregular rhythms, such as slow or fast heartbeat. Arrhythmias can take place in a healthy heart and be of minimal consequence (e.g., respiratory sinus arrhythmia, which is a natural periodic variation in heart rate, corresponding to respiratory activity), but they may also indicate a serious problem that may lead to stroke or sudden cardiac death (Sandoe & Sigurd, 1991).

Several researchers have addressed the problem of the automatic detection and classification of cardiac rhythms. Some techniques are based on the detection of a single arrhythmia type and its discrimination from normal sinus rhythm, or the discrimination between two different types of arrhythmia utilizing time-domain analysis (Throne, Jenkins, & DiCarlo, 1991), the sequential hypothesis-testing algorithm (Thakor, Zhu, & Pan, 1990), threshold-crossing intervals (Clayton, Murray, & Campbell, 1993), artificial neural networks (Clayton, Murray, & Campbell, 1994; Yang, Device, & Macarlane, 1994), time-frequency analysis (Afonso & Tompkins, 1995; Tsipouras & Fotiadis, 2004), fuzzy adaptive resonance theory mapping (Ham & Han, 1996), and the sequential detection algorithm (Chen, Clarkson, & Fan, 1996). Another category of methods for arrhythmia detection and classification is based on the detection of different heart rhythms and their classification in two or three arrhythmia types, and the normal sinus rhythm. Techniques belonging to this category include multiway sequential-hypothesis testing (Thakor, Natarajan, & Tomaselli, 1994), wavelet analysis (Khadra, Al-Fahoum, & Al-Nashash, 1997), artificial neural networks (Minami, Nakajima, & Toyoshima, 1999), complexity measure (Zhang, Zhu, Thakor, & Wang, 1999), multifractal analysis (Wang, Zhu, Thakor, & Xu, 2001), wavelet analysis combined with radial basis function neural networks (Al-Fahoum & Howitt, 1999), and nonlinear dynamical modeling (Owis, Abou-Zied, Youssef, & Kadah, 2002). It is noticeable that all methods address the detection of only a few types of arrhythmia (atrial tachycardia, ventricular tachycardia, atrial fibrillation, and ventricular fibrillation). ECG beat-by-beat classification is another field of interest, where each beat is classified into several different rhythm types utilizing artificial neural networks (Dokur & Olmez, 2001), fuzzy neural networks (Osowski & Linh, 2001), the "mixture of experts approach" (Hu, Palreddy, & Tompkins, 1997), hermite functions combined with self-organizing maps (Lagerholm, Peterson, Braccini, Ebendrandt, & Sornmo, 2000), and time-frequency analysis combined with knowledge-based systems (Tsipouras, Fotiadis, & Sideris, 2002). These methods classify more arrhythmic beat types, but they focus on single-beat classification and not arrhythmic episode detection.

Most of the studies are based on the analysis of the ECG signal. In these methods, ECG features are extracted and used for the detection and/or classification of arrhythmias. However, the presence of noise makes feature extraction difficult and in some cases impossible. Also, most of the methods are time consuming and ineffective for real-time analysis. An alternative would be to use only the RR-interval signal. In this case, it is expected that certain types of arrhythmias can be detected and classified.

A recent work for an arrhythmia-detection method based on time and time-frequency analysis (Tsipouras & Fotiadis, 2004) utilizes only the RR-interval signal and heart-rate features. Initially, the RR-interval duration signal is extracted from ECG recordings and segmented into small intervals. The analysis is based on both time and time-frequency features. Time-domain measurements are extracted and several combinations between the obtained features are used to train a set of neural networks. Short-time Fourier transform, and several time-frequency distributions are used in the time-frequency analysis. The final decision is made using a set of rules. The proposed approach is tested using the *MIT-BIH Arrhythmia Database* (Harvard-MIT Division of Health Sciences and Technology, 1997), and satisfactory results are obtained for both sensitivity and specificity for arrhythmic segment detection (87.5% and 89.5% respectively for time-domain analysis, and 90% and 93% respectively for time-frequency-domain analysis).

Another approach for arrhythmic beat classification and arrhythmic episode detection and classification (Tsipouras, Fotiadis, & Sideris, in press) is also based only on the RR-interval signal. A three RR-interval sliding window is used in the arrhythmic beat classification algorithm. Classification is performed for four categories of beats: normal, premature ventricular contractions, ventricular flutter and fibrillation, and 2^{o} heart block. The beat classification is used as the input of a knowledge-based, deterministic automaton to achieve arrhythmic episode detection and classification. Six rhythm types are classified: ventricular bigeminy, ventricular trigeminy, ventricular couplet, ventricular tachycardia, ventricular flutter and fibrillation, and 2^{o} heart block. The achieved scores for the *MIT-BIH Arrhythmia Database* indicate high performance: 98% accuracy for arrhythmic beat classification and 94% accuracy for arrhythmic episode detection and classification.

In Table 2, several systems and methodologies that address the problem of arrhythmic beat classification are presented.

Table 2. Comparison of several research attempts for arrhythmic beat classification

Method	Signal	Dataset	Acc[1] (%)
Feature extraction: cumulants of the second, third and fourth order Classification: fuzzy hybrid neural network (Osowski, & Linh, 2001)	ECG	7,185 beats from MIT-BIH 4,035 training – 3,150 testing N : 2,250 A : 658 L : 1,200 V : 1,500 R : 1,000 I : 472 E : 105	96.06%

1Acc: Accuracy

CONCLUSION

We presented a general review of ECG diagnosis using decision-support systems. Computerized ECG processing can be divided into several stages. The most important ones are the analysis and the diagnosis. The variety of the systems developed in order to address the automation of these two tasks shows the great interest for this scientific area and its clinical importance. The developed methods differ in terms of accuracy, but each one of them has unique advantages. A proper combination of the above techniques can improve the results of ECG analysis and diagnosis. The physician, however, remains responsible to evaluate the systems' output and make the final diagnosis.

KEY TERMS

Artificial Neural Network: An artificial neural network is a massive parallel, distributed processor made up of simple processing units. It has the ability to learn from knowledge, which is expressed through interunit connection strengths, and can make this knowledge available for use.

Data-Mining Association Rules: The process of discovering valuable information from large amounts of data stored in databases, data warehouses, or other information repositories is called data mining. Association-rule mining is the discovery of association relationships or correlations among a set of items.

Genetic Algorithm: Genetic algorithms are derivative-free, stochastic optimization methods based loosely on the concepts of natural selection and evolutionary processes.

Heart-Rate Variability: The alterations of the heart rate between consecutive heartbeats.

Ischaemic Episode: An ischaemic episode is defined as a time period of no less than 30 seconds containing ischaemic beats.

RR-Interval Signal: The signal produced from the durations between consecutive R waves.

Sensitivity: The sensitivity of a test defines the probability that the test will be positive (pathologic) when the outcome is positive (pathologic).

Specificity: The specificity of a test defines the probability that the test will be negative (normal) when the outcome is negative (normal).

ABSTRACT

The revolution of technology has lead to a change; from the analogic to the digital function of medical devices. Some of them were produced in the last years to improve the quality of images. Although the procedure of acquiring and using the devices has been very complicated, the analysis of the images is so dependable that a big amount of the annual budget is spent for their acquisition.

INTRODUCTION

The rapid development of science and the continuous manufacture of pioneer medical technological products, together with the modern requirements for high-quality medical services, led to the growth and introduction of modern technologies in the health sector. This development has been really impressive and rapid.

At the beginning of the 20th century, the progress of applied sciences, such as chemistry, physics, microbiology, physiology, pharmacology, and so forth enforced medical research, which resulted in the continuous discoveries in medical technology. In 1895, W. K. Roentgen discovered X-rays, which was a turning point for medical imaging and diagnostics in general. In the 1950s, there was the development of computerized systems, while in the 1960s, there were applications such as the transport of biological signals from equipped space missions and teletransfers of information.

To be more specific, the dynamic entry and the enforced intervention of sciences such as informatics gave an enormous impulse to the medical field and created new data for treatment and diagnosis. Thus, we now have the interaction and participation of many different scientific sectors, which aim at the best medical care. One of these sectors is the imaging and treatment of medical pictures, whose development and use are a crucial point in modern therapeutics.

Medical imaging is related to issues such as the descriptive principles of medical images and their elaboration, together with whatever they include. Therefore, it is easy for someone to understand the importance and the role of imaging in diagnosis, treatment, and recovery in general.

This chapter will discuss the basic concepts, such as the analysis of medical images, their elaboration, various uses and applications, as well as an analysis of the functional requirements of such applications in order for them to be fulfilled.

DIGITAL ELABORATION OF IMAGES

The digital elaboration of images is actually a new sector of informatics and has been applied for only 15 years. Its development is revolutionary in the health field and constitutes a major contribution for the promotion of health.

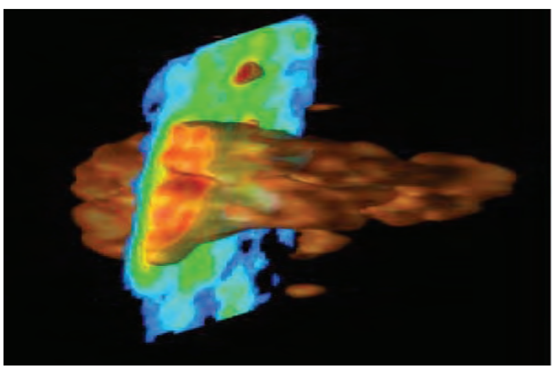
The vast amount of optical information and the need for elaborating them led scientists and technicians to the discovery of storage means for the images and their elaboration by using computers combined with the development and improvement of biomedical equipment.

Digital elaboration, as the title itself declares, deals with the digital registration of images and their elaboration by computers. The objective of elaboration can be the quality improvement of images, the straining of recording or transmission noises, the compression of the amount of information, the storage of images, and their digital transmission and depiction.

In the picture below, we schematically represent all the necessary equipment that is needed to fulfill a digital registration of images to be elaborated by the appropriate personnel in order to give all the necessary information and conclusions.

Thus, everyone can understand that for the elaboration of three-dimensional medical images, a device for the admission of images is required, and this can be an axial tomographer, a magnetic tomographer, an ultrasound device, or even more developed depiction systems. A computer is also required, with all the necessary equipment in order to elaborate the images, analyse them, and store and transmit them, and finally all the appropriate exit devices that will project the images will be needed, which can be terminal stations, special films, and printers. Finally, it is very important that the whole system will support network

Figure 1. Three dimensional imaging



communications so that all information can be available to the scientific community fast and safely with both quality and reliability. Before we introduce some of the depiction devices of three-dimensional medical images that are widely used by the scientific community nowadays, it is important to study some necessary notions for the comprehension of the way this elaboration of three-dimensional images occurs.

An image is a two-dimensional signal. Thus, for the analysis and elaboration of this signal, all the techniques and mathematic relations of digital signal elaboration can be used. Specifically, in the health field, we introduce the notion of modality, which is a biomedical signal that represents one view or one function of the organization. Therefore, the depiction devices receive modalities and with the appropriate processes turn them into images. The dimension of a signal depends on the number of independent variables it has. Consequently, the two-dimensional signals have as independent variables the two dimensions of the surface.

Therefore, the elements that should be included in a digital system for the elaboration of images are the following:

- **Image Elaborator:** This is the hardcore of the system that receives the image, temporarily stores and elaborates it on a low level, and finally demonstrates it on a primary level.
- **Digitizer:** It arithmetically represents the image in order for it to be received by a computer.
- **Digital Computer:** It performs an extensive elaboration.
- **Storage Devices**
- **Screens and Recording Devices**

We will now proceed to analyse the above elements in order to realize their participation in the elaboration of images, and at the same time we will present all the processes that occur at each level.

Image Elaborator

The evolution of technology, as mentioned above, was the vaulting bar for the development and evolution of medical depiction devices and machines, something that proved to be beneficial for health services. Today, there is a large number of medical apparatuses that fills any kind of diagnostic demands. More specifically, in the three-dimensional depiction area, there are now many options

Figure 2. Image elaborator

that suit every demand. The categories of medical images are as follows.

- Digital abstraction angiography
- Ultrasound system
- Computed tomography (CT)
- Magnetic resonance imaging (MRI)
- Gamma camera
- Computed tomographies of nuclear medicine (single-photon-emission computed tomography [SPECT] and positron-emission tomography [PET])

Digital Abstraction Angiography

It is a medical diagnostic examination that depicts the condition of the vessels. It is extremely useful in the sector of cardiology and helps to with the prevention of many diseases of the cardiac system. Its characteristic is that it produces a vast number of data, especially as we move from one-dimensional systems to two-dimensional ones and from a still image to a moving one (video).

Ultrasound System

It depicts the resonance of high-frequency sound waves, which depend on the auditory properties of tissues that are produced by different organs and are examined as brightness in the image. One application of the ultrasound system is the ultrasound of the heart and vessels (Doppler), which is developed in real time and depicts the flux speed of the blood.

Computed Tomography

It uses X-rays for the creation of images, which means that the patient is exposed to radiation during the examination. The part of the body that needs to be examined receives X-rays through different transmission angles. With the use of mathematic transformations and calculations on the counted prices from these different angles, we receive images that are cross and plane sections. Each ray penetrating the body is recording densities of tissues.

Figure 3. Digital angiography

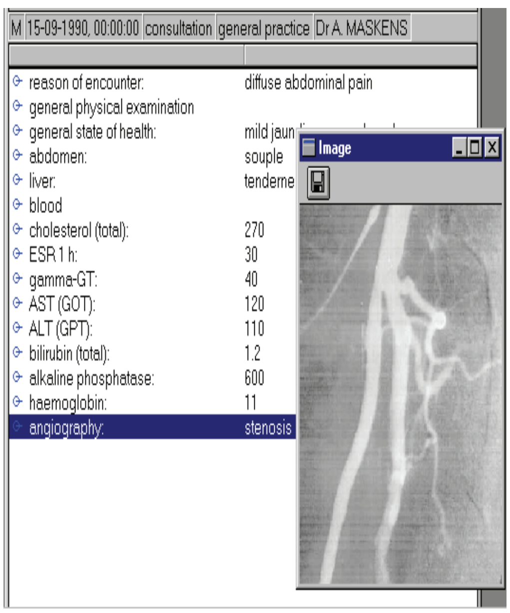


Figure 4. MRI depiction

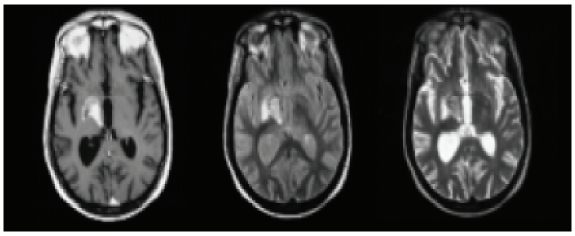

Figure 5. Depiction in SPECT

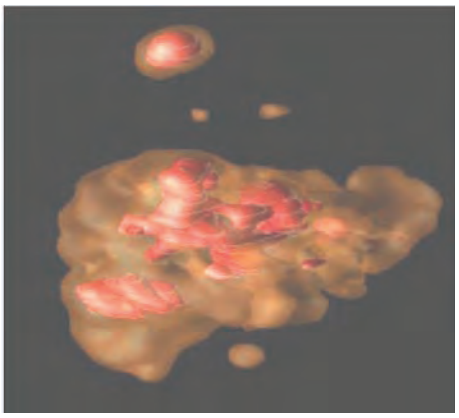

Magnetic Tomography

It is a nonpenetration diagnostic method that produces a series of images that represent biological differences among tissues. Furthermore, the patient does not have to be exposed to harmful radiation. It is based on the application system of a magnetic field in order to obtain magnetic tomographies.

By applying a magnetic field, the cells orient to the rotation frequency and thus we have the production of resonance through the pulse of radiofrequency. Afterward, we have a rest so that the cells can reorient to their initial positions. The produced signal depends on the density and type of cells and, thus, magnetic tomographies show a high contrast on the soft tissues.

Gamma Camera

It is a diagnostic method that belongs to the field of nuclear medicine. It is based on the calculation of the position and concentration of a radioactive isotope that is provided to the patient before the examination. It gathers clinical information about the normal function while its discernibility is very low.

Computed Tomographies of Nuclear Medicine (PET and SPECT)

This section is about diagnostic examinations that are related to the physiology of the organization and are the most modern in technological terms in the field of diagnostics. SPECT involves the computed tomography of photon transmission, something that shows that the signal-production process is based on photon transmission. PET involves tomography with positron transmission.

The diagnostic devices mentioned are the means of acquiring medical images in analogous or digital forms. The device used may have the ability to store digitally; otherwise, the digitalization occurs with the use of a digitizer before storage. Next we have the process of compressing images.

Digital Image Compression

The term compression is mentioned in a number of technicalities and algorithms aiming to reduce the required memory for the representation and storage of digital images. The storage of a digitalized image leads to a squandering of the memory of the computing system. Thus, in the medical field, where the amount of image information is enormous, a major problem rises because of the amount of memory required for image storage. For this reason, faster compression and decompression algorithms for images have been searched for. Besides sparing memory, compression provides a reduction in the time and the width needed for transmission.

The techniques for the compression of digital images can be divided into two categories.

In medicine, where even the smallest detail in depiction can be of vital importance, we choose lossless techniques.

Compression is based on redundant information that is included in the images. The more redundancy there is, the more is the achieved compression. The whole process is called source coding, and it is based on a system that includes the following:

- **Transformer:** It transforms the initial image into a more appropriate one for compression.
- **Quanter:** It quants the transformed image either with graduation or with vector.
- **Coder:** A sequence of bits corresponds with each quant level. The code can be of a specific or variable length.

Compression with no losses does not use a quanter system because a quant always shows a loss of information.

The used patterns of image compression are as follows:

- G3, G4, GBIG—binary images
- JPEG—firm images
- H.261 MPEG1, MPEG2, MPEG4, MPEG7—movable images

After the compression process, we have the process of storage to the PACS system and recuperation from RIS.

Storage of Medical Images and Their Recuperation

Medical images, according to the diagnostic device used, have large sizes due to the need for high-quality analysis and clearness, thus demanding a large storage space. The recuperation time differs according to the kind of examination and the demanded number of images in each examination.

When the image reaches the final stage of elaboration, the goals are then the improvement of the quality of the given information with the use of the appropriate graphic-elaboration software (e.g., clearness, brightness, contrast), and also the exploitation of specific information with the use of special operations and transformations like division and recombining.

Quality Improvement of Images

The quality improvement of images is achieved with the use of software that helps to reach the desired levels of analysis aiming to exploit and evaluate the information given from an image. During the process of recording images, certain deformities appear. These are:

- Dimness,
- Noise of recording, and
- Geometrical deformities.

All these deformities should be corrected in order to eliminate all kinds of alterations. The elimination of dimness is done with the process of restoration. The process of restoration is extremely important in the elaboration of moving images because movement creates dimness. In most cases, a filtering of the image is also required in order to remove sound. This can be achieved with various linear or nonlinear filters. Usually, nonlinear filters are preferred because they preserve the contrast of outlines, which are an important factor for human vision. Moreover, the general contrast of the image can be improved with special nonlinear techniques.

One other important procedure for image analysis is the recognition of outlines. Usually, the areas of an image are coloured with false colours.

Finally, we achieve improvement of quality by adjusting the proper clearness, brightness, and contrast with the use of appropriate technical equipment that allows us to exploit all these tools provided by the graphic software for quality improvement.

Image Division

By dividing a medical image, we are able to divide the image in different sections that show some cognitive interest according to the speciality under examination. Thus, according to the reason why the diagnostic examination occurs, the scientist can focus on a specific part of the image to process suitably and find the needed information without the redundancy of information to trouble him or her.

Furthermore, with the appropriate software, we can store to the computed system only those parts of the image that interest us, thus sparing storage space and making it more easy to recuperate the images from the used medical databases.

Medical Image Recombination

With medical image recombination, we can have a combination of different views from various depiction examinations (e.g., ultrasound+CT, MRI+PET, MRI+SPECT), giving us a three-dimensional representation of composition.

Indeed, medical image recombination is extremely important in medical depiction. Each diagnostic examination allows the scientist to extract specific information through it. With this recombination method, the scientist can have the elements and information provided by different diagnostic examinations in only one image, can elaborate them and analyse them in any way he

Figure 6. Division of image received by an MRI

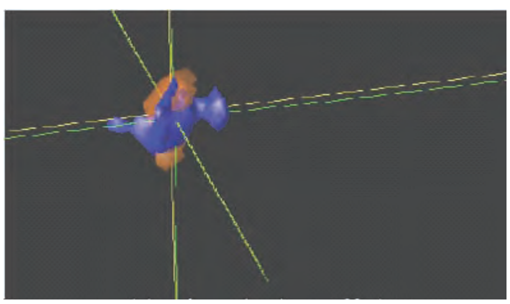

Figure 7. Image recombination MRI + PET + CT

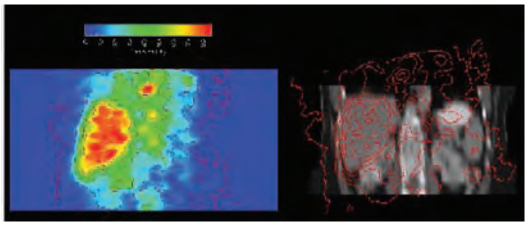

Figure 8. Image recombination SPECT + CT

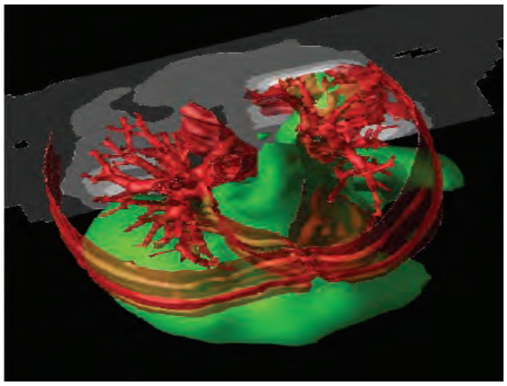

or she desires, and, finally, can reproduce them in a three-dimensional environment. The whole undertaking occurs through complex graphic software, which should have certain characteristics in order to be an actual diagnostic tool in the hands of the scientist vs. an obstacle in his or her effort to do the job.

The characteristics of the elaboration software include the following:

- Friendly user interface
- Large number of choices that are easy to overcome
- Support of the established models of compression and image management
- Support of future applications
- Safe use
- Is easy to learn

CONCLUSION AND PERSPECTIVES

Three-dimensional image elaboration is a very strong tool in medical diagnostics. Many of the diseases of tissue and microscopic interest are able to be diagnosed early and therefore can be cured. Especially benefited are the fields of research in medicine, pharmacology, and genetics, where the elaboration and depiction of three-dimensional models is extremely crucial for their development. The appearance of more and more evolved depiction devices and the growth of more powerful and more complete software for digital graphic elaboration will predispose even bigger steps of evolvement in the near future.

Chapter 3.15
Mobile Medical Image Viewing Using 3G Wireless Network

Carrison K. S. Tong
Pamela Youde Nethersole Eastern Hospital, Hong Kong

Eric T. T. Wong
Hong Kong Polytechnic University, Hong Kong

INTRODUCTION

Teleradiology is a routine practice for radiologists to make urgent diagnosis by remote viewing radiological images such as computed tomographic (CT), magnetic resonance (MR), computed radiographic (CR), and digital radiographic (DR) images outside their hospitals. Traditionally, due to limited network bandwidth and huge image file sizes, this technique was limited to fixed-point communication using an integrated services digital network (ISDN) and broadband network. Without any prior information, most radiologists would invariably require high-quality display units and lossless compressed images for their clinical diagnosis. Besides the technical issues involved in the uninterrupted provision of a 24-hour teleradiology service, most hospital administrators have to consider a series of management issues on the quality of this service such as data confidentiality, integrity, and accessibility.

This article presents the implementation process of a high-quality teleradiology service using the third-generation (3G) wireless network. In the provision of this service, several high-quality notebook computers with a 15-inch liquid crystal display (LCD) screen of resolution 1,024 x 768 pixels and 32-bit color have been configured to view medical images in the digital imaging and communications in medicine (DICOM) format using a Web browser. These notebook computers are connected with 3G mobile phones so that users could access the Internet using Web browsers through the 3G network at a speed of at least 384 kbps. The users could also use the Web browser for logging into the hospital network through an application tunneling technique in a virtual private network (VPN). When logging into the VPN, for security purposes the network authentication is enhanced by a one-time and two-factor authentication (OTTFA) mechanism. In OTTFA, the user password contains two parts: a personal password and a randomly generated password. After successfully logging into the hospital network, the user has to log into the image server using another account name and password. The above are all important to ensure the high standard of confidentiality of the system.

The data volume of the image server is about 1 TB, stored in a level-5 configured redundant array of inexpensive disks (RAID). For management of this huge amount of data, the location of each image in the storage unit is stored in a Structural Query Language (SQL)-based database. Each image also has DICOM tags for storage of the patient name, identity (ID) number, study date, and time. After the success of each login, the user can query the image server for related images using the patient's demographic data such as the study date. These are used to enhance the integrity of the system.

There are three image servers configured in a high available (HA) cluster using a load-balancing switch. The user could access any one of the servers for diagnostic purpose using the teleradiology technique. This setting is used to ensure the availability of the service 24 hours a day/7 days a week. The above system has operated for six months, and zero downtime was recorded. This leads to the belief that it is feasible to operate a quality teleradiology system using 3G networking technology with the important concerns of data confidentiality, integrity, and accessibility being dealt with in an effective manner.

BACKGROUND

Teleradiology is the process of sending radiologic images from one point to another through digital, computer-assisted transmission, typically over standard telephone lines, a wide-area network (WAN), or over a local area network (LAN). Through teleradiology, images can be sent to another part of the hospital or around the world.

In a hospital environment, it is not unusual that sometimes certain senior or experienced clinical staff would not be available onsite. These senior clinical staff may standby at home, on business trip, or just on their way to work. For urgent medical cases, remote consultation is required. It is important to have multimedia communication, including voice, text, and picture, between the senior clinicians and the hospital. A reliable, secure, easy-access, manageable, high-speed, standardized, multimedia medical consultation system is required.

PROBLEM

Today, teleradiology is still facing many limitations such as low network bandwidth, limited locations, and implementation issues associated with security, standards, and data management.

Limited Locations and Low Network Bandwidth

Depending on data-transfer rate requirements and economic considerations, images can be transmitted by means of common telephone lines using twisted pairs of copper wire, digital phone lines such as ISDN, coaxial cable, fiber-optic cable, microwave, satellite, and frame relay or T1 telecommunication links.

Today most teleradiology systems run over standard telephone lines. Over the next couple of years, we should see a substantial migration to switched-56 and ISDN lines, which offer higher speed and better line quality than standard dial-up phone lines. Other high-speed lines, including T1 and SMDS (shared multimegabit data services), will also become more popular as prices continue to drop.

However, remote consultation on fixed lines can only be performed in pre-installed locations such as a radiologist's home. A wide-area wireless network can provide a more flexible teleradiology service for the users (Oguchi, Murase, Kaneko, Takizawa, & Kadoya, 2001; Reponen et al., 2000; Tong, Chan, & Wong, 2003).

Security in a 3G Network

The fragile security of 2.5G and 3G wireless applications was abundantly evident in Japan recently when malicious e-mails to wireless handsets unleashed a malevolent piece of code which took control of the communications device and, in some cases, repeatedly called Japan's national emergency number. Other cell phones merely placed several long-distance calls without the user's knowledge, while others froze up, making it impossible for subscribers to use any of the carrier's services. Incidents like this and others involving spamming, denial of service (DoS), virus attacks, content piracy, and malevolent hacking are becoming rampant. The security breaches that have posed a constant threat to desktop computers over the last decade are migrating to the world of wireless communications where they will pose a similar threat to mobile phones, smart phones, personal digital assistants (PDAs), laptop computers, and other yet-to-be-invented devices that capitalize on the convenience of wireless communications

SOLUTIONS

Standard

In 2003, the American College of Radiology (ACR) published a technical standard of teleradiology in which the DICOM standard (Bidgood & Horii, 1992) was used as a framework for medical-imaging communication. The DICOM standard was developed by the ACR and the National Electrical Manufacturers Association (NEMA) with input from various vendors, academia, and industry groups. Based upon the open system interconnect (OSI) reference model, which defines a seven-layer protocol, DICOM is an application-level standard, which means it exists inside layer 7. DICOM provides standardized formats for images, a common information model, application service definitions, and protocols for communication.

3G Network

3G stands for third generation (Collins & Smith, 2001) and is a wireless industry term for a collection of international standards and technologies aimed at increasing efficiency and improving the performance of mobile wireless networks (data speed, increased capacity for voice and data, and the advent of packet data networks vs. today's switched networks). As second-generation (2G) wireless networks evolve into third-generation systems around the globe, operators are working hard to enable 2G and 3G compatibility and worldwide roaming, including WCDMA, CDMA2000, UMTS, and EDGE technologies. In this project 3G technology was applied in teleradiology service for improving the speed of communication.

Types of 3G

Wideband Code Division Multiple Access (WCDMA)

This is a technology for wideband digital radio communications of Internet, multimedia, video, and other capacity-demanding applications. WCDMA has been selected for the third generation of mobile telephone systems in Europe, Japan, and the United States. Voice, images, data, and video are first converted to a narrowband digital radio signal. The signal is assigned a marker (spreading code) to distinguish it from the signal of other users. WCDMA uses variable rate techniques in digital processing and can achieve multi-rate transmissions. WCDMA has been adopted as a standard by the ITU under the name IMT-2000 direct spread.

Code Division Multiple Access 2000 (CDMA 2000)

Commercially introduced in 1995, CDMA quickly became one of the world's fastest-growing wireless technologies. In 1999, the International Telecommunications Union selected CDMA as the industry standard for new "third-generation" wireless systems. Many leading wireless carriers are now building or upgrading to 3G CDMA networks in order to provide more capacity for voice traffic, along with high-speed data capabilities. Today, over 100 million consumers worldwide rely on CDMA for clear, reliable voice communications and leading-edge data services.

Universal Mobile Telecommunication (UMTS)

This is the name for the third-generation mobile telephone standard in Europe, standardized by the European Telecommunications Standards Institute (ETSI). It uses WCDMA as the underlying standard. To differentiate UMTS from competing network technologies, UMTS is sometimes marketed as 3GSM, emphasizing the combination of the 3G nature of the technology and the GSM standard which it was designed to succeed. At the air interface level, UMTS itself is incompatible with GSM. UMTS phones sold in Europe (as of 2004) are UMTS/GSM dual-mode phones, hence they can also make and receive calls on regular GSM networks. If a UMTS customer travels to an area without UMTS coverage, a UMTS phone will automatically switch to GSM (roaming charges may apply). If the customer travels outside of UMTS coverage during a call, the call will be transparently handed off to available GSM coverage. However, regular GSM phones cannot be used on the UMTS networks.

Enhanced Data for Global Evolution (EDGE)

EDGE is a technology that gives GSM the capacity to handle services for the third generation of mobile telephony. EDGE was developed to enable the transmission of large amounts of data at a high speed, 384 kilobits per second. EDGE uses the same TDMA (time division multiple access) frame structure, logic channel, and 200 kHz carrier bandwidth as today's GSM networks which allows existing cell plans to remain intact.

Image Resolution

Digital images, whether viewed on a computer monitor, transmitted over a phone line, or stored on a hard disk or archival medium, are pictures that have a certain spatial resolution. The spatial resolution, or size, of a digital image is defined as a matrix with a certain number of pixels (information dots) across the width of the image and down the length of the image. The more pixels, the better the resolution. This matrix also has depth. This depth is usually measured in bits and is commonly known as shades of gray: a 6-bit image contains 64 shades of gray; 7-bit, 128 shades; 8-bit, 256 shades; and 12-bit, 4096 shades.

The size of a particular image is referenced by the number of horizontal pixels "by" (or "times") the number of vertical pixels, and then by indicating the number of bits in the shades of gray as the depth. For example, an image might have a resolution of 640×480 and 256 shades of gray, or 8 bits deep. The number of bits in the data set can be calculated by multiplying $640 \times 480 \times 8$ equals 2,457,600 bits. Since there are 8 bits in a byte, the 640×480 image with 256 shades of gray is 307,200 bytes or .3072 megabytes of information.

Data Compression

Although images should be permanently archived as raw data or with only lossless data compression (no data is destroyed), hardware and software technologies exist that allow teleradiology systems to compress digital images into smaller file sizes so that the images can be transmitted faster. Compression is usually expressed as a ratio: 3:1, 10:1, or 15:1. The compression ratio refers to the ratio of the size of a compressed file to the original uncompressed file.

Certain images can withstand a substantial amount of compression without a visual difference: computed tomography and magnetic resonance images have large areas of black background surrounding the actual patient image information in virtually every slice. The loss of some of those pixels has no impact on the perceived quality of the image nor does it significantly change reader-interpretive performance.

Image Transmission

Image-transmission time is directly proportional to the file size of the digital image. The greater the amount of digital information in an image which involves the image matrix size and the number of bits per pixel, the longer the time required to transmit the image from one location to another. A radiological image contains a large amount of digital information. For example, an image with a relatively low resolution of 512 × 512 × 8 bits contains 2,097,152 bits of data, and a 1,024 × 1,024 × 8-bit image has 8,388,608 bits of data. Transmission time has to follow the laws of size. The only way to decrease the transmission time is either to increase the speed of the modem or reduce the number of bits (compress the image) being sent. The following formula is used to calculate the time to transmit an image:

(Matrix Size) × (Matrix Depth + 2 bits) × (Percentage of Compression) / (Modem Speed) = Seconds to Transmit

Matrix Depth is the shades of gray as shown in Table 1.

For modem or router control, most devices add 2 bits when transmitting as overhead.

Data Management

According to the ACR Technical Standard for Teleradiology, each examination data file must have an accurate corresponding patient and examination database record that includes patient name, identification number, examination date, type of examination, and facility at which the examination was performed. A Structural Query Language (SQL) database has been installed for the registration of each incoming and query of studies.

Web Technology

Web technology offers a significant advantage to physicians who need to receive images quickly,

Table 1. Shades of gray and matrix depth

Shades of Gray	Matrix Depth	Shades of Gray	Matrix Depth
256	8 bits	16	4 bits
128	7 bits	8	3 bits
64	6 bits	4	2 bits
32	5 bits	2	1 bit

and who require real-time image navigation and manipulation to perform diagnostic tasks effectively. It facilitates the use of graphical-user interfaces, making teleradiology and picture achieving and communication system (PACS) applications easier to use and more responsive. Additionally, clients and servers can be run on different platforms, allowing end users to free themselves from particular proprietary architectures. Software applications designed for client-server computing can interface seamlessly with most hospital information systems (HISs) (RCR, 1999) or radiology information systems (RISs), while providing rapid soft-copy image distribution.

Storage

RAID (Marcus & Stern, 2003) stands for redundant array of inexpensive (or identical) disks. RAID employs a group of hard disks and a system that sorts and stores data in various forms to improve data-acquisition speed and provide improved data protection. To accomplish this, a system of levels (from 1 to 5) "mirrors," "stripes," and "duplexes" data onto a group of hard disks. All images were stored in the RAID of the server for high availability of the service.

Display

Today, most of the gray shades were produced by a mixing of primary colors in the video boards. Three types of video boards are commonly available, including 16-bit, 24-bit, and 32-bit color video cards. The video board with higher bits can be configured in a lower bit mode. The 16-bit color mode is called "High Color" mode with almost "good enough" quality to show photo images, at least for most purposes; 16-bit color is 5 bits each of red, green, and blue packed into one 16-bit word (2 bytes per pixel). Five bits can show 32 shades of each primary RGB channel, and 32 × 32 × 32 is 32K colors. Green used the extra one bit for 6 bits to achieve 64K colors overall, but half of them are green. The human eye is most sensitive to green-yellow, and more shades are a bigger advantage there. Green has twice the luminance of red and six times more than blue, so this is very reasonable. Video boards do vary, but 24 bits is normally not so much better in most cases, except in wide smooth gradients.

Video boards for the last few years are 24-bit color or "true color"; 24-bit color is 8 bits each of RGB, allowing 256 shades of each primary color, and 256 × 256 × 256 = 16.7 million color combinations. Studies show that the human eye can detect about 100 intensity steps (at any one current brightness adaptation of the iris), so 256 tones of each primary is more than enough. We would not see any difference between RGB (90,200,90) and (90,201,90), but we can detect 1% steps (90,202,90) (on a cathode ray tube (CRT) tube, but 18-bit LCD panels show 1.5% steps). So our video systems and printers simply do not need more than 24 bits.

Theoretically, there is no true 32-bit color display mode. The confusion is that 24-bit color mode normally uses 32-bit video mode today, referring to the efficient 32-bit accelerator chips (word size). The 24-bit color mode and so-called 32-bit video mode show the same 24-bit colors, the same 3 bytes RGB per pixel; 32-bit mode simply discards one of the four bytes (wasting 25% of video memory), because having 3 bytes per pixel severely limits video acceleration functions. Processor chips can only copy data in byte multiples (8, 16, 32, or 64 bits). A 24-bit copy done with a hardware video accelerator would require three 8-bit transfers per pixel instead of one 32-bit transfer; 32-bit video mode is for speed, and it shows 24-bit color.

Liquid Crystal Display (LCD)

In teleradiology, it is more convenient to use LCD for image display than CRT. In LCD, there are no CRTs. Instead, thin "sandwiches" of glass contain liquid-crystal filled cells (red, green, and blue cells) that make up a pixel. Arrays of thin film transistors (TFTs) provide the voltage power, causing the crystals to untwist and realign so that varying amounts of light can shine through each, creating images. This particular sensitivity to light makes LCD technology very useful in projection such as LCD front projectors, where light is focused through LCD chips.

Specifically, there are five layers to the LCD display: a backlight, polarized glass sheet, colored pixel layering, coating of liquid crystal solution that responds to signals off a wired grid of x and y coordinates, followed by a second glass sheet. To create an image, electrical charges, precision coordinated in various degrees and volts, effect the orientation of the liquid crystals, opening and closing them and changing the amount of light that passes through specific colors of pixels. LCD technology has increased its accuracy that can produce sharp and more accurate color images than earlier passive-matrix technologies.

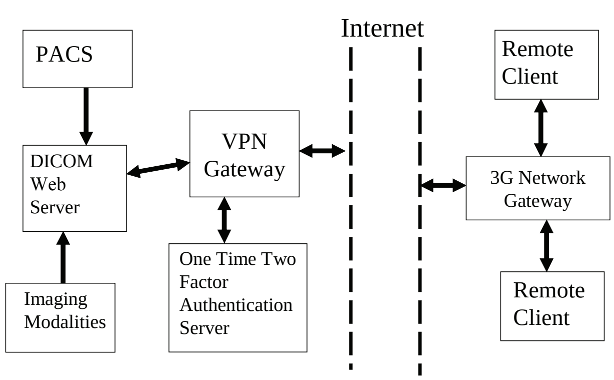
One-Time and Two-Factor Authentication

OTTFA is an authentication protocol that requires two independent ways to establish identity and privileges in which at least one is continuously and non-repetitively changing. This contrasts with traditional password authentication, which requires only one factor such as the knowledge of a password in order to gain access to a system. OTTFA technique provides a secure authentication protocol for the teleradiology service.

Application Tunneling (Port Forwarding)

Application tunneling (or port forwarding) is a combination technique of routing by port combined with packet rewriting. A convention router examines the packet header and dispatches the packet on one of its other interfaces, depending on the packet destination address. Port forwarding examines the packet header and forwards it on to another host with the header rewriting depending on the destination port. The application of application tunneling is its inability of the destination machine to see the actual originator of the forwarded packets and instead seeing them as originating from the router. One of the applications of application tunneling is in a virtual private network gateway, as shown in Figure 1. Using the application tunneling technique, the security of the teleradiology system can be strengthened considerably.

Figure 1. Schematic diagram of 3G wireless medical image viewing system



High Available Server Cluster

The purpose of high available (HA) clustering is to maintain a non-stop teleradiology service for the users. In the current design, there are three image servers configured to form an HA cluster using a load-balancing switch. The user could access any one of the servers for making of diagnosis using the teleradiology technique. Other clustering techniques being used include operating system clustering, Internet protocol (IP) failover, and fault tolerance (FT) techniques.

Implementation Result

The overall design of the 3G wireless medical image viewing system is shown in Figure 1. The medical images received from the PACS or imaging modalities were stored in the DICOM Web server.

The operation of the system is shown in Figures 2 through 10. The users can use a laptop computer as a remote client for the connection to the Internet through a 3G network gateway provided by their service provider (see Figure 2). From the Internet, the users can make a connection to the VPN gateway and be authenticated by the OTTFA server. After login, the VPN gateway will redirect the user to the DICOM Web server using the application tunneling technique. After another login of the DICOM Web server, users can query the server for related studies. Finally, once the related studies are found and selected, all related images can be retrieved and displayed as shown in Figures 9 and 10.

FUTURE TRENDS

4G Wireless Network

4G is the next generation of wireless networks that will replace 3G networks sometimes in future. In another context, 4G is simply an initiative by academic R&D laboratories to move beyond the limitations and problems of 3G to meet its promised performance and throughput. In reality, as of the first half of 2002, 4G is a conceptual framework for or a discussion point to address future needs of a universal high-speed wireless network that will interface with the wireline backbone network seamlessly. 4G also represents the hope and ideas of a group of researchers at Motorola, Qualcomm, Nokia, Ericsson, Sun, HP, NTT DoCoMo, and other infrastructure vendors who must respond to the needs of MMS, multimedia, and video applications if 3G never materializes in its full glory.

CONCLUSION

The above-mentioned 3G wireless medical image viewing system is providing a transfer speed of 384 kbps, which is comparable to a T1 fixed line of a speed of 1.4 mbps, but with greater accessibility and confidentiality. This system has been used successfully to ensure the availability of the teleradiology service 24 hours a day and 7 days a week. Throughout its construction and operation, it is found that the ACR and DICOM standards have provided useful guidelines on achieving the quality assurance and integrity expectations of this kind of service.

Chapter 3.16
Imaging the Human Brain with Magnetoencephalography

Dimitrios Pantazis
University of Southern California, USA

Richard M. Leahy
University of Southern California, USA

ABSTRACT

Magnetoencephalography is a relatively new medical imaging modality for the monitoring and imaging of human brain function. Extracranial magnetic fields produced by the working human brain are measured by extremely sensitive superconducting sensors, called SQUIDs, enclosed in a liquid helium-filled dewar. Mathematical modeling allows the formation of images or maps of cortical neuronal currents that reveal neural electrical activity, identify cortical communication networks, and facilitate the treatment of neuronal disorders, such as epilepsy.

INTRODUCTION

Magnetoencephalography (MEG) is a noninvasive technique for measuring neuronal activity in the human brain. Electrical currents flowing through neurons generate weak magnetic fields recorded using magnetic sensors surrounding the head. The MEG method is part of a broad area of research referred to as biomagnetism, which involves studies of magnetic fields emanating from several organs of the human body, notably the brain and heart.

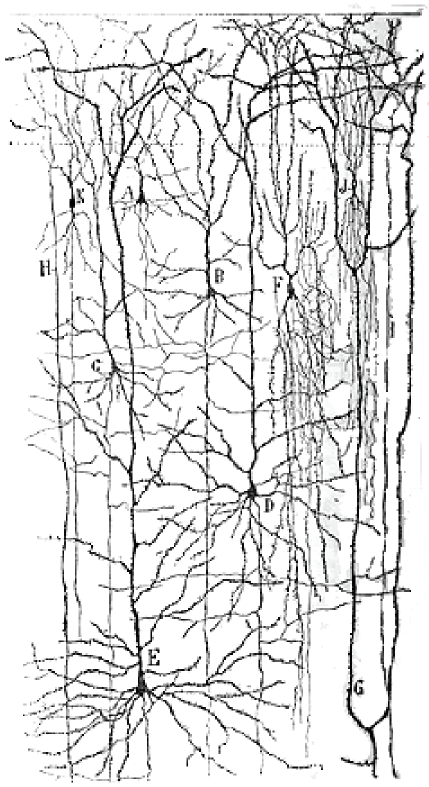
The temporal resolution of MEG is in the millisecond (ms) range, the timescale at which neurons communicate. Therefore, we can follow the rapid cortical activity reflecting ongoing signaling between different brain areas. This is a great advantage compared to other medical imaging modalities such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), where temporal resolution is on the order of seconds. Furthermore, unlike other methodologies that measure brain metabolism or the relatively slow hemodynamic response, MEG directly measures electrical brain activity. Electroencephalography (EEG) is a complimentary method to MEG, measuring electrical scalp potentials rather than magnetic fields. It offers similar temporal resolution to MEG, but the spatial resolution is less accurate because electrical potentials measured on the scalp are heavily influenced by strongly inhomogeneous conductivity of the head, whereas magnetic fields are mainly produced by currents that flow in the relatively homogeneous intracranial space.

NEURAL BASIS OF ELECTROMAGNETIC SIGNALS

A neuron consists of the cell body (or soma), which contains the nucleus; branching dendrites, which receive signals from other neurons; and a projection called an axon, which conducts the nerve signal. When a pulse arrives at an axon of a presynaptic cell, neurotransmitter molecules are released from the synaptic vesicles into the synaptic cleft. These molecules bind to receptors located on target cells, opening ion channels (mostly Na^+, K^+, and Cl^-) through the membrane. The resulting flow of charge causes an electrical current along the interior of the postsynaptic cell, changing the postsynaptic potential (PSP). When an excitatory PSP reaches the firing threshold at the axon hillock, it initiates an action potential that travels along the axon with undiminished amplitude.

The conservation of electric charge dictates that intracellular currents, commonly called primary currents, give rise to extracellular currents flowing through the volume conductor. Both primary and volume currents contribute to magnetic fields outside the head; however, only locally structured arrangements of cells can achieve sufficient coherent superposition of currents as to produce measurable external fields. Clusters of thousands of synchronously activated pyramidal cortical neurons are believed to be the main generators of MEG signals (Figure 1). In particular, the currents associated with large dendritic trunks, which are locally oriented in parallel and perpendicular to the cortical surface, are believed to be the primary source of the neuromagnetic fields outside the head. In contrast, the temporal summation of currents for action potentials, which have duration of only 1 ms, is not as effective as for dendritic currents flowing in neighboring fibers, so action potentials are believed to contribute little to MEG measurements.

Figure 1. Cerebral frontal cortex drawn by Ramón y Cajal using a Golgi staining technique. Pyramidal (A, B, C, D, E) and nonpyramidal (F, K) cells are clearly depicted. Currents flowing in the dendritic trunks of pyramidal cells are believed to be the primary generators of magnetic signals outside the head.



INSTRUMENTATION

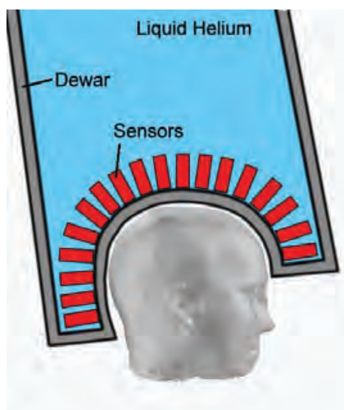
Empirical observations indicate that we observe sources on the order of 10 nA-m, and consequently, the neuromagnetic signals are typically 50 to 500 fT, that is, 10^9 or 10^8 times smaller that the geomagnetic field of the earth (Hämäläinen, Hari, Ilmoniemi, Knuutila, & Lounasmaa, 1993). The only detector that offers sufficient sensitivity to measure such fields is the superconducting quantum interference device (SQUID) introduced in the late 1960s by James Zimmerman (Zimmerman, Thiene, & Harding, 1970). The first measurement of brain magnetic fields using a SQUID magnetometer was carried out by David Cohen (1972) at the Massachusetts Institute of Technology, and it consisted of the spontaneous alpha activity of a healthy participant and abnormal brain activity in an epileptic patient.

The SQUID is a superconducting ring interrupted by thin insulating layers to form one or two Josephson junctions (Barone & Paterno, 1982). One important property associated with Josephson junctions is that magnetic flux is quantized in units of . If a constant biasing current is maintained in the SQUID device, the measured voltage oscillates as the magnetic flux increases; one period of voltage variation corresponds to an increase of one flux quantum. Counting the oscillations allows one to evaluate the flux change that has occurred, and therefore detect magnetic fields on the order of a few fT. The sensitivity of the SQUID can be increased to 1 fT by attaching a coil of superconducting wire or flux transformer. The latter is placed as close to the human head as possible, and depending on its shape, it can be configured as a first-order planar or axial gradiometer, a second-order axial gradiometer, or a simple magnetometer (Hämäläinen et al., 1993). The gradiometer configurations produce measurements proportional to the spatial gradient of the magnetic field, thus offering robustness to interference from distant magnetic field sources.

Modern MEG systems consist of a few hundred SQUID sensors placed in a liquid-helium-filled dewar, with the flux-transformer pickup coils surrounding a helmet structure (Figure 2). Worldwide, three companies build the majority of whole-head MEG systems: 4-D Neuroimaging (formerly Biomagnetic Technologies Bti), Elekta Neuromag Oy, and VSM MedTech Ltd. (manufacturers of the CTF Systems). In recent years, all three vendors have introduced dense arrays comprising over 200 SQUID channels.

Brain magnetic signals are very weak compared to ambient noise. Outside disturbances include fluctuations of the earth's geomagnetic field, power-line fields, electronic devices, eleva-

Figure 2. Whole-head CTF Omega MEG system with 275 axial gradiometers (left), and MEG sensors using low-temperature electronics cooled by liquid helium (right)



tors, and radio-frequency waves. Nearby artifacts are caused by instrumentation noise and body interference, such as heart, skeletal muscle, and spontaneous or incoherent background brain activity. Shielded rooms made of successive layers of mu-metal, copper, and aluminum effectively attenuate high-frequency disturbances. Furthermore, gradiometer flux transformers cancel distant noise sources that produce magnetic fields with small spatial gradients.

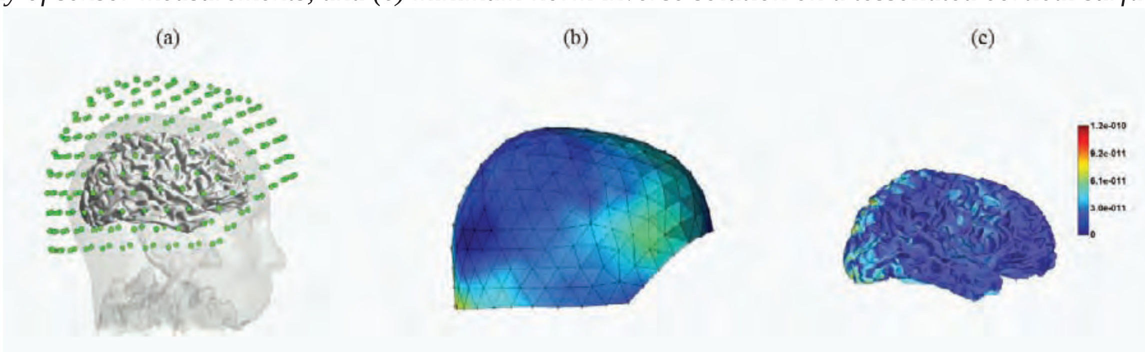
MODELING

To estimate the neural sources of magnetic fields, one must first solve the associated forward problem, that is, the forward model that maps sources of known location, strength, and orientation to the MEG sensors. The most common source model is the current dipole (Baillet, Mosher, & Leahy, 2001), used to approximate the flow of an electrical current in a small area of the brain. The typical strength of a current dipole, generated by the synchronous firing of thousands of neurons, is 10 nA-m. Alternatively, to avoid the identifiability problem that arises when too many small regions and their dipoles are required to represent a single large region of coherent activation, we can use multipolar models, consisting of dipoles, quadrupoles, octupoles, and so on (Mosher, Leahy, Shattuck, & Baillet, 1999).

Since the useful frequency spectrum for electrophysiological signals is largely below 100 Hz, the physics of MEG can be described with the quasistatic approximation of Maxwell's equations. The propagation of electromagnetic fields inside the head is estimated based on the conductivities of the scalp, skull, gray and white matter, cerebrospinal fluid, and other tissue types. Head models that consist of a set of nested concentric spheres with isotropic and homogeneous conductivities have closed-form solutions. Even though spherical head models work surprisingly well, more accurate solutions use realistic head models based on anatomical information from high-resolution magnetic resonance (MR) or x-ray computed tomography (CT) volumetric images. To estimate the parameters of these models, numerical solutions using boundary-element methods (BEMs), finite-element methods (FEMs), or finite-difference methods (FDMs) are necessary (Darvas, Pantazis, Kucukaltun-Yildirim, & Leahy, 2004).

To make inferences about the brain activity that gives rise to a set of MEG data, we must solve the inverse problem, that is, find a neuronal current-source configuration that explains the MEG measurements. Inverse methods for MEG can be roughly categorized into two classes: imaging methods and dipole-fitting or -scanning methods. The imaging approaches are based on the assumption that the primary sources are intracel-

Figure 3. MEG model depicting: (a) Sensor arrangement of a 275-channel CTF MEG system, (b) topography of sensor measurements, and (c) minimum-norm inverse solution on a tessellated cortical surface



lular currents in the dendritic trunks of cortical pyramidal neurons that are aligned normally to the cortical surface. Consequently, a tessellated representation of the cerebral cortex is extracted from a coregistered MR image, and the inverse problem is solved for a current dipole located at each vertex of the surface. In this case, since the position and orientation of the dipoles are fixed, image reconstruction is a linear problem and can be solved using standard techniques. The dipole-fitting or -scanning methods assume that the sources consist of only a few activated regions, each of which can be represented by an equivalent current dipole of unknown location and orientation. The standard approach to localization is to perform a least-squares fit of the dipole model to the data (Lu & Kaufman, 2003). More recently, scanning methods have been developed that are also based on the dipole model, but involve scanning a source volume or surface and detecting sources at those positions at which the scan metric produces a local peak (Baillet et al., 2001). Examples of these methods include the MUSIC (multiple signal classification) algorithm (Mosher, Leahy, & Lewis, 1992) and the LCMV (linearly constrained minimum variance) beamformer (VanVeen, van Drongelen, Yuchtman, & Suzuki, 1997).

Due to intrinsic spatial ambiguities of the electromagnetic principles that underlie MEG, the spatial resolution is lower than that of PET and fMRI. These ambiguities force a choice between low-resolution linear cortical imaging methods, or potentially higher resolution methods based on parametric models, or Bayesian or other nonlinear imaging methods incorporating physiological priors that reflect the expected characteristics of neural activation. A consensus is developing in the research community that no single method suits all MEG applications; each method has strengths and weaknesses, reflecting the ill pose of the inverse problem. The characteristics of expected neural activation, as well as model-fitting techniques, can facilitate the proper choice of inverse methodology.

STATISTICAL ANALYSIS

Given the large number of localization methodologies, it is important to perform validation and statistical analysis under different experimental settings, such as the number, location, and time series of neuronal sources. Furthermore, several methods require the fine-tuning of parameters, such as the subspace correlation threshold for the MUSIC algorithm. The receiver operating characteristic (ROC) curve is a standard tool to evaluate the trade-off between sensitivity and specificity, and to compare different inverse methods. By varying a threshold applied to localization maps, we can estimate two performance measures: the sensitivity or true positive fraction (TPF), and 1-specificity or false positive fraction (FPF). The ROC curve is a plot of the TPF vs. FPF as a detection threshold is varied. When comparing two detection methods, the one whose ROC curve gives higher sensitivity at matched specificity, and vice versa, for all points on the curve is the better detector. A simple metric to compare methods is the area under the ROC curve (AUC), where the method with the largest AUC is superior. The use of free-response ROC, an ROC variant that can handle the presentation and detection of multiple targets per image, is demonstrated in Yildirim, Pantazis, and Leahy (in press) for the evaluation of minimum-norm and scanning-inverse methods.

In addition to evaluating the relative performance of different methods, it is important to establish some degree of confidence in the results of real data analysis. Dipole-scanning methods often produce unstable solutions, and the reproducibility of the reconstructed dipoles is not guaranteed. A number of different approaches have been investigated for assessing dipole-localization accuracy, including Cramer Rao lower bounds, perturbation analysis, and Monte Carlo simulation. To avoid strict distributional assumptions, a resampling alternative based on bootstrap theory was proposed in Darvas, Rautiainen, et al. (2005). The principle underlying the bootstrap theory is that although the distribution of the data is unknown, it can be approximated by the empirical distribution of a set of independent trials. By sampling with replacement over independent trials collected during an event-related MEG study, the position, variance, and time series of current dipoles can be estimated reliably.

In contrast to dipole-scanning methods, imaging methods are hugely underdetermined, resulting in low-resolution localization maps; interpretation is further confounded by the presence of additive noise exhibiting a highly nonuniform spatial correlation. In this case, we need a mechanism to decide which features in the data are indicative of true activation vs. those that are noise artifacts. To determine a suitable threshold for detecting statistically significant activation, the familywise error rate (FWER), that is, the chance of any false positives under the null hypothesis of no activation (Type 1 error), is typically controlled. Parametric random-field methods and nonparametric permutation methods are used to estimate familywise-corrected thresholds in Pantazis, Nichols, Baillet, and Leahy (2005). Alternatively, the control of the false discovery rate (FDR), that is, the proportion of false positives among those tests for which the null hypothesis is rejected, can produce more sensitive thresholds.

Recent literature in MEG statistical analysis has been mostly limited to pairwise comparisons at each cortical surface element for event-related averages. However, extensions of this methodology to the investigation of multiple effects using analysis of variance (ANOVA) and analysis of covariance (ANCOVA) in individuals and groups is possible, as, for example, in Brookes et al. (2004).

APPLICATIONS

Applications in MEG include both basic and clinical research. One of the most important clinical applications is the detection, classification, and localization of abnormal neuronal activity in epilepsy patients. MEG has been successfully used to localize three different spontaneous interrictal signal components: epileptic spikes, slow-wave activity, and fast-wave activity (Lu & Kaufman, 2003). The neurosurgical planning of medically intractable epilepsy often includes the identification of epileptogenic lesions with MEG (Ossadtchi, Baillet, Mosher, Thyerlei, Sutherling, & Leahy, 2004; Stefan et al., 2003). Furthermore, recent literature investigates the possibility of seizure prediction based on a drop in the complexity of neural activity immediately before seizures (Maiwald, Winterhalder, Aschenbrenner-Scheibe, Voss, Schulze-Bonhage, & Timmer, 2004).

In addition to the diagnosis of epilepsy, MEG is currently used for functional brain mapping. Evoked response fields have been used to identify somatosensory-, motor-, and vision-related activity (Lu & Kaufman, 2003). Several MEG studies (Pantazis, Merrifield, Darvas, Sutherling, & Leahy, 2005) have localized language-specific cortical activity using either equivalent current dipoles or distributed cortical imaging, with promising results for clinical application in neurosurgery. Time-frequency analysis of MEG oscillatory-evoked responses (Pantazis, Weber, Dale, Nichols, Simpson, & Leahy, 2005) has detected networks of cortical interactions and determined the functional specificity of several frequency bands. A wide range of signal-processing techniques including image modeling and reconstruction, blind source separation, phase synchrony estimation, nonlinear analysis, and chaos theory are under investigation to reveal complex cognitive processes such as attention and working memory.

Recent literature investigates how evoked response fields relate to neuronal disorders, such as Alzheimer's disease, autism, dyslexia, brain tumors, and Parkinson's disease. Furthermore, MEG has been used in conjunction with trans-axial magnetic stimulation to ameliorate abnormal brain activity (Anninos, Tsagas, Sandyk, & Derpapas, 1991).

CONCLUSION

Magnetoencephalography is a relatively new medical imaging modality for the monitoring and imaging of human brain function. While spatial resolution is significantly lower than that of PET and fMRI, the ability to monitor neuronal activation at the millisecond time scale makes this modality, together with EEG, a unique window on the human brain. Recent developments in instrumentation have lead to the manufacture of whole-head MEG arrays with an excess of 300 magnetometers. Coupled with new data-analysis tools for mapping brain function from MEG data, these systems will lead to important new insights into the workings of the human brain with applications in both clinical and cognitive neuroscience.

KEY TERMS

ANOVA and ANCOVA: Analysis of variance or covariance is a collection of statistical models and their associated procedures that compare means by splitting the overall observed variance into different parts.

Current Dipole: Popular source model in MEG, representing a point's current source. It is a convenient representation for the coherent activation of a large number of pyramidal cells, possibly extending over a few square centimeters of gray matter.

EEG: Electroencephalography measures neuronal activity by recording electrical potentials with electrodes attached on the human scalp. The resulting waveforms are used to localize brain activity and assess brain damage, epilepsy, or even in some cases brain death.

fMRI: Functional magnetic resonance imaging uses powerful magnets to create a field that resonates the nuclei of atoms in the body. The oscillating atoms emit radio signals that are converted by a computer into 3-D images of the human body and cerebral blood flow.

LCMV Beamformer: Linearly constrained minimum-variance beamformer applies spatial filtering to sensor array data to discriminate between signals from a location of interest and those originating elsewhere. In the application to MEG, the goal is to find a spatial filter that minimizes the output power of the beamformer subject to a unity gain constraint at the desired location on the brain.

MUSIC: Multiple signal classification is a localization algorithm that uses the subspace correlation between the data and model subspace to identify the origin of signals. It is often used in MEG to estimate the location, orientation, and strength of current dipoles.

PET: Positron emission tomography is a non-invasive imaging modality that measures the distribution of radioactive-labeled molecules inside a biological system. By using molecular probes that have different rates of uptake depending on the type of tissue involved, PET can localize lesions, and detect regional blood flow and gene expression among others.

INTRODUCTION

Radiology is the branch of medicine that deals with the diagnostic and therapeutic applications of radiation. It is often used in X-rays in the diagnosis and treatment of a disease. Filmless radiology is a method of digitizing traditional films into electronic files that can be viewed and saved on a computer. This technology generates clearer and easier-to-read images, allowing the patient the chance of a faster evaluation and diagnosis. The time saved may prove to be a crucial element in the patient's treatment process. With filmless radiology, images taken from various medical sources can be manipulated to enhance resolution, increasing the clarity of the image. Images can also be transferred internally within departments and externally to other locations such as the office of the patient's doctor. This is made possible through the picture-archiving and communication system (PACS; Dreyer, Mehta, & Thrall, 2001), which electrsonically captures, transmits, displays, and saves images into digital archives for use at any given time. The PACS functions as a state-of-the-art repository for long-term archiving of digital images, and includes the backup and bandwidth to safeguard uninterrupted network availability. The objective of the picture-archiving and scommunications system is to improve the speed and quality of clinical care by streamlining radiological service and consultation. With instant access to images from virtually anywhere, hospital doctors and clinicians can improve their work processes and speed up the delivery of patient care. Besides making film a thing of the past, the likely benefits would include reduced waiting times for images and reports, and the augmented ability of clinicians since they can get patient information and act upon it much more quickly. The creation of a permanent, nondegradable archive will eliminate the loss of film and so forth. Today, the growing importance of PACS on the fight against highly infectious disease is also identified.

BACKGROUND

PACS (Huang, 2004) started with a teleradiology project sponsored by the U.S. Army in 1983. A follow-up project was the Installation Site for

Digital Imaging Network and Picture Archiving and Communication System (DIN/PACS) funded by the U.S. Army and administered by the MITRE Corporation in 1985. Two university sites were selected for the implementation—the University of Washington in Seattle and Georgetown University and George Washington University Consortium in Washington, DC—with the participation of Philips Medical Systems and AT&T. The U.S. National Cancer Institute funded one of UCLA's first PACS-related research projects in 1985 under the title Multiple Viewing Stations for Diagnostic Radiology.

The early installations of PACS in public health-care institutions were in Baltimore Veterans Administration Medical Center (United States), Hammersmith Hospital (United Kingdom), and Samsung Medical Center (Korea). In Hong Kong, there was no PACS-related project until the establishment of Tseung Kwan O Hospital (TKOH) in 1998. The TKOH was a newly built 600-bed acute hospital with a hospital PACS installed for the provision of filmless radiological service. The design and management of the PACS for patient care will be discussed in this article. The TKOH was opened in 1999 with PACS installed. At the beginning, due to immature PACS technologies, the radiology service was operating with film printing. A major upgrade was done in 2003 for the implementation of server clustering, network resilience, liquid crystal display (LCD), smart card, and storage-area-network (SAN) technologies. This upgrade has greatly improved the reliability of the system. Since November 2003, TKOH has started filmless radiology service for the whole hospital. It has become one of the first filmless hospitals in the Greater China area (Seto, Tsang, Yung, Ching, Ng, & Ho, 2003; Tsou, Goh, Kaw, & Chee, 2003).

MAIN FOCUS OF THE ARTICLE

It certainly goes without saying that most equipment is designed for reliability, but breakdowns can still occur, especially when equipment is used in a demanding environment. A typical situation is what could be called a "single-point failure." That is, the entire system fails if only one piece of equipment such as a network switch fails. If some of the processes that the system supports are critical or the cost of a system stop is too high, then building redundancy into the system is the way to overcome this problem. There are many different approaches, each of which uses a different kind of device, for providing a system with redundancy.

The continuous operation of a PACS in a filmless hospital for patient care is a critical task. The design of a PACS for such a system should be high speed, reliable, and user friendly (Siegel & Kolodner, 2001). The main frame of the design is avoiding the occurrence of any single point of failure in the system. This design includes many technical features. The technical features of the PACS installed in a local hospital include the archiving of various types of images, clustering of Web servers installed, redundancy provision for image distribution channels, and adoption of barcode and smart-card systems. All these features are required to be integrated for effective system performance and they are described below.

ARCHIVING OF MULTIPLE IMAGE TYPES

In order to make connections with different imaging modalities, a common international standard is important. The Digital Imaging and Communications in Medicine (DICOM) standard developed by the American College of Radiology (ACR) and the National Electrical Manufacturers' Association (NEMA) is the most common standard used today. The DICOM standard is extremely comprehensive and adaptable. It covers the specification image format, a point-to-point connection, network requirements, and the handling of information on networks. The adoption of DICOM by other specialties that generate images (e.g., pathology, endoscopy, dentistry) is also planned.

The fact that many of the medical imaging-equipment manufacturers are global corporations has sparked considerable international interest in DICOM. The European standards organization, the Comitâ Europâen de Normalisation, uses DICOM as the basis for the fully compatible MEDICOM standard. In Japan, the Japanese Industry Association of Radiation Apparatus and the Medical Information Systems Development Center have adopted the portions of DICOM that pertain to the exchange of images on removable media and are considering DICOM for future versions of the Medical Image Processing Standard. The DICOM standard is now being maintained and extended by an international, multispecialty committee. Today, the DICOM standard has become a predominant standard for the communication of medical imaging devices.

WEB TECHNOLOGY

The World Wide Web (WWW) began in March 1989 at CERN (CERN was originally named after its founding body, the Conseil Europeen pour la Recherche Nucleaire, that is now called the European Laboratory for Particle Physics.). CERN is a meeting place for physicists from all over the world who collaborate on complex physics, engineering, and information-handling projects. Thus, the need for the WWW system arose from the geographical dispersion of large collaborations and the fast turnover of fellows, students, and visiting scientists who had to get up to speed on projects and leave a lasting contribution before leaving.

Set off in 1989, the WWW quickly gained great popularity among Internet users. For instance, at 11:22 a.m. of April 12, 1995, the WWW server at the SEAS (School of Engineering & Applied Science) of the University of Pennsylvania responded to 128 requests in 1 minute. Between 10:00 and 11:00, it responded to 5,086 requests in 1 hour, or about 84 requests per minute. Even years after its creation, the Web is constantly maturing: In December 1994 the WWW was growing at roughly 1% a day—a doubling in a period of less than 10 weeks (Berners-Lee, 2000).

The system requirements for running a WWW server (Menasce & Almeida, 2001, 2004) are minimal, so even administrators with limited funds had a chance to become information providers. Because of the intuitive nature of hypertext, many inexperienced computer users were able to connect to the network. Furthermore, the simplicity of the hypertext markup language, used for creating interactive documents, has allowed many users to contribute to the expanding database of documents on the Web. Also, the nature of the World Wide Web provided a way to interconnect computers running different operating systems, and display information created in a variety of existing media formats. In short, the Web technology provides a reliable platform for the distribution of various kinds of information including medical images.

Another advantage of Web technology is its low demand on the Web client. Any computer running on a common platform such as Windows or Mac can access the Web server for image viewing just using Internet Explorer or Netscape. Any clinical user can carry out his or her duty anytime and anywhere within a hospital.

CLUSTERING OF DICOM WEB SERVERS

The advantage of clustering computers for high availability (Piedad & Hawkings, 2000) is that if one of the computers fails, another computer in the cluster can then assume the workload of the failed computer at a prespecified time interval. Users of the system see no interruption of access. The advantages of clustering DICOM Web servers for scalability include increased application performance and the support of a greater number of users for image distribution.

There is a myth that to provide high availability (Marcus & Stern, 2003), all that is required is to cluster one or more computer-hardware solutions. To date, no hardware-only solution has been able to deliver trouble-free answers. Providing trouble-free solutions requires extensive and complex software to be written to cope with the myriad of failure modes that are possible with two or more sets of hardware.

Clustering can be implemented at different levels of the system, including hardware, operating systems, middleware, systems management, and applications. The more layers that incorporate clustering technology, the more complex the whole system is to manage. To implement a successful clustering solution, specialists in all the technologies (i.e., hardware, networking, and software) are required. The authors used the clustering of Web servers by connecting all of the Web servers using a load-balancing switch. This method has the advantage of a low server overhead and requires no computer-processor power.

RAID TECHNOLOGY

Patterson, Gibson, and Katz (1988) at the University of California, Berkeley, published a paper entitled "A Case for Redundant Arrays of Inexpensive Disks (RAID)." This paper described various types of disk arrays, referred to by the acronym RAID. The basic idea of RAID was to combine multiple small, inexpensive disk drives into an array of disk drives, which yields performance exceeding that of a single large, expensive drive (SLED). Additionally, this array of drives appears to the computer as a single logical storage unit or drive.

The mean time between failure (MTBF) of the array will be equal to the MTBF of an individual drive divided by the number of drives in the array. Because of this, the MTBF of an array of drives would be too low for many application requirements. However, disk arrays can be made fault tolerant by redundantly storing information in various ways.

Five types of array architectures, RAID-1 through RAID-5, were defined by the Berkeley paper, each providing disk fault tolerance and each offering different trade-offs in features and performance. In addition to these five redundant array architectures, it has become popular to refer to a nonredundant array of disk drives as a RAID-0 array.

In PACS, RAID technology can provide protection for the availability of the data in the server. In RAID level 5, no data is lost even during the failure of a single hard disk within a RAID group. This is essential for a patient-care information system. Extra protection can be obtained by using spare global hard disks for automatic protection of data during the malfunctioning of more than one hard disk. Today, most SANs for high capacity storage are built on RAID technology.

STORAGE AREA NETWORK

A storage area network (Marcus & Stern, 2003; Toigo & Toigo, 2003) is a high-speed, special-purpose network (or subnetwork) that interconnects different kinds of data-storage devices with associated data servers on behalf of a larger network of users. Typically, a storage-area network is part of the overall network of computing resources for an enterprise. A storage-area network is usually clustered in close proximity to other computing resources such as SUN (SUN Microsystems) servers, but it may also extend to remote locations for backup and archival storage using wide-area-network carrier technologies such as ATM (Asynchronous Transfer Mode) or Ethernet.

Storage-area networks use fiber channels (FCs) for connecting computers to shared storage devices and for interconnecting storage controllers and drives. Fiber channel is a technology for transmitting data between computer devices at data rates of up to 1 or 2 Gbps and 10 Gbps in the near future. Since fiber channel is 3 times as fast, it has begun to replace the small computer system interface (SCSI) as the transmission interface between servers and clustered storage devices. Another advantage of fiber channel is its high flexibility; devices can be as far as 10 km apart if optical fiber is used as the physical medium. Standards for fiber channel are specified by the Fiber Channel Physical and Signaling standard, and the ANSI (The American National Standards Institute) X3.230-1994, which is also ISO (International Organization for Standardization) 14165-1.

Other advanced features of a SAN are its support of disk mirroring, backup, and restoring; archival and retrieval of archived data; data migration from one storage device to another; and the sharing of data among different servers in a network. SANs can also incorporate subnetworks with network-attached storage (NAS) systems.

REDUNDANT NETWORK FOR IMAGE DISTRIBUTION

Nevertheless, all of the PACS devices still need to be connected to the network, so to maximize system reliability, a PACS network should be built with redundancy (Jones, 2000). To build up a redundant network (Marcus & Stern, 2003), two parallel gigabit-optical fibers were connected between the PACS and the hospital networks as two network segments using four Ethernet switches. The Ethernet switches were configured in such a way that one of the network segments was in active mode while the other was in standby mode. If the active network segment fails, the standby network segment will become active within less than 300 ms to allow the system to keep running continuously.

BAR-CODE SYSTEM

Recognizing that manual data collection and keyed data entry are inefficient and error prone, bar codes evolved to replace human intervention. Bar codes are simply a method of retaining data in a format or medium that is conducive to electronic data entry. In other words, it is much easier to teach a computer to recognize simple patterns of lines, spaces, and squares than it is to teach it to understand written characters or the English language. Bar codes not only improve the accuracy of entered data, but also increase the rate at which data can be entered.

A bar-code system includes printing and reading the bar-code labels. In most hospital information systems, the bar-code system has commonly been adopted as a part of the information system for accurate and fast patient-data retrieval. In PACS, bar-code labels are mostly used for patient identification and DICOM accession. They are used to retrieve records on patient examinations and studies.

SMART-CARD SYSTEM

A smart card is a card that is embedded with either a microprocessor and a memory chip or only a memory chip with nonprogrammable logic. The microprocessor card can add, delete, and otherwise manipulate information on the card, while a memory-chip card, such as prepaid phone cards, can only undertake a predefined operation. Smart cards, unlike magnetic-stripe cards, can carry all necessary functions and information on the card. Smart cards can also be classified as contact and contactless types. The contactless smart card communicates with the reader using the radio frequency (RF) method.

In PACS, a contactless smart-card system was installed for the authentication of the user. The information about the user name, log-in time, and location are stored in a remote server through a computer network.

NO-FILM POLICY

No film was printed when the patients were still under hospital care. Film was printed only when the patient was transferred to another hospital. Under the no-film policy, the chance of spreading infectious diseases through film is reduced.

EMBEDDED LCD MONITOR

To display medical images in the hospital, LCD monitors were installed on the walls in ward areas adjacent to existing light boxes. LCD displays utilize two sheets of polarizing material with a liquid crystal solution between them. An electric current passed through the liquid causes the crystals to align so that light cannot pass through them. Each crystal, therefore, is like a shutter, either allowing light to pass through or blocking the light. Monochrome LCD images usually appear as blue or dark-grey images on top of a greyish-white background. Colour LCD displays use two basic techniques for producing colour: Passive matrix is the less expensive of the two technologies. The other technology, called thin film transistor (TFT) or active matrix, produces colour images that are as sharp as traditional CRT (Cathode Ray Tube) displays, but the technology is expensive. Recent passive-matrix displays using new colour super-twist nematic (CSTN) and double-layer super-twisted nematic (DSTN) technologies produce sharp colours rivaling active-matrix displays.

Most LCD screens used are transmissive to make them easier to read. These are a type of LCD screens in which the pixels are illuminated from behind the monitor screen. Transmissive LCDs are commonly used because they offer high contrast and deep colours, and are well suited for indoor environments and low-light circumstances. However, transmissive LCDs are at a disadvantage in very bright light, such as outdoors in full sunlight, as the screen can be hard to read. In PACS, the LCD monitors were installed in pairs for the comparison of a large number of medical images. They were also configured in portrait mode for the display of chest X-ray CR (computed radiography) images.

IMPLEMENTATION

In the design of the TKOH PACS (Figure 1), all computed tomographic (CT), magnetic resonance (MR), ultrasound (US) and computed radiographic images were archived in image servers of the PACS (Figure 2). During the diagnosis and monitoring of patients with highly infectious diseases, CT and CR scans were commonly used for comparison. A large storage capacity for the present and previous studies was required. The capacity of the image servers designed was about 5 terabytes using 2.3-terabyte SAN technology and a DICOM compression of 2.5. The image distribution to the clinicians was through a cluster of Web servers, which provided high availability of the service. The connection between the PACS and the hospital network was through a cluster of automatic fail-over switches as shown in Figure 3. Our users can use a Web browser for X-ray-image viewing for the diagnosis or follow-up of patients. The Web-based X-ray-image viewers were set up on the computers in all wards, intensive care

Figure 1. X-ray imaging modalities in the TKOH PACS

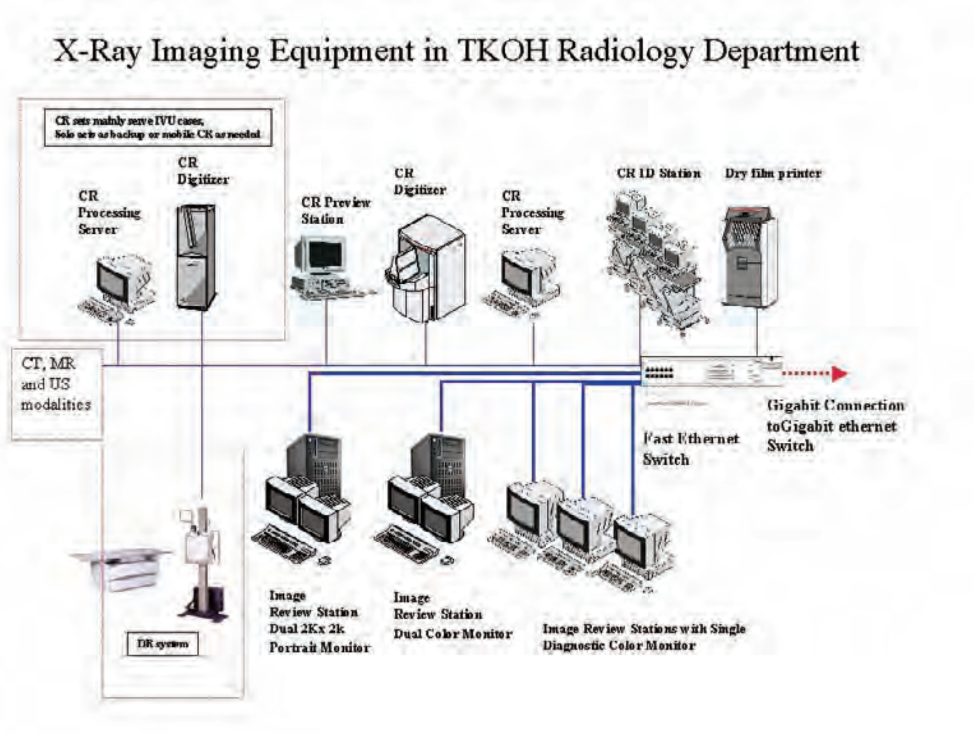

Figure 2. Design of the TKOH PACS

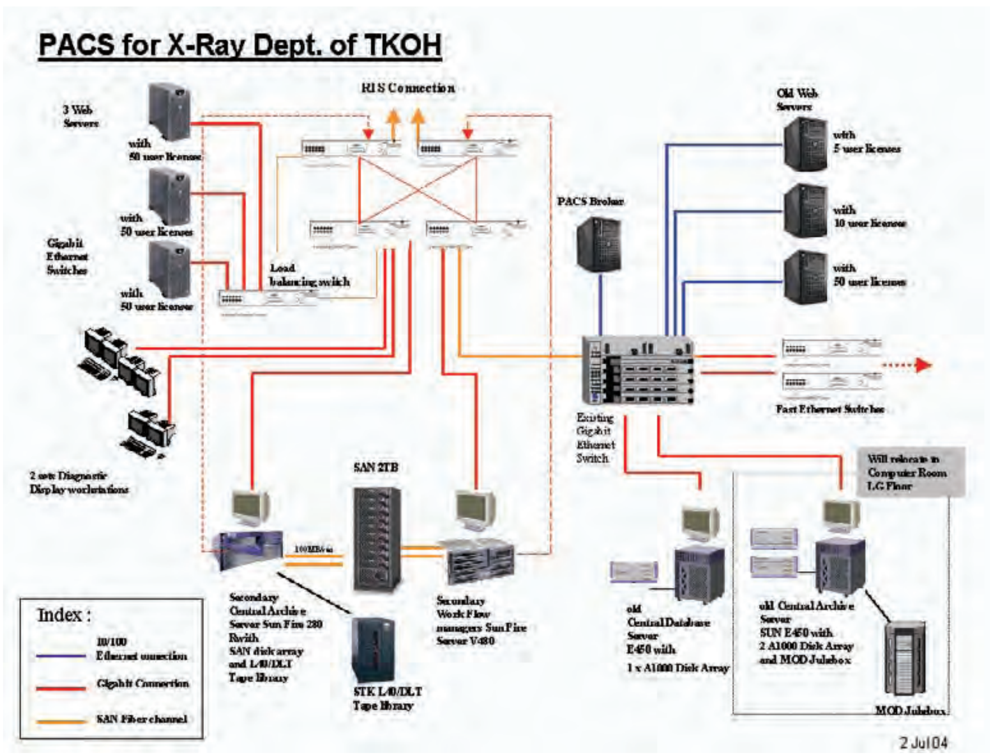

Figure 3. Design of a PACS and hospital network interface

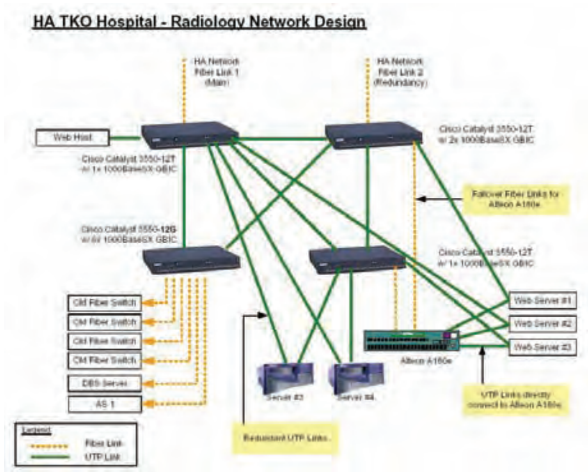

Figure 4. X-ray image viewer in wards

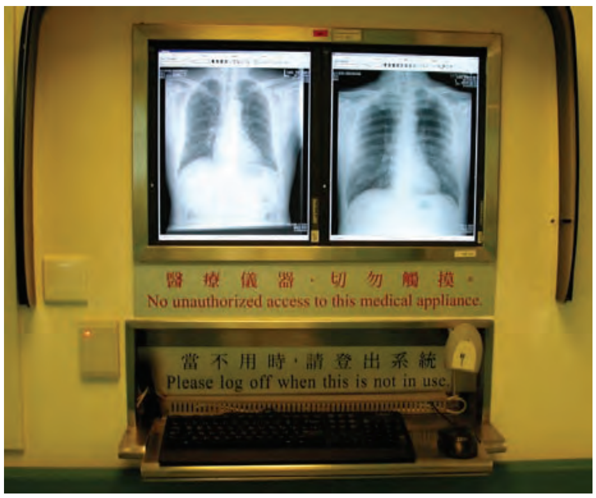

units, and specialist and outpatient departments to provide a filmless radiological service. The design of the computers for X-ray-image viewing in wards is shown in Figure 4. These computers were built using all the above technologies for performance and reliability.

After 10 months of filmless radiological operation in TKOH, less than 1% of the cases required special X-ray film for follow-up. Basically, X-ray-image viewing through a computer network was sufficient for the radiological diagnosis and monitoring of patients. Furthermore, filmless radiology (Siegel & Kolodner, 2001) service definitely reduced the chance for spreading highly infectious diseases through health-care staff. No staff member from the radiology department became infected during the outbreak of the severe acute respiratory syndrome (SARS) in 2003. No film-loss and film-waiting times were recorded.

FUTURE TRENDS

In PACS, most of the hard disks used in the RAID are expensive fiber-channel drives. Some RAID manufacturers are designing their RAID controllers using mixed ATA (Advanced Technology Attachment) and fiber-channel drives in the same array with 100% software compatibility. This design has many benefits. It can reduce the data backup and restore from seconds to hours, keep more information online, reduce the cost of the RAID, and replace the unreliable tap devices in the future. Another advanced development of PACS was in the application of voice recognition (Dreyer et al., 2001) in radiology reporting, in which the computer system was able to automatically and instantly convert the radiologist's verbal input into a textual diagnostic report. Hence, the efficiency of diagnostic radiologists can be further improved.

CONCLUSION

It has been reported (Siegel & Kolodner, 2001) that filmless radiological service using PACS could be an effective means to improve the efficiency and quality of patient care. Other advantages of filmless radiological service are infection protection for health-care staff and the reduction of the spreading of disease through the distribution of films. In order to achieve the above tasks, many computer and multimedia technologies such as the Web, SAN, RAID, high availability, LCD, bar code, smart card, and voice recognition were applied. In conclusion, the applications of computer and multimedia technologies in medicine for efficient and quality health care is one of the important areas of future IT development. There is no boundary and limitation in this application. We shall see doctors learning and using computers in their offices and IT professionals developing new medical applications for health care. The only limitation we have is our imagination.

KEY TERMS

Clustering: A cluster is two or more interconnected computers that create a solution to provide higher availability, higher scalability, or both.

Computed Radiography (CR): Computed radiography is a method of capturing and converting radiographic images into a digital form. The medium for capturing the X-ray radiation passing through the patient and generated by a standard X-ray system is a phosphor plate that is placed in a standard-size cassette, replacing the regular radiographic film. The X-ray exposure forms a latent image on a phosphor plate that is then scanned (read or developed) using a laser-beam CR reader. The CR unit displays the resultant digital image on a computer-monitor screen. By the end of the short process, the phosphor plate is erased and ready for another X-ray image exposure.

Computed Tomography (CT): Computed tomography is a specialized radiology procedure that helps doctors see inside the body. CT uses X-rays and computers to create an image. The images show up as a cross-sectional image.

Digital Imaging and Communications in Medicine (DICOM): Digital Imaging and Communications in Medicine is a medical image standard developed by the American College of Radiology and the National Electrical Manufacturers' Association.

Picture-Archiving and Communication System (PACS): A picture-archiving and communication system is a system used for managing, storing, and retrieving medical image data.

Redundant Arrays of Inexpensive Disks (RAID): RAID is a method of accessing multiple individual disks as if the array were one larger disk, spreading data access out over these multiple disks, thereby reducing the risk of losing all data if one drive fails and improving access time.

Severe Acute Respiratory Syndrome (SARS): Severe acute respiratory syndrome is a newly emerged infectious disease with moderately high transmissibility that is caused by a coronavirus.

Storage-Area Network (SAN): A storage-area network is a networked storage infrastructure (also known as a fabric) that provides the any-to-any connectivity between servers and storage devices, such as RAID disk systems and tape libraries.

Chapter 3.18
Imaging Technologies and Their Applications in Biomedicine and Bioengineering

Nikolaos Giannakakis
National and Kapodistrian University of Athens, Greece

Efstratios Poravas

ABSTRACT

New developments are making the technology faster, more powerful, less invasive, and less expensive. While the technology evolves, new devices are developed, in purpose to be used in the hospitals. Many new imaging methods are used in biomedical applications today and can predict the growth of a tumor or detect a disease. The advantages are numerous, but the problems, during the acquisition and use by the staff, are also remarkable.

INTRODUCTION

We have come from the family doctor's signature black bag in the first half of the 20th century to the powerful scanning equipment of the modern medical center, from tens of thousands dying in influenza epidemics to hundreds of thousands of seniors receiving their annual flu shots, and from an average life expectancy of about 50 years to our present expectancy of 75 years. The biomedical community is taking advantage of the power of computing and technology so as to manage and analyse data. Imaging technologies save day to day more and more people.

X-rays, endoscopes, CT (computed tomography) scans, MRI (magnetic resonance imaging), digital mammography—these imaging technologies make it possible for medical scientists to peer into the body without cutting through the skin. With video monitors and robotic equipment, surgery becomes less invasive and less traumatic to the body (Sawchuck, 2000). Noninvasive means of looking into the human body are now being used to diagnose a wide variety of diseases, including cancer, Alzheimer's disease, stroke, heart failure, and vascular disease (President's

Committee of Advisors on Science and Technology, 2000). The first imaging technologies, the X-ray (discovered by W. K. Roentgen) and EEG (electroencephalogram), were primitive by today's standards, but both have been considerably improved and provided the conceptual base of the other amazing imaging technologies that have recently emerged.

The most common, CAT (computer-assisted tomography) scans, combine X-rays with computer technology to create cross-sectional images of the patient's body, which are then assembled into a three-dimensional picture that displays organs, bones, and tissues in great detail. MRI scanners use magnets and radio waves instead of X-rays to generate images that provide an even better view of soft tissues, such as the brain or spinal cord (President's Committee of Advisors on Science and Technology, 2000).

Much of today's imaging technology relies on microprocessors and software. In addition, the great advances in noninvasive sensing, tomography, and imaging technologies now allow repeated studies with minimal stress and damage (National Research Council, & Institute for Laboratory Animal Research, 2002).

Medical imaging is often thought of as a way of viewing anatomical structures of the body. Indeed, X-ray computed tomography and magnetic resonance imaging yield exquisitely detailed images of such structures. It is often useful, however, to acquire images of physiologic function rather than of anatomy. Such images can be acquired by imaging the decay of radioisotopes bound to molecules with known biological properties. This class of imaging techniques is known as nuclear medicine imaging.

Although the mathematical sciences were used in a general way for image processing, they were of little importance in biomedical work until the development in the 1970s of computed tomography for the imaging of X-rays (leading to the CAT scan) and isotope-emission tomography (leading to positron-emission tomography [PET] scans and single-photon-emission computed tomography [SPECT] scans). In the 1980s, MRI eclipsed the other modalities in many ways as the most informative medical imaging methodology (Webb, 1988).

Table 1 summarises some of the imaging methods used in biomedical applications.

Technologies such as those in Table 1 are all being investigated in small-animal models. The goal

Table 1. Imaging methods used in biomedical applications

- X-ray projection imaging (discovered in 1895)

- Micro computerised axial tomography (MicroCAT)
- Optical and thermal diagnostic imaging (OCT, DOT)

is to marry fundamental advances in molecular and cell biology with those in biomedical imaging to advance the field of molecular imaging (TA-Datenbank-Nachrichten, 2001). The two basic starting points in evaluating the overall utility of a medical technology are efficacy and safety. If a technology is not efficacious, it should not be used. In addition, efficacy and safety data are needed to evaluate the cost effectiveness of a technology (Banta, Clyde, & Williams, 1981).

Biomedical imaging devices have been used to obtain anatomical images and to provide localised biochemical and physiological analysis of tissues and organs. The ability of these devices to provide anatomical images and physiological information has provided unparalleled opportunities for biomedical and clinical research, and has the potential for important improvements in the diagnosis and treatment of a wide range of diseases (National Institute of Biomedical Imaging and Bioengineering [NIBIB], 2002).

Technological devices visualise and enlarge somatic space, rendering images of our most infinitesimal cells, molecules, and genetic structures, which allows for a more precise manipulation of our muscles, tissues, and bones (Sawchuck, 2000). Imaging tests now provide much clearer and more detailed pictures of organs and tissues. New imaging technology allows us to do more than simply view anatomical structures such as bones, organs, and tumours. Functional imaging—the visualisation of physiological, cellular, or molecular processes in living tissues—enables us to observe activity such as blood flow, oxygen consumption, or glucose metabolism in real time.

Imaging technology already has had lifesaving effects on our ability to detect cancer early and more accurately diagnose the disease (especially the PET device). Generally, the purpose of the biomedical imaging techniques is the early detection, clinical diagnosis, and staging of a disease, and therapeutic applications (*Biomedical Imaging Symposium: Visualizing the Future of Biology and Medicine*, 1999). Imaging technologies have many applications in biomedicine. Oncology, cardiology, and ophthalmology are only some of its sections that use these technologies, which everyday are developed more and more.

PROBLEMS AND DISADVANTAGES OF IMAGING TECHNOLOGIES

Despite all the promises, the use of imaging technologies in biomedicine and bioengineering evoke many problems. All biomedical imaging devices suffer from various limitations that can restrict their general applicability. Some major limitations are sensitivity, spatial resolution, temporal resolution, and the ease of the interpretation of data. One way to circumvent these limitations is to develop technological and methodological approaches that improve and extend the sensitivity and the information content of individual imaging techniques. Another way is to combine two or more complementary biomedical imaging techniques (like MRI and PET, MRI and MEG, and optical MRI).

Table 2 summarises some problems of the imaging technologies.

There is no crystal ball to predict the future of medical imaging technologies. New applications continue to be explored for both diagnosis and treatment (Canadian Institute for Health Information, http://www.cihi.ca). Biomedical imaging has seen truly exciting advances in recent years. New imaging methods can now reflect internal anatomy and dynamic body functions heretofore only derived from textbook pictures, and applications to a wide range of diagnostic and therapeutic procedures can be envisioned. Not only can technological advances create new and better ways to extract information about our bodies, but they also offer the promise of making some existing imaging tools more convenient and economical.

Advances based on medical research promise new and more effective treatments for a wide

Table 2. Problems and disadvantages of imaging technologies

- The high cost of equipment and their maintenance, which aggravates the national economy for medicine
- Wasteful expenditures because of bad usage by users and technical staff (20 to 40%)
- The technology changes rapidly and devices may become out of date
- Users need education to learn how to break the new technologies in
- Physicians and the nursing staff must continuously be acquainted through articles related to the new technologies and equipment
- New technologies cause disruption and disappointment for staff
- They are venturous for patients because the levels of radiation they are exposed to may be too high

variety of diseases. New noninvasive imaging techniques for the earlier detection and diagnosis of disease are essential to take full advantage of new treatments and to promote improvements in healthcare. The development of advanced genetic and molecular imaging techniques is necessary to continue the rapid pace of discovery in molecular biology. Several breakthrough imaging technologies, including MRI and CT, have been developed primarily abroad (American Institute for Medical and Biological Engineering, http://www.aimbe.org).

Key paradigms of emerging imaging technologies from different technological areas will be presented, and the engineering principles and research findings leading to the design of efficient bioimaging technologies will be introduced and analysed. Specifically, imaging technologies from space or aerospace research have been identified and successfully applied toward the development of novel high-resolution, multisensor medical imaging systems, with potential applications in digital radiography and CT. Similarly, experimental research findings for defence applications have been applied toward the development of multifusion optical sensing imaging systems and techniques for efficient disease detection (Giakos, 2003).

Today, as for all products and services in all sectors, there exists the DICOM (Digital Imaging and Communications in Medicine) Standards Committee. Its purpose is to create and maintain international standards that help the allocation of medical pictures (like radial tomographies, magnetic tomographies, etc.), and the communication of biomedical diagnostic and therapeutic information in disciplines that use digital images and associated data (DICOM, 2004). DICOM is used or will be used by every medical profession that utilises images within the healthcare industry.

CONCLUSION

The rapid progress in imaging technologies during the last decades has stimulated many developments and applications in medicine, biology, industry, aerospace, remote sensing, meteorology, oceanography, and the environment.

New developments are continually making the technology faster, more powerful, less invasive, and less expensive. Imaging technology was primarily used in medical diagnosis initially, but it is being increasingly used in pure neuroscience, psychological research, and many other fields. The quantitative nature of data will be relevant for the effective diagnosis as well as therapeutic management of patients, whichever disease they have (“Nuclear Medicine Sextet,” 1999).

KEY TERMS

Assessment of Imaging Technology: Research on and development of methods for the evaluation and comparison of new and existing imaging technologies to establish their effectiveness, robustness, and range of applicability.

Bioengineering: The application of engineering principles to the fields of biology and medicine, as in the development of aids or replacements for defective or missing body organs. It is also called biomedical engineering.

Biomedicine: A branch of medical science concerned especially with the capacity of human beings to survive and function in abnormally stressful environments and with the protective modification of such environments. Broadly, it is medicine based on the application of the principles of the natural sciences, especially biology and biochemistry.

Development of Imaging Devices: Research and development of generic biomedical imaging technologies before specific applications are demonstrated.

Diagnostic Imaging: A study section reviews applications dealing with the development and evaluation of new technology for imaging, including instrumentation and software for producing, evaluating, storing, and transmitting images for anatomical, physiological, metabolic, diagnostic, and therapeutic information.

Image Exploitation: Development, design, and implementation of algorithms for image processing and information analysis, including advanced methods for the acquisition, storage, and display of images; research and development on image-guided procedures; and techniques for using multidimensional images to understand physiology and normal and abnormal function.

Medical Device: Any instrument, apparatus, appliance, material, or other article, whether used alone or in combination, including the software necessary for its proper application, intended for the purpose of the diagnosis, prevention, monitoring, treatment, alleviation, or investigation of a disease, injury, or handicap.

Medical Imaging: Term describing the various technologies that produce pictures or images of the body and its structures. Imaging technologies include X-ray, CT scanning, PET scanning, and ultrasound. This term also includes technology such as digital cameras, which produce digital images.

Medical Imaging Technologies: A study section reviews all modalities of medical imaging, including gamma ray; MRI; functional MRI; PET; SPECT; X-ray; CT; visible, infrared, and ultraviolet photons; and optical, photo-acoustic, microwave-acoustic, and exotic imaging methods.

Minimally Invasive Technologies: Basic research involving the use of robotics technologies for actuation, sensing, control, programming, and the human-machine interface, and the design of mechanisms to determine research end points such as diagnosis and the automated or remote treatment of disease.

Chapter 3.19
Inertial Sensing in Biomechanics:
Techniques Bridging Motion Analysis and Personal Navigation

Angelo M. Sabatini
ARTS Lab, Scuola Superiore Sant'Anna, Italy

ABSTRACT

Sensing approaches for ambulatory monitoring of human motion are necessary in order to objectively determine a person's level of functional ability in independent living. Because this capability is beyond the grasp of the specialized equipment available in most motion analysis laboratories, body-mounted inertial sensing has been receiving increasing interest in the biomedical domain. Crucial to the success of this certainly not new sensing approach will be the capability of wearable inertial sensor networks to accurately recognize the type of activity performed (context awareness) and to determine the person's current location (personal navigation), eventually in combination with other biomechanical or physiological sensors — key requirements in applications of wearable and mobile computing as well. This chapter reviews sensor configurations and computational techniques that have been implemented or are considered to meet the converging requirements of a wealth of application products, including ambulatory monitors for automatic recognition of activity, quantitative analysis of motor performance, and personal navigation systems.

INTRODUCTION

At present, human motor performance can be accurately assessed with several measuring instruments, the use of which is spread in many motion analysis laboratories throughout the world. The most important technology used to detect and track human body motion is video-motion sensing. In common with other motion tracking technologies, such as infrared, electromagnetic, ultrasound, video-motion sensing is externally referenced, in the sense an external source — optical, magnetic, acoustic — is needed to determine position and orientation information concerning the moving object of interest (Meyer, Applewhite, & Biocca, 1992). Usually, this source is effective over a relatively small working space. In addition to the range restriction, interference, distortions and occlusions can easily result in erroneous location and orientation information, thereby leading, in critical situations, to a complete loss of track (You, Neumann, & Azuma, 1999). The availability of dedicated laboratory setups is, therefore, a prerequisite for the application of externally referenced sensing techniques. However, from a clinical viewpoint, motor performance measured in laboratory settings may not accurately reflect functional ability in daily-life environments, since behavior of patients in laboratory is not necessarily representative of their daily-life behavior. There is a need for ambulatory monitoring systems that are able to provide objective assessment of human functional ability in the absence of the behavioral modifications induced by performing within constraining laboratory settings.

The capability of inertial sensors of sensing their own motion is the sourceless feature that makes them so attractive for the development of ambulatory monitoring systems (Verplaetse, 1996). Body-mounted sensors of this kind make it possible to determine position and orientation information based on the measurement of physical quantities (acceleration, angular velocity), which are directly related to the motion of the body part where they are positioned. Being internally referenced, inertial sensors can then be proposed to detect and track body motion over a virtually unrestricted working space. Until recent years, inertial sensors have only found use to monitor the motion of man-made vehicles, including spaceships, planes, ships, submarines, cars, and, more recently, wheeled and legged robots. Recent advances in microelectromechanical systems (MEMS) technologies have led to the development of a new generation of inertial sensors (Bachmann, Yun, McKinney, McGhee, & Zyda, 2003), the specifications of which — in terms of encumbrance, robustness, power consumption, measuring performance and cost — seem to be appropriate for applications in the biomedical field.

In inertial systems, the main problem is that position and orientation are found by time-integrating the signals from accelerometers and gyroscopes, as well as any sensor drift and noise superimposed to them. As a result, position and orientation errors tend to grow unbounded. This problem is especially acute when low-cost MEMS inertial sensors are used. Their sensitivity and bias stability are, in fact, orders of magnitude less than the sensitivity and bias stability of the high-grade inertial sensors that are embedded in military and aviation navigation systems (Foxlin, 2002). Another drawback of inertial sensors is that they are not well-suited for determination of absolute position and orientation. In order to be accurate, the integration process needs to be started from accurately known initial conditions, which inertial sensors are unable to provide at all (position and velocity), or can provide to just a limited extent (orientation). Hence, the use of inertial systems is most effective in those applications which involve relative motion.

In this chapter, we are not interested in the viewpoint of those who aim at designing new and better sensors. Rather, we intend to survey the main computational techniques that have been investigated so far, in the effort to take measurements from available sensors and construct the best possible characterization of human body motion. The traditional approach to data processing for navigational purposes has involved the development of filtering algorithms to fuse measurements from inertial sensors and other sensors, such as global positioning system (GPS) receivers and Earth's magnetic field sensors. It has also involved the exploitation of suitable environment maps so as to deal with the person's location uncertainty during indoor and outdoor navigation. Other computational techniques have been designed with a stronger biomechanical inspiration. They specifically aim at obtaining valuable information about either absolute or relative motion of body parts from simple configurations of single or multiple inertial sensors, in the effort to gain a deeper understanding of how we humans perform functional activities, including gait, balance and postural transitions, in normal or pathological conditions.

The borderline between the use of inertial sensors as functional and navigational sensors in biomechanics is becoming increasingly fuzzy. As it will be seen, a better prediction of the errors incurred in the mathematical reconstruction of the walked path can be achieved by exploiting signatures which characterize how certain functional activities such as walking are performed. Conversely, the knowledge of temporo-spatial features of the walked path, reconstructed from navigational sensors, has relevant functional implications, when, for instance, an objective assessment of the person's physical activity in daily-life conditions is desired. Ideally, we would like to determine accurately the current person's location and recognize what he or she is doing and how, without incurring in any significant limitation in the extension of the measurement space and in the duration of the observation records.

At present, ambulatory monitoring systems based on sole inertial sensing cannot accomplish this ambitious goal, although they can already be used with remarkable success. In this chapter we will survey how inertial sensing has been applied in biomechanically-oriented works, with particular emphasis on the sensor configurations and adopted signal processing techniques. In doing that, we hope to give convincing support to the claim that another valuable analytical weapon is ready for inclusion in the repertoire of tools available to measure and study human motor performance.

BACKGROUND

Introductory Remarks

An inertial sensor is a motion sensor the references of which are internal, with the exception of initialization (Curey, Ash, Thielman, & Barker, 2004). It can be used for the determination of position and orientation by measuring physical quantities, such as linear accelerations and angular velocities. An inertial sensor assembly (ISA) is a structure that contains multiple inertial sensors (accelerometers and/or gyroscopes) in fixed orientations relative to one another. An inertial measurement unit (IMU) measures linear and angular motion in the three-dimensional space without external references. Using the outputs from an IMU, an inertial navigation system (INS) estimates a body's position and orientation, in connection with a gravitational field model and the operation of a reference clock.

Earth's magnetic field sensing is formally externally referenced, although it can be used in practice as though it is internally referenced. This is because the Earth's magnetic field is available anywhere, and no environmental modifications are required to operate an Earth's magnetic field sensor, or magnetic sensor in short. The importance of magnetic sensors in human-machine interface applications and human body motion tracking systems has been widely acknowledged (Foxlin, 2002), in part because of the recent market availability of miniaturized tri-axis inertial/magnetic sensors packages. Using a geomagnetic field model, magnetic sensors can help specify the location of an INS during initialization, and mitigate the INS error growth during flight. Magnetic sensors will be included in the sensor configurations of interest to our review in this chapter.

Inertial and Magnetic Sensors

Accelerometers are sensors that measure the applied acceleration acting along a sensitive axis. A range of different transducers are available to measure the acceleration. In virtually all applications in human movement science piezoresistive accelerometers are used (Verplaetse, 1996). Piezoresistive materials have the property of modifying their electrical resistance when they are strained or deflected. In terms of functionality, body-mounted piezoresistive accelerometers respond to either static accelerations, such as gravity, or dynamic accelerations, such as linear/rotational accelerations due to body movements (Figure 1). When exposed just to gravity, a body-mounted tri-axis accelerometer can be used to estimate the inclination relative to the vertical of the body segment where the device is positioned.

Gyroscopes, gyros in short, are sensors that measure the rate of rotation about a sensitive axis. The most popular design of a gyro for applications in the field of human movement science is of the vibrating type (Verplaetse, 1996). Vibrating gyros use the Coriolis acceleration effect to sense when they rotate. In the absence of rotation, the vibrating element embedded in the sensor continuously vibrate within a plane. In the presence of a rotation about an axis perpendicular to the plane of vibration, the vibrating element deviates from its plane of vibration under the Coriolis acceleration effect and the amplitude of the out-of-plane vibration is proportional to the rate of rotation (Abbott & Powell, 1999). Gyros with a vibrating element are more sensitive to temperature and shock than accelerometers, due to mechanical fastening of the vibrating beam inside the sensor case. Compared with accelerometers, gyros have also relatively higher cost and larger size.

Magnetic sensors resolve the components of the local magnetic field along a sensitive axis. A magnetic compass is an electronic device that measures its heading relative to magnetic north by measuring the direction of Earth's local magnetic field (Abbott & Powell, 1999). The Earth's magnetic field has a component parallel to the Earth's surface that always points toward magnetic north, hence its projection on the horizontal plane can be used to determine compass direction (Caruso, 1997). Common designs of magnetic sensors integrate three magnetic sensors with sensitive axes mutually perpendicular in the same package, so as to reconstruct the horizontal component, provided that the inclination of the sensor case is estimated from gravity sensors (tilt compensation) (Figure 2).

In applications in the field of human movement science, the capability to sense the Earth's magnetic field is the horizontally-sensing principle needed to complement the vertically-sensing principle of accelerometers, so as to enable three-dimensional monitoring of orientation (Kemp, Janssen, & van der Kamp, 1998).

Figure 1. A piezoresistive single-axis accelerometer measures the projection (in the direction of the sensitive axis) of an equivalent acceleration resulting from the sum of the acceleration due to the accelerometer's own motion and the equivalent gravity acceleration acting on its mechanical structure.

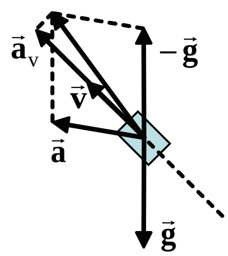

Figure 2. Inclination of the compass device relative to the Earth's local horizontal plane as defined by gravity direction (a). Earth's magnetic field resolved in (x, y, z) coordinates (b).

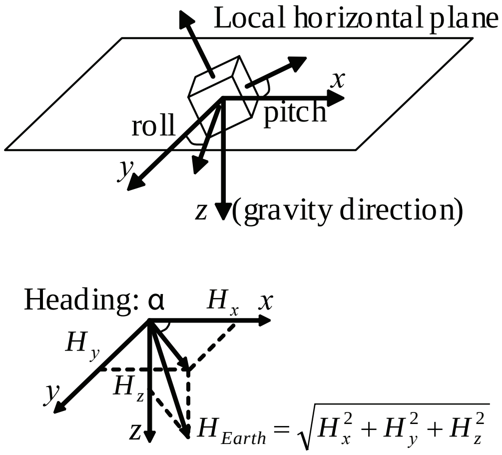


The Strapdown Approach to INS Design

Consider a rigid body in space and define a coordinate system attached to the body — the body frame, $\mathcal{B}$. In a strapdown INS, the sensitive axes of the ISA sensors are permanently aligned along the axes of $\mathcal{B}$ (Curey et al., 2004). Orientation determination means to specify the orientation of the axes of $\mathcal{B}$ with respect to the Earth's reference frame $\mathcal{E}$; position determination means to specify the origin of $\mathcal{B}$ relative to $\mathcal{E}$.

Suppose that a vector $\vec{\mathbf{x}}$ is resolved along the axes of $\mathcal{B}$ and $\mathcal{E}$, to yield the 3×1 column-vectors $\vec{\mathbf{x}}^B$ and $\vec{\mathbf{x}}^E$ respectively. The transformation between the 3×1 column-vector $\vec{\mathbf{x}}$\ as expressed in the body frame and in the reference frame is:

$$\vec{\mathbf{x}}^B = \overset{E\to B}{C}\ \vec{\mathbf{x}}^E \qquad (1)$$

where $\overset{E\to B}{C}$ is the direction cosine matrix for the transformation from $\mathcal{E}$ and $\mathcal{B}$. Furthermore, suppose a single-axis accelerometer is attached to the body at point $\vec{\mathbf{p}}(t)$, and the orientation of its sensitive axis is denoted by the unit vector $\vec{\mathbf{v}}(t)$. In principle, the accelerometer measures the projection of the acceleration of point $\vec{\mathbf{p}}(t)$, along $\vec{\mathbf{v}}(t)$.

$$\vec{\mathbf{a}}^E(t) = \left[\dot{\vec{\omega}}(t)\times\vec{\mathbf{p}}(t) + \vec{\omega}(t)\times\vec{\omega}(t)\times\vec{\mathbf{p}}(t) + \vec{\mathbf{a}}_o(t) + \vec{\mathbf{g}}\right]\cdot\vec{\mathbf{v}}(t) \qquad (2)$$

where $\vec{\mathbf{a}}_o(t)$ is the acceleration of the origin of $\mathcal{B}$ $\vec{\mathbf{o}}(t)$, is the gravitational acceleration, and $\vec{\omega}$ is the angular velocity of $\mathcal{B}$ relative to $\mathcal{E}$, resolved in $\mathcal{B}$. In (2), × and · denote the standard vector cross-product and dot-product, respectively.

The determination of the direction cosine matrix, also called attitude matrix, is usually performed by numerically integrating non-linear systems of first-order differential equations from initial conditions that are assumed to be known (initialization, or alignment) (Bortz, 1971). In this approach, the differential equations involve the components of $\vec{\omega}$, which are usually measured by a tri-axis gyro. Alternatively, the attitude can be determined by vector matching in $\mathcal{E}$ and $\mathcal{B}$ (Wertz, 1978).

Vector matching, also known as Wahba's problem, calculates the attitude solution by matching two non-zero, non-colinear vectors that are known in $\mathcal{E}$ and measured in $\mathcal{B}$. The Earth's gravitational field and the Earth's magnetic field are two these vectors. Vector matching solves the alignment process and forms, in principle, an alternative to the use of gyros in determining the attitude matrix (Gebre-Egziabher, Elkain, Powell, & Parkinson, 2000). While suitable to track slow movements, this gyro-free method is not suited for fast movements, yielding quite large orientation errors during the motion.

To understand why, let $\vec{\mathbf{o}}(t)$ be the point whose position in $\mathcal{E}$ is to be determined. It is apparent from (2) that the output of a body-mounted accelerometer depends on where it is placed, its orientation relative to the subject, the subject's posture and activity. In the absence of motion, the accelerometer output is determined by its orientation relative to the vertical. Knowing the accelerometer orientation relative to the subject, the accelerometer can be used to determine the subject's orientation relative to the vertical. In the presence of motion, the resulting signal depends on the subject's posture and activity.

The orientation estimate is used twice in the strapdown approach to position determination. First, the accelerometer senses the body's acceleration $\vec{\mathbf{a}}_o^B(t)$ as the superposition of the sensed acceleration in $\mathcal{B}$, $\vec{\mathbf{a}}^B(t)$ and the projection of the gravitational acceleration $\vec{\mathbf{g}}$ on $\mathcal{B}$:

$$\vec{\mathbf{a}}_o^B(t) = \vec{\mathbf{a}}^B(t) - \overset{E\rightarrow B}{C}(t)\,\vec{\mathbf{g}} \qquad (3)$$

The next step requires integration of $\vec{\mathbf{a}}_o^E(t) = \overset{B\rightarrow E}{C}(t)\vec{\mathbf{a}}_o^B(t)$ to derive the position estimate:

$$\vec{\mathbf{o}}^E(t) = \int_0^t dt' \int_0^{t'} \overset{B\rightarrow E}{C}(t')\,\vec{\mathbf{a}}_o^B(t'')dt''. \qquad (4)$$

Any numerical integration routine can be used to solve (4). The flow of information underlying the strapdown approach is illustrated in Figure 3.

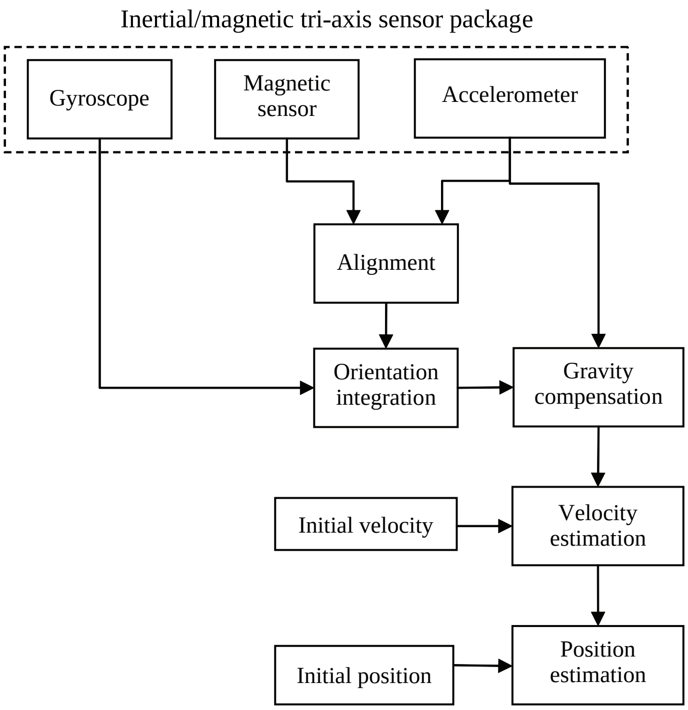
Drift in the orientation determination comes from gyro biases, defined as the output produced by gyros at rest. Uncompensated gyro biases lead to a constant rate of drift after integration. More than the biases in itself, their time-stability is a matter of concern. Time-stable biases can be measured when the INS is stationary and compensated for. There is also drift in the linear position determination which arises from several sources. First, there are the effects of accelerometer biases, the compensation of which is not so straightforward as the compensation of the gyro biases (Lötters, Schipper, Veltink, Olthius, & Bergveld, 1998). Second, since position is obtained by double integration, uncompensated accelerometer biases result in a position drift error which grows quadratically in time. Third, the orientation errors incurred by gyros lead to imperfect gravity cancellation during the double integration.

Additionally, the capability of geomagnetic compassing to correct drift is poor in many environments, because the Earth's magnetic field is weak and easily masked by magnetic disturbances within or near the measurement space.

In conclusion, it is critical to achieve high accuracy in position/orientation determination by strapdown INSs incorporating low-cost inertial/magnetic sensors, the stand-alone accuracy and run-to-run stability of which are poor. Different applications may involve different accuracy requirements relative to the duration of each observation run. In the absence of special precautions, the requirements of human motion tracking applications are shown to be violated when the duration of the observation run exceeds just several seconds (Foxlin, 2002).

There appear to be different means to deal with these problems, as stated below. An approach is to use externally referenced aids, such as GPS, and carry out the integration process underlying the combined use of GPS and INS technologies with Kalman filters (KFs). Another approach is

Figure 3. Strapdown approach to the design of an inertial navigation algorithm



to exploit idiosyncrasies of the human motion dynamics by designing algorithms that can keep the drift rate low (Foxlin, 2002; Sabatini, 2005). Alternatively, in some applications, the difficulty inherent in the strapdown approach can be circumvented by using signal features the construction of which do not require time integration from uncertain initial conditions.

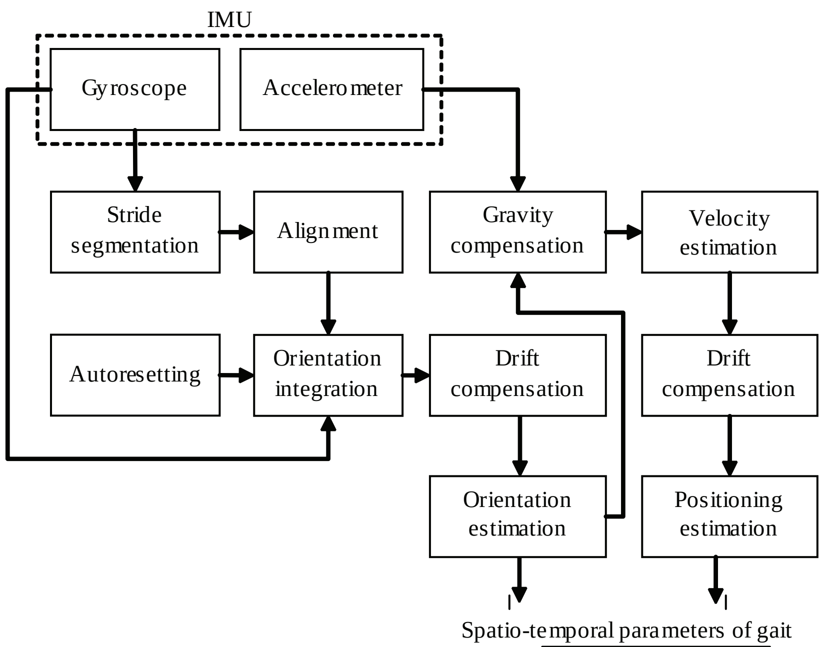
TAXONOMY OF APPLICATIONS

Ambulatory Monitoring of Human Motion

The use of accelerometry to perform ambulatory measurements of human motion is well established (Gage, 1964; Smidt, Arora, & Johnston, 1971; Morris, 1973). Morris (1973) suggests to calculate the general displacement of a rigid body with one point fixed—a rotation about an axis through the fixed point—from three acceleration measurements, followed by three additional acceleration measurements to resolve the motion of the fixed point with respect to the Earth's reference frame. Valuable considerations are made by this author concerning the problem of IMU alignment and drift correction. In the case of shank motion during level walking, the redundancy of the information on shank motion during the foot-flat phase of the walking cycle is exploited to calculate the initial orientation (alignment). Because of the cyclical nature of leg motion, the initial angular velocity and rotation, translation acceleration and velocity can be made equal to the values of these functions at the beginning of the next cycle (drift correction).

IMUs composed of several single-axis accelerometers with their sensitive axes properly positioned in space relative to one another have been proposed and lead, for the estimation of the components of angular velocity, to systems of nonlinear coupled differential equations (IMU with six accelerometers) and linear uncoupled

Figure 4. Strapdown approach to the design of an inertial navigation algorithm, specifically intended for gait analysis applications (Sabatini, 2005)



The need for alignment exists unless the change of orientation is the quantity of interest. This is the case when, for instance, the change of orientation is introduced in simple symmetric gait models of extended limbs to determine stride length (Miyazaki, 1997).

Assessment of Gait

A full kinematic analysis of the body motion based on body-mounted sensors would be impossible without incurring in the "Christmas tree" effect (Meijer, Westerkerp, Verhoeven, Koper, & ten Hoor, 1991), even in the limit of a simplified two-dimensional analysis (Mayagoitia, Nene, & Veltink, 2002). Fortunately, in clinical practice, the values of simple temporo-spatial parameters of gait, including stride time/length, cadence and walking speed, turn out to be good indicators of how well a person walks, and of how effective are different rehabilitation techniques or exercise programs in facilitating ambulatory recovery (Weir & Childress, 1997; Maki, 1997). Valuable information concerning a person's gait can also be obtained by measuring temporo-spatial features related to the displacement of particular anatomical points, such as the vertical displacement of the sacrum during walking (Weir & Childress, 1997).

Simple parameters of gait can be determined from waist, thigh, heel accelerations (Evans, Duncan, & Gilchrist, 1991; Auvinet, Chaleil, & Barrey, 1999; Aminian et al., 1999a; Zijlstra & Hof, 2003); from thigh, shank, heel, foot instep angular velocities (Miyazaki, 1997; Tong & Granat, 1999; Pappas, Popovic, Keller, Dietz, & Morari, 2001; Aminian, Najafi, Büla, Leyvraz, & Robert, 2002; Sabatini et al., 2005). The parameterization of gait requires the detection of subsequent foot contacts. The commonest approach to the detection of foot contacts with inertial sensors is based on a search for distinctive and stable signal features occurring at the time of heel-strike (when the foot first touches the floor) and toe-off (when it last takes off) during a gait cycle. Usually, the detection and time-localization of these features require (a combination of) peak or zero-crossing detectors applied to signals contaminated by relatively high-frequency noise components. In a number of papers (Aminian et al., 1999; 2002; Paraschiv-Ionescu, Buchser, Rutschmann, Najafi, & Aminian, 2004) the use of wavelet packages is proposed to perform the process of gradually focusing on the exact location of heel-strikes and toe-offs. In particular, the claim of these authors is that wavelet packages are well adapted for gait events identification, such as heel-strike and toe-offs, because they allow detection of a specified frequency at a specified time. In general, for biomechanical signal processing applications, the superiority over standard filtering techniques of wavelet denoising and smoothing of kinematic data related to complex motions is documented (Ismail & Asfour, 1999). Another good point in favour of wavelets is that the existence of fast algorithms for carrying the multiresolution analysis would allow to implement gait parameterization in real-time conditions, although this point has not been yet investigated.

The spatial parameters of gait can be determined by so-called indirect methods or by integrating the strapdown equations (direct method). Indirect methods are based on the recognition of few important features of human's walking patterns. These include the good correlation existing between the stride length and the cadence, or the influence of walking speed on the amplitudes of the acceleration signals at different point on the legs. Recent studies demonstrate that during walking trunk accelerations exhibit patterns with fixed relationships to spatio-temporal gait parameters. Zijlstra and Hof (2003) analyze the 3D-acceleration pattern of the lower trunk at different walking speeds, and develop algorithms to determine the instant of foot contacts during each step. Based on a simple inverted pendulum model of the body's center of mass (BCOM) trajectory, the step length is predicted by the peak-to-peak trunk vertical displacement, which is obtained from double integration of the high-pass filtered vertical component of trunk acceleration. An advantage of computing peak-to-peak displacements is that sensor calibration and initialization issues are insignificant, although inaccurate placement of the sensor device in the frontal plane is a matter of concern for achieving good test-retest reliability, as discussed by Moe-Nillsen (1998), who prefer to work in the domain of root mean square (RMS) values from 3D-waist accelerometer data.

In the attempt to include the incline of the walked surface in the number of variables that are known to correlate with walking speed, the parameterization of body accelerations at the waist and heel is performed in (Aminian, Robert, Jéquier, & Schutz, 1995) on the basis of simple features, such as means, standard deviations, correlation coefficients between various acceleration components, step time, and so forth. Two artificial neural networks (ANNs) are designed, one for predicting the walking speed (averaged over a single stride), one for predicting the incline of the walked surface, according to standard design procedures for training and testing multilayer perceptrons. Subject-specific training is performed by presenting examples of treadmill walking at different combinations of walking speed/incline, so as to account for individual walking styles. Testing is performed during overground walking. Results show that only marginal improvements are due to using ANN technology in the walking speed prediction, as compared with the results of a stepwise linear regression analysis. Conversely, owing to the possible presence of strong nonlinearities in the complex relationships between the acceleration parameters selected for the study and the incline, the ANN use is shown to remarkably improve the incline estimate. It is worthy noting that ANNs exhibit significant generalization abilities in this application, although the training phase must be necessarily subject-specific.

Common to all indirect methods, intra-individual physiological variability and environmental conditions heavily influence the accuracy of the relationships exploited to infer the quantities of interest. Hence, frequent calibration procedures may be needed, which requires additional sensors (Perrin, Terrier, Ladetto, Merminod, & Schutz, 2000; Terrier, Ladetto, Merminod, & Schutz, 2000). Another limitation of indirect methods is that they are approaches which suffer from changes in walking style. It is expected that, in particular situations, such as crowded streets and many indoor environments, the human displacements occur with frequent walking strategy adaptations. Finally, the generalization implied by indirect methods is critical when walking is performed over irregular terrain or in the face of frequent changes of inclines.

At the expense of greater computational costs, direct methods would be more appropriate than indirect methods. Anecdotal evidence highlights the remarkable accuracy of direct methods for the estimation of gait spatio-temporal parameters (Sagawa, Sato, & Inooka, 2000; Veltink et al., 2003). In support of this claim, a recent study analyzes the performance of a direct method during level/uphill/downhill treadmill walking (Sabatini et al., 2005).

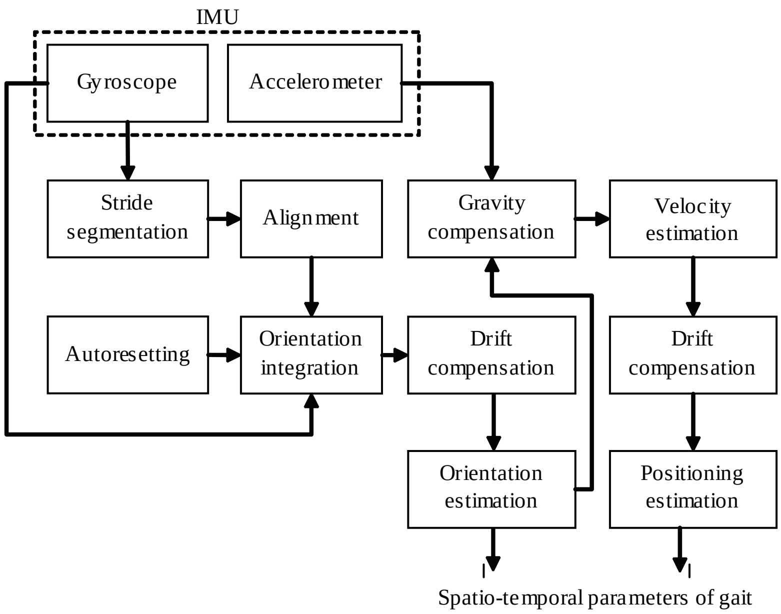
Assessment of Physical Activity and Energy Expenditure of Daily-Life Activities

Physical activity is an important part of human behavior and it may be related to various aspects of health and disease; intense research is therefore undergoing to find means for its objective assessment (Mejier et al.,1991). The complex nature of physical activity makes this goal very difficult to pursue. At present, the energy expenditure due to physical activity is widely accepted as the standard reference for physical activity. Together with heart rate monitoring, motion sensors such as accelerometers are considered suitable to obtain a quantitative estimation of the energy expenditure incurred in daily-life activities.

The use of accelerometers is based on relationships between accelerometer output and energy expenditure or oxygen uptake that are documented in several studies on gait analysis and ergonomics (Bouten, Koekkoek, Verduin, Kodde, & Janssen, 1997; Bussmann, Hartgerink, van der Woude, & Stam, 2000). Regardless where the right location of body-mounted accelerometers is for the best prediction of the energy expenditure, or which the effects of placement and orientation are (Bouten, Sauren, Verduin & Janssen, 1997), we cannot expect extremely accurate estimates of energy expenditure with the use of accelerometers (Bussmann et al.,2000). Albeit dynamic activities such as walking greatly contribute to daily-life physical activity, and are a prerequisite to many other activities, the contribution to energy expenditure due to static activities is also relevant, for instance weight bearing in the upright posture, work of isometric contractions, and so forth. Of course, motion sensors are totally blind to this part of the energy budget.

Since double integration of acceleration to retrieve position and compute external work is not believed accurate enough for long-term monitoring, the general consensus is that the summation of the time integrals of acceleration components in various measurement directions, and the time integral of the acceleration vector norm result in the most accurate prediction of energy expenditure during dynamic activities (Bouten et al.,1997). More precisely, the various acceleration components are high-pass filtered to subtract gravity influence; the numeric integration is carried out, then the integral(s) are normalized to the duration of the integration interval. Possibly, energy expenditure estimation can be improved by adopting nonlinear regression models to capture the relationship between the acceleration statistical feature and the energy expenditure (Chen & Sun, 1997). The improvement is especially important in estimating light-intensity activities, whose energy expenditure is generally underestimated by linear models (Bouten et al.,1997a).

Figure 4. Strapdown approach to the design of an inertial navigation algorithm, specifically intended for gait analysis applications (Sabatini, 2005)



Besides walking speed, the assessment of the energy expenditure during walking is influenced by many other parameters, including the incline. Without an external measurement of the slope, the standard method of analysis of body accelerations cannot accurately predict the energy cost of uphill/downhill walking (Terrier, Aminian, & Schutz, 2001). Use of additional processing techniques, such as ANNs (Aminian et al.,1995), have shown success in estimating the incline along which the subject is walking. Use of a direct method based on strapdown integration from a foot IMU is discussed in Sabatini, Martelloni, Scapellato and Cavallo (2004), in connection with the use of empirical models for determining the energy cost of walking.

Automatic Recognition of Activity

Another problem existing with the assessment of physical activity by motions sensors as previously described is that these methods do not provide information on the type of activity. In order to assist a clinician in diagnosis, choosing the most suitable therapy for a patient, monitoring patient progress and assessing the effects of treatment, the "quantity" of motion is certainly an important issue, but aspects of mobility and locomotion related to the specific activity where energy is spent ought to be elucidated as well. Ambulatory monitors have been designed with the goal to identify and classify sets of postures and activities (Table 1).

Most systems have used only accelerometers (Bussmann, Veltink, Koelma, van Lummel, & Stam, 1995; Foerster & Fahrenberg, 2000; Mathie, Celler, Lovell, & Coster, 2003), while other systems have used accelerometers together with another type of sensor to improve discrimination. Najafi et al. (2003) and Parischev-Ionescu et al. (2004) are interesting works where inertial sensors of different types are integrated into ambulatory monitors where activity recognition and some (limited) form of gait analysis are jointly differential equations (IMU with nine accelerometers) (Padgaonkar, Krieger, & King, 1975). The angular velocity components are then used to estimate the attitude matrix (Bortz, 1971). Double-integration of gravity-compensated accelerometer signals yields positioning information. Giansanti, Macellari, Maccioni, and Cappozzo (2003) analyze these IMU configurations in depth, and conclude that severe restrictions exist in the time duration over which motion tracking is feasible by accelerometry methods in routine biomechanical applications.

The determination of angular acceleration is probably the commonest computational task solved by accelerometry for the ambulatory monitoring of human motion. The main application is the clinical assessment of gait. Under the simplifying assumption of a gait motion planar model, a minimal configuration set composed of two leg-mounted single-axis accelerometers with parallel sensitive axes would be enough. In the attempt to circumvent the problem of integration drift, pairs of accelerometers on each segment are used to resolve the relative angle between two segments, namely the joint angle, without integration (Willemsen, van Alsté, & Boom, 1990). The potential of such an accelerometric angle sensor is highlighted in (Willemsen, Frigo, & Boom, 1991), where the most important error sources are analyzed in detail, namely not fulfilling the gait motion planar model and the rigid-body condition by external fixation of body-mounted sensors.

Luinge and Veltink (2004) propose to use one tri-axis accelerometer to measure inclination during dynamic tasks without requiring additional sensors. A Kalman-based filtering algorithm is designed to separate the different acceleration components: gravity, linear acceleration, bias, measurement noise, in accordance with a model of the linear acceleration components which relies on reasonable assumptions about the dynamics of human motion. The resulting inclination error is shown to be significantly smaller than the inclination error obtained by the method of low-pass filtering the accelerometer signals, especially as the speed of motion increases. Usually, low-pass filtering is used to separate the gravitational component from the linear acceleration components (Veltink, Bussmann, de Vries, Martens, & van Lummel, 1996; Foerster & Fahrenberg, 2000; Williamson & Andrews, 2001). Unfortunately, since the procedure of bias compensation works only in the direction of gravity, the bias estimate in all measurement directions is accurate only when the sensor is rotated over large angles.

As for the computation of joint angles, an alternative to the use of accelerometers is represented by the use of gyros (Miyazaki, 1997; Williamson & Andrews, 2001). Two approaches are possible to compensate the gyro bias during integration: a) high-pass filtering of the signals (Miyazaki, 1997) — this technique is not recommended for non-cyclical motions, for instance postural transitions, for whom a zero frequency component of angular velocity cannot be expected; (b) automatic nulling and resetting (Williamson & Andrews, 2001). The underlying basis for the implementation of automatic nulling is that, when the gyro is at rest, the angular velocity is null and the bias can then be estimated by averaging. The underlying basis for the implementation of automatic resetting is that, for cyclical motions, the values of angular rotation would be identical at each instance of a specific event occurring in the gait cycle, for instance foot-flat (Sabatini, Martelloni, Scapellato, & Cavallo, 2005). Automatic nulling and resetting imply the capability of discriminating rest and dynamic conditions by algorithmic means—a precursor to more sophisticated methods for automatic recognition of activity, as discussed later in this section. Another problem of gyroscopic sensing is that gyros measure changes of orientation rather than absolute orientation. Gravimetric tilt sensing and geomagnetic compassing are then required (Kemp et al.,1998), however alignment would be performed only in the time intervals between successive flights of the involved body segment (Figure 4) (Sabatini, 2005).

performed.

There are a number of difficulties in developing ambulatory monitors (Kiani, Snijders, & Gelsema, 1997; Foerster & Fahrenberg, 2000). The problems concern the algorithms that have to be designed to provide a reliable detection and discrimination of motions patterns and posture and the optimal sensor configuration set (type, number, placement). Algorithms for the detection of postures and motion patterns are a crucial aspect of this approach. The research is still intense on methods to achieve adequate data reduction and discrimination power, in the face of the generally ample variety of strategies existing in performing a particular daily-life motor activity and the large inter- and intra-subject variability. Optimality means that the highest discrimination ability would be achieved for a spectrum of motor activities as broad as possible, while keeping sensor number at minimum so as to increase subject's compliance and usability, and to reduce overall system complexity and cost.

An example of a decision tree for discriminating a set of postures and mobility-related activities by an accelerometry-based system is sketched in Figure 5.

Each node of the tree has multiple branches leading to all of the movements of interest at the next level of the hierarchy. At each node, all the possible classifications are considered, including the fallback case, namely the case that is accepted after that all other classifications have been discarded, and the most likely candidate is retained. Decision trees of this kind are presented in several works (Bussmann et al.,1995; Veltink et al.,1996; Kiani et al.,1997; Mathie, Celler, Lovell, & Coster, 2004), based on the particular mode of operation of the ambulatory system (clinical assessment or event monitoring), the specific hardware configuration, and the strategy upon which the development of the pattern recognition system is based.

Each node of the tree must have a classification algorithm associated to it. Only two approaches have been used to a greater extent in the design of these classifiers. In fixed-threshold classification, motion patterns are detected and discriminated by applying a threshold to the signal of interest. The threshold setting is critical, since intra- and inter-individual variations could easily lead to wrong classification.

In reference-pattern-based classification, the detection of motion patterns could be improved by developing a template pattern for each postural and activity condition and cross-correlating the signal with this (Veltink et al.,1996; Foerster & Fahrenberg, 2000). The precise placement of sensors is essential when thresholds are used for the classification of motion.

A classification that is based on individual reference patterns appears to be less susceptible than threshold-based classification, although careful sensor placement is critical for achieving good test-retest reliability.

Posture detection (sitting, standing, lying and their subtypes) (see Figure 5) requires that the orientation of a number of body segments (trunk, thigh, and so forth) relative to the gravitational field is computed, which involves necessarily the creation of a suitable sensor configuration arrangement. Crucial to the success of posture detection is then the ability to discriminate between gravitational and motion-related components of the raw acceleration signal. With some abuse of terminology, these components are commonly referred to as DC and AC components, respectively. Underlying this definition is the approach of low-pass filtering the raw signals for their separation, which is usually achieved by threshold-based tests for significant deviations of acceleration norm from gravity (Veltink et al.,1996).

Postural transitions are usually detected by threshold-based methods, and classified according to the nature of the static activities which precede and follow them. The process is claimed to be more robust when motion patterns are analyzed in specific frequency bands via wavelet-based multi-

Table 1. Summary of a collection of relevant past and ongoing work on automatic recognition of activity using inertial sensors

Reference	Activity	Sensor number	Sensor type and placement	Subjects	Accuracy [%]

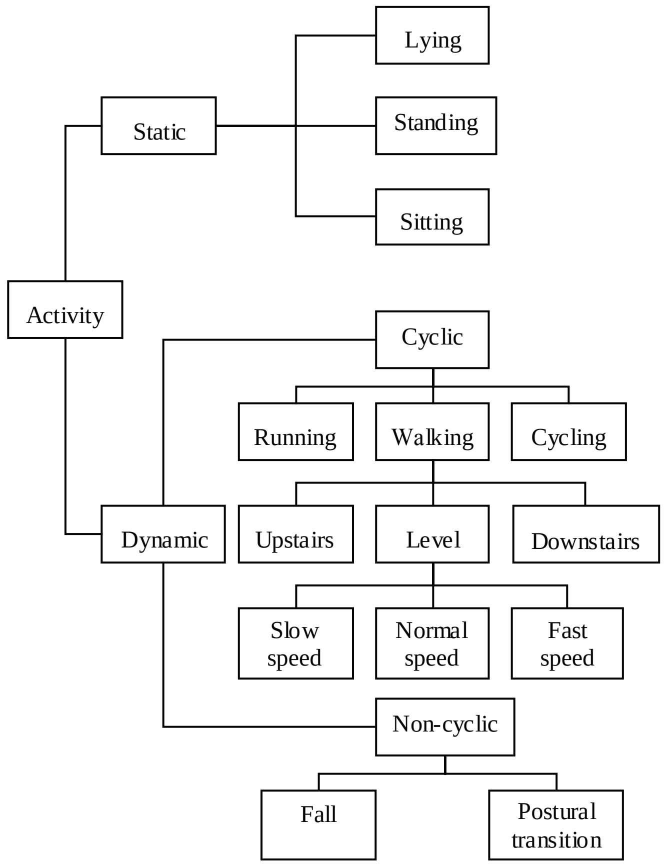
Figure 5. Decision tree showing relationships between different movements of interest in a generic ambulatory monitor



With a few exceptions, the behaviors most ambulatory monitors attempt to discriminate are standing, sitting, lying, postural transitions and walking. Standing, sitting, lying are instances of static activities, subtypes of which may be: "standing in stooped position, in upright position, lateral bending to the left, lateral bending to the right" (Kiani et al. 1997), "sitting upright or flexed," "standing upright or flexed" (Paraschiv-Ionescu et al., 2004), "standing lying on the left, on the right, supine or with back supported" (Foerster & Fahrenberg, 2000). Motion patterns may be non-cyclical (postural transitions) or cyclical (walking). Postural transitions such as "sit-to-stand, stand-to-sit, upright-to-lying, lying-to-upright" are included in the decision tree, among others, by Mathie et al. (2004) and Paraschiv-Ionescu et al. (2004). Walking is the most common example of cyclic dynamic activity, subtypes of which are "level walking at slow, normal, fast speed" (Kiani et al., 1997) and "walking upstairs, downstairs" (Bussmann et al. 1995; Foerster & Fahrenberg, 2000). Other dynamic activities may include cycling (Bussmann et al., 1995).

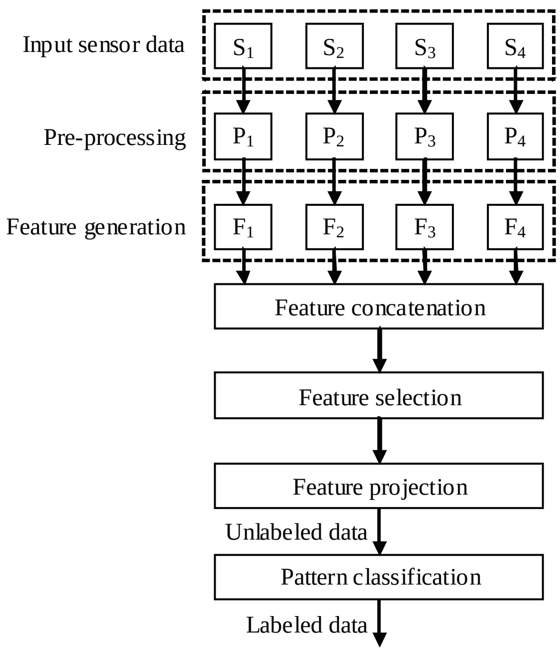
resolution analysis, which is also a better approach to deal with the discrimination between AC and DC components (Paraschiv-Ionescu, 2004).

Dynamic activity classification is based upon the observation that acceleration signals per cycle may differ in several aspects: morphology, statistical moments, and so forth, which calls for a suitable strategy upon which the development of the pattern recognition systems would be based.

The statistical approach to pattern recognition represents a pattern by features, viewed as points in suitably high-dimensional spaces (Figure 6). Machine-learning techniques are needed to turn raw data into useful contextual information, that is, information useful to provide knowledge about the state of the subject. To maximize the pattern recognition ability, these techniques would be able to generate and select data representations (features) with high discrimination ability. To perform classification, training patterns, captured from a large set of sampled movements and a range of conditions, can be used to determine the decision boundaries. There appears to be general consensus that a number of challenges exist in this regard. Different activities do not undergo abrupt changes, which makes their detection difficult. The variability in performing these activities by humans is generally high. The amount of information we can get from simple sensors is limited and noisy. Increasing the number of sensors, not necessarily inertial sensors, to achieve higher redundancy and robustness is not without practical (wearability, computational bottlenecks) or theoretical limits (curse of dimensionality, incurred by any machine learning approach we may favor). Numerous are the contact points between automatic recognition of activity as stated above and the research on methods for augmenting a computer with sensors which can make it aware of the context, as carried out in robotics and artificial intelligence.

Albeit identification of context without requiring external supervision seems to be better suited to become aware of context (Krause, Siewiorek, Smailagic, & Farringdon, 2003), most current approaches to the problem of automatic recogni-

Figure 6. The general structure of a pattern recognition system



tion of activity are based on using supervised machine learning techniques. The choice of good features is a fundamental step in statistical pattern recognition and a highly problem dependent task. A systematic approach to the search for features usable for analyzing daily-life motor activities is illustrated in Kiani et al. (1997), where simple statistics such as cumulative sums, means, standard deviations, RMS values computed over sliding windows with selectable size and overlap are shown to be generally quite effective. Other possible choices include frequency-domain features (energy distribution, entropy, and so forth), and features that specifically measure correlations among signals from different sites and measurement directions—the latter ones are especially useful in the attempt to improve recognition of activities involving movements of multiple body parts (Bao & Intille, 2004).

The design of the clustering layer reflects different choices and approaches to the problem of feature selection and projection. Feature selection, either driven by an expert or by step-wise methods of selection, is an important step to deal properly with the issue of curse of dimensionality. Sometimes, the generation of additional features is costly (more sensors are needed), and their actual use may even be harmful to achieve optimality (Loosli, Canu, & Rakotomamonjy, 2003; Bao & Intille, 2004).

The ANN approach is perceived as a good tool to cluster noisy data from several sensors (Kiani et al.,1997; Van Laerhoven, Aidoo, & Lowette, 2001; Mäntyjärvi, Himberg & Seppänen, 2001). ANNs are used in (Mäntyjärvi et al.,2001). After raw accelerometer data are submitted to wavelet analysis for computation of the statistical power at selected scales of analysis, the principal component analysis (PCA) and the independent component analysis (ICA) are used for dimensionality reduction. Clustering is based on using a multilayer perceptron with back-propagation learning. The rationale for using PCA and ICA is to find directions and scales where the sensor signals would be more informative for discrimination purposes. Van Laerhoven et al. (2001) discuss in depth advantages and disadvantages of using ANNs for clustering, in particular Kohonen self-organizing maps (KSOM). Their strong point is that activity contributes highly to context awareness, and adaptivity is indispensable in context awareness. Indisputably, the main disadvantage of many machine-learning algorithms is in their limited capability to properly handle the stability-plasticity dilemma, in the face of highly dynamic contexts (Van Laerhoven & Cakmakci, 2000). To overcome the limitations of KSOM in keeping up with the learning process over time, these authors consider the addition of a k-nearest neighbors clustering cascaded to the KSOM as a feasible way to stabilize its behavior.

Activity recognition on the selected features can be performed using any of different algorithms, including rule-based activity recognition, standard k-nearest neighbors search, naïve Bayes classifiers, and support vector machines (SVMs). Rule-based activity recognition seems to be good in capturing correlations between feature values that may lead to good recognition accuracy (Bao & Intille, 2004). Standard k-nearest neighbors search is shown to be a good work-horse in general problems of activity recognition (Van Laerhoven & Cakmakci, 2000; Bao & Intille, 2004). The problem with a naïve Bayes approach may be the excessive reliance on assumptions of conditional independence between different features in the Bayesian update (Golding & Lesh, 1999), and its greediness of training data to accurately model feature value distributions (Bao & Intille, 2004). In an attempt to overcome some limitations of neural network-based modeling, SVMs are increasingly recognized for their good performance on difficult classification tasks. Despite their emergence as a valuable tool for several applications in the biomedical field, including gait analysis (Begg & Kamruzzaman, 2005), only Loosli et al. (2003), to the best of our knowledge, have used them in the attempt to perform automatic recognition of activity. These authors claim that their implementation of SVMs is largely superior to the algorithms described in Van Laerhoven and Cakmakci (2000) and Van Laerhoven et al. (2001) over exactly the same datasets and selected features, although this claim has to be tempered by other findings of theirs, which show how SVMs are substantially equivalent to k-nearest neighbors clustering directly applied to the statistical features elaborated in Van Laerhoven and Cakmakci (2000).

An important step to improve upon the design of a pattern recognition system for analysis of daily-life motor activities is the addition of a supervision layer to introduce memory, so that individual movements are not classified in isolation (Mathie et al.,2004). Beside the classical approach to have a rule-based system to check sequences of classified movements and to correct those sequences which would be impossible, other approaches can be based on methods such as Markov modeling (Van Laerhoven & Cakmakci, 2000). The supervision layer on top of the classifier can supervise transitions from one context to another. A probabilistic finite state machine architecture is used where each context is represented by a state, and transitions are represented by arcs between states. A probability measure is built for each change of contexts, so every time a transition occurs, the supervision model checks if this is really likely (update of the probability). Observed state transitions that have a low probability to occur can thus be suspected to come from erroneous detections performed by the classification algorithms associated to the corresponding nodes of the decision tree.

Regarding a complex behavior as the juxtaposition of a sequence of elementary movements leads quite naturally to consider the hidden Markov model (HMM) analytical framework as a promising avenue of research in the field of automatic recognition of activity. An HMM is a doubly stochastic process with an underlying process of transitions between hidden states of the system and a process of emitting observable outputs, and, as such, it is ideal to implicitly model all of the many sources of spatio-temporal variability inherent in real movements. So far, HMMs have been used for representation and recognition of speech, handwriting and, of particular importance in the present context, gestures. Mäntyla, Mäntyjärvi, Seppänen, and Tuulari (2001) attempt to use hand gesture recognition, using cybergloves or accelerometer-based systems studied as a method of computer input for people with severe speech and motor impairment. Kallio, Kela and Mäntyjärvi (2003) develop a small wireless gesture-based input device based on accelerometers to provide methods to interact with different kinds of devices and environments. In both cases, trainable pattern recognition methods, namely HMMs, clustering and vector quantization are used to develop models for describing prototype gestures and to examine the gesture recognition performance. If we refer to gesture as a specific, intentional action by a human in which part of the body is moved in a predefined way indicating a specific event (Chambers, Venkatesh, West, & Bui, 2002), the way is paved to consider HMM-based gesture recognition a possible means to provide context knowledge, useful, in particular within occupational settings, not only to improve on standard clinical decision-making procedures (Uiterwal, Glerum, Busser, & van Lummel, 1998), but also to reduce the cognitive load on a worker during complex real world tasks (Lukowicz et al.,2004).

A final point is important to discuss. At first sight, it seems not difficult to achieve high values of accuracy, sensitivity and specificity in recognizing a relatively small set of postures and activities, although, sometimes, specific activities are resistant to robust classification and are frequently confused with one another, for instance level walking and upstairs walking (Veltink et al.,1996; Foerster & Fahrenberg, 2000). However, it should be pointed out that the highly specific system and methodologies used by each group make it difficult to directly compare different approaches. In most cases, these approaches are intended to meet the requirements of specific applications, and are tested in restricted environments and with small-size pools of subjects. Ironically, ambulatory systems intended to overcome the limitations of traditional laboratory-based systems for assessing motor performance are victims of their own validation being pursued, in the vast majority of cases, within laboratory environments which may artificially constrict and influence subject activity (Foerster, Smeja, & Fahrenberg, 1999). A thorough discussion about the need to use naturalistic data in training and testing ambulatory monitors is in Bao and Intille (2004). Needless to say, this need to cope with the idiosyncrasies of real-life worlds is precisely one of the driving factors behind the current interest in advanced methods for context-awareness and ambient intelligence among the artificial intelligence and robotic communities.

Functional Assessment of Specific Motor Disorders

Traditionally, accelerometers are applied to the quantitative analysis of tremor time series. The quantification of amplitude, frequency and occurrence time of tremor in patients affected with Parkinson's disease (PD) and its relation to posture and motion is described in Van Someren et al. (1998) and Foerster and Smeja (1999). The theory of spectral estimation is applied in Timmer, Lauk and Deuchl (1996) to assess whether a spectrum of accelerometric recordings exhibits multiple significant peaks and discuss different approaches to determine the amplitude and frequency of the tremor components from the spectrum. Another approach considers detection algorithms looking at tremor-related features in the time-domain, as in Van Someren et al. (1997), where the discrimination of tremor from intentional movements is based on the persistency of some features, such the temporal distances occurring between consecutive zero-crossings, the values of these periods of half waves, and the values of the peak-to-peak amplitudes in each half wave. Because of the time-varying nature of tremor-related components in accelerometric recordings, and the need for distinguishing the components that are due to voluntary movements and the components that are due to the movement disorder of interest, adaptive filtering techniques have also been considered, such as the Fourier Linear Combiner (Riviere, Rader, & Thakor, 1998) and the cascade learning architecture (Riviere & Khosla, 1997).

The assessment of postural stability is studied in Mayagoitia, Lötters, Veltink and Hermens (2002), where a tri-axis accelerometer-based system is developed for determining the long-term ability to maintain balance while standing. The acceleration measurement at the BCOM level allows one to introduce a number of performance parameters, similar to those that are extracted from force plates in classical posturographic studies. Two other approaches are interesting for their connection, in terms of the processing tools adopted, to the studies on assessment of physical activity (Cho & Kamen, 1998; Moe-Nilssen, 1998). More complex IMUs are those reported in Lee, Laprade and Fung (2001) and Wall and Weinberg (2003). Wall and Weinberg (2003) propose a balance prosthesis for postural control. In order to prevent falls in the balance impaired, body-tilt information is displayed to the subject via an array of tactile vibrators. The body-tilt information is obtained by integrating the information from a waist dual-axis accelerometer with the information from a single-axis gyro. Lee et al. (2001) deal with the problem of monitoring the lumbar spine motion, and to this aim they develop a portable system for three-dimensional motion analysis. A recent contribution towards the use of inertial sensing for the monitoring of specific motor disorders during postural transitions is illustrated in the work by Najafi, Aminian, Loew, Blanc and Robert (2002). They analyze the trunk tilt, corresponding to the angle between the vertical axis and anterior wall of the subject's thorax, and the trunk vertical displacement during stand-sit transfers, in the attempt to introduce good indicators of the risk of falls sustained by elderly people.

As for the assessment of gait, Smidt et al. (1971) apply Fourier series analysis to define a measure of smoothness of walking, which is found to provide an effective method for discriminating between normal gait patterns and gait patterns of subjects with gait defects. The approach by Sekine, Tamura, Togawa and Fukui (2000) and Sekine et al. (2002) is interesting for the connection established between wavelet properties and characteristics of motor fluctuations in normal and pathological conditions. In Sekine et al. (2000), waist 3D-accelerations are submitted to wavelet analysis in order to discriminate different types of walking in healthy subjects. Also in Sekine et al. (2002), the approach is further refined so that the distribution of wavelet coefficient power over selected scales of analysis is subject to a complexity analysis for the determination of a fractal dimension (the Hurst exponent) in different groups—healthy, elderly, subjects with PD. The Hurst exponent is shown to be significantly different among three types of walking (level/upstairs/downstairs) for individual subjects and show a great reproducibility. Moreover, the fractal dimensions are higher for elderly and PD patients as compared with healthy subjects.

The study of motor fluctuations in PD patients is reviewed in Keijsers, Hornstink and Gielen (2003). Their goal, in particular, is to assess levodopa-induced dyskinesia in these subjects. Dyskinesia are involuntary movements — jerky and characterized by sudden contractions followed by stretching, twisting and rotation — that usually occur after several years of using levodopa, a drug which is widely used to treat the symptoms of PD. The ambulatory monitor developed by Keijsers et al. (2003) is composed of several tri-axis accelerometes (at both upper arms, at both upper legs, at the wrist of the most dyskinetic side, and at the top of the sternum). Due to the complex, time-varying relations between voluntary movements and motor disorders, a simple supervised ANN is the selected classification technique exercised over a number of time- and frequency-domain features. The features with the highest discriminative ability are survivors of a pruning phase, which is part of the design procedure. At the end, the system is successfully trained to detect and assess the severity of dyskinesia, provided that the score of the severity of the symptoms is given by an experienced clinician.

Personal Navigation

The ability to locate the position/orientation of a person is of great importance in a number of applications, including electronic travel aids for the blind or visually impaired, integrated navigation systems for the dismounted infantry soldier, and, in general, context-aware applications in wearable and mobile computing.

The location-sensing techniques for personal navigation systems are based on either relative or absolute position measurements. Traditionally, inertial sensors have been employed for implementing dead-reckoning techniques, a variant of relative position measurements whose fundamental idea is to integrate incremental motion information over time. The problem of absolute positioning in outdoor environments is seemingly straightforward to solve by an externally referenced sensing technology such as GPS. However, the disadvantages with GPS—inability to work in indoors, unavailability of satellite signals in environments such as urban canyons, poor accuracy in relation to the needs of a specific application, inability to provide static heading information—suggest that dead-reckoning based on inertial sensing and GPS would have a better chance to work in practice (Ladetto, van Seeters, Sokolowski, Sagan, & Merminod, 2002). In the case of indoor environments, one approach for overcoming dead-reckoning limitations is to acquire location information by adding intelligence to the environment, so that it can supply location information to users via special infrastructures (Want, Hopper, Falcão, & Gibbons, 1992; Krumm, Williams, & Smith, 2002)—applications of externally referenced sensing techniques. The traditional computational techniques used to improve the performance of dead-reckoning systems aim at implementing either map matching or in-line sensor calibration procedures based on KFs which use external aids, such as GPS, in the attempt to estimate bias drifts of inertial sensors and compass disturbances.

The key problem in the design of a personal navigation system is to find a method to measure length and direction of displacement using step time as the basic unit of time, so as to determine the distance and heading from a known origin at an acceptable level of accuracy. Detecting step occurrences can be based on accelerometers or gyros, as stated above with regard to the problem of assessing temporal parameters of gait. A simple model-based approach to the problem of estimating step length hypothesizes that, once a method is available to determine step time, step length estimation can be based on cadence. Judd (1997) suggests that the step length could be estimated online based on a linear relationship between measured cadence and step length, whose validity, discussed in Ladetto et al. (2002), is however limited to level walking in open spaces. The approach by Ladetto et al. (2002) is an interesting example of so-called biokinematic navigation (Elwell, 1999), an inexpensive technique that matches an individual's gait to inertial measurements. Ladetto et al. (2002) exploit the relationship existing between walking speed and statistical features, such as the RMS values of waist 3D-accelerations, under the premise that the main goal of locomotion is to promote the BCOM displacement in space. The fact that step length is a time-varying process, with large environment-dependent variations, motivates the use of additional sensors for online model calibration, for instance GPS as in Perrin et al. (2000), Ladetto et al. (2002) and Jirawimut, Ptasinski, Garaj, Cecelia and Balachandran (2003) or to incorporate additional features of human walking dynamics into the algorithm (Vildjiounaite, Malm, Kaartinen, & Alahuhta, 2002; Lee & Mase, 2002). These authors note that, when the step length is longer, the accelerations in different parts of the legs tend to be higher. Hence, it may be hypothesized that the greater the vertical acceleration during a step, the greater the distance that has been traveled across the ground. This relationship can be exploited to adjust the pre-calculated step length and hence reduce the error associated with fixed values by using sensor look-up tables (Vildjiounaite et al.,2002) or a simple fuzzy-logic reasoning method (Lee & Mase, 2002).

Determining heading may require the implementation of gyro-compassing techniques. After INS alignment is performed, heading is estimated by gyro and magnetic compass data, provided both data are available. In contrast with a gyro, magnetic compass is not prone to drift, however its use is critical. Sometimes, serious inaccuracies in the magnetic compass readings are found which cannot be traced back to imperfect tilt compensation, but are likely due to perturbations in the magnetic field near or within the measurement space. The presence of magnetic disturbance can be checked by comparing the rate of change of the heading estimates from gyro and magnetic compass (Ladetto & Merminod, 2000). The conflicts in data interpretation existing about the existence and extent of turns indicated by gyro and magnetic compass warn not to consider magnetic compass reliable. Otherwise, its long-term low-frequency response can be combined with the high-frequency response of gyros. The use of GPS to dynamically recalibrate the heading error is appropriate in this context. In theory this combination should give the most accurate results. In particular, computed GPS heading can allow one to model the bias of the magnetic compass (Jirawimut et al.,2003) and the gyro bias and drift (Ladetto et al.,2002). In indoor applications, where GPS is unavailable, the performance of biokinematic navigation algorithms would be improved by map matching, as pointed out in Lee and Mase (2002) and Vildjiounaite et al. (2002). These authors show that the task of determining the person's location when the navigation space is constrained, such as within a building, can be greatly simplified by having some form of environment knowledge available to the navigation algorithm. This knowledge can be limited to indicate where some locations, or transition between locations, are in the map, such as the transition from one room to the next, the transition from level to upstairs, the presence of a corridor. When this knowledge is combined with an even relatively crude heading information, irregular walking styles or strong perturbations in the magnetic field can be accommodated and reasonably accurate estimates of person's location can still be obtained.

In our view, the important point is that there is something peculiar to the way humans move which makes personal navigation so different from vehicular navigation. Walking styles of humans imply frequent changes of speed and orientation, for reasons of stability, safety, and so forth, depending on the environment the activity is actually performed—the context. Because of this complexity, the prediction of the walked path from one point to another turns out to be de facto impossible. Moreover, inertial/magnetic sensors record movements depending on their actual placement on the body. Four examples point at the difficulties inherent with their use: changes of orientation that occur with minimal displacement changes (on-the-spot turning); changes of orientation not recorded, in spite that they occur over large angles (backward displacements, side-stepping); instantaneous changes of orientation that are recorded, in spite that the actual direction of displacement does not change (lateral bending of the trunk while walking straight ahead); steps which are not taken with normal rhythm or style, hence requiring special algorithms for their detection (side-stepping). Of course, these examples are not comprehensive of all situations taking place in practice. However, they point at the need that personal navigation systems would be capable of classifying "movements," and, for each classified movement, of reliably estimating length and direction of displacement in real-time conditions.

EMERGING TRENDS

In this chapter, the main computational approaches to use motion sensing based on inertial and magnetic sensors have been reviewed, in connection with a wealth of biomedical applications, including assessment of motor performance, automatic recognition of activity, and personal navigation.

Of utmost importance is the point that the answers to the problems raised by each application ought not to be considered in isolation, because of the relevant overlapping they have with each other:

1. Advanced signal processing and machine-learning techniques are used in the effort to identify signatures of human motion and perform motor pattern recognition;
2. Constraints in navigation space and dynamic features of unrestrained human motion concur to provide accurate long-term solutions to the navigation problem;
3. Topological information merged with an estimate of the traveled distance by dead-reckoning methods leads to improve the accuracy of methods for automatic recognition of activity.

The most promising avenue of research is in how artificial intelligence and biomechanics can reinforce each other, in the direction to pave a new way of inertial sensing that will not be hampered by the idiosyncrasies of current-generation sensing hardware. Impressive technological advances are about to turn wireless, wearable distributed multi-sensor systems into reality and further advances are also expected in the field of MEMS technologies. However, the capability of performing a robust, accurate real-time reconstruction of the trajectory of selected anatomical points, such as, for instance, the sacrum, the stern, the foot instep, by inertial and magnetic sensors is still the prerequisite for making body personal area networks attractive for long-term ambulatory monitoring of human subjects engaged in functional activities involving motion in unrestrained conditions. Interesting research is yet to be performed in regard to the signal processing algorithms the practitioners in the field will have to create in order to successfully cope with the difficult behavior of the motion sensors discussed in this chapter.

INTRODUCTION

Buried within the human body, the heart prohibits direct inspection, so most knowledge about heart failure is obtained by autopsy (in hindsight). Live immersive inspection within the human heart requires advanced data acquisition, image mining and virtual reality techniques. Computational sciences are being exploited as means to investigate biomedical processes in cardiology.

IntraVascular UltraSound (IVUS) has become a clinical tool in recent several years. In this immersive data acquisition procedure, voluminous separated slice images are taken by a camera, which is pulled back in the coronary artery. Image mining deals with the extraction of implicit knowledge, image data relationships, or other patterns not explicitly stored in the image databases (Hsu, Lee, & Zhang, 2002). Human medical data are among the most rewarding and difficult of all biological data to mine and analyze, which has the uniqueness of heterogeneity and are privacy-sensitive (Cios & Moore, 2002). The goals of immersive IVUS image mining are providing medical quantitative measurements, qualitative assessment, and cardiac knowledge discovery to serve clinical needs on diagnostics, therapies, and safety level, cost and risk effectiveness etc.

BACKGROUND

Heart disease is the leading cause of death in industrialized nations and is characterized by diverse cellular abnormalities associated with decreased ventricular function. At the onset of many forms of heart disease, cardiac hypertrophy and ventricular changes in wall thickness or chamber volume occur as a compensatory response to maintain cardiac output. These changes eventually lead to greater vascular resistance, chamber dilation, wall fibrosis, which ultimately impair the ability of the ventricles to pump blood and lead to overt failure. To diagnose the many possible anomalies and heart diseases is difficult because physicians can't literally see in the human heart. Various data acquisition techniques have been invented to partly remedy the lack of sight: non-invasive inspection including CT (Computered Tomography), Angiography, MRI (Magnetic Resonance Imaging), ECG signals etc. These techniques do not take into account crucial features of lesion physiology and vascular remodeling to really mine blood-plaque. IVUS, a minimal-invasive technique, in which a camera is pulled back inside the artery, and the resulting immersive tomographic images are used to remodel the vessel. This remodeling vessel and its virtual reality (VR) aspect offer interesting future alternatives for mining these data to unearth anomalies and diseases in the moving heart and coronary vessels at earlier stage. It also serves in clinical trials to evaluate results of novel interventional techniques, e.g. local kill by heating cancerous cells via an electrical current through a piezoelectric transducer as well as local nanotechnology pharmaceutical treatments. Figure 1 explains some aspects of IVUS technology.

However, IVUS images are more complicated than medical data in general since they suffer from some artifacts during immersed data acquisition (Mintz et al., 2001):

- Non-uniform rotational distortion and motion artifacts.
- Ring-down, blood speckle, and near field artifacts.
- Obliquity, eccentricity, and problems of vessel curvature.
- Problems of spatial orientation.

The second type of artifacts is treated by image processing and therefore falls outside the scope of this paper. The pumping heart, respiring lungs and

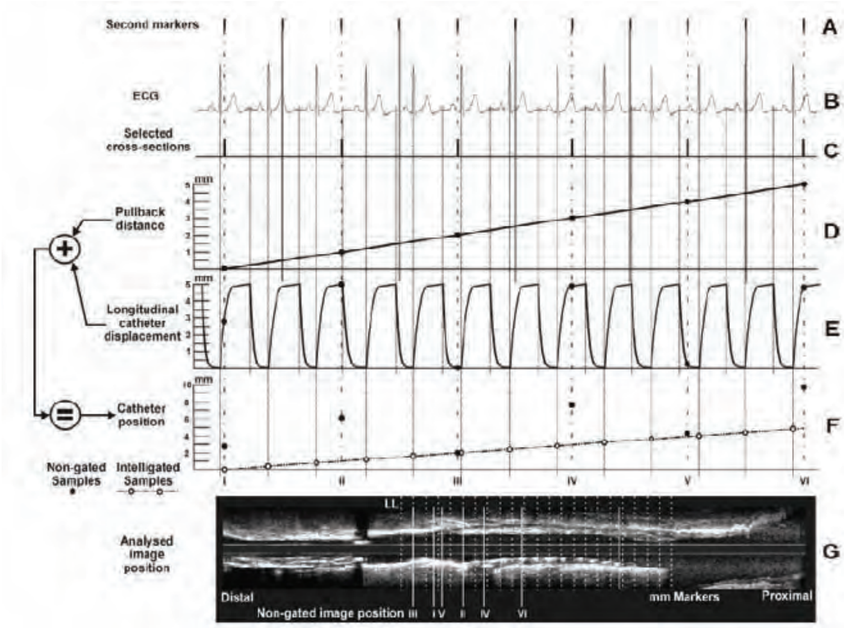
Figure 2. Trajectory position anomalies of the invasive camera



moving immersed catheter camera cause the other three types of artifacts. These cause distortion on longitudinal position, x-y position, and spatial orientation of the slices on the coronary vessel. For example, it has been reported that more than 5 mm of longitudinal catheter motion relative to the vessel may occur during one cardiac cycle (Winter et al., 2004), when the catheter was pulled back at 0.5 mm/sec and the non-gated samples were stored on S-VHS videotape at a rate of 25 images/sec. Figure 2 explains the longitudinal displacement caused by cardiac cycles during a camera pullback in a segment of coronary artery. The catheter position equals to the sum of the pullback distance and the longitudinal catheter displacement. In F, the absolute catheter positions of solid dots are in disorder, which will cause a disordered sequence of camera images. The consecutive image samples selected in relation to the positions of the catheter relative to the coronary vessel wall are highlighted in G. In conclusion, these samples used for analysis are anatomically dispersed in space (III, I, V, II, IV, and VI).

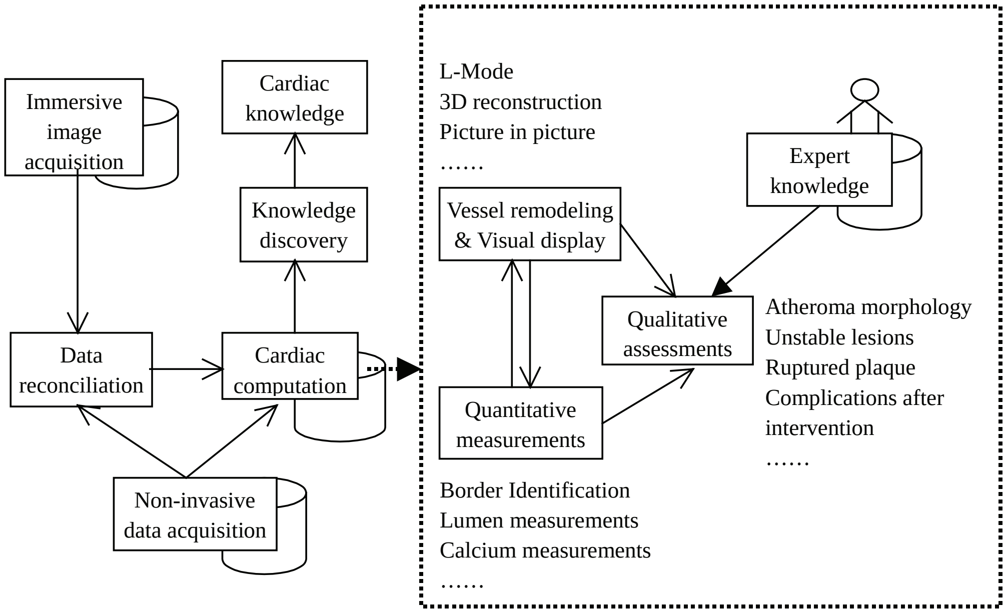
The data of IVUS sources are voluminous separated slices with artifacts, and the quantitative measurements, the physicians' interpretations are also essential components to remodel the vessel, but the accompanying mathematical models are poorly characterized. Mining in these datasets is more difficult and it inspires interdisciplinary work in medicine, physics and computer science.

MAIN THRUST

Immersive Image Mining Processes in Cardiology IVUS

IVUS image mining includes a series of complicated mining procedures due to the complex immersive data: data reconciliation, image mining, remodeling and VR display, and knowledge discovery. Figure 3 shows the function-driven processes.

Figure 3. Immersive IVUS image mining



The data reconciliation compensates or decreases artifacts to improve data, usually fused with non-invasive inspection cardiology data such as angiography and ECG etc. This data mining extracts features in the individual dataset to use for data reconciliation.

Cardiac computation is taken on the reconciled individual dataset. Quantitative measurement calculates features such as lumen, atheroma, calcium and stent on every slice. Vessel remodeling based on these measurements forms a straight 3D volume, and the fusion with the pullback path determined from angiography yields an accurate spatio-temporal (4D) model of the coronary vasculature. This 4D model is used for further cardiac computation to gain VR display and volume measurements on the vessel. IVUS images are fundamentally different from histology and cannot be used to detect and quantify specific histologic contents directly. But based on quantitative measurements and VR display, combined cardiac knowledge, the qualitative assessment such as atheroma morphology, unstable lesions and complications after intervention may be gained semi-automatically or artificially by the physicians.

These quantitative measurements and qualitative assessments may be organized and stored in a database or data warehouse. Statistics-based mining on colony data and mining on individual history data lead to knowledge discovery of heart diseases.

Individual Data Mining to Reconcile the Data

Data reconciliation is the basis and most important step to cardiac computation, and it is expecting more effective methods to attack the data artifacts. Three types of methods are applied: parsimonious data acquiring, data fusion of invasive and non-invasive data, and hybrid motion compensation.

- **Parsimonious Phase-Dependent Data Acquisition:** Cardiac knowledge dictates systolic/diastolic timing features. It has been suggested to select IVUS images recorded in the end-diastolic phase of the cardiac cycle, in which the heart is motionless and blood flow has ceased so that their influences on the catheter can be neglected. Online ECG-gated pullback has been used to acquire phase-dependent data but the technology is expensive and prolongs the acquisition procedure. Instead, a retrospective image-based gating mining method has been studied (Winter et al, 2004; Zhu, Oakeson, & Friedman, 2003). In this method, the different features are mined from sampled IVUS images over time by transforming the data with spectral analysis, to discover the most prominent repetition frequencies of appearance of these image features. From this mining, the near images at the end-diastolic phases can be inferred. The selection of images is parsimonious: only about 5% of the dataset are selected, wherein about 10% of the selections are mispositioned.
- **Data Fusion:** The motion vessel courses provide helpful information to identify space and time of the IVUS camera in the coronary of the moving heart. Fusion of complementary information from two or more differing modalities enhances insights into the underlying anatomy and physiology. Combining non-invasive data mining techniques to battle measurement errors is a preferred method. The positioning for the camera could be remedied if from angiograms the outer form of a vessel is available, as a path-road for the camera. Fusing the route and IVUS data, a simulator generates a VR reconstruction of the vessel (Wahle, Mitchell, Olszewski, Long, & Sonka, 2000; Sarry & Boire, 2001; Ding & Friedman, 2000; Rotger, Radeva, Mauri, & Fernandez-Nofrerias, 2002; Weichert, Wawro, & Wilke, 2004). This should help to detect the absolute catheter spatial positions and orientations, but usually the routes are static and data are parsimonious, phase-dependent, or without exhibiting the distortion. There are few papers on the consecutive motion tracking of the coronary tree (Chen & Carrol, 2003; Shechter, Devernay, Coste-Maniere, Quyyumi, & McVeigh, 2003), but they omitted the stretch of the arteries that is an important property for accurate positioning analyses.
- **Hybrid Motion Compensation:** Physical prior knowledge would predict space and time of the global position of IVUS camera, if it would be fully modeled. The many mechanical and electrical mechanisms in a heart make a full model intractable, but if most of its mechanisms could be dispensed with, the prediction model would become considerably simplified. A hybrid approach could solve the problem if a full 'Courant-type' model would be available, coined by the term "Computational Cardiology" (Cipra, 1999). An effective and pragmatic model is futuristic yet. Timinger reconstructed the catheter position on 3D roadmap by a motion compensation algorithm based on an affine model for compensating the respiratory motion and ECG gating method for the catheter positions acquired using a magnetic tracking system (Timinger, Krueger, Borgert, & Grewer, 2004). Fusing the empirical features of the coronary longitudinal movement with a motion compensation model is a novel way to resolve the longitudinal distortion of the IVUS dataset (Liu, Koppelaar, Koffijberg, Bruining, & Hamers, 2004).

Cardiac Computation to Quantitative and Qualitative Analysis

Cardiac computation aims at quantitative measurements, remodeling and qualitative assessments on the vessel and the lesion zones. The technologies of border detection of image processing and pattern recognition of the vessel layers are important in the process of cardiac calculation (Koning, Dijkstra, von Birgelen, Tuinenburg, et al., 2002). For qualitative assessments, expert knowledge of physicians must be fused within reasoning to get the assessments.

Quantitative Measurements

- **Cross-Sectional Slices Calculation:** The normal coronary artery consists of the lumen surrounded by intima, media, and adventitia of the vessel wall (Halligan & Higano, 2003). The innermost layer consists of a complex of three elements: intima, atheroma (diseased arteries), and internal elastic membrance. After gaining vessel layers and their attributes through edge identification and pattern recognition of image processing, every slice is calculated separately and the measurements such as lumen area, EEM (external elastic membrance) area, and maximum atheroma thickness can be reported in detail.
- **Vessel Remodeling and Virtual Display:** Based on the above calculation results, vessel layers including plaques can be remodeled and visualized in longitude. VR display is an important way to assist inspecting the artery and the distribution of plaque and lesions, to help navigate in guided surgery facilities for minimally invasive surgery. For examples, L-Mode display sets of slices taken from a single cut plane in longitude (Figure 1, panel D); 3D reconstruction display a shaded or wire-frame image of the vessel to give an entire view (Figure 1, Panel E).
- **Derived Measurements:** Calculating on the virtual remodeled vessel, the derived measurements can be obtained such as hemodynamics, length, volumes of the vessel and special lesion zones.
- **Qualitative Assessments:** IVUS images are fundamentally different from histology and cannot be used to detect and quantify specific histologic contents directly. However, based on quantitative measurements and a virtual model, as well as combined cardiac knowledge, the qualitative assessment such as atheroma morphology, unstable lesions and complications after intervention may be gained semi-automatically or artificially to serve physicians.

Knowledge Discovery in Cardiology

Once a large amount of quantitative and qualitative features are in hand, mining on these data can reveal knowledge about the forming and regression of some heart diseases, and can simulate the different stages of the disease as well as assess surgical treatment procedure and risk level.

Some papers are reported on medical knowledge discovery in cardiology using data mining. Pressure calculation by using fluid dynamic equations on 3D IVUS volumetric measurements predicts the physiologic severity of coronary lesions (Takayama & Hodgson, 2001). Artificial intelligence methods: a structural description, syntactic reasoning and pattern recognition method are applied on angiography to recognize stenosis of coronary artery lumen (Ogiela & Tadeusiewicz, 2002). Logical Analysis of Data is a method based on combinatory, optimization and theory of Boolean functions is used on 21 variables dataset to predict coronary risk, but these dataset do not include any medical images information (Alexe, 2003). Mining in single proton emission computed tomography images accompanied by clinical information and physician interpretation using inductive machine learning and heuristic approaches to mimic cardiologist's diagnosis (Kurgan, Cios, Tadeusiewicz, Ogiela, & Goodenday, 2001).

Immersive data mining or fusing the mined data with other cardiac data is a challenge for improving medical knowledge in cardiology. Mining will contribute to some difficult cardiology applications, for example: interventional procedures and healthcare; mining coronary vessel movement anomalies; highlight local abnormal cellular growth; accurate heart and virtual vessel reconstruction; adjust ferro-electric materials to monitor heart movement anomalies; prophylactic patient monitoring etc. Some technicalities should be considered in this mining field.

- **Volume and complexity in data:** First, IVUS data have a large volume in one acquisition procedure for one person. Second, usually tracing a patient needs a long time: more than several years. Third, the data from patients maybe are incomplete. Finally, immersive data acquisition is a complicated procedure depending on body condition, immersive mechanical system, and even operating procedure. The immersive complexity may even bias the historical data from the same heart.
- **Data standards and semantics:** IVUS images, especially the qualitative assessments, need a consistent standard and semantics to support mining. IVUS documents (Mintz, et al., 2001) and DICOM IVUS standards may be the base to follow. It is necessary to consider the importance of relative parameters, spatial positions, multi-interpretations of image quantitative measurements, which also need to be addressed in the IVUS standards.
- **Data fusion:** Since heart diseases are complicated, IVUS is one of the preferred diagnose tools, so mining IVUS needs considering other clinical information including physician's interpretation at the same time.

FUTURE TRENDS

Immersive image mining in cardiology is a new challenge for medical informatics. In mining our body physicians thus inspire interdisciplinary work in medicine, physics and computer science which will improve monitoring heart data to many deep applications serving clinical needs in diagnostics, therapies, safety level, cost and risk effectiveness. For instance, in due course of time nanotechnology will mature to a degree of immersive medical mining equipment, physicians will directly control medicine by instruction via mobile communication because of a transducer inside the human body.

CONCLUSION

Over the last several years, IVUS has developed into an important clinical tool in the assessment of atherosclerosis. The limitations on data artifacts and difficult discerning between entities with similar echodensities (Halligan & Higano, 2003) are waiting for better solution. Hospitals have stored a large amount of immersive data, which may be mined for effective application in cardiac knowledge discovery.

Data mining technologies play crucial roles in the whole procedures in IVUS application: from data acquisition, data reconciliation, image processing, vessel remodeling and virtual display, knowledge discovery, disease diagnosing, clinical treatment, etc. Reconciling coronary longitudinal movement with a motion compensation model is a novel way to resolve the longitudinal distortion of the IVUS dataset. This fusion with other cardiac datasets and online processing are very important for future application, which means more effective and efficient mining methods on the complicated datasets need to be studied.

KEY TERMS

Cardiac Data Fusion: Fusion of complementary information from two or more differing cardiac modalities (IVUS, ECG, CT, physician's interpretation etc.) enhances insights into the underlying anatomy and physiology.

Computational Cardiology: Using mathematic and computer model to simulate the heart motion and its properties as a whole.

Immersive IVUS Images: The real-time cross-sectional images obtained from a pullback IntraVascular UltraSound transducer in human arteries. The dataset is usually a volume with artifacts caused by the complicated immersed environments.

IVUS Data Reconciliation: Mining in the IVUS individual dataset to compensate or decrease artifacts to get improved data using for further cardiac calculation and medical knowledge discovery.

IVUS Standards and Semantics: It refers to the standard and semantics of IVUS data and their medical quantitative measurements, qualitative assessments. The consistent definition and description improve medical data management and mining.

Medical Image Mining: It involves extracting the most relevant image features into a form suitable for data mining for medical knowledge discovery; or generating image patterns to improve the accuracy of images retrieved from image databases.

Virtual Reality Vasculature Reconstruction: For effective applications of intravascular analyses and brachytherapy, reconstruct and visualize the vessel-wall's interior structure in a single 3D/4D model by fusing invasive IVUS data and non-invasive angiography on?

ABSTRACT

This chapter describes the application of a number of text mining techniques to discover patterns in the health insurance schedule with an aim to uncover any inconsistency or ambiguity in the schedule. In particular, we will apply first a simple "bag of words" technique to study the text data, and to evaluate the hypothesis: Is there any inconsistency in the text description of the medical procedures used? It is found that the hypothesis is not valid, and hence the investigation is continued on how best to cluster the text. This work would have significance to health insurers to assist them to differentiate descriptions of the medical procedures. Secondly, it would also assist the health insurer to describe medical procedures in an unambiguous manner.

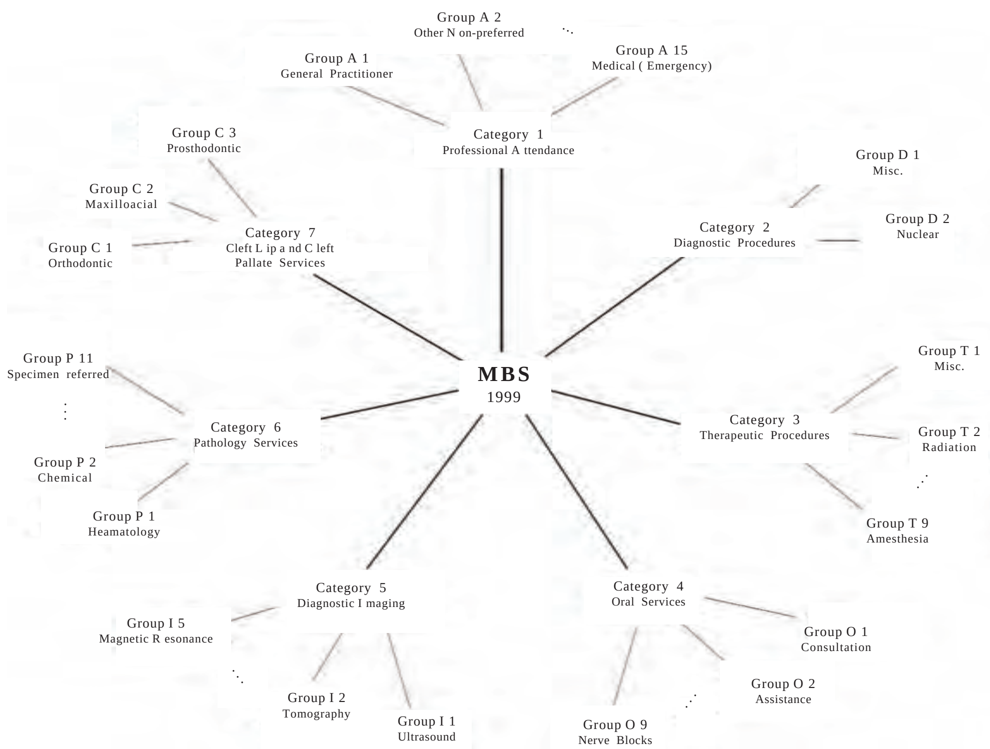
AUSTRALIAN HEALTH INSURANCE SYSTEM

In Australia, there is a universal health insurance system for her citizens and permanent residents. This publicly-funded health insurance scheme is administered by a federal government department called the Health Insurance Commission (HIC). In addition, the Australian Department of Health and Ageing (DoHA), after consultation with the medical fraternity, publishes a manual called Medicare Benefit Schedule (MBS) in which it details each medical treatment procedure and its associated rebate to the medical service providers who provide such services. When a patient visits a medical service provider, the HIC will refund or pay the medical service provider at the rate published in the MBS[1] (the MBS is publicly available online from http://www.health.gov.au/pubs/mbs/mbs/css/index.htm).

Therefore, the description of medical treatment procedures in the MBS should be clear and unambiguous to interpretation by a reasonable medical service provider as ambiguities would lead to the wrong medical treatment procedure being used to invoice the patient or the HIC. However, the MBS has developed over the years, and is derived through extensive consultations with medical service providers over a lengthy period. Consequently, there may exist inconsistencies or ambiguities within the schedule. In this chapter, we propose to use text mining methodologies to discover if there are any ambiguities in the MBS.

The MBS is divided into seven categories, each of which describes a collection of treatments related to a particular type, such as diagnostic treatments, therapeutic treatments, oral treatments, and so on. Each category is further divided into groups. For example, in category 1, there are 15 groups, A_1, A_2, …, A_{15}. Within each group, there are a number of medical procedures which are denoted by unique item numbers. In other words, the MBS is arranged in a hierarchical tree manner, designed so that it is easy for medical service providers to find appropriate items which represent the medical procedures provided to the patient.[2] This underlying MBS structure is outlined in Figure 1.

Figure 1. An overview of the MBS structure in the year of 1999



This chapter evaluates the following:

- **Hypothesis** — Given the arrangement of the items in the way they are organised in the MBS (Figure 1), are there any ambiguities within this classification? Here, ambiguity is measured in terms of a confusion table comparing the classification given by the application of text mining techniques and the classification given in the MBS. Ideally, if the items are arranged without any ambiguities at all (as measured by text mining techniques), the confusion table should be diagonal with zero off diagonal terms.
- **Optimal grouping** — Assuming that the classification given in MBS is ambiguous (as revealed in our subsequent investigation of the hypothesis), what is the "optimal" arrangement of the item descriptions using text mining techniques (here "optimal" is measured with respect to text mining techniques)? In other words, we wish to find an "optimal" grouping of the item descriptions together such that there will be a minimum of misclassifications.

The benefits of this work are as follows:

- From the DoHA point of view, it will allow the discovery of any existing ambiguities in the MBS. In order to make procedures described in the MBS as distinct as possible, the described methodology can be employed in evaluating the hypothesis in designing the MBS such that there would not be any ambiguities from a text mining point of view. This will lead to a better description of the procedures so that there will be little misinterpretation by medical service providers.
- From a service provider's point of view, the removal of ambiguities would allow efficient computer-assisted searching. This will limit misinterpretation, and allow the implementation of a semi-automatic process for the generation of claims and receipts.
- While the "optimal grouping" process is mainly derived from a curiosity point of view, this may assist the HIC in re-grouping some of their existing descriptions of items in the MBS, so that there will be less opportunities for misinterpretation.

Obviously, the validity of the described method lies in the validity of text mining techniques in unambiguously classifying a set of documents. Unfortunately, this may not be the case, as new text mining techniques are constantly being developed.

However, the value of the work presented in this paper lies in the ability to use existing text mining techniques and to discover, as far as possible, any ambiguities within the MBS. This is bound to be a conservative measure, as we can only discover ambiguities as far as possible given the existing tools. There will be other ambiguities which remain uncovered by current text mining techniques. But at least, using our approach will clear up some of the existing ambiguities. In other words, the text mining techniques do not claim to be exhaustive. Instead, they will indicate ambiguities as far as possible, given their limitations.

The structure of this chapter is as follows: In the next section, we describe what text mining is, and how our proposed techniques fall into the general fabric of text mining research. In the following section, we will describe the "bag of words" approach to text mining. This is the simplest method in that it does not take any cognizance of semantics among the words; each word is treated in isolation. In addition, this will give an answer to the hypothesis as stated above. If ambiguities are discovered by using such a simple text mining technique, then there must exist ambiguities in the set of documents describing the medical procedures. This will give us a repository of results to compare with those when we use other text mining techniques.

In the next section, we describe briefly the latent semantic kernel (LSK) technique to pre-process the feature vectors representing the text. In this technique, the intention is that it is possible to manipulate the original feature vectors representing the documents and to shorten them so that they can better represent the "hidden" message in the documents. We show results which do not assume the categories as given in the MBS.

TEXT MINING

In text mining, there are two main issues: retrieval and classification (Berry, 2004).

- **Retrieval techniques** — used to retrieve the particular document:
  - *Keyword-based search* — this is the simplest method in that it will retrieve a document or documents which matches a particular set of key words provided by the user. This is often called "queries".
  - *Vector space-based retrieval method* — this is often called a "bag of words" approach. It represents the document in terms of a set of feature vectors. Then, the vectors can be manipulated so as to show patterns, for example, by grouping similar vectors into clusters (Nigam, McCallum, Thrun, & Mitchell, 2000; Salton, 1983).
  - *Latent semantic analysis* — this is to study the latent or hidden structure of the set of documents with respect to "semantics". Here "semantics" is taken to mean "correlation" within the set of documents; it does not mean that the technique will discover the "semantic" relationships between words in the sense of linguistics (Salton, 1983).
  - *Probabilistic latent semantic analysis* — this is to consider the correlation within the set of documents within a probabilistic setting (Hofmann, 1999a).
- **Classification techniques** — used to assign data to classes.
  - *Manual classification* — a set of documents is classified manually into a set of classes or sub-classes.
  - *Rule-based classification* — a set of rules as determined by experts is used to classify a set of documents.
  - *Naïve Bayes classification* — this uses Bayes' theorem to classify a set of documents, with some additional assumptions (Duda, 2001).
  - *Probabilistic latent semantic analysis classification* — this uses the probabilistic latent semantic analysis technique to classify the set of documents (Hofmann, 1999b).
  - *Support vector machine classification* — this is to use support vector machine techniques to classify the set of documents (Scholkopf, Burges, & Smola, 1999).

This chapter explores the "bag of words" technique to classify the set of documents into clusters and compare them with those given in the MBS. The chapter also employs the latent semantic kernel technique, a technique from kernel machine methods (based on support vector machine techniques) to manipulate the features of the set of documents before subjecting them to clustering techniques.

BAG OF WORDS

If we are given a set of m documents $D = [d_1, d_2, ..., d_m]$, it is quite natural to represent them in terms of vector space representation. From this set of documents it is simple to find out the set of vocabularies used. In order that the set of vocabularies would be meaningful, care is taken by using the stemmisation technique which regards words of the same stem to be one word. For example, the words "representation" and "represent" are considered as one word, rather than two distinct words, as they have the same stem. Secondly, in order that the set of vocabularies would be useful to distinguish documents, we eliminate common words, like "the", "a", and "is" from the set of vocabularies. Thus, after these two steps, it is possible to have a set of vocabularies w_1, w_2,..., w_n which represents the words used in the set of documents *D*. Then, each document can be represented as an n-vector with elements which denote the frequency of occurrence of the word in the document d_i, and 0 if the word does not occur in the document d_i. Thus, from a representation point of view, the set of documents *D* can be equivalently represented by a set of vectors *V* - $[\mathbf{v}_1, \mathbf{v}_2,..., \mathbf{v}_m]$, where $\mathbf{v}_i$ is an n-vector. Note that this set of vectors *V* may be sparse, as not every word in the vocabulary occurs in the document (Nigam et al., 2000). The set of vectors *V* can be clustered together to form clusters using standard techniques (Duda, 2001).

In our case, we consider each description of an MBS item as a document. We have a total of 4030 documents; each document may be of varying length, dependent on the description of the particular medical procedure. Table 1 gives a summary of the number of documents in each category.

After taking out commonly occurring words, words with the same stem count, and so on, we find that there are a total of 4569 distinct words in the vocabulary.

We will use 50% of the total number of items as the training data set, while the other 50% will be used as a testing data set to evaluate the generalisability of the techniques used. In other words, we have 2015 documents in the training data set, and 2015 in the testing data set. The content of the training data set is obtained by randomly choos-

Table 1. An overview over the seven categories in the MBS

Category	Number of items
1	158
2	108
3	2734
4	162
5	504
6	302
7	62
Total	4030

Table 2. A confusion table showing the classification of documents (the actual classifications as indicated in the MBS are given horizontally; classifications as obtained by the naïve Bayes method are presented vertically)

Category	1	2	3	4	5	6	7	Total	% Accuracy
1	79	0	0	0	0	0	0	79	100.00
2	1	25	9	0	12	7	0	54	46.30
3	12	3	1323	15	10	3	1	1367	96.78
4	1	0	62	18	0	0	0	81	22.22
5	0	3	18	0	229	1	1	252	90.87
6	0	2	0	0	1	148	0	151	98.01
7	3	0	1	1	2	0	24	31	77.42

Table 3. Category-4 Items 52000, 52003, 52006, and 52009 misclassified by the naïve Bayes method as Category-3 items

Item No	Item Description
52000	Skin and subcutaneous tissue or mucous membrane, repair of recent wound of, on face or neck, small (not more than 7 cm long), superficial
52003	Skin and subcutaneous tissue or mucous membrane, repair of recent wound of, on face or neck, small (not more than 7 cm long), involving deeper tissue
52006	Skin and subcutaneous tissue or mucous membrane, repair of recent wound of, on face or neck, large (more than 7 cm long), superficial
52009	Skin and subcutaneous tissue or mucous membrane, repair of recent wound of, on face or neck, large (more than 7 cm long), involving deeper tissue

Table 4. Some items in Category 3 which are similar to items 52000, 52003, 52006, and 52009

Item No	Item Description
30026	Skin and subcutaneous tissue or mucous membrane, repair of wound of, other than wound closure at time of surgery, not on face or neck, small (not more than 7cm long), superficial, not being a service to which another item in Group T4 applies
30035	Skin and subcutaneous tissue or mucous membrane, repair of wound of, other than wound closure at time of surgery, on face or neck, small (not more than 7cm long), involving deeper tissue
30038	Skin and subcutaneous tissue or mucous membrane, repair of wound of, other than wound closure at time of surgery, not on face or neck, large (more than 7cm long), superficial, not being a service to which another item in Group T4 applies
30041	Skin and subcutaneous tissue or mucous membrane, repair of wound of, other than wound closure at time of surgery, not on face or neck, large (more than 7cm long), involving deeper tissue, not being a service to which another item in Group T4 applies
30045	Skin and subcutaneous tissue or mucous membrane, repair of wound of, other than wound closure at time of surgery, on face or neck, large (more than 7cm long), superficial
30048	Skin and subcutaneous tissue or mucous membrane, repair of wound of, other than wound closure at time of surgery, on face or neck, large (more than 7cm long), involving deeper tissue

ing items from a particular group so as to ensure that the training data set is sufficiently rich and representative of the underlying data set.

Once we represent the set of data in this manner, we can then cluster them together using a simple clustering technique, such as the naïve Bayes classification method (Duda, 2001). The results of this clustering are shown in Table 2.

The percentage accuracy is, on average, 91.61%, with 1846 documents out of 2015 correctly classified. It is further noted that some of the categories are badly classified, for example,

Table 5. Some correctly classified Category-1 items

Item No	Item description
3	Professional attendance at consulting rooms (not being a service to which any other item applies) by a general practitioner for an obvious problem characterised by the straightforward nature of the task that requires a short patient history and, if required, limited examination and management -- each attendance
4	Professional attendance, other than a service to which any other item applies, and not being an attendance at consulting rooms, an institution, a hospital, or a nursing home by a general practitioner for an obvious problem characterised by the straightforward nature of the task that requires a short patient history and, if required, limited examination and management -- an attendance on 1 or more patients on 1 occasion -- each patient
13	Professional attendance at an institution (not being a service to which any other item applies) by a general practitioner for an obvious problem characterised by the straightforward nature of the task that requires a short patient history and, if required, limited examination and management -- an attendance on 1 or more patients at 1 institution on 1 occasion -- each patient
19	Professional attendance at a hospital (not being a service to which any other item applies) by a general practitioner for an obvious problem characterised by the straightforward nature of the task that requires a short patient history and, if required, limited examination and management -- an attendance on 1 or more patients at 1 hospital on 1 occasion -- each patient
20	Professional attendance (not being a service to which any other item applies) at a nursing home including aged persons' accommodation attached to a nursing home or aged persons' accommodation situated within a complex that includes a nursing home (other than a professional attendance at a self contained unit) or professional attendance at consulting rooms situated within such a complex where the patient is accommodated in a nursing home or aged persons' accommodation (not being accommodation in a self contained unit) by a general practitioner for an obvious problem characterised by the straightforward nature of the task that requires a short patient history and, if required, limited examination and management -- an attendance on 1 or more patients at 1 nursing home on 1 occasion -- each patient

Table 6. Some correctly classified Category-5 items

Item No	Item description
55028	Head, ultrasound scan of, performed by, or on behalf of, a medical practitioner where: (a) the patient is referred by a medical practitioner for ultrasonic examination not being a service associated with a service to which an item in Subgroups 2 or 3 of this Group applies; and (b) the referring medical practitioner is not a member of a group of practitioners of which the first mentioned practitioner is a member (R)
55029	Head, ultrasound scan of, where the patient is not referred by a medical practitioner, not being a service associated with a service to which an item in Subgroups 2 or 3 of this Group applies (NR)
55030	Orbital contents, ultrasound scan of, performed by, or on behalf of, a medical practitioner where: (a) the patient is referred by a medical practitioner for ultrasonic examination not being a service associated with a service to which an item in Subgroups 2 or 3 of this Group applies; and (b) the referring medical practitioner is not a member of a group of practitioners of which the first mentioned practitioner is a member (R)
55031	Orbital contents, ultrasound scan of, where the patient is not referred by a medical practitioner, not being a service associated with a service to which an item in Subgroups 2 or 3 of this Group applies (NR)
55033	Neck, 1 or more structures of, ultrasound scan of, where the patient is not referred by a medical practitioner, not being a service associated with a service to which an item in Subgroups 2 or 3 of this Group applies (NR)

category-2 and category-4. Indeed, it is found that 62 out of 81 category-4 items are misclassified as category-3. Similarly, 12 out of 54 category-2 items are misclassified as category-5 items.

This result indicates that the hypothesis is not valid; there *are* ambiguities in the description of the items in each category, apart from category-1, which could be confused with those in other categories. In particular, there is a high risk of confusing those items in category-4 with those in category-3.

A close examination of the list of the 62 category-4 items which are misclassified as category-3 items by the naïve Bayes classification method indicates that they are indeed very similar to those in category-3. For simplicity, when we say items in category-3, we mean that those items are also correctly classified into category-3 by the classification method. Tables 3 and 4 give an illustration of the misclassified items. It is noted that misclassified items 52000, 52003, 52006, and 52009 in Table 3 are very similar to the category-3 items listed in Table 4.

It is observed that the way items 5200X are described is very similar to those represented in items 300YY. For example, item 52000 describes a medical procedure to repair small superficial cuts on the face or neck. On the other hand, item 30026 describes the same medical procedure except that it indicates that the wounds are *not* on the face or neck, with the distinguishing feature that this is not a service to which another item in Group T4 applies. It is noted that the description of item 30026 uses the word "not" to distinguish this from that of item 52000, as well as appending an extra phrase "not being a service to which another item in Group T4 applies". From a vector space point of view, the vector representing item 52000 is very close[3] to item 30026, closer than other items in category-4, due to the few extra distinguishing words between the two. Hence, item 52000 is classified as "one" in category-3, instead of "one" in category-4. Similar observations can be made for other items shown in Table 3, when compared to those shown in Table 4.

On the other hand, Tables 5 and 6 show items which are correctly classified in category-1 and category-5 respectively. It is observed that items shown in Table 5 are distinct from those shown in Table 6 in their descriptions. A careful examination of correctly-classified category-1 items, together with a comparison of their descriptions with those correctly-classified category-5 items confirms the observations shown in Tables 5 and 6. In other words, the vectors representing correctly-classified category-1 items are closer to other vectors in the same category than other vectors representing other categories.

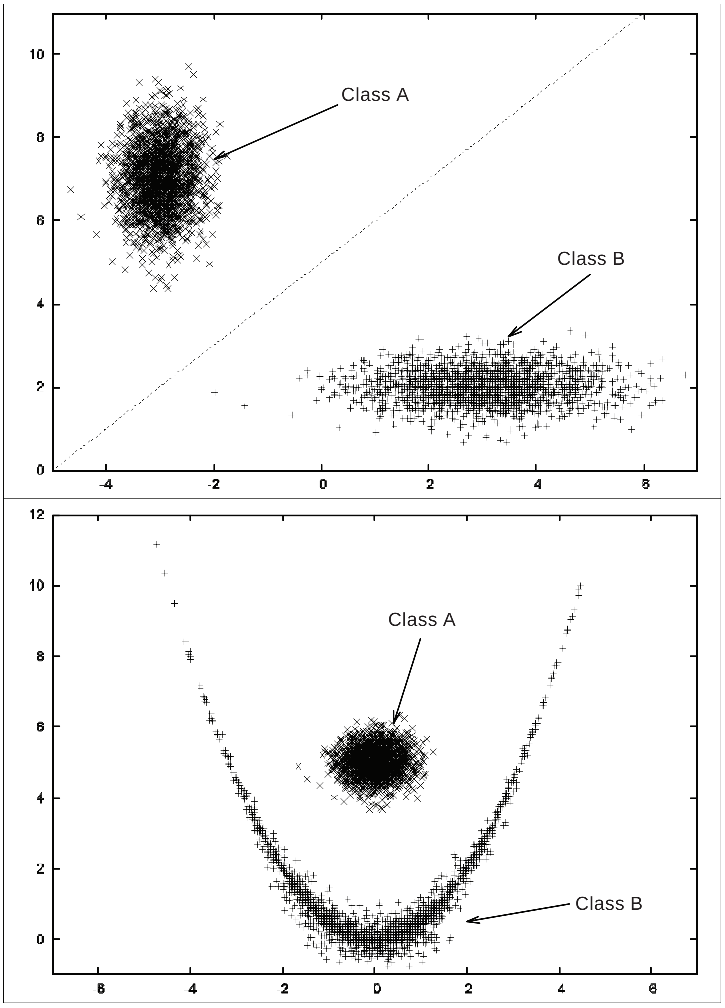
SUPPORT VECTOR MACHINE AND KERNEL MACHINE METHODOLOGIES

In this section, we will briefly describe the support vector machine and the kernel machine techniques.

Support Vector Machine and Kernel Machine Methodology

In recent years, there has been increasing interest in a method called support vector machines (Cristianni & Shawe-Taylor, 2000; Guermeur, 2002; Joachims, 1999; Vapnik, 1995). In brief, this can be explained quite easily as follows: Assume a set of (n-dimensional) vectors $\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n$. Assuming that this set of vectors is drawn from two classes, 1 and -1. If these classes are linearly separable, then there exists a straight line dividing these two classes as shown on the left of Figure 2. In Figure 2, it is observed that the vectors are well separated. Now if the two classes cannot be separated by a straight line, the situation becomes more interesting. Traditionally, in this case we use a non-linear classifier to separate the classes as shown on the right of Figure 2. In general terms, any two collections of n-dimensional vectors are

Figure 2. Illustration of the linear separability of classes (the two classes at top are separable by a single line, as indicated; for the lower two classes there is no line that can separate them)



said to be linearly separable if there exists an (n-1)-dimensional hyper-plane that separates the two collections.

One intuition is inspired by the following example: In the exclusive-OR case, we know that it is not possible to separate the two classes using a straight line, when the problem is represented in two dimensions. However, we know that if we increase the dimension of the exclusive-OR example by one, then in three dimensions one can find a hyper-plane which will separate the two classes. This can be observed in Tables 7 and 8, respectively.

Here it is observed that the two classes are easily separated when we simply add one extra dimension. The support vector machine uses this insight, namely, in the case when it is not possible to separate the two classes by a hyper-plane; if we augment the dimension of the problem sufficiently, it is possible to separate the two classes by a hyper-plane. $f(\mathbf{x}) = \mathbf{w}^T \phi(\mathbf{x}) + b$, where $\mathbf{w}$ is a set of weights, and b a constant in this high-dimensional space. The embedding of the vectors $\mathbf{x}$ in the high-dimensional plane is to transform them equivalently to $\phi(\mathbf{x})$, where $\phi(\cdot)$ is a coordinate

Table 7. Exclusive-OR example

x	y	class
0	0	1
1	1	1
0	1	0
1	0	0

Table 8. Extended exclusive-OR example

x	y	z	class
0	0	0	1
1	1	1	1
0	1	0	0
1	0	0	0

transformation. The question then becomes: how to find such a transformation $\phi(\cdot)$?

Let us define a kernel function as follows:

$$K(\mathbf{x}, \mathbf{z}) \le \phi(\mathbf{x}), \phi(\mathbf{z}) >\equiv \phi(\mathbf{x})^T \phi(\mathbf{z}) \quad (1)$$

where ϕ is a mapping from X to an inner product feature space F. It is noted that the kernel thus defined is symmetric, in other words $K(\mathbf{x}, \mathbf{z}) = K(\mathbf{z}, \mathbf{x})$. Now let us define the matrix $\mathbf{X} = [\mathbf{x}_1\ \mathbf{x}_2\ \ldots\ \mathbf{x}_3]$. It is possible to define the symmetric matrix:

$$X^T X = \begin{bmatrix} x_1^T \\ x_2^T \\ \vdots \\ x_n^T \end{bmatrix} \begin{bmatrix} x_1 & x_2 & \cdots & x_n \end{bmatrix} \quad (2)$$

In a similar manner, it is possible to define the kernel matrix:

$$\mathbf{K} = [\phi(\mathbf{x}_1)\ \phi(\mathbf{x}_2)\ \ldots\ \phi(\mathbf{x}_n)]^T\ [\phi(\mathbf{x}_1)\ \phi(\mathbf{x}_2)\ \ldots\ (\mathbf{x}_n)] \quad (3)$$

Note that the kernel matrix $\mathbf{K}$ is symmetric. Hence, it is possible to find an orthogonal matrix $\mathbf{V}$ such that $\mathbf{K} = \mathbf{V}\Lambda\mathbf{V}^T$, where Λ is a diagonal matrix containing the eigenvalues of $\mathbf{K}$. It is convenient to sort the diagonal values of Λ such that $\lambda_1 \ge \lambda_2 \ge \ldots \ge \lambda_n$. It turns out that one necessary requirement of the matrix $\mathbf{K}$ to be a kernel function is that the eigenvalue matrix Λ must contain all positive entries, in other words, $\lambda_i \ge 0$. This implies that in general, for the transformation $\phi(\cdot)$ to be a valid transformation, it must satisfy some conditions such that the kernel function formed is symmetric. This is known as the Mercer conditions (Cristianni & Shawe-Taylor, 2000).

There are many possible such transformations; some common ones (Cristianni & Shawe-Taylor, 2000) being:

Power kernel:

$$K(\mathbf{x}, \mathbf{z}) = (K(\mathbf{x}, \mathbf{z}) + c)^p \text{ where } p = 2, 4, \ldots$$

Gaussian kernel:

$$K(\mathbf{x}, \mathbf{z}) = \exp\left(\frac{K(\mathbf{x},\mathbf{x}) + K(\mathbf{z},\mathbf{z}) - 2K(\mathbf{x},\mathbf{z})}{\sigma^2}\right).$$

There exist quite efficient algorithms using optimisation theory which will obtain a set of support vectors and the corresponding weights of the hyper-plane for a particular problem (Cristianni & Shawe-Taylor, 2000; Joachims, 1999). This is based on re-formulating the problem as a quadratic programming problem with linear constraints.

Once it is thus re-formulated, the solutions can be obtained very efficiently.

It was also discovered that the idea of a kernel is quite general (Scholkopf, Burges, & Smola, 1999). Indeed, instead of working with the original vectors **x**, it is possible to work with the transformed vectors $\phi(\mathbf{x})$ in the feature space, and most classic algorithms, for example, principal component analysis, canonical correlation analysis, and Fisher's discriminant analysis, all have equivalent algorithms in the kernel space. The advantage of working in the feature space is that the dimension is normally much lower than the original space.

Latent Semantic Kernel Technique

The latent semantic kernel method follows the same trend as the kernel machine methodology (Cristianini, Lodhi, & Shawe-Taylor, 2002). The latent semantic kernel is the kernel machine counterpart of the latent semantic technique, except that it operates in a lower dimension feature space, and hence is more efficient.

In latent semantic analysis, we have a set of documents represented by D, in terms of $V = [\mathbf{v}_1, \mathbf{v}_2, ..., \mathbf{v}_m]$. This set of vectors can be concatenated into a matrix **D**, then we may apply a singular value decomposition on the matrix **D** as follows:

$$\mathbf{D} = \mathbf{U}\sum\mathbf{V}^T \qquad (4)$$

where **D** is a n m matrix, **U** is an ortho normal n n matrix such that $\mathbf{U}\mathbf{U}^T = \mathbf{I}$, **V** is an ortho normal m m matrix, such that $\mathbf{V}^T\,\mathbf{V} = \mathbf{I}$, and $\sum$ is a n m matrix, with diagonal entries $\sigma_1, \sigma_2, ..., \sigma_n$, if $n > m$ or $\sigma_1, \sigma_2, ..., \sigma_m$ if $m > n$.

Often the singular values σ are arranged so that $\sigma_1 \geq \sigma_2 \geq ... \geq \sigma_n$. Thus, the singular values σ give some information on the "energy" of each dimension. It is possible that some of the σ may be small or negligible. In this case, it is possible to say that there are only a few significant singular values. For example, if we have $\sigma_1 \geq \sigma_2 \geq \sigma_i >> \sigma_{i+1} \geq \sigma_n$, then it is possible to approximate the set by $\sigma_1 \geq \sigma_2 \geq ... \geq \sigma_i$. In this case, it is possible to perform a dimension reduction on the original data so that it conforms to the reduced order data. By reducing the order of representation, we are "compressing" the data, thus inducing it to have a "semantic" representation.

The idea behind the latent semantic kernel is, instead of considering the original document matrix **D**, to consider the kernel matrix $\mathbf{K} = \mathbf{D}^T\,\mathbf{D}$. In this case, the feature space dimension is smaller, as we normally assume that there are more words in the vocabulary than the number of documents, in other words, $n \gg m$. Thus, by operating on m m matrix $\mathbf{D}^T\,\mathbf{D}$, it is a smaller space than the original n dimensional space. Once it is recognised that the kernel is K, we can then operate on this kernel, for example, performing singular value decomposition on the matrix **K**, and find the corresponding singular values.

One particular aspect of performing a singular value decomposition is to find a reduced order model such that, in the reduced order space it will approximate the model in the original space in the sense that the approximated model contains most of the "energies" in the original model. This concept can also be applied to the latent semantic kernel technique. It is possible to find a reduced order representation of the original features in such a manner that the reduced order representation contains most of the "energies" in the original representation.

The latent semantic kernel algorithm (Cristianini, Lodhi, & Shawe-Taylor, 2002) can be described as follows:

Given a kernel K, training set $d_1, ..., d_m$ and a number T:

for $i = 1$ to m do:

$norm2[i] = K(d_i, d_i)$;

for $j = 1$ to T do:

$i_j = \arg\max_i (norm2[i])$;

$index[j] = i_j$;

$size[j] =$;

for $i = 1$ to m do:

;

$norm2[i] = norm2[i]$ - $feat(i, j)$* $feat(i, j)$;

end;

end;

return $feat[i, j]$ as the j^{th} feature of input i;

To classify a new example d:

for $j = 1$ to T do:

;

end;

return $newfeat[j]$ as the j^{th} feature of the example d.

In our work, we use the latent semantic kernel method as a pre-processing technique in that we have a set of documents represented by the matrix **D**, and as mentioned previously, the matrix is quite sparse in that there are many null values within the matrix. Hence, our aim is to project this representation onto a representation in a reduced order space so that most of the "energies" are still retained. Once we obtain this set of reduced order representation, we can then manipulate them in the same way as we manipulate the full feature vectors.

Application of Latent Semantic Kernel Methodology to the Medical Benefit Schedule

We wish to apply the latent semantic kernel technique to the set of descriptions of items as contained in the MBS. The vector representation as described in in the *Bag of Words* section is used in the latent semantic kernel (LSK) approach, and it is known as the full feature vectors or, in short, full features.

We apply the LSK algorithm to the *full features* and produce reduced features which have a dimension determined by a variable T ($T \leq n$, the number of words in the corpus). In this paper, we will use the term LSK reduced features to represent such features.

We use the following procedures in our experiments with the latent semantic kernel:

- Run **bag of words method** to produce full features.
- Run **LSK algorithm** to produce LSK reduced features.
- Experiments with both **LSK** and **full features** including:
  - *Binary classification* — this will allow only binary classification using support vector machine techniques
  - *Multi-classification* — this will allow multi-class classification using support vector machine techniques
  - *Clustering the items in the MBS* using both full features and reduced features
  - *Compare the clustering result* using multi-classification results

EXPERIMENTS USING BINARY CLASSIFICATION

In this section we report the results of using a binary classification support vector machine technique for the classification of the items (Joachims, 1999). This is interesting in that it shows us the results of assuming one class, and the other items are assumed to be in a different class.

Originally, items in the MBS are classified into seven categories: 1, 2,..., 6 and 7. We have trained a binary classifier for both the full features and for the reduced features regarding each category versus the others. For example, we use category-1 and assume all the other categories are grouped as another class.

We run experiments on reduced features for each category where the dimension *T* of the reduced features was chosen from a set of values within the range [16; 2048].

We show the results of category-1 versus other categories first, and then summarise other situations and draw some general conclusions concerning the experiments.

For the experiment about category-1 versus others (see Table 9), we observe that the accuracy climbs from T = 16 rapidly to a stable position of a maximum at T= 32. Note that even though the accuracies oscillate about this maximum value for later values of T, this can be observed to be minor, and can be attributed to noise. From this, we can conclude that if we classify category-1 versus all the other categories, then using T= 32 is sufficient to capture most of the gain. What this implies is that most of the energies in the document matrix are already captured with 32 reduced order features. This shows that the LSK algorithm is very efficient in compressing the features from 4569 words in the vocabulary to only requiring 32 reduced features. Note that it is not possible to *interpret* the reduced features, as by nature they consist of a transformed set of features.

For experiments involving other sets, for example, using category-2 versus all the other categories, and so on, similar conclusions to that shown for category-1 are observed. It is found that in general a small value of T is sufficient to capture most of the energies in the document matrix. Each category versus the rest peaks at a particular value of T. On average it is found that T = 128 would capture most of the gain possible using the reduced features.

These experiments show us that the LSK algorithm is a very efficient pre-processing unit. The observed efficiency is likely due to the sparseness

Table 9. Accuracy on the training data and testing data set for Category 1 with various values of T and full features

T	**Train**		**Train**	
	Accuracy	**Correct (out of 2015)**	**Accuracy**	**Correct (out of 2015)**
16	99.60	2007	99.31	2001
32	100	2015	99.75	2010
64	100	2015	99.75	2010
128	100	2015	99.80	2011
256	100	2015	99.80	2011
400	100	2015	99.70	2009
512	100	2015	99.75	2010
800	100	2015	99.75	2010
1024	100	2015	99.75	2010
1200	100	2015	99.80	2011
1400	100	2015	99.75	2010
1600	100	2015	99.75	2010
1800	100	2015	99.75	2010
2000	100	2015	99.75	2010
2048	100	2015	99.75	2010
full features	100	2015	99.75	2010

of the full feature space. It can capture most of the energies contained in the document matrix using a small reduced feature set, in other words, with a value of T = 128.

EXPERIMENTS USING MULTIPLE CLASSIFICATIONS

In this section, we report on experiments with multi-classification using support vector machine (SVM) methodology. We first discuss the generalisation of SVM's to multi-class classification, then we describe the experimental results.

SVM, as a method proposed in Vapnik (1995), is suitable for two-class classifications. There are a number of extensions which extend this method to multi-class classification problems (Crammer & Singer, 2001; Guermeur, 2002; Lee, Lin, & Wahba, 2002). It turns out that it is possible that, instead of weighing the cost function as an equal cost (indicating that both classes are equally weighed in a two-class classification problem), one can modify the cost function and weigh the misclassification cost as well (Lee, Lin & Wahba, 2002). Once formulated in this manner, the usual formulation of SVM's can be applied.

In the *Experiments Using Binary Classification* section, we showed that by using a small reduced feature such as T = 128, we can capture most of the energies in the document matrix. The following result is obtained by running multi-class classification using support vector machine on reduced features with the same training and testing data sets as previously. The average accuracy is 88.98%, with 1793 correctly classified out of 2015 (Table 10).

Note that once again some of the HIC categories are poorly classified. For example, out of 81 HIC category-4 items, 71 are classified as category-3, while only 9 are classified as category-4. This further confirms the results obtained in the *Bag of Words* section, namely that there are ambiguities in the HIC classifications of item descriptions.

EXPERIMENTS WITH CLUSTERING ALGORITHMS

So far, we have experimented on MBS items which are classified by categories as contained in the MBS. We have shown that the MBS contained ambiguities using the bag of words approach. In this section, we ask a different question: If we ignore the grouping of the items into categories as contained in the MBS, but instead we apply clustering algorithms to the item descriptions, how many clusters would we find? Secondly, how

Table 10. A confusion table showing the classification of documents (the row gives the actual classification as indicated in the MBS, while the column shows figures which are obtained by using the support vector machine)

Category	1	2	3	4	5	6	7	total	% accuracy
1	74	0	0	0	0	4	1	79	93.67
2	0	28	13	0	8	5	0	54	51.85
3	1	6	1310	16	20	2	12	1367	95.83
4	0	0	71	9	0	0	1	81	11.11
5	0	11	25	0	211	4	1	252	83.73
6	0	5	5	1	4	136	0	151	90.07
7	0	0	4	0	0	2	25	31	80.65

efficient would these clusters be in classifying the item descriptions? Efficiency is measured in terms of the confusion matrix in classifying unseen data.

The methodology which we used is as follows:

- Use a clustering algorithm to cluster the document matrix into clusters, and label the clusters accordingly.
- Evaluate the efficiency of the clustering algorithm using a support vector machine. The efficiency is observed by examining the resulting confusion matrix.

The main reason why we need to take a two-step process is that the clustering algorithm is an unsupervised learning algorithm and that we do not have any *a priori* information concerning which item should fall into which cluster. Hence, it is very difficult to evaluate the efficiency of the clusters produced. In our methodology, we evaluate the efficiency of the clusters from the clustering algorithm by assuming that the clusters formed are "ideal", label them accordingly, and use the SVM (a supervised training algorithm) to evaluate the clusters formed.

Clustering Using Full Features: Choice of Clustering Method

The first experiment was performed on the full features (in other words, using the original document matrix). Different clustering methods were evaluated using various criteria; we found that the repeated bisection method of clustering gives the best results. Hence, we choose to use this clustering method for all future experiments.

In the clustering algorithm (Karypis, 2003; Zhao & Karypis, 2002), the document matrix is first clustered into two groups. One of the groups is selected and bisected further. This process continues until the desired number of clusters is obtained. During each step, the cluster is bisected so that the resulting two-way clustering solution optimises a particular clustering criterion. At the end of the algorithm, the overall optimisation function is minimised. There are a number of optimising functions which can be used. We use a simple criterion which measures the pair-wise similarities between two documents S_i and S_j as follows:

$$\sum_{d_q \in D_i, d_r \in D_j} \cos(d_q, d_r) = \sum_{d_q \in D_i, d_r \in D_j} d_q^T d_r \quad (5)$$

For a particular cluster S_r of size n_r, the entropy is defined as:

$$E(S_r) = -\frac{1}{\log q} \sum_{i=1}^{q} \frac{n_r^i}{n_r} \log \frac{n_r^i}{n_r} \quad (6)$$

where q is the number of classes in the data set, and n_r^i is the number of documents of the i-th class that were assigned to the r-th cluster. The entropy of the entire clustering solution is defined as:

$$E = \sum_{r=1}^{k} \frac{n_r}{n} E(S_r) \quad (7)$$

Perfect clustering means that each cluster will contain only one type of document, that is, each document in the same class belong to the same type. In this case, the entropy will be zero. In general, this is impossible. The clustering result which provides the lowest entropy would be the best clustering result. In this chapter, we made use of the Cluto software (Karypis, 2003) for performing the clustering.

Clustering Using Reduced Features into k-Clusters and Use of Support Vector Machine to Evaluate Cluster Accuracy

For experiments in this section, we used reduced features with T = 128, together with the repeated bisection clustering method. Our aim was to use a clustering algorithm with the repeated bisection method to group item descriptions into clusters irrespective of their original classification in the MBS. We divided the item descriptions into *k* (constant) clusters.

The detailed experimental procedures are as follows:

- Use reduced features of all MBS items obtained using the latent semantic kernel method as inputs into the clustering algorithm in order to group items into k-clusters, where k is a variable determined by the user.
- The output from the clustering algorithm gives *k* clusters. We perform clustering, do a classification on MBS items using the reduced features and the SVM methodology, however in this case cluster the item belonging to results from the clustering method, not the MBS category.
- The classification output can be displayed in a confusion table which can inform us on how well the clustering algorithm has performed.

In this section, we use the following notations:

- **Cluster category** — this is the cluster obtained using the clustering algorithm.
- **HIC category** — this is the category which is provided by the MBS.

Clusters (k = 7)

First, we ran a clustering algorithm to create seven cluster categories. From Table 11, we observe how items in HIC categories are distributed into cluster categories.

From this it is observed that the clusters as obtained by the clustering algorithm are quite different from those indicated in the HIC category.

We then validated the classification results from the clustering algorithm using SVM's. This informed us of the quality of the clustering algorithm in grouping the item descriptions. A classification accuracy of 93.70% on the testing data set (that is, 1888 correct out of 2015) was found.

Note that for these experiments, we used the 50% training and 50% testing data sets as in all previous experiments. The distribution of items in the training and testing data sets for each cluster category was selected using a random sampling scheme within each identified category.

Clusters (k = 8)

In this section, we experimented with eight clusters instead of seven. This provided the clustering algorithm with more freedom to choose to cluster the item descriptions. When we chose seven clusters, we implicitly tell the cluster algorithm that *no matter how the underlying data look like*, we nevertheless only allow seven clusters to be found. In this manner, even though the underlying data may be more conveniently clustered into a higher number of clusters, by choosing seven clusters we force the cluster algorithm to merge the underlying clusters into seven. On the other hand, if we choose eight clusters, this provides more freedom for the clustering algorithm to cluster the underlying data. If it is truly seven clusters, then the algorithm will report that there are seven clusters found. On the other hand, if the data is more conveniently clustered into eight clusters, then by choosing to allow for the possibility of eight clusters, it will allow the clustering algorithm to find one.

First, we ran a clustering algorithm to create eight cluster categories (Table 13).

Table 11. Distribution of MBS items into cluster categories (the cluster categories are given horizontally, and HIC categories are presented vertically)

Class	1	2	3	4	5	6	7
1	0	3	10	0	230	0	0
2	10	39	442	16	107	69	6
3	0	0	1269	62	9	1	3
4	148	13	65	2	7	17	18
5	0	4	297	34	20	0	12
6	0	12	505	47	18	35	21
7	0	37	146	1	113	180	2

Table 12. A confusion table obtained using the support vector machine method

Class	1	2	3	4	5	6	7	total	% accuracy
1	112	0	1	0	1	0	6	120	93.33
2	0	312	2	4	11	5	4	338	92.31
3	0	3	661	2	8	6	3	683	96.78
4	2	4	0	119	3	2	1	131	90.84
5	0	1	1	5	173	1	4	185	93.51
6	1	1	6	2	9	282	4	305	92.46
7	0	13	0	4	6	1	229	253	90.51

Table 13. Distribution of MBS items into eight cluster categories (the cluster categories are given horizontally, and HIC categories are presented vertically)

Class	1	2	3	4	5	6	7
1	0	4	10	0	244	0	0
2	10	39	326	17	104	70	6
3	0	0	1264	61	8	1	3
4	0	2	223	3	9	1	0
5	148	12	53	2	7	16	18
6	0	4	290	32	20	0	12
7	0	13	501	46	15	30	21
8	0	34	67	1	97	184	2

From Table 13, it is observed that the clusters as obtained by the clustering algorithm are quite different from those indicated in the HIC category.

We then validated the classification results from the clustering algorithm using SVM's. This informed us of the quality of the clustering algorithm in grouping the item descriptions. A classification accuracy is 94.14% (in other words, 1897 correct out of 2015 resulted).

Summary of Observations

It was observed that:

1. The categories as given by the clustering algorithm are good in grouping the medical item descriptions together. The evaluation using the SVM method shows that it is accurate in grouping them together, as

Table 14. A confusion table using support vector machine to validate the quality of cluster categories

Class	1	2	3	4	5	6	7	8	total	% accuracy
1	127	0	1	0	0	1	0	3	132	96.21
2	0	259	2	0	3	5	1	5	275	94.18
3	0	3	657	1	1	11	3	4	680	96.62
4	0	0	0	106	0	7	0	2	115	92.17
5	2	2	0	2	108	4	5	2	125	86.40
6	0	2	1	3	2	170	2	0	180	94.44
7	0	3	5	4	2	8	280	1	303	92.41
8	0	3	0	4	2	5	1	190	205	92.68

the confusion table has dominant diagonal elements, with few misclassified ones. The SVM is a supervised method. Once it is trained, it can be used to evaluate the generalisation capability of the model on testing results with known classifications. Thus, by examining the confusion table produced, it is possible to evaluate how well the model classifies unseen examples. If the confusion table is diagonally dominant, this implies that there are few misclassifications. On the other hand, if the confusion table is not diagonally dominant, this implies that there are high numbers of misclassifications. In our experiment, we found that the confusion table is diagonally dominant, and hence we can conclude that the grouping as obtained by the clustering algorithm is accurate. In other words, the clustering algorithm was able to cluster the underlying data together into reasonably homogeneous groupings.

2. The classification given by the clustering algorithm increases with the number of clusters, in other words, the degree of freedom in which the clustering algorithm is provided. Obviously there will be an upper limit to a reasonable number of clusters used, beyond which there will not be any further noticeable increase in the classification accuracy. It is observed that the accuracy of assuming seven clusters (93.70%) and the accuracy of using eight clusters (94.14%) are very close to one another. Hence we can conclude that the "optimum" number of clusters is around seven or eight.
3. It is noted that the items in the HIC categories are distributed in the cluster categories. This confirms our finding in the *Bag of Words* section that the HIC categories are not "ideal" categories from a similarity point of view, in that it can induce confusion due to their similarity.

CONCLUSION

We have experimented with classification and clustering on full features and reduced features using the latent semantic kernel algorithm. The results show that the LSK algorithm works well on Health Insurance Commission schedules. It has been demonstrated that the HIC categories are ambiguous in the sense that some item descriptions in one category are close to those of another. This ambiguity may be the cause of misinterpretation of the Medicare Benefits Schedule by medical service providers, leading to wrong charges being sent to the HIC for refund. It is shown that by using clustering algorithms, the item descriptions can be grouped into a number of clusters, and moreover, it is found that seven or eight clusters would be sufficient. It is noted, however, that the item descriptions as grouped using the clustering algorithm are quite different to those of the HIC categories. This implies that if the HIC wishes to re-group item descriptions, it would be beneficial to consider the clusters as grouped by using clustering algorithms.

Note that one may say that our methodology is biased towards the clustering algorithm or classification methods because we only use the simple top HIC categories — categories 1 through 7 as shown in Figure 1. This is only a very coarse classification. In actual fact, the items are classified in the MBS according to a three-tiered hierarchical tree as indicated in Figure 1. For example, an item belongs to category-x group-y item number z, where x ranges from 1 to 7, y ranges from 1 to y_i (where *i* indicates the category that it is in), and *z* ranges from 1 to z_j (where *j* depends on which group the item is located). This is a valid criticism in that the top HIC categories may be too coarse to classify the item descriptions. However, at the current stage of development of text mining methods, it is quite difficult to consider the hierarchical coding of the algorithms, especially when there are insufficient numbers of training samples. In the MBS case, a group may contain only a few items. Thus there is an insufficient number of data to train either the clustering algorithm or SVM. Hence our approach in considering the top HIC categories may be one possible way to detect if there are any inconsistencies in the MBS given the limitations of the methodology.

Even though in this chapter we have concentrated on the medical procedure descriptions of a health insurer, the techniques can be equally applicable to many other situations. For example, our developed methodology can be applied to tax legislation, in identifying whether there are any ambiguities in the description of taxable or tax-exempted items. Other applications of our methodology include: description of the social benefit schedule in a welfare state, and the description of degree rules offered by a university.

ACKNOWLEDGMENT

Financial support is gratefully acknowledged from both the Australian Research Council and the Health Insurance Commission through an ARC Linkage Project grant.

ENDNOTES

1. Note that this scheduled cost is somewhat different from those set by the medical service provider associations. A medical service provider can elect to charge at the scheduled cost set by the medical service provider associations, or a fraction of it, and any gaps in between the charge and the refund by the HIC will need to be met either by the patient, or through additional medical insurance cover specifically designed to cover the gap payment.
2. Note that the Medical Benefit Schedule is a living document in that the schedules are revised once every few years with additional supplements once every three months. The supplements contain minor modifications to particular sections of the schedule, while the major revisions may contain re-classification of the items, deletion or addition of items, mainly for newly introduced medical services, due to technological advances, or clarification of the intent of existing items. The version of MBS used in this chapter is based on the November, 1998, edition with supplements up to and including June 1, 2000.
3. Close here means the cosine of the angle between the two vectors is close to 1.

Chapter 3.22
A Software Tool for Reading DICOM Directory Files

Ricardo Villegas
Universidad de Carabobo, Venezuela

Guillermo Montilla
Universidad de Carabobo, Venezuela

Hyxia Villegas
Universidad de Carabobo, Venezuela

ABSTRACT

DICOMDIR directory files are useful in medical software applications because they allow organized access to images and information sets that come from radiological studies that are stored in conformance with the digital imaging and communication in medicine (DICOM) standard. During the medical application software development, specialized programming libraries are commonly used in order to solve the requirements of computation and scientific visualization. However, these libraries do not provide suitable tools for reading DICOMDIR files, making necessary the implementation of a flexible tool for reading these files, which can be also easily integrated into applications under development. To solve this problem, this work introduces an object-oriented design and an open-source implementation for such reading tool. It produces an output data tree containing the information of the DICOM images and their related radiological studies, which can be browsed easily in a structured way through navigation interfaces coupled to it.

INTRODUCTION

The digital imaging and communications in medicine (DICOM) standard (National Electrical Manufacturers Association (NEMA0, 2004a; Revet, 1997) was published in 1993. Its main goal was to establish norms for handling, storing, and interchanging medical images and associated digital information within open systems. Also it was to facilitate the interoperability among acquisition equipments and other medical devices, as well as their integration within specialized information systems in the medical and health care area.

Since then, the appearance and use of computer-assisted medical applications have increased, as a result of the accelerated technological development and the standardization process of medical information representation and handling, which generated a greater demand of development tools for those applications.

These applications range from health care information systems and picture archiving and communication systems (PACS) () solutions, to technological support systems for medical procedures, such as image-based diagnosis and surgical planning, which previously depended on the knowledge and expertise of the physicians.

In such applications, the handling of images coming from different acquisition modalities is essential. These images generated from radiological studies and stored according to the specifications of parts 10, 11 and 12 of the DICOM standard (NEMA, 2004e, f,& g) must be retrieved from storage media as a bidimensional display or in tridimensional reconstructions and other special processes, such as fusion and segmentation of images. The use of DICOMDIR directory files is almost mandatory for searching, accessing, and browsing medical images because they index the files belonging to the patient on whom the studies were performed, thus making it easier to access to those images and their associated medical information.

During the medical application software development, the use of programming interfaces (APIs) or class libraries is frequent in order to solve the computation and visualization needs, as well as for providing DICOM support to the applications. In that sense, there exist numerous public domain applications that can be used by radiologists and other specialists for reading and displaying DICOM images files and even for reading DICOMDIR index files, which cannot be integrated into applications under development because of their proprietary code.

Companies, such as Lead Technologies, ETIAM, Merge, Laurel Bridge, and DeJarnette, have commercial software development kits (SDKs) that provide complete implementations of the DICOM standard, but the acquisition costs for these SDKs are high. Open-source libraries are an alternative choice for integrating DICOM support into applications. Regarding this matter, libraries, such as visualization tool kit (VTK) (), insight segmentation and registration tool kit (ITK), DICOM tool kit (DCMTK), and virtual vision machine (VVM), allow the reading of DICOM images, but they do not provide mechanisms for reading DICOMDIR files. Like in the DCMTK case, there are other libraries that provide tools for a basic and low-level access to the information contained in the files. However, they have disadvantages, such as troublesome information retrieving process and reading tools, which are difficult to integrate into the applications.

Due to the lack of an adequate tool for reading and handling DICOMDIR files in a structured and simple way, which could be also easily coupled to browsing interfaces and attached to medical application under development, we introduce in this article the design and implementation of a DICOMDIR files reader. This tool has been successfully integrated into an application for neurosurgery preoperative planning (Montilla, Bosnjak, Jara, & Villegas, 2005), but it also can be attached to any other software under development that requires the handling of DICOM images and DICOMDIR directory files.

The next sections include the revision of related works, the essential theoretical background that frames this work within the DICOM standard context; the description of the methodology used for the implementation of the tool; and, finally, the discussion and conclusions obtained from the integration and test of the implemented reader into a medical application.

ANTECEDENTS AND RELATED WORKS

The creation of the American College of Radiology (ACR)-NEMA committee in 1983 was the product of earlier attempts by the American College of Radiology (ACR) and the National Electrical Manufacturers Association (NEMA) to establish a normative for exchanging, transmitting, and storing medical images and their associated information. The version 1.0 of the standard was published by this joint committee in 1985, under the document ACR-NEMA No. 300-1985, followed in 1988 by the document ACR-NEMA No. 300-1988 of version 2.0. Previous to these normatives, medical images were stored in files by the acquisition devices under their own proprietary formats and transferred through point-to-point communication or by removable storage media. Versions 1.0 and 2.0 established a standardized terminology and information structure, as well as hardware interfaces, software commands sets, and consistent data formats.

The most recent version, known as DICOM 3.0 (NEMA, 2004a) was published in 1993, and it was structured in parts, or documents, to facilitate its support and extension. In the last version, objects for the representation of patients, studies, reports, and other data sets were added, as well as unique identifiers for these objects, enabling the transmission of information through communication networks using the TCP/IP protocol. The DICOM 3.0 standard facilitates the transfer of images and related information within open systems containing different medical equipments and the integration with medical information systems and applications.

DICOM parts 3, 6, 10, and 12 (NEMA, 2004b, d, 4e, & g) were of particular interest for our tool design. They define and describe the DICOMDIR directory object and other information objects; attributes and representation values of DICOM information model entities; and specifications for files formats and information storage in physical media.

We have not found formal research papers related to the design and implementation of open-source tools for reading DICOMDIR files and their integration within medical applications. Nevertheless, there exist documented development libraries that include support for this kind of file. On the other hand, regarding the complexity of searching and decoding information contained in DICOM files and the fact that the tool had to be integrated into a medical application developed with C++ language, we decided to search for open-source development libraries, based upon C++ and with DICOM support in order to use them as a base for the tool development.

Just a few development libraries, besides the expensive commercial ones, enable the reading and analysis of DICOMDIR files. Due to their structures or features only three open-source libraries, based upon C++ language, were deemed appropriate to be used as reference for the tool design and implementation; the remaining APIs were found either to have a complicated structure or were based upon Java language.

GDCM (GDCM, 2005) is an API supported by Centre de Recherche et d'Applications en Traitement de l'Image et du Signal (CREATIS), which provides a fairly complete support for reading DICOMDIR files and a simple access to the information extracted from them. However, it implements only part 5 of the DICOM standard; therefore, it would be of little use as a base library for medical applications that require the implementation of other features defined by the standard.

Dicomlib library (DicomLib, 2005) provides a fuller implementation of the DICOM standard, and it also features the reading of DICOMDIR files. Although this library tries to ease the huge intrinsic complexity in the use of the DICOM standard, its access and presentation of the DICOMDIR compiled information is not the best one to be integrated into the applications.

Finally, DICOM tool kit (DCMTK) (DCMTK, 2005) from Oldenburger Forschungs und Entwicklungsinstitut für Informatik-Werkzeuge und Systeme (OFFIS) is another complete library, having several years of evolution and continous use in medical applications development. Although DCMTK provides support for the creation, modification, and opening of DICOMDIR files, it does not offer structured and simple access to the information gathered from the files. However, we selected DCMTK as the base library for the reader development due to its robustness, flexibility, and ability to handle of DICOM images.

Thus, starting from the basic functions for information searches and decoding that provides DCMTK, it was possible to develop the tool for reading the information contained in DICOMDIR files and attach this tool to medical applications that require organized access to DICOM image sets from medical studies.

THEORETICAL BACKGROUND

A lot has been written about the DICOM standard ever since it was published, including revisions and extensions. The scope of DICOM is so wide that the researcher certainly gets overwhelmed by the amount and complexity of the information contained in the standard documents. In our case, as in any other case of software development that involves the handling of information within the DICOM scope, the revision of basic fundamentals for real-world information representation according to the DICOM standard was necessary.

Within DICOM's structure, the term "information" refers to medical images coming from different acquisition modalities, signals, curves, look-up tables, and structured reports, as well as to other information gathered during patient visits to the healthcare specialist and the studies derived from them. This information and its generating agents are represented by the standard through models.

DICOM Application and Information Models

DICOM structures and organizes medical data and information through models that emulate the real-world hypothetical situation, where a patient visits a health care specialist, who later orders a set of radiological studies as shown in Figure 1.

Figure 1. Correspondence between the radiological exam environment and the DICOM Information Model

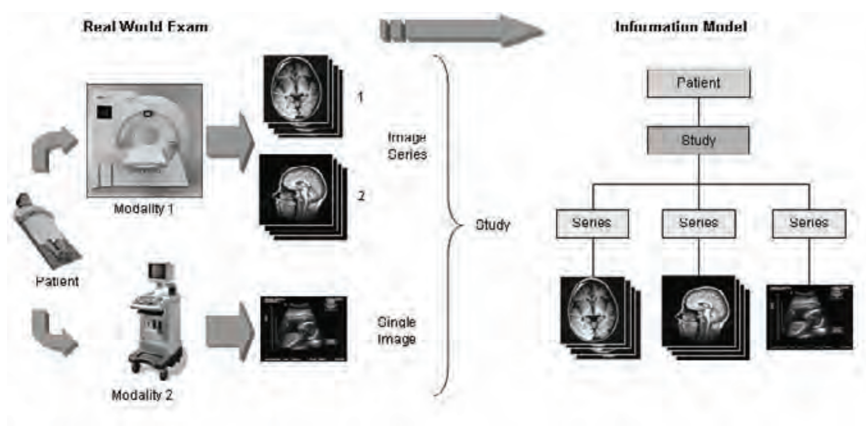

Figure 2. Simplified DICOM application model showing information entities and relationships among them

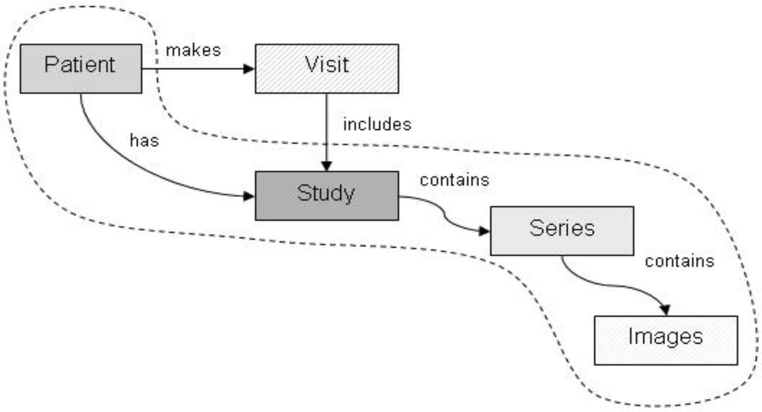


An application model is defined as an entity/relationship diagram (see Figure 2) that relates real-world objects inside the standard scope. Its diagram derives from the way hospitals' radiology departments handle images from one or more acquisition modalities. Those images are ordered in a series, according to some spatial or temporal relationship, and then stored in a folder for each patient.

Although the application model contains entities for representing several DICOM objects, such as exams results, medical reports, and study procedures, in this work only the patient, study, series, and image entities were considered because they are directly associated to data contained within the images. This consideration produces the simplified version of the DICOM application model shown in Figure 2, where the dashed region contains the entities of interest.

The DICOM information model derives from the application model and its entities are known as information object description (IOD). In an abstract way, an IOD describes real-world objects that share the same properties (NEMA, 2004b). This abstraction keeps a close relationship to the object-oriented design and programming paradigm.

Information model entities are featured by attributes whose types, multiplicities, and contents change depending upon the entity to which they belong. Attributes or data elements are defined in part 5 of the standard (NEMA, 2004c), and they are cataloged in part 6 of the data dictionary (NEMA, 2004d). An attribute is classified according to its presence in obligatory (types 1 and 2), conditional (types 1C and 2C), and optional (type 3).

Attributes are identified in the data dictionary through a tag composed from an ordered 16-bit number duple (*gggg,eeee*) expressed in hexadecimal form. These numbers represent the group and the element number within that group. The standard attributes have an even group number, different from 0000, 0002, 0004, and 0006, whereas private attributes, not contained in the data dictionary, have an odd group number, different from 0001, 0003, 0005, 0007, and FFFF. All aforementioned group numbers are reserved by the standard.

In addition to the tag, there are other data fields that also belong to the attributes structure, such as value representation (VR), value multiplicity (VM), length, and contained value. The VR describes, through a 2-byte character string, the type and format of the data contained in the attribute value field, such as integer or floating numbers, dates, string characters, and sequences. The VM specifies the cardinality or number of values that are codified in the value field. The length contains the attribute's value size in bytes. Finally, the value field stores the attribute data, according to its respective presence type.

For each IOD there are defined operation sets and named services that are executed on the information objects. When an entity needs to perform an operation over an IOD, it must request the proper service to another entity, which behaves as a server. Each object-defined service establishes a service-object pair (SOP), and the whole service set that is applicable to a particular IOD is a named SOP class.

The *media storage service class* and the *queryrRetrieve service class* are examples of SOP classes. The first one comprises the M-READ, M-WRITE, and M-DELETE services set, applied to the reading, writing, and deleting of files with image IODs coming from acquisition modalities. The second class groups the C-FIND, C-MOVE, and C-GET services that can be requested for querying and transferring information from IODs associated with different entities.

An SOP instance is the occurrence of an IOD that is operated within a communication context, through a specific service set. For example, DICOMDIR directory files are SOP products from requesting the information writing service from a directory IOD to a physical storage media.

The simplified model from our research considers only four entities and their corresponding IODs. The patient entity contains data of the patient for whom radiological studies were performed as described by the study entity. The series entity models information resulting from radiological studies, such as images or signals, and keeps some kind of spatial or temporal relationship among them. The image entity represents the images coming from some of the existing acquisition modalities, for example, computed tomography (CT), magnetic image resonance (MRI), or ultra sound (US).

DICOM File Format

The DICOM file format, described in part 10 of the standard (NEMA, 2004e), defines the way data representing a SOP instance is stored in a physical storage media. The data is encapsulated as a stream of bytes, preceded by a header with metainformation required for identifying the SOP instance and class.

The header has an organized sequence of components, named file ID, which organizes files hierarchically. An ID has up to eight components, where each one is a string of one to eight characters separated by backslashes. The file ID generally corresponds to a directory path and to a filename, for example, SUBDIR1\SUBDIR2\SUBDIR3\ABCDEFGH.

Located after the header is the data set associated with the information model entity that is stored in the file. Depending upon the entity nature, this stream of bytes could represent some of the following objects: images, curves, signals, overlay annotations, lookup tables for transforming images pixel values according to acquisition modalities or values of interest, presentation images descriptions, structure reports, or raw data.

Within the context and scope of our research, we considered only DICOM files containing images associated with studies performed on patients. Therefore, the stored data describes the image plane and the pixels features, as well as values for mapping the image to color or gray scales, overlay planes, and other specific features.

DICOM files are gathered in collections sharing a common name space, such as storage volumes or directory trees, and having unique file identifiers within it. The file collection is an abstraction of a container where files can be created or read. Each collection must be accompanied by an index file with a DICOMDIR identifier, corresponding to a

DICOM directory object instance. Part 12 of the standard (NEMA, 2004g) describes the way the DICOM file information is encoded inside the physical storage media. It depends upon the file system used by the computer system for the files creation and interchange, as well as the physical media used for it.

DICOMDIR File Format

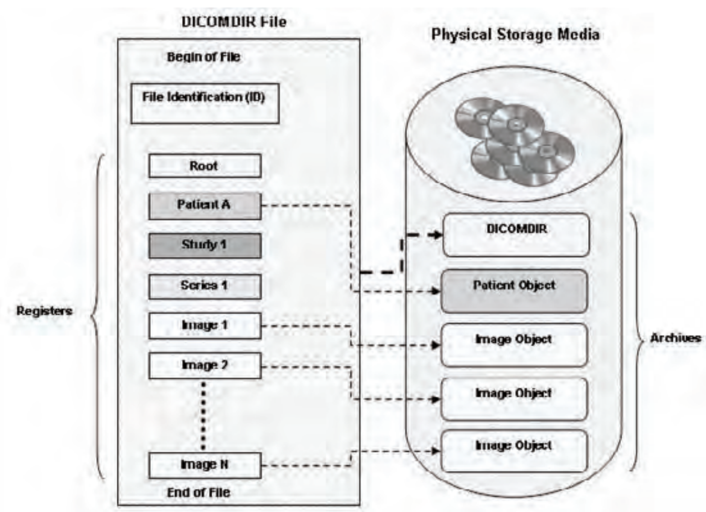
The DICOM standard defines a special object class as a named basic directory object, whose purpose is to serve as an organizing index for DICOM files stored in a physical media. The instance of a DICOM directory class object is a file with a unique filename and ID named DICOMDIR. The formal definition of the DICOMDIR object and its content are in part 3 annex F of the DICOM standard (NEMA, 2004b), whereas its structure complies with the DICOM files format specified in section 7 of part 10 (NEMA, 2004e).

There are registers in the DICOMDIR file with the information associated to objects stored in a DICOM files set, and it does not make reference to files that do not belong to the set. Each register contains a field identifying the represented information type, such as patient, study, series, and image, besides a group of specific fields with attributes extracted from the stored SOP instance. The registers are hierarchically sorted, and they are linked among themselves in the same hierarchy level and to the next lower level in the hierarchy (Figure 3).

The preceding information is generally present in the file, such as indicated in the standard, but some data fields can be optional, such as those related to the complementary information of the patient (birth date, sex, and age) and the studies (referring physician, institution, protocols, and diagnoses), as well as image descriptive information, for example, dimensions, samples by pixel, photometric interpretation, and gray-level window.

There should be a unique DICOMDIR file for each DICOM files set contained in a storage media. The DICOMDIR file location is related to the storage media directory organization, and it is commonly found at the root directory. DICOMDIR files help to make fast queries and searches throughout media contained images, without the need for reading whole file sets. Otherwise, searching and browsing images and information

Figure 3. Structure of a DICOMDIR file and its representation in a physical storage media



within file sets becomes an intensive, tedious, and difficult task.

DICOMDIR FILE READER IMPLEMENTATION

Description

The implemented tool enables DICOMDIR files to be opened in order to obtain the most relevant information from the DICOM-file collection they index. This information is organized in a hierarchical data structure, which can be easily consulted, and when coupled to a suitable graphic interface, permits the interactive browsing of the information related to the collection. The implementation was made using C++ language, based upon an object-oriented design that allows new DICOM data fields to be added to the reader. Some DCMTK library classes and methods (DCMTK, 2005) were used to facilitate the searching and decoding of the data contained within DICOMDIR files, thus avoiding the inherent complexity in the handling of the information stored under DICOM standard specifications.

Data Structures

The references to SOP instances contained in DICOMDIR files are linked according to the entities' hierarchy of PATIENT-STUDY-SERIES-IMAGE, which is implicitly established in the DICOM information model, thus establishing a natural correspondence between the hierarchy and a tree data structure. This tree has heterogeneous content nodes that correspond to the DICOM simplified application model (Figure 2), so there are five node types: root, patient, study, series, and image. The entities' relationship cardinality sets the offspring multiplicity, that is, a patient could be object from several studies, whereas each one of them could have several image series.

During the reading of a directory file, all of the file's hierarchical links are traveled, and the related collection file information is gathered for filling the nodes' specific fields, thus building the data tree structure. At the end of the reading process, the tree has the relevant collection information, having a structure similar to that shown in Figure 4. This data structure could be browsed in order to consult the information without the need of accessing the whole file set again.

An approach was considered for the tree structure implementation where the nodes behave

Figure 4. Structure of the data tree structure built by the reading tool

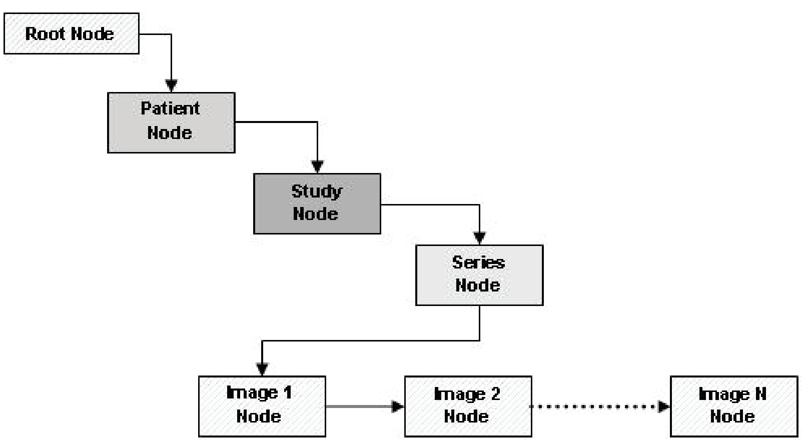


Figure 5. Data tree implementation using linked node lists as data containers

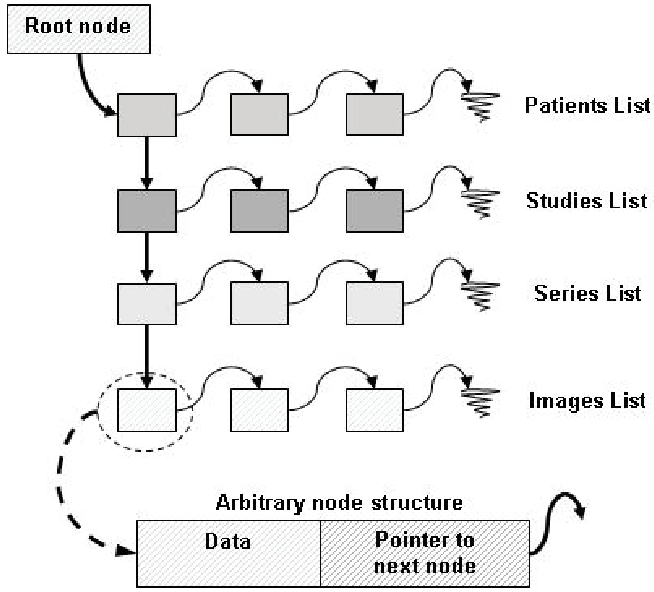

simultaneously as structural elements and data containers. In this way, the nodes establish the tree hierarchical structure and each one of them also stores the information associated to the corresponding entity. Hierarchy levels are made up of linked node lists, and each one of these lists have a children's list, corresponding to elements from the next lower hierarchy level (Figure 5). This approach facilitates the travelling of the tree and its coupling to browsing interfaces.

A class hierarchy was defined for enabling the nodes polymorphic handling through virtual methods. In this hierarchy, the base class, DICOMDIRNode, defines the basic structure for the other nodes, as well as the virtual methods for accessing and travelling the tree. All subclasses deriving from it, that is, DICOMDIRRootNode, DICOMDIRPatientNode, DICOMDIRStudyNode, DICOMDIRSeriesNode, and DICOMDIRImageNode, redefine their contents and behavior according to the corresponding DICOM application model entity to which they belong.

Collected DICOM Data Fields

DICOM files contain rather large data-element groups that are cataloged in the DICOM data dictionary (NEMA, 2004d). However, not all of these elements are useful in the scope of software applications that handle medical images, and for that reason, a selection of relevant elements was made in order to limit the number of data fields gathered during the DICOMDIR files reading process. Table 1 shows the collected data fields with their tags, value representations, multiplicities, presence attributes, and corresponding DCMTK classes and C++ standard types.

One selection criteria for the data fields is based upon the information provided by the image processing. Among the selected fields are the image dimensions, the samples per pixel number, and the gray-level window. Another criterion is the general information that guides the user during the search and selection of images, for example, patient's data, description, and modality of the study. Complementary fields that do not provide significant information for the image processing or to the user applications were not used for the gathering process, for example, address, occupation, and medical antecedents of the patient, and the technical information from the image acquisition devices.

Reading Process

The reader uses Algorithm 1 for the DICOMDIR information retrieving process.

It can be observed that in this algorithm starting from the parent nodes, each tree node and its children's nodes are recursively travelled, level by level, until reaching the deepest tree level. Only nodes from PATIENT, STUDY, SERIES, and IMAGE types are taken into account, though it is possible to extend the consideration to other types of nodes. For each visited node, the selected fields are compiled according to the node type (see Table 1). However, as explained in the DICOMDIR File Format section, not all the fields have an obligatory presence inside the DICOMDIR file, therefore the missing information must be completed from the corresponding DICOM image file, once its file identifier is known.

Some methods from the DCMTK library are used to travel through the DICOMDIR structure and retrieve its data. These methods can handle

Table 1. DICOM attributes compiled during DICOMDIR file reading process. Attributes are grouped by node type, showing main DICOM data fields and corresponding DCMTK/ C++ data types for each one of them

data elements encoded either in *big Endian* or *little Endian* byte ordering, or with any kind of representation values and cardinalities. The retrieving methods are invoked by the data element tag each time a node is visited, whereas the travelling methods are used during recursive calls to the tool's main reading method.

RESULTS AND DISSCUSSION

The DICOMDIR reader was integrated for its test and validation into software for neurosurgery and brachytherapy planning, developed with the VVM library (Montilla, Bosnjak, & Villegas, 2003). A graphical interface was coupled to the reader in order to enable the navigation of the information in a simple way. By just opening the associated DICOMDIR file, users will be able to have the interface display the patients' study images and

Algorithm 1.

```
Open DICOMDIR file for reading
Assign DICOMDIR file root register to NODE variable
With NODE, do recursively /* Begin of recursive block */
{

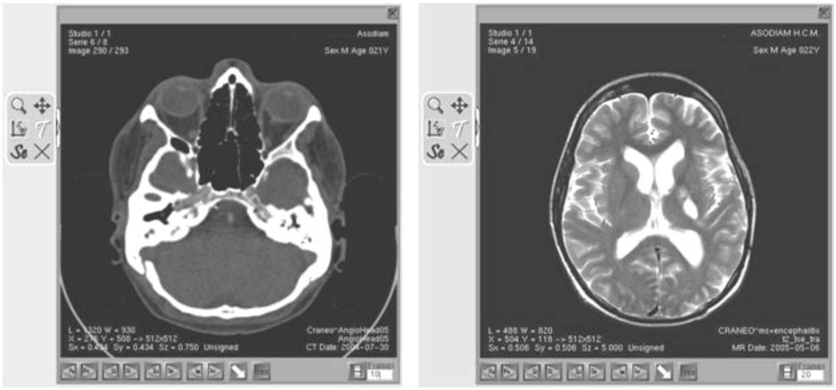
        Select according to Next_Register type
        {
        Case PATIENT:
                  Get patient node related information
                  Create a new DICOMDIR_PatientNode node object
                  Fill node members with gathered information
                  Insert node in the data tree
                  Assign Next_Register to NODE
                  Call recursive block with new NODE value
Complete missing patient information extracted from related image file
        Case STUDY:
                  Get study node related information
                  Create a new DICOMDIR_StudyNode node object
                  Fill node members with gathered information
                  Insert node in the data tree
                  Assign Next_Register to NODE
                  Call recursive block with new NODE value
Complete missing study information extracted from related image file
        Case SERIES:
                  Get series node related information
                  Create a new DICOMDIR_SerieNode node object
                  Fill node members with gathered information
                  Insert node in the data tree
                  Assign Next_Register to NODE
                  Call recursive block with new NODE value
Complete missing series information extracted from related image file
        Case IMAGE:
                  Get image node related information
                  Create a new DICOMDIR_ImageNode node object
                  Fill node members with gathered information
                  Insert node in the data tree
                  Assign Next_Register to NODE
                  Call recursive block with new NODE value
        }
        Assign NODE next child to Next_Register
  }
}                 /* End of recursive block */
```

Figure 6. Results achieved from the integration of the DICOMDIR reading tool into a medical application for neurosurgery planning. The tool is coupled with a graphical interface for browsing throughout studies, series and images.



their related medical information. Control widgets provided by the interface were used for interactively browsing and selecting the images.

The reading process was verified with DICOMDIR files associated to several image sets, coming from studies of CT and MRI performed on different patients. It could be proved that the reader recollected the information specified by the class definitions for each type of node, enabling display of its structure through the interface. Two examples from the tests are shown in Figure 6. In both examples, the studies were made on the patient's head but with two different modalities. The CT study has an eight-image series, whereas the MRI study contains 14 images.

It was observed that access to the information collected from the studies can be made in an organized and fast way, making transparent the navigation process of data structures and improving the efficiency in the use of the software. The tool is able to be integrated with other applications under development that require the handling of DICOM images and DICOMDIR files.As is usual in software projects implying code reusability, benefits from using our tool are going to be directly reflected in ease and speed of development.

CONCLUSION

The design used for the DICOMDIR file reader allows the medical application programmer to effortlessly incorporate the feature for the handling of this kind of file in software under development. Also, it avoids exhaustively understanding the DICOM standard and DCMTK classes and methods, which can be really hard and bothersome, enabling the programmer to focus on the integration of the tool into the application, as well as on the development of a navigation interface, according to the application's needs. Because the reading tool has open-source code, it can be reused and modified at will by the programmers. In addition, the design used for the tool development enables inclusion of new data fields to the presently used entities, as well as to add other information model entities to the data tree structure.

By integrating the tool into a medical application that handles DICOM image sets, it was proved it facilitates the browsing and searching of the information contained in the image sets, accelerating the fulfillment of these tasks and improving the efficiency and performance of the application. Open-source programming tools of this type also facilitate the development of medical applications and help to reduce software costs, thus making it more accessible to health institutions, physicians, and patients, particularly in regions where investment in health care solutions is either limited or not a priority issue.

FUTURE WORKS

We are considering the future implementation of tools for converting images from other formats to the DICOM format and for the creation of DICOMDIR files from nonindexed studies files. A tool for anonymization of DICOM fields also could be useful in protecting patient confidentiality during the sharing of clinical data among research teams. We hope that the implementation and subsequent use of this tool set will represent an incremental increase in the efficiency, quality, and speed of development of medical informatics software, producing applications that will be more complete and flexible at same time.

ACKNOWLEDGMENT

The authors want to express their gratitude to Dr. Luis Iván Jara, a neurosurgeon appointed to the Hospital Metropolitano del Norte (Valencia-Venezuela), for providing us the DICOM image sets used for the functional verification and evaluation of the reading tool. Financial support for this research was granted by Scientific and Humanistic Development Council of the University of Carabobo, Venezuela, under project CDCH-UC No. 0461-06.

APPENDIX

Glossary of Terms

American College of Radiology (ACR)/ National Electrical Manufacturers Association (NEMA)(ACR): This joint committee is responsible for the development and maintenance of the DICOM standard.

Acquisition modalities: These imaging techniques and devices provide radiological images from patients' anatomy. Most commonly used modalities are CT (computed tomography), MRI (magnetic resonance imaging) and US (ultra sound).

Application programming interfaces (APIs): A set of specialized functions, class libraries, and tools used by software programmers to facilitate the application development process.

Attribute: A property of an information object represented as a data element.

Big Endian: An encoding scheme where multiple byte values are encoded with the most significant byte first, followed by the remaining bytes in decreasing order of significance.

Browsing interfaces: These mechanisms and widgets provide a way to navigate information within software applications.

Data element: This is a single atomic information unit that is related to a real-world object attribute and is defined by an entry in the DICOM data dictionary.

Digital imaging and communications in medicine (DICOM): This standard establishes norms for handling, storing, and interchanging medical images and associated digital information.

DICOM application model: An entity/relationship diagram used to model the relationships existing between real-world objects within the DICOM standard's scope.

DICOM data dictionary: This is a catalog of DICOM data elements that describes the semantics and contents of each one of them.

DICOM information model: An entity/relationship diagram used to model the relationships between the information-object definitions representing classes of real-world objects defined by the DICOM application model.

DICOMDIR file: This is a unique and mandatory file that accompanies a file set and indexes these files.

Entity/relationship diagram: This is a graphical representation of a set of objects and the relationships existing among them.

Image-based diagnosis: Techniques used by health care specialists to diagnose patients' diseases through analysis of radiological imaging studies.

I**nformation object description (IOD):** This is an abstract definition for real-world objects that share the same properties.

Little Endian: An encoding scheme where multiple byte values are encoded with the least significant byte first, followed by the remaining bytes in increasing order of significance.

Open source: Programming paradigm based upon software engineering principles that pursues software code reutilization to facilitate the development of applications.

Proprietary code: Programming paradigm that establishes that the software applications code is protected and is not available either for modification or reutilization.

Software development kits (SDKs): See APIs.

Service: This is an operation that can be requested for acting over an information object.

Service-object pair (SOP): This is a relationship that is established between an information object and an operation or the service applicable over it.

SOP class: This is the whole set of services applicable over an information object.

Surgical planning: This describes the preoperative procedure where the surgeon determines surgical protocols and approachg trajectories to be followed during the intraoperative stage of the surgery.

Value multiplicity (VM): This is the DICOM data field that specifies the cardinality or number of values existing for a data element.

Value Representation (VR): This is the DICOM data field that specifies the data type and format of values existing for a data element.

Chapter 3.23
Technology in Physician Education

Michelle LaBrunda
Cabrini Medical Center, USA

Jose A. Cortes
Cabrini Medical Center, USA

ABSTRACT

How physicians are trained has been heavily influenced by the advent of the technology era. Technology has progressed faster than society has been able to integrate it. The same is true within schools of medicine and residency training programs. Many technological advances are available to medical educators, and the goal is to make educators aware of the possible educational tools. Traditionally, medicine has been a learn-by-doing discipline. This is becoming less and less acceptable in modern society, and new training methods are being sought, developed and implemented. Some of the modalities available to medical educators include intranet, hand-helds, virtual reality, computerized charting, computerized access to information and electronic monitoring student education. Technological advances in medical education have their uses, but there are also many drawbacks, including hardware limitations, computer failure, security issues, patient confidentiality issues, property rights, maintenance and poor attitude of those required to implement new learning systems.

INTRODUCTION

In the United States (U.S.), more than $810.7 billion per year is spent on medical expenses (Agency for Health Care Research and Quality, 2005). This is about 8% of our entire gross national income. Technological improvements have allowed for significant advances in all aspects of medicine, which aid in saving many lives each year. However, this same technology is associated with the rising costs of medical care. How this $810.7 billion is utilized within the health care system is largely determined by physicians. A physician in training is taught to use a specific, methodical thought process as part of his or her training. First, all possibilities, even the improbable ones, are considered. The most likely causes of a problem are determined and the best diagnostic tests to verify or disprove clinical suspicions are done. Only then is treatment determined and a course of action implemented. The tremendous infusion of technology into the medical field has complicated physician training by making available a plethora of diagnostic and testing options. Medical educators are faced with the challenge of appropriately integrating technological considerations into a fledgling physician's clinical thought process. This challenge is further exacerbated by the need to educate physicians to utilize appropriate technology in training and in practice among patients from a multitude of educational, cultural and linguistic backgrounds. In a nation where hospitals and medical centers must serve the needs of an enormously diverse population, it is important to be aware of the interaction of medical technology and culture.

This chapter describes the structure of medical education and the way technology is being used in the education of physicians. It discusses some advantages and disadvantages of technology in medical education and how these technological advances may impact a culturally diverse population.

BACKGROUND

It has been difficult for the medical education community to keep pace with the ever more sophisticated technologies developed on a seemingly weekly basis. There are more and more tests that can be ordered, increasingly innovative procedures that can be performed, and the emergence of new treatments that can be offered. Keeping in mind that all medical interventions have side effects, some of which are predictable and others not, where is the line to be drawn between what is medically warranted and what is too invasive, too unlikely or too expensive? As a physician, these issues must constantly be addressed, and often, a concrete demarcation does not exist. Promoting skill in the use of decision-making technology while continuing the intense depth and scope of traditional physician training is a major challenge facing medical educators today. Technology is seen in all facets of medical education, and it affects medical students on at least two levels. First, in the continually evolving world of medicine, students must not only be aware of new advances but must also learn when to apply them. Second, technology may be used to assess the quality of training or to evaluate the learning and performance of a medical student. An intranet, personal digital assistants (PDAs), virtual reality and computerized charting, as well as other available technologies, have the potential to revolutionize not only the way medicine is practiced, but the way it is taught, as well.

Medical technology, however, is not without some controversy. Unfamiliarity of some patients with the imposing appearance of even common technologies does little to promote a healthful and healing experience. While technology is generally touted as a marvelous educational and diagnostic tool, it can also have the effect of interfering with the learning process of a physician in training. Physicians must be able to function effectively while utilizing the latest technological innovations; custom and language cannot be barriers. It is equally important, however, that physicians be able to function effectively without an abundance of technological gadgetry. Verbal communication is still the cornerstone of the patient-physician relationship, and all too frequently, this relationship is sacrificed on the altar of technological advances.

It is important to remember when training physicians that emergency situations often arise at places where the latest technology is not readily available. Although there are many benefits to using technology over more invasive, traditional methods of diagnostic assessment, treatment and diagnosis of patients is trending toward an over-reliance on technology. This over-reliance is being perpetuated in the way medical students are being trained. The medical education community must determine how to most effectively optimize the use of technology without forgetting to look at the face of the patient on the other side of the device; in other words, how to practice the science of medicine without losing the art of medicine. The art of medicine includes empathy, communication skills and bedside manner. This is particularly essential in cases where patients do not have a clear command of English and may not have a full understanding of what is occurring. Technology should assist in the utilization of both clinical acumen (the science) and productive patient-physician relationships (the art), not handicap the problem-solving skills of medical students. With time, a proper balance will be found between the integration of technology and traditional medical skills, but the technological explosion has been so rapid that medical educators have been struggling to keep up.

Structure of Medical Education

Becoming a physician in the U.S. is a lengthy process, requiring years of formal education and practical training. First, the student has to complete at least 3 years of undergraduate work, although most students typically complete a bachelors of science degree in a biological science. Next, a satisfactory score on the arduous Medical College Admission Test (MCAT) exam must be achieved. The MCAT is a 1-day exam consisting of multiple-choice blocks of questions on the physical, biological and chemical sciences as well as an essay writing section that demonstrates proficiency in written communication. Once the required transcripts documenting sufficient grade point average have been compiled with MCAT test scores and letters of recommendation, a student wishing admittance to medical school may then fill out the lengthy application form and, if accepted, enter medical school.

Most medical schools are designed so that the first 2 years consist of the basic sciences and the second 2 years comprise the clinical sciences. The basic sciences are the building blocks of medicine, and include subjects such as biochemistry, histology (the study of tissues), pathology (the study of diseased tissue), physiology (the study of normal functioning) and statistics. The clinical sciences can be considered application of the basic sciences. These courses tend to focus on how to examine a patient, the recognition of disorders and diagnosis of disease. They teach skills that bridge the basic sciences and their application at patient bedsides. Courses in legal medicine and ethics are usually included throughout the curriculum and, increasingly, sensitivity to and awareness of cultural diversity is entering the course of study. After graduation from medical school, the medical doctor (MD) or doctor of osteopathic medicine (DO) is granted and the student is considered a physician, but for many, this may only be the halfway point of their education. Most physicians choose to specialize by entering into a residency program. A residency program consists of physicians with minimal clinical experience practicing medicine in a specific specialty under close supervision of more experienced physicians. Depending on the area of specialization, residency may last anywhere from 3 to 5 years. In addition, after residency many physicians choose to enroll in a fellowship program. A fellowship allows a physician to sub-specialize after residency. It is like residency in that a more experienced physician supervises a less experienced one. A fellowship usually lasts 1 to 3 years, but could be longer, and multiple fellowships may be completed by a diligent physician.

To become a physician in the U.S., mastery of academic medical content as well as effective application of knowledge and skill must be demonstrated by satisfactory scores on a rigorous series of medical examinations. Passing scores on four exams are required to obtain a professional license to practice medicine: the U.S. Medical

Licensing Exams (USMLE) Step 1; USMLE Step 2 Clinical Knowledge (CK); USMLE Step 2 Clinical Skills (CS); and USMLE Step 3. Three of the four exams are multiple choice in format and computer based. USMLE Step 2 CS involves actors feigning illnesses and an evaluation of the future physician's ability to interact with a patient, perform an adequate physical exam and determine appropriate diagnostic steps. USMLE Step 3, in addition to the multiple-choice blocks, has a section of interactive case studies that require insightful application of academic knowledge and competent judgment in the assessment of patient treatments. Step 1 evaluates the basic sciences, Step 2 (CK and CS) the clinical knowledge base and skills, and Step 3 the application of the clinical sciences. Additional exams are administered after the completion of residency and fellowship. These additional examinations are not required to practice medicine within the area of specialization, but are required if the physician wishes to be board certified.

The requirements for licensure vary from state to state. All states currently require that the USMLE exams or equivalent be passed. Some require additional years of supervised training, especially if the physician graduated from a foreign medical school.

On July 1, 2003, the Accreditation Council for Graduate Medical Education imposed a new set of guidelines limiting the workweek of physicians in residency to 80 hours. Prior to this date, residents were often required to work many more than 80 hours per week. This exposed them to the largest number of clinical scenarios possible during their years of residency training and maximized the hands-on learning experience. With the new restrictions on resident work hours, new, more efficient methods must be employed to ensure sufficient, practical physician training.

Technology in Medical Education

Traditionally, medicine was a learn-by-doing discipline. This has become less and less acceptable in modern society due to risks associated with inexperience. To cover any possible gaps in the training of resident physicians, new training methods are being sought, developed and implemented. There are a variety of technology modalities through which medical education may be enhanced. PDAs, virtual reality and computerized charting are technologies gaining a strong foothold in the diagnosis of patient ailments, the organization and availability of pertinent patient records and the training of new physicians.

Intranets

Many medical schools and hospitals have installed campus-wide intranet networks. The intranet systems are similar to the Internet except they have more limited access. These local systems provide a structured environment for residents and allow great access to information. This information pertains specifically to issues of importance to medical students. It could be information on schedules, required reading, lecture notes, photographs, or audio and video clips. Since many medical students are off campus for the last year of medical school, these local networks give the possibility of a virtual campus and provide continuity of education (Ward, Gordon, Field, & Lehmann, 2001). Medical tasks now require more processing, communication and transfer of greater amounts of information. Intra-institutional communication systems, such as intranets, are useful in organizing this information. Intranets can allow the most current information on a patient to be immediately available to many people at various sites. This allows laboratory values, radiology results and consultations from specialists to be available to both students and medical workers at the same time. Patient care is increasingly shifting from inpatient to ambulatory care, and training models have not kept up with the change. Hospital settings create a "captive" population from which medical students can learn. As medicine shifts toward a more outpatient-oriented environment, physicians in training have less access to patients undergoing treatment. Intranets make possible a simplified media through which many people may have access to an interesting case while respecting the patient's right to privacy. An intranet has much more utility for medical students than just permitting access to patient information. It can serve as a repository for evaluation forms, instruction, schedules, directory, and as a bulletin board for transmitting important information (Zucker, White, Fabri, & Khonsari, 1998). Intranets increase the accuracy of information, because the data is only entered one time rather than being transferred and transcribed numerous times as seen in traditional paper-based systems.

PDAs

PDAs include the Palm system and Pocket PCs. Both are being used more and more commonly in the field of medicine. PDAs have many utilities in the field of medical education. They allow for quick access to medication information, including drug-drug interactions, diagnostic manuals and medical calculators.

Currently, there are programs integrating physicians' PDAs into the hospital computer system. This permits rapid and accurate access to patient information as well as bedside data entry. Wireless communication is rapidly facilitating communication between health care providers of different departments, even though they are not able to see the patient at the same time. It is common during physician education that a student is only exposed to one aspect of a patient's care. The surgery residents are minimally exposed to a patient's other medical problems, and the medical residents are peripherally aware of the surgical issues. PDA systems allow students and residents to have access to all pertinent information simultaneously. Legibility problems are corrected by the typed format and subsequent errors are minimized. PDAs have other useful purposes in the education of physicians. They can serve as a procedural log. As a log, it has been shown that PDAs have high reliability, dependable data integrity, low data-entry workload and rapid feedback for residents and program directors for residents' procedural experience (Nicolaou & Davis, 2001). They are relatively low in cost, are very easy to use and require minimal or no training. It is clear that soon physicians will use PDAs for prescribing, ordering studies, checking results, capturing charges and dictating notes. Information can be integrated from multiple sites and gives students and residents access to pertinent information, scientific calculators and drug interaction information, and alerts physicians and pharmacists of potential conflicts with medications. Basic clinical guides and medication prescribing information may be stored on PDAs and quickly accessed. This is important, since medical residents are usually responsible for initiating therapy in emergency situations at hospitals with residency programs. PDAs are increasingly being integrated into the hospital environment, and it is important that medical students become confident in employing them as effective tools that provide access to critical information, even when they are not integrated into hospital databases.

Virtual Reality

As technology has progressed, so have the available treatment and diagnostic modalities. The traditional learning-by-doing methodology has become less acceptable as more invasive and delicate procedures are required for optimal patient care. Students are expected to master complex skills with no errors and minimal experience. Medical educators are forced to create options other than practicing on live patients. These alternative options include Web-based education, virtual reality and high-fidelity human patient simulator. An additional benefit of this training is the ability to practice patient comfort in the presence of technological devices. Care for the patient includes more than just the application of modern technologies. A patient's background, experience and command of English can have a significant influence on his sense of well-being during treatment and can affect the success of an important procedure. A trusting patient-physician relationship is especially important when working with patients with different cultural and linguistic backgrounds.

One of the most promising types of virtual reality is called augmented reality. Augmented reality consists of superimposing a virtual world on the real one so both are experienced simultaneously (Vozenilek, Huff, Reznek, & Gordon, 2004). For example, a virtual image of a complicated fracture may be superimposed on a patient's leg, allowing a surgeon to "see" the broken bone before beginning a surgery. Fluoroscopy is an X-ray that may be taken during surgery. It has many applications, most of which are related to placement of external devices into the body. Fluoroscopy allows the position of these devices to be observed and adjusted while a surgical procedure is still in process. The disadvantages include radiation exposure of medical personnel and patients from the fluoroscopy machine and poor quality of fluoroscopic images. Continuing with the broken leg example from above, virtual reality allows a surgeon to take an initial set of fluoroscopic images and load them into a virtual reality program, then observe an image of the broken bone projected by the virtual reality simulator. These virtual images can be used during surgery to obtain proper alignment of the bones while minimizing radiation exposure. These true life images can be recorded and used by medical faculty for educational purposes while avoiding exposure of students and residents to radiation (Gruntzner & Suhm, 2004).

Most virtual reality has been designed with particular surgical specialties in mind, although some are also useful for emergency medicine. Many of these virtual-reality systems have been designed with the goal of producing high-fidelity patient simulators that can give realistic tactile, auditory and visual stimuli. Full-body simulation allows physicians to practice procedural skills with no patient risk. Immersive simulators are emerging that may also be useful in emergency medicine. They provide a complete computer-generated environment, not just a specific portion of the environment, which allows for organized team simulations (Vozenilek et al., 2004; Medical Readiness Trainer Team, 2000).

Medical schools in the field of psychiatry are also beginning to integrate virtual reality into their programs. One of the treatments for phobias is to gently expose a patient to that which he or she fears. Traditionally, this was done through photographs and visualization techniques. Virtual reality is being used by many psychiatrists as part of the treatment regime. Immersing a patient with a phobia into a virtual simulation requires a delicate approach, and medical students clearly must be adequately supervised and trained (Krijin, Emmelkamp, Olafsson, & Biemond, 2004; Klinger et al., 2005). Rehabilitation medicine is also adapting virtual-reality training to assist recuperating patients. Virtual reality enables patients to try motor skills without risk of injury. Although there may have been some initial doubt as to the effectiveness of this treatment, it has been shown that patients can learn motor skills from virtual reality (Holden, 2005). Medical students need to be aware that these types of rehabilitation options exist, and rehabilitation residents should have some exposure to virtual rehabilitation as part of their training.

Simulated patients made out of electrical conductors, computer chips and circuits all wrapped in a thin layer of plastic emulating human skin have been designed for use in training medical personnel in various diagnostic simulations. There are a number of types of these patient simulators and each is designed for educational accommodation in a specific medical area. They may be used to learn how to place IVs, for auscultation of heart sounds and for practicing management of a patient whose heart stops, among other uses. Depending on the model, different degrees of reality are mimicked and students can practice procedures related to both common medical situations and emergencies. Interactive patient simulators allow students to learn to anticipate common reactions, avoid common mistakes and become acquainted with high-risk, adrenaline-filled situations in a safe environment.

Integration of simulators into medical programs is becoming more and more common, but is still a slow and expensive process. Currently, robotic surgeries are being done and robotic surgery simulators are being implemented in a number of programs. Both in the simulator and during the real surgery, robotic arms are controlled at a console. The advantage of the simulator in this case is that the simulator can be set on record mode and can give feedback as to whether or not the surgical movements were safe. Also, alternate options and approaches can be explored by the physician. What would have happened if X or Y had been performed are questions that cannot be answered using patients as practice subjects, but simulators can answer these sorts of questions. Currently, each surgical robot costs about $1.2 million (Conn, 2004), but as technology advances the price will drop, making these robots available to more training programs.

Pulmonologists who train on bronchoscopy simulators are just as fast and competent as someone who had done several bronchoscopies on human subjects (Conn, 2004). It can be inferred from the very limited amount of data available that high-quality patient simulators would decrease the number of procedural complications by allowing physicians with less experience to master difficult skills in a non-life-threatening environment. It is possible that as technology progresses, simulator training will become so integrated into the medical system that it will become part of the certification process for medical specialties that require procedural skills. In fact, expertise with video games has been shown to enhance surgeons' skills. Surgeons who spend more time on video games work 27% faster and make 37% fewer mistakes than those who do not (Conn, 2004).

Computerized Charting

Currently, many hospitals are converting from a paper-based charting system to computerized patient tracking. Electronic medical records give medical staff easy access to all patient information at one site. The information can be accessed from computers throughout the hospital or from physicians' PDAs. In hospitals, there is often difficulty assembling all pieces of information relevant to a patient because there are a number of different departments and sources of information involved. Specialists are consulted, radiographs taken and blood work drawn, and decisions are made by a number of different medical services. A large portion of a student physician's time may be spent trying to get all relevant information together in one place at one time for any specific patient. To provide the optimum care, access to information from a patient's previous admissions should be readily available and consulted. Computerized charting gives students and residents access to all relevant patient information, allowing for a more comprehensive understanding of each case. From an economic standpoint, computerized charting saves money. It decreases the rate at which diagnostic tests are inadvertently repeated on the same patient, helps prevent tests from being performed on the wrong patient or at the wrong site, and generally decreases the total length of hospital stay. Medical education must include training for students in how to deal with financial issues within the hospital as well as in the outpatient clinics if the future physician is to achieve economic stability. Part of this training should include how to utilize computerized charting to manage patient care in an expedient, practical and economical form.

Another technological advance is the picture-archiving and communication system. This system allows x-rays and other radiological studies to be viewed on computer rather than via printed films. A picture-archiving communication system makes it easy for students to compare films from various patients with similar diseases or from one patient over a period of time, both of which are important in clinical diagnoses as well as in learning to read radiological studies. This system is slowly being integrated by many institutions and is preferred by physicians over regular films (Nissen, Abdulla, Khandheria, Kienzle, & Zaher, 2004).

ACCESS TO INFORMATION

The current model in medical education is the mentored student. In this model, the one with least experience is responsible for undertaking all the responsibilities of patient care. When a challenge is met that the student/resident is unsure how to handle, he or she contacts the next higher-up doctor in the chain of command, and so on. On rounds, the physician with the most experience takes time to go over the individual cases and redirect medical care if needed.

This system presents a number of difficulties. Recently, there has been a move towards treating patients in a more outpatient environment. There are fewer hospitalizations, so physicians in training have less access to patients. Conversely, these patients have significantly less opportunity for treatment from a senior or highly experienced physician. The tolerance of mistakes in medicine is zero. In an effort to reduce medical mistakes so the number of errors is as close to zero as possible, physicians with more experience may be reluctant to allow residents to manage their patients. Physicians at various times are expected to care for their patients in the hospital, see patients in their office, supervise residents, perform and publish leading-edge research, and write grant proposals that bring funding to the hospital. Often, one or more of these services is performed with no compensation. The demands on a physician's time are enormous and seem to be increasing all the time. Physicians have less and less time to devote to supervision and teaching. Because of the new direction medicine is taking, all learning opportunities must be fully utilized and new learning opportunities made available. One way to maximize the learning process is through improved access to information. The paperless charting systems, intranet and PDAs already mentioned are examples of improved access to information, but other information modalities are available. For example, sound and video clips may be integrated into presentations. Some computer systems even allow for interactive videos (Nissen et al., 2004). A newer approach to teaching medicine is problem-based learning (Ward et al., 2001). Problem-based learning is different from the traditional approach to medicine in that a specific problem is simultaneously addressed from multiple vantage points. Environmental, behavioral, nutritional, social, economic, cultural and religious factors can be taken into consideration, as well as any obvious medical problems. Technology allows a single problem to be addressed from many perspectives. Chat rooms and video conferences allow experts from various fields in geographically distant locations to interact with each other, provide consultation advice and give feedback to medical students (Whitcomb, 2003).

A shortcoming of many medical education programs is the failure to treat medical students as adults (Barnete, 1995). A student's unavoidable and inevitable lack of experience is sometimes confused for ignorance. Partially because of this attitude, and partially because of the sheer amount of material that must be mastered, students are increasingly finding the lecture-based method of education unsatisfactory. Strømø, Grøttum, and Lycke (2004) showed that the introduction of computer-supported, problem-based learning systems had a positive influence on student learning. The students tended to increase their use of Web-based resources, expand their interaction with experts and lessen the use of textbooks, which are often outdated by the time they are in print (Strømø et al., 2004). Lectures can be informative, but applying skills and knowledge to case studies and interactive simulations can be much more meaningful and effective. Health care professionals must continually learn new skills, procedures and diagnostic techniques. Education never actually ends. Physicians must frequently update their knowledge base and train in new techniques. Modern communication and computerized learning tools help achieve these goals (Zak, 2004). In addition to requiring re-certification exams, many states also require practicing physicians to participate in a program of continuing medical education credits. These credits are becoming increasingly available through Web-based teaching environments. This makes both delivering and receiving the required medical education credits easier and more flexible. These more accessible educational credits may help improve compliance of physicians with the credit requirements. This requirement also offers opportunities for residents and physicians to enhance their knowledge of how cultural and religious traditions among diverse patients can impact medical treatment, and how best to respectfully and appropriately treat an individual rather than a disease or disorder.

MONITORING STUDENT EDUCATION

Computer technology can be used to directly monitor students' progress through their academic studies. There are numerous computer applications available, such as access to journal articles and abstracts, downloadable textbooks and drug information databases that can be consulted to improve educational outcomes and enrich the educational experience. Also, problems that result from poor penmanship are avoided. Presently, when one medical shift changes to another, a process called sign-out occurs. During sign-out all relevant patient information and a to-do list is passed from one shift to the next. It is done by medical residents, attending physicians, nursing staff and anyone else responsible for patient care. Medical mistakes may result if important information is not transmitted correctly or is forgotten by either shift. Technology, especially PDAs, allows for electronic sign out. Specific data on each patient may be transferred electronically. A resident, especially during off shifts, may be responsible for the well-being of 50 or more patients, often on different wards. Electronic access to basic patient information, such as a list of medical problems, current medication list and any active issues (such as a blood transfusion, for example) minimizes the risk of medical errors made due to lack of information on a specific case. In addition, electronic sign-out allows alarms to be set, reminding on-call residents of tasks that need to be done or patients that need to be checked.

Databases can be accrued for each student that monitor clinical experience and ensure that students receive comprehensive training. Students can enter patient contacts and residents can log procedures into PDAs for easy evaluation, allowing any omissions in education or experience to be identified (Fischer, Stewart, Mehta, Wax, & Lapinsky, 2003). Additionally, computers and PDAs can be used in data collection for research. Every year, more than 2 million medical journal articles are published (Hancock, 1996). This is in addition to the existing base of medical knowledge. Medical educators are already maximizing the amount of information that a student can learn in the amount of time allotted. It is impractical to extend the length of time of medical training, so methods of being more efficient must be evaluated. Technology plays a primary role in this trend toward greater efficiency.

DISADVANTAGES

People today are living longer lives than ever before, and the productive period of those lives has been greatly extended. Survival rates of the ill or injured are at an all-time high. A major contributor to this happy state of affairs is technology. This includes not only technology for diagnostic and treatment purposes, but also innovations used for development of medications and training of highly capable physicians. Technological advances have led the way to many improvements in modern medicine. However, there are also drawbacks to a dependence upon technology. These include hardware and software limitations, computer failure, security issues, patient confidentiality issues, property rights, maintenance and poor attitude among those required to implement new learning systems (Ward, Gordon, Field, & Lehmann, 2001). Currently, one of the primary problems in medical technology is lack of bandwidth. Adequate bandwidth is required for proper data transfer (Fischer et al., 2003). Also, the resources required to develop a specific technology can be prohibitively expensive (Whitcomb, 2004).

Technology is not without patient risk. Risks and costs are often underemphasized in medicine for financial and social motives (Schroeder, 1981) or because the health care provider underestimates or is unaware of the risks associated with a given technology. For example, a full-body computed tomography (CT) scan has a 0.08% chance of causing cancer (Brenner & Elliston, 2004). Students must be well aware of the potential side effects of all diagnostic procedures and treatments, and must learn to convey this information in an understandable manner to the patient.

As the health care industry evolves, the demands on physicians continue to grow, and time constraints in the physicians' day are surfacing as a common and worsening problem. In order to adapt to new technologies directed at enhancing medical education, instructors must spend additional time learning the technology themselves. Extensive training may be required of physician educators to gain adequate mastery before introducing procedures to students. Many health care professionals simply do not have time to devote to this requirement. Medical education includes extensive role modeling and learning through observation. It is through this role modeling that students learn bedside manner and communication skills with both patients and other physicians (Zucker et al., 1998). The introduction of many of the technologies previously described decreases the amount of role-model learning and peer interaction. Strømø et al. (2004) showed that the introduction of computer-supported, problem-based learning made students' attitudes towards cooperation more negative, making them less likely to work together (Strømø et al., 2004). Technology that decreases role modeling could hinder the acquisition of patient-doctor interaction skills. This may be particularly significant in treating those whose linguistic abilities limit their ease of understanding physicians and procedures in the first place.

The medical field tends to attract science- and technology-directed thinkers, but these individuals may not be the best people for treating a patient in a holistic manner. In medicine, there is a need to treat the whole patient, and treatment often includes behavioral modifications. The vast majority of disease is preventable through proper diet, regular exercise, not smoking, consuming little alcohol and safe sexual practices. It seems most people are not taught good habits as children. Changing behavior to promote healthy lifestyles does prevent disease. Behavior modification requires educating patients so they are convinced they need to change bad habits. As technology becomes more advanced, the tendency is toward a deterioration in close patient-doctor relationships, which can result in lessening ability to persuade patients toward long-lasting behavioral changes. In addition, patient diversity is greater than ever, and medical students might never learn proper communication skills that allow them to influence their patients' choices. Preventive medicine is the discipline where the greatest impact can be made in improving overall health. The science-geared minds frequently attracted to medicine tend to be less interested in preventive care than in the challenges of curing disease (Clawson, 1990). To adequately apply preventive medicine, social, cultural, ethnic and behavioral factors affecting a patient's life must be weighed equally with scientific knowledge, or the desired change in patient attitude or behavior is less likely to occur. That is to say, someone with a solid grounding in patient care and communication skills but possessing minimal clinical knowledge can have a more profound impact on long-term health of a patient than a doctor with outstanding clinical knowledge who lacks interpersonal skills. As technology increasingly enters into the educational process there, is the possibility that health care providers may continue to become more science-centered and less person-centered.

Medicine is taught as both an art and a science. The science in medicine is obvious, but the importance of non-scientific factors within the field of medicine is underestimated by both medical personal and the lay person. Traditionally, doctors accept a sick person as a patient and then try to treat the medical condition. The best doctors also identify risk factors for disease and try to prevent disease. The preventive branch of medicine includes vaccination, smoking cessation programs, diabetes screening and education, weight loss promotion, nutrition counseling, regular Pap smears and exercise consultations. Communication, not technology, is required for disease prevention. Medical technology becomes important primarily when prevention has failed. The art of medicine requires physicians to learn how to conduct an interview with an endless variety of patients in a non-judgmental format. This puts the patient at ease with him or herself and the physician. The interview must follow a well-organized format, so relevant medical information is extracted and a trusting doctor-patient relationship is forged. Technology may misguide inexperienced physicians and medical students into forgetting that it is the subjective symptoms of the patient that first and foremost lead to the correct diagnosis. Only with this basic piece of information clearly in mind is the physical exam and laboratory data of any value. The principle skill used in clinical work is problem solving. Medicine is like detective work. First, information must be obtained from the patient and his or her family. Next, that information, which may or may not be completely accurate, has to be combined with the physical exam, laboratory and radiology studies. A physician must be able to combine all the information, look for the source of the problem and determine possible treatments, then select the one most suitable for the individual patient. Technology is a master at providing useful information, but the physician must solve the problem (Clawson, 1990). With the pervasiveness of advanced technologies, there is a risk of over-reliance on computer-generated information and an under-emphasis on transmission of thinking and problem-solving skills.

An additional problem with technology is equitable application; economically underprivileged patients often have a medical disadvantage. However, there is a tendency when new technology is found to be advantageous to utilize that technology at every promising opportunity. Over time, the expense of the technology is spread out over many patients, and the price gradually decreases, making it available to more people. During the price-dropping interim, the poorer population may have less access to cutting-edge technology. The medical residents and students who train in facilities serving a lower socioeconomic population will also have less opportunity to work with high technology, resulting in a potentially poorer education.

Other problems exist associated with the integration of technology into medical education. One of these is that students are sometimes more experienced with common technologies than their teachers (Salas & Anderson, 1997). Or, sometimes educators lack enthusiasm for new technological concepts and this is inevitably conveyed to the students (Moberg & Whitcomb, 1999). Occasionally, technology projects are promoted by an individual instructor who leaves that teaching position and the technology component falls by the wayside, which indicates a lack of long-term support and organizational interest (Barnete, 1995). In addition, it is very expensive to fund medical education, and most of this expense is shouldered by the student physician. It is a problem if the cost of medical education sees a significant increase due to more technological requirements (Jones & Korn, 1997). Educating future doctors is a difficult task. Technology provides an almost limitless number of directions educator can pursue. The key is to be aware of available options and the advantages and disadvantages of each, and choose the options most likely to provide long-term educational benefit to the educator, future physicians and the great diversity of patients whose lives this physician will impact. It is inevitable that technology will play a vital role in medical education, and educators must be ready for the challenge.

FUTURE TRENDS

There is much promise on the horizon in medical technology. Technological improvements include better organization of data and improved access to information; collegial exploration of ethical, cultural and social issues; improvements in communication and consultation capabilities; an increase in online educational opportunities; and the evolution of medical technology itself.

One of the major problems in the utilization of technology in physician education is organizing the amount of available information into a usable format. The organizational systems available are lagging behind the technological advances. An expanding number of organizational systems to enhance a physician's ability to effectively utilize technology will be emerging in the near future. One method the medical community has employed to help assimilate and utilize the body of available information is through an approach called evidence-based medicine. Evidence-based medicine is relatively new and operates by collecting all the available research studies on a topic, rating them according to their quality and combining them into one easily accessible location so the work can be summarized and meaningful conclusions can be drawn from the combined findings of all the studies. This is a large change from the mentor-based system, where medical traditions were passed on, often without question, from one generation of physicians to the next. There is considerable enthusiasm for evidence-based medicine. It helps to provide optimum care for patients, and in the future is likely to become even more well known.

Future applications of medical technology contain a number of ethical issues, and the study of ethical implications is already on the rise. Ethics is generally an understudied aspect of technology, because there is little to be gained financially by research sponsors. Ethical issues will play a growing role in medical education as technology and the procedures that technology makes possible continue to evolve. Stem cell research, deoxyribonucleic acid (DNA) testing, preserving the lives of comatose patients indefinitely and replacement organs for treatment of the elderly or infirm are but a few of the issues already at hand, and the list is growing daily.

Newer, faster, smarter, better, smaller, more powerful and so forth are descriptions anticipated in the future of medical technology. In general, physicians and medical students even in the near future must be prepared to work with computers in ways we can hardly imagine today. The trend is a move toward exclusively electronic data storage and retrieval in all aspects of patient care. Basic keyboarding, once a class only for secretaries, is now one of the most important preparatory classes a student can take. Even now, it is often being taught in elementary school, where traditionally it was a high school course. Innovative technologies emerge more rapidly than an educator can master, so training must focus on basic technological skills with an accent on thinking logically and adapting creatively to new circumstances.

It is becoming apparent that the federal government may have a greater regulatory hand in technology and its application in the future. At a national level, the U.S. government is proposing standards for health information technology (HIT) and backing it up with legislative proposals. The National Health Information Incentive Act of 2005 aims to facilitate the development and adoption of national standards in health technology, provide initial financial support and ongoing reimbursement incentives for physicians in smaller practices to adopt the HIT policies, and support quality improvement activities (ACP Press release Feb 11, 2005). The National Nanotechnology Initiative (NNI) (www.nano.gov) is a federal research and development program established to coordinate the multi-agency efforts in nanoscale science, engineering and technology. The goals of the NNI are to maintain a world-class research and development program intended to realize the full potential of nanotechnology, and to facilitate the transition of new technologies into products for economic growth, jobs and other public benefit. These goals include development of educational resources, training of a skilled workforce, creation of a supporting infrastructure, development of tools to advance nanotechnology and finding ways to support responsible development of nanotechnology. Awards have been given to medical schools and research institutes to establish new research initiatives focusing on creating advanced nanotechnologies to analyze and detect arterial plaque formation on the molecular level in its early stages. Another group has been awarded grants to detect, monitor, treat and eliminate vulnerable plaques. Nanotechnology clearly has a large role in the future of medicine, and is already used for noninvasive imaging and sensing, targeted therapies and drug delivery systems, as well as for treatment of heart, lung, blood and sleep disorders.

At this point, there is limited application for nanotechnology in the training of medical students. The field is in its infancy. It is important though, that students are aware that the technology exists and to understand the tremendous potential it holds in the field of medicine.

CONCLUSION

Looking back to the earliest days of modern medical science, we can see that the progress of medicine, as it evolved from conjecture and superstition into a science of diagnosis and treatment, has been fueled by daring minds that had the courage to question, challenge, explore, postulate new ideas, try new approaches and prove to others the need for change. We have moved from an informal, poorly structured and chaotic system to one that attempts to tie the clinical practice of medicine to the scientific evidence available. Technology has stoked the current momentum and provided a fertile environment that fosters the exploration of new frontiers in health care. During the renaissance period, we ventured into the “inner sanctum” of the human body to learn its anatomy; we printed materials to distribute to others; we expanded knowledge and communicated theory; all of which obligated us to ask more questions. We have moved at the pace our technology has allowed and grappled with serious ethical dilemmas along the way. As a society, we have had to make room in our ideals to evaluate and assimilate current technologies and develop plans for future advances we can only imagine. Those who work as medical educators and health care professionals are obligated to create an ethical balance and provide safeguards for society while preserving life through available technology.

One can only wonder at the expanse of the unknown and where current technology will take us. Medical students are becoming familiar with a virtual world that makes information available immediately. Medical educators are earnestly responding by integration of evidence-based educational tools into the medical school curriculum and teaching early on the need to discern the true quality of the evidence being presented by a publication. This is a life-long skill needed by every physician. Physicians as a group have embraced the concept and practice of intranet, handheld devices, virtual teaching, microsurgery and technology-dependent modalities. Technology will continue to push the boundaries of diagnosis and treatment of diseases and, in the hands of a caring and skilled physician, can foster the treatment of people as diverse, unique individuals rather than emphasizing treatment of disease.

Chapter 3.24
Technology in Primary and Secondary Medical Education

Sarah R. Edmonson
Baylor College of Medicine, USA

ABSTRACT

There is an increasing need for cost control and improved outcomes in both primary and secondary medical education. This chapter reviews the characteristics of medical learners and summarizes shortcomings of traditional medical training that may be amenable to technological intervention. Technologies useful for educating medical students and practicing physicians will be described along with examples pertaining to each technology. The chapter concludes with a summary of potential barriers to the adoption of medical education technology.

INTRODUCTION

Doctors spend the first years of their career completing an intensive primary medical education. Sadly, this primary medical training can become obsolete in a remarkably short time; new products and research constantly change the definition of "best medical practice." Consequently, secondary training—usually referred to as continuing medical education or CME—is also an important component of a complete medical education.

Medical education presents some unique challenges for curriculum design. Further, ample evidence suggests that the traditional medical curricula could be considerably improved upon. In developing new approaches to clinical training, medical educators draw from a rich field of theory and evidence about professional education in other arenas. These generalizations tend to be quite successful when the source material was designed for learners with similar qualities; they can be stunningly unsuccessful when the two learner populations differ. The first section in this chapter describes qualities of medical learners that may be relevant to instructional design, and the following section outlines barriers to successful learning in a traditional medical education setting.

The next section describes technologies that hold particular promise for solving specific medical education challenges. Examples of successful implementations provide concrete examples of these technologies in action. In recent years, a broad variety of technical tools has been employed in an effort to provide cheaper, more accessible, and more effective medical training. However, the application of technological tools in medical education is not without controversy, and the chapter closes with a discussion of some barriers to medical education technology implementation.

THE MEDICAL LEARNER

As noted, medical education begins with an intensive primary training and ongoing learning that continues throughout the physician's career. Medical learners at any stage share some common characteristics, but important differences between the two groups may influence which educational approach is most successful.

DEFINITIONS

Primary medical education describes the period in which the future physician builds a knowledge base *de novo* and learns to apply that knowledge effectively (D'Eon & Crawford, 2005). Learning tasks during medical school are both didactic and experiential; the student absorbs a fund of knowledge and also masters a repertoire of procedural skills. Generally, the student begins with a heavily didactic courseload, which transitions to a primarily experiential curriculum by the end of his training.

Secondary medical education refers to the ongoing efforts of a practicing physician to renew and update his or her knowledge and skills. Because medical practices change over time, most licensing organizations require doctors to complete ongoing medical education—although the content and format of this education is often not specified. Thus, the main educational tasks a practicing physician faces are the identification of knowledge deficiencies, and the selection of appropriate training to correct those deficiencies (Curran & Fleet, 2005). In response to that need, the physician will find a selection of continuing medical education programs offering a variety of educational content and structure.

The formal medical education process begins with university and/or medical school, then proceeds through a series of additional training steps, which may include internship, residency, public service, and fellowship training. At some point, a transition from "medical student" to "doctor" occurs. Studies of the medical education process suggest that the transition occurs as a dramatic step, rather than a gradual evolution (Prince, Van De Wiel, Scherpbier, Can Der Vleuten, & Boshuizen, 2000). Unfortunately, the exact timing of this transition is unclear and may differ from student to student. Thus, one of the major challenges in medical education is determining whether an educational tool should be optimized for the primary or secondary learner.

Common Characteristics

For both primary and secondary medical training, the designer can count on at least some commonality among medical learners. All are adult learners—no nation trains children to be physicians. For most, a record of academic achievement encourages robust self-efficacy for medical learning tasks. The direct applicability of the material provides an inherent motivation to learn. And, the learning content is all drawn from a finite, if large, pool of knowledge.

Considerations for Primary Medical Education

Superficially, curriculum design at the medical school level is simplified by a reasonably uniform body of learners and by a fairly universal curriculum. The core material to be mastered does not vary significantly, and standardized testing is available for measuring how effectively this material has been taught. Learners share similar educational backgrounds and a common career goal; in addition, medical students are typically people who have previously demonstrated high levels of motivation and academic skill. The students also share similar levels of ignorance at the outset. Unfortunately, a truly generalizable primary medical curriculum must account for many types of diversity, which may influence the effectiveness of a learning tool both within an institution and between institutions. In the United States, medical school is a post-secondary degree. Globally, the requirement for a separate university-level degree is often waived in lieu of a longer medical school curriculum. Thus, medical learners from different nations differ, in maturity and academic experience. The impact of these differences on their response to educational technology has not been well studied. In addition, a student's understanding of the material may be driven by cultural background. Language differences may bias how the material is received. Learning style also varies widely between individuals, an effect that is likely to impact educational effectiveness (Cook, 2005).

Considerations for Continuing Medical Education

How does continuing medical education differ from primary medical education? In many ways, the established physician's learning task is easier than that of the medical student. New knowledge can be incorporated into an existing framework and assessed based on the doctor's own experience.

The diversity among medical students increases enormously among secondary medical learners, and the task of preparing educational material for this group is correspondingly harder. Physician learning requirements will be driven not only by personality and cultural background, but also by specialty, experience levels, and the unique requirements of individual professional duties (Holm, 1998).

Motivation for learning also changes as the physician's career progresses. Primary medical education provides a feedback structure of grades, teacher assessments, and direct supervision; these mechanisms offer immediate motivation for educational performance. After graduation, the availability of this sort of feedback drops. Practicing physicians cite many reasons for seeking continuing education, including professional responsibility to their patients, curiosity, entertainment, fear of litigation, and maintenance of licensing and accreditation requirements (Dolcourt, Zuckerman, & Warner, 2006).

BARRIERS TO EFFECTIVE MEDICAL EDUCATION

In an atmosphere of increasing concerns about the quality of healthcare, medical education reform takes a prominent role (Bradley, 2006; Harden, 2005). Unfortunately, the most commonly used methods for medical education—including printed materials, lectures, clinical practice guidelines, and opinion leaders—have not been very effective for improving clinical care or patient health (Bloom, 2005; Davis, Thomson, Oxman, & Haynes, 1995). Educational reform will need to address the factors underlying the failures observed with traditional educational approaches: the body of information to be mastered is overwhelming, skill acquisition requires ethically questionable hands-on practice, the learners cannot always be assembled in a central location, and the cost of education is increasingly high.

Information Overload

The body of knowledge required to practice medicine effectively is overwhelmingly large and highly inter-related (D'Eon et al., 2005). In traditional lecture and text-based learning, material is presented in a linear fashion and segregated into discrete subject categories such as anatomy or pharmacology. This approach makes it more difficult for the medical learner to see the relationships between topics. Educational tools that facilitate mastery of large bodies of facts, or that highlight the relationships between topics, would be a welcome improvement. Additionally, if students could master the necessary clinical knowledge more efficiently, more time would be available for instruction in clinical and communication skills (Bradley, 2006).

Hands-On Experience

Medical students must also learn a variety of procedural skills. Like all such things, medical procedures are most effectively mastered with practice—exhaustive repetitions of the same process until it becomes automatic. Two factors make this element of the doctor's training problematic. The first is that the procedures will ultimately be applied to human patients and there are obvious logistical and ethical difficulties with practicing an uncertain skill on real patients. The second problem is the mastery of less-commonly needed skills. The student is in training for a limited number of years, and may not see enough patients who actually need the procedure in question.

Geographic Barriers

Physicians must practice where their patients live, and in some cases patients live a long way from any medical education facility. Often, practicing physicians in remote locations have only limited resources available for their continuing education (Curran et al., 2005). The geographic separation of medical practices and educational facilities has been another strong argument for new approaches to medical training.

While issues of distance and travel have been particularly prominent for doctors seeking continuing education, even primary teaching settings have limited access to training resources in some parts of the world. The "brain-drain" phenomenon—emigration of healthcare professionals from impoverished to wealthier health-care systems—is highly related to educational opportunity since the majority of emigrants initially relocate in order to participate in educational opportunities (Dodani & LaPorte, 2005). Educational tools that can be disseminated worldwide may reduce the rate of emigration, as well as improving training for those who choose not to leave low-resource nations. Educational technology, then, may play a vital role in achieving a globally uniform standard of medical practice.

Financial Considerations

Many innovations in medical education arise from a desire to decrease the cost of clinical training. The primary educational cost is substantial—in 2005, the average cost of 4-year medical school in the United States was estimated to be around \$140,000 for public medical schools and \$225,000 for those private schools whose curriculum is not supplemented by state and national funding (Morrison, 2005). These bills have escalated far in excess of inflation, and 80% of U.S. physicians graduate with debt between \$104,000 and \$140,000 (Morrison, 2005). Continuing medical education costs seem trivial in comparison to those of the primary training, but the expenses associated with arranging facilities, materials, faculty, and time away from a medical practice can add up—particularly for practitioners without easy access to an academic medical center. Logically, the cost of medical care reflects, in part, the cost of training the providers of medical care, so the high cost of medical education translates to higher prices for healthcare consumers as well. Consequently, cost reduction is a major goal of educational innovation at all levels.

TECHNOLOGY MODALITIES PARTICULARLY HELPFUL FOR MEDICAL EDUCATION

Following are descriptions and examples of medical education technologies. Some of these represent improvements on techniques that are already commonly used by medical learners. Others demonstrate adoption of useful educational tools from other industries. All, however, address one or more problems inherent to traditional medical education.

Automated Drilling

Medical students memorize a stunning quantity of facts and figures. Anatomy classes alone introduce hundreds of body structures, each with its own name, function, and location. Clinical terminology is often arbitrary, nonsystematic, and yet essential to the practice of medicine.

Automated tools can be enormously helpful for memorizing blocks of material. Automated flashcard programs are an excellent example of how computerized tools can improve the flexibility and efficiency of a classic learning tool. Electronic cards can be edited and reproduced very easily, offering an immediate advantage over traditional handmade or commercial paper cards.

Flashcards have some inherent flaws and an electronic flashcard tool overcomes many of these flaws. The most important flaw is that in repetitively viewing a set of cards, the student may "learn the card" —generating the answer on the card because of cues about the card itself, such as color, shape, handwriting, or order in the stack. A flashcard computer program can randomly vary card features as well as continuously reshuffling the card order so cues about the shape or color of card do not confound the mastery of the information. The program may also customize instruction to individual learning needs, and adaptively change the current card stack in response to student performance. Accomplishing such tasks with traditional flashcards might be possible, but would be time-consuming.

Games can also be helpful adjuncts to memorization. Software programs that generate crossword puzzles, word-find tasks, and other games can be applied to medical material. Both the creation and the solving of the puzzle serve as learning mechanisms (Bailey, Hsu, & DiCarlo, 1999).

Example: Flashcard Exchange

Flashcard Exchange (http://flashcardexchange.com) is an example of a drilling tool that can easily be adapted to medical learning. The site currently contains hundreds of collections of flashcards, entered by users, covering medical topics from acupuncture to neuroscience. For card review, users can randomize the cards, display them with either question or answer first, sort them according to prior performance, and alter visual features such as font, size, and text alignment. Session performance is reported in table and pie chart format. Cards can also be reviewed by playing a memory game.

In summary, computerized tools can offer additional functionality to improve student drilling on material to be memorized. These programs overcome several educational barriers: they enable mastery of larger volumes of information, are generally inexpensive, can be shared electronically with anyone in the world, and can be edited easily to reflect new understanding. Further, automating the memorization task frees up instructor time for more sophisticated material.

Computerized Tutorials

Brute memorization may help the student pass an upcoming exam, but may be an ineffective approach to long-term learning (D'Eon et al., 2005). In some cases, the task of memorization can be ameliorated by better understanding of the material. So, for example, anatomy terms may be better retained if they are presented in the context of human physiology and medical problem solving (Miller, Perrotti, Silverthorn, Dalley, & Rarey, 2002). Relationships between different components of clinical knowledge may be seen as branching or networked, rather than linear. As a result, the linear format of traditional lecture and text-based instruction cannot entirely represent the material. Further, the constructivist school of adult learning suggests these learners may master the material most efficiently when allowed to navigate the material freely, according to their own curiosity (Harden, 2005).

Fortunately, we can employ technical solutions to allow better representation of the interrelationships between medical concepts. One of the simplest approaches is to indicate, within a block of learning material, where other material relates. Hyperlinked text—text on the screen that, when clicked, connects the learner to a different page with the related information—was quickly recognized as a powerful tool for adult constructivist learning. Within a hyperlinked tutorial student may move freely between discussions or multimedia demonstrations of the anatomic, physiologic, and clinical aspects of the subject matter. New terms in the hyperlinked tutorial are presented in context, but link directly to a glossary. The insights from one domain improve the understanding and retention for the others. Hyperlinked learning materials are relatively easy to design, but are interactive and empowering for the student. As an added bonus, the computer environment easily incorporates tools to track the progress of the student through the material (Hilty et al., 2006).

Example: IVIMEDS

The goal of the International Virtual Medical School (IVIMEDS) is to provide a complete, four-year undergraduate medical education using a combination of e-learning and face-to-face learning with medical educators and institutions all over the world. Founded by a worldwide partnership of institutions, IVIMEDS proposes a 4-year medical school curriculum whose core elements include problem-based and system-based lessons based on a bank of virtual patients and an extensive database of reusable digital learning objects. The learning objects comprise the heart of the IVIMEDS philosophy. Each object consists of a small, discrete chunk of information—perhaps a short block of explanatory text, or a video clip, or an audio file—which can be combined with other objects to create a course of study. When medical knowledge changes, only those objects relating to that knowledge need to be updated. Thus, the program design includes a plan for low-impact maintenance. (Harden, 2005)

In addition, self-directed hyperlinked tutorials are quite simple to deploy to an Internet environment. The availability of such materials on the World Wide Web means that good quality and effective training can be made available globally, alleviating the struggle to provide high-quality education in remote or low-resource parts of the world.

Virtual Reality and Simulation

In addition to absorbing the knowledge base required for effective medical practice, medical students eventually apply that knowledge to real-world patients. Mastery of the facts and figures may not be adequate to ensure that the student will be able to apply the knowledge in the complex, rapidly changing environment found in the hospital or clinic (Hilty et al., 2006). Most students master this synthesis with practice; unfortunately, in order to practice, the lives of real patients are put at risk.

In addition to the practice required for intellectual synthesis, students need to master a set of manual skills. These involve physical examination skills such as using a stethoscope, and procedural skills, such as drawing blood or suturing a wound. Again, skills are only perfected through extensive practice—and how many patients wish to be the subject of a student's practice?

Not only is it ethically questionable to ask patients to submit to the inexperienced hands of an untried student, but the patient supply may also be inadequate for the student's education. For example, a student is fortunate to have a single opportunity to recognize and treat a rare syndrome such as Kawasaki's syndrome in pediatric patients.

Historically, to gain experience that couldn't be ethically carried out on humans, students turned to alternatives—dissecting cadavers to perfect surgery skills, treating animals to understand physiological responses to drugs, and interviewing actors imitating real patients to practice diagnosis and bedside manner. While helpful, all of these approaches have limitations. Actors may allow a student to listen to the heart, but not to administer electric shocks to restart it. Actors also require training, expect to be paid, and can meet with only one student at a time. Subjecting animals to procedures to which no human would consent is ethically troublesome, and furthermore animals differ from humans in physiologically important ways. And, cadavers are surprisingly difficulty to come by, can be dissected only once, and cannot demonstrate all the possible anatomical variants the student needs to learn.

Simulation tools, if integrated into the broader medical curriculum, allow the student to gain those experiences that are difficult to acquire in the real world (Hilty et al., 2006). Simulation may involve simple programs or devices, designed to demonstrate a simple concept. Or, a simulation model may be highly complex, designed to represent the interactions of as many variables as possible.

A well-known example of simulation technology is the life-sized dummies used for cardiopulmonary resuscitation (CPR) (Bradley, 2006). These simple tools allow the user to learn through trial and error how to position the body correctly to administer mouth-to-mouth breathing and chest compressions. Integrated circuitry provides warning lights or tones when the student is not performing the procedures correctly. And, the dummy can be used over and over again by one or many students—unlike actual hospital resuscitations! Higher resolution resuscitation simulations incorporate animated behaviors such as breathing, pulse, or blood pressure, responsive behaviors such as eye blinking, and feedback in the form of changes in the above behaviors as well as visual or auditory alarm systems (Bradley, 2006).

Example: "SimMan" Full-Scale Patient Simulation

The SimMan full-scale patient simulator assists students in practicing anesthesiology procedures and scenarios. Used worldwide, this adult-size simulator not only offers physical representations of the mouth and airway, but also produces breath sounds and chest wall movements, and can recognize and respond realistically to more than eighty types of injected drugs (Gabriel, 2001). Experienced anesthesiologists judged the SimMan tool to be "acceptably realistic" or "highly realistic" in fifteen of sixteen parameters (Hesselfeldt, Kristensen, & Rasmussen, 2005).

Simulations can take the form of interactive case studies, often using the hyperlinked multimedia format described above; physical models with integrated feedback like the resuscitation dummy; or high-fidelity "virtual reality" equipment which may incorporate haptic simulators, eye movement tracking, and highly complex algorithms to simulate real-world events (Bradley, 2006).

Intuitively, learning through simulation should lead to better mastery of the material and the higher the simulation fidelity the better the learning should be. A recent review of the literature on simulation suggested that, in fact, the most successful simulations were those who adopted sophisticated approaches such as feedback, variable difficulty levels, a range of scenarios, and adaptability (Issenberg, McGaghie, Petrusa, Lee Gordon, & Scalese, 2005). Research evidence supporting this intuition remains limited, however, perhaps because the technology to produce high-resolution simulation has only recently been available at a reasonable cost.

Traditional Content Delivered Remotely

Remote delivery technologies offer a chance to vastly improve the educational offerings available to physicians in remote practices. Geographic barriers are particularly formidable for practicing physicians. Medical students live near academic facilities and follow an established curriculum, but medical practices position themselves in proximity to the patients. Traditionally, community physicians receive continuing medical education in two ways: they read printed materials such a journals and textbooks, and they attend educational conferences. Unfortunately, with both of these formats, the content of the education is determined externally; the doctor receives what the editor thought was important, which may not reflect what she actually needed to learn (Curran et al., 2005; Harden, 2005).

Certainly a physician can seek out an educational conference addressing the topics of most interest. However, when the practicing doctor needs continuing education, he must locate appropriate training, schedule time to participate, and, often, travel to the training location--if, in fact, he or she finds an available program about the topic of interest at all. The productivity loss, from time spent traveling to and from the training, increases the overall cost of continuing education dramatically. Thus, remote learning—accessing medical education resources from remote locations—offers a distinct benefit to practitioners.

The simplest form of remote learning is simply broadcast of a traditional lecture session. Providers can observe the session by way of television, radio, telephone, or Internet access points, depending on the technology chosen. For those individuals who are unable to be present at the time of the actual conference, audio or video tapes of educational conference sessions can be distributed, allowing a broader audience to benefit. This mechanism is particularly helpful when the topic under discussion is new or poorly disseminated, so that very few people are qualified to teach it.

However, as previously noted, traditional lecture formats are often a less effective approach for presenting clinical knowledge; adult learners benefit from interactive settings. Interactivity can be incorporated into real-time lecture broadcasts when the technology allows two-way communication. Telephone conference calls, for example, allow the lecturer to invite comment or respond to questions from the audience. As satellite-based telephone and Internet communication become more comprehensive, more and more locations can benefit from this type of offering.

Remote access to traditional lecture and classroom discussion resources does expand the practicing physician's educational options, but does not address any of the inherent flaws in traditional medical teaching. Fortunately, continuing medical education learners may find it easier to follow and retain lecture material, because they often already know part of the material. Their broader knowledge base also makes it easier for them to recognize how new material relates to the things they already know.

Web-Based Learning

Web-based education is increasingly available and popular for continuing medical education (Harden, 2005). Hundreds of sites offer free or low-price "e-learning" about a broad variety of topics. Additional sites list and catalog online continuing medical education resources, so that clinicians can easily find a program that fits their needs.

At minimum, the Internet serves as a useful medium for distributing print materials or recorded lectures to a wide audience. At this level, Internet-based learning already offers obvious advantages. Large numbers of people, in a variety of places, can partake at trivial additional cost. And, learners can access the material when it is convenient for them, allowing them to pursue instruction without disrupting clinical care (Curran et al., 2005).

The best of the Web-based education offerings are pedagogically impressive, offering far more value than mere availability and time efficiency. They present content via multiple media, including text, pictures, audio, and movie clips. They offer interactivity—mechanisms such as self-test questions increase the learner's motivation to pay close attention to the material, and have been associated with improved efficacy in educational technology (Harden, 2005). They can monitor learner progress, and direct the learner to material that hasn't yet been viewed.

Just-in-Time Learning

Theories on adult learning all agree that motivation is highly correlated with successful learning. It makes sense that students would make the strongest effort to learn when they know the material will be immediately valuable to them.

For clinicians, the point at which knowledge is most desirable may be in the clinic at the moment when they realize they don't know something relevant to the patient in front of them. Estimates vary on how often doctors have unanswered questions while caring for patients, but all agree it happens daily and probably multiple times every day (Curran et al., 2005). Thus, integration of learning resources into the clinical workflow—"just-in-time" learning—appears to be an excellent opportunity.

Just-in-time learning can take two forms. The first is a passive availability of knowledge resources in the clinical setting so that the physician can access information as needed. Often passive just-in-time resources are computer-based; the electronic format allows storage of many resources in a confined space, and these resources can be indexed and cross-referenced to speed up query response time. The effectiveness of passive just-in-time resources, however, seem to be limited by the willingness of clinicians to stop and check the resources in the midst of clinical care (Butzlaff et al., 2004).

The second type of just-in-time learning attempts to more actively offer information that appears to be needed during the course of clinical care. So, for example, if an abnormal lab value is typically associated with a diagnosis, the system might offer information about that diagnosis when the result is viewed. The implementation of active just-in-time learning requires an extensive infrastructure, including a structured database of patient information, a decision logic about when to offer information, and a forum for offering instruction that the physician will see at the appropriate time (Hilty et al., 2006). Such systems are usually associated with existing clinical systems including online lab reporting, computerized order entry, or fully implemented computerized medical records.

The same programming used to offer just-in-time learning can also be employed for monitoring physician performance (Holm, 1998). If a review of clinical behavior reveals that a physician is performing incorrectly in some area, an offer for specific education coupled with a status report to the physician may increase learning motivation.

BARRIERS TO THE USE OF TECHNOLOGY-BASED MEDICAL EDUCATION

The technological innovations previously described have the potential to address existing shortcomings in both primary and secondary medical education. Why, then, haven't all medical schools replaced their existing teaching methods with high-tech tools? Barriers to the use of medical education technology include concerns about their efficacy for long-term learning; struggles with development costs; doubts about equipment reliability; and lack of academic recognition for faculty who develop educational technology.

Efficacy

The role that technological innovation may play in medical education is intellectually compelling. However, the effort is not worthwhile unless the innovations are shown to improve educational outcomes (Hilty et al., 2006). Unfortunately, when new educational tools are reported on in the literature, efficacy is not well tested and variable results are seen. In part, this is because it is difficult to design good studies in this arena (D'Eon et al., 2005). Even within medicine, educational experiences are highly individual with respect to medium, setting, learner profiles, instructional approach, and presentation of the material. Consequently, comparative studies are overwhelmed by potentially confounding factors and variable interactions (Cook, 2005).

Kirkpatrick (1994) outlined four potential levels of evaluation for training programs: user satisfaction, learning outcomes, performance improvement, and the result of the training on the process outcome. Literature supporting user satisfaction with technological innovations in medical education is plentiful. The data supporting learning outcomes is less impressive; while many studies show that the students learn from these modalities (Curran et al., 2005), few of them report findings in comparison to traditional education. In at least some studies, short- and long-term behavior changes are seen with the use of educational technology; again, these studies do not compare the effect to that seen with more traditional approaches.

Published studies demonstrating improved clinical outcomes as a result of training are difficult to find for any area of medical education. However, only educational developers from academic settings typically report their findings in the peer-reviewed professional literature. Commercial developers may be satisfied with internal technical reports to be shared with users and clients. Outcomes data that is reported to accrediting agencies also often does not appear in the published literature. Thus, substantial unrecognized outcomes data may be found in the "grey literature" (Curran et al., 2005).

Automated education systems have potential shortcomings that may undermine their effectiveness, particularly in at the performance improvement and process outcome levels. For example, one of the finer points of medical reasoning is recognizing when a case does not fit the common condition. There is a danger that students exposed to pre-programmed educational tools will come to believe that there is always one right answer to every scenario. It is also difficult to program automated education to teach and test at the conceptual level rather than simply presenting a set of facts and figures. Particularly when both teaching and testing are automated, it may be difficult to identify students who have mastered the facts without understanding the big picture, or to identify students with subtle misunderstandings. Finally, the role of personal factors in the effectiveness of technology-based education remains unclear. Students differ in their prior exposure to technology, their preferred learning styles, and their cultural viewpoints. Any of these factors could cause a student to find diminished value in a computer-based educational intervention.

Some relevant outcomes associated with new educational interventions are not assessed by Kirkpatrick's schema. For example, many studies document the usage of a resource (Curran et al., 2005). Intuitively, if a new form of education matches the efficacy of traditional forms, but is used more frequently, better learning should result.

Cost

The cost of developing high-quality computer-based educational interventions can be substantial (Hilty et al., 2006). Even a simple automated flash card program requires an initial investment to create the utility and enter the learning material. Each modification to improve learning efficacy raises the complexity of the program, with corresponding impact on set-up cost. The specialized equipment needed to deploy educational technology can also be very costly. Simulations and virtual reality programs are particularly expensive to produce. Even the classic resuscitation dummy is a fairly expensive specialty item.

The cost of developing educational technology does not stop when the program is deployed, either. Medicine is constantly changing; new knowledge is introduced and old knowledge becomes obsolete. Traditional lecturers update their notes; textbook publishers produce new editions; likewise, developers of educational technology must update their materials to reflect the state of the art.

Further, many physicians are not comfortable using computers. A lack of familiarity with the equipment is a commonly cited reason for why physicians do not participate in Web-based continuing medical education, for example (Curran et al., 2005). Poor technical skills may also deter medical faculty from choosing high-tech forums for training; often the students are more familiar with technology than are their teachers (Hilty et al., 2006). Training programs, perhaps associated with traditional CME programs, may ameliorate this barrier but add another cost to the adoption of technology-based educational tools.

Reliability

As noted, specialized equipment is necessary for both the creation and the deployment of technology tools. Virtually every application demands that the student have access to a personal computer. Often, good quality recording equipment is needed to capture audio or visual media. Web-based materials must be designed, programmed, and maintained on an active server. Even when educational technology is affordable and demonstrated to be effective, potential users may be deterred by concerns about the reliability of the medium.

Because these tools depend on their specialized equipment to run, technology failures such as a power outage or computer virus may completely stall the educational effort.

Professionalism and Ethics

The tools described in this chapter all, to some extent, replace teaching by human faculty. It is important to remember that the practice of medicine involves more than application of facts and mastery of procedures. In a traditional medical education setting, the ongoing contact between learners and faculty leads to lessons in ethical conduct, bedside manner, and professional values (Mel-B, 2002) —all things, even well written computer programs, are unlikely to supply.

Faculty Incentives

The adoption of educational technology may also be stalled by a lack of well-developed material and a lack of incentive to develop such material. Unfortunately, development of educational technology doesn't fit well into the academic productivity paradigm. Faculty who invest time in writing a book chapter or presenting a lecture are rewarded with academic recognition; a teacher who devotes energy to the development of pedagogically strong automated learning tools often receives no recognition for the effort.

CONCLUSION

Traditional medical education has many shortcomings, both at the level of the primary medical learner in medical school, and at the level of the practicing physician seeking continuing medical education. In particular, medical educators struggle with the high cost of medical education, the difficulty of delivering quality education to remote locations, the challenge of a large and continuously changing body of medical knowledge, and the need to provide extensive hands-on experience to medical learners.

Technological innovations that have the potential to address those shortcomings include programs for automated drilling like computerized flashcards, self-directed tutorials utilizing hyperlinks to establish the relationships between ideas, virtual reality and simulation tools, and remote learning mechanisms such as teleconferencing, Web-based learning, and just-in-time learning technologies.

While these educational technologies show promise for improving the overall quality of medical education, their efficacy is not yet firmly established. In addition, the cost of developing and deploying such tools has proved a barrier to adoption, as has concern about their reliability. When these barriers are overcome, medical learners will have access to a much broader set of tools for both primary and continuing medical education.

KEY TERMS

Primary medical education: Describes the period in which the future physician builds a knowledge base de novo and learns to apply that knowledge effectively.

Secondary medical education: Refers to the ongoing efforts of a practicing physician to renew and update her knowledge and skills.

Information overload: Refers to the phenomenon in which the body of information to be mastered is too large to be assimilated by the student.

Procedural Skills: Are those physician skills that require hands-on manipulation of the patient, such as physical examination, obstetrical delivery, or surgery.

The "Brain-Drain" Phenomenon: Refers to emigration of healthcare professionals from impoverished to wealthier health-care systems.

Automated Flashcard Programs: Are computer programs that allow the user to quiz himself about terms and their definitions, onscreen. They are an excellent example of how computerized tools can improve the flexibility and efficiency of a classic learning tool.

The Constructivist School of Adult Learning: Suggests these learners may master the material most efficiently when allowed to navigate the material freely, according to their own curiosity.

Hyperlinked Text: Text on the screen that, when clicked, connects the learner to a different page with the related information.

Simulation Tools: Learning tools in which a real-life situation is simulated using models or interactive computer programs.

Just-In-Time Learning: Learning tools that attempt to offer knowledge at the point when the physician would most need it, often in the course of clinical care.

Kirkpatrick's Levels of Evaluation: Four potential levels of evaluation for training programs: user satisfaction, learning outcomes, performance improvement, and the result of the training on the process outcome.

Chapter 3.25
Care2x in Medical Informatics Education

Andreas Holzinger

Harald Burgsteiner
Graz University of Applied Sciences, Austria

Helfrid Maresch
Graz University of Applied Sciences, Austria

ABSTRACT

In this chapter the authors report about their experiences in education of both students of healthcare engineering at Graz University of Applied Sciences, and students of medicine at the Medical University Graz, gained during the winter term 2004. Care2x is an open source Web-based integrated healthcare environment (IHE). It allows the integration of data, information, functions, and workflows in one environment. The system is currently consisting of four major components, which can also function independently: hospital information system (HIS), practice management (PM), a central data server (CDS) and a health exchange protocol (HXP). Although the components are under heavy development, the HIS has reached a degree of stability, where one can use it at least for educational purposes. Various groups also report the usage of enhanced versions of Care2x in real life settings. Our experiences in both—very different—student groups have been very promising. In both groups the acceptance was high and Care2x provided good insights into the principles of a hospital information system. The medical students learned the principal handling of a HIS, whereas the engineering students had the possibility to go deeper into technical details.

INTRODUCTION

In this chapter, the authors report about their experiences in the education of students of healthcare engineering (HCE) at Graz University of Applied Sciences, and students of medicine at the Medical University Graz, gained during the winter term of 2004. Care2x is an open-source Web-based integrated healthcare environment (IHE). It allows the integration of data, information, functions, and work flows in one environment. The system currently consists of four major components, which can also function independently: the hospital information system (HIS), practice management (PM), a central data server (CDS), and a health exchange protocol (HXP). Although the components are under heavy development, the HIS has reached a degree of stability so that one can use it at least for educational purposes. Various groups also report the usage of enhanced versions of Care2x in real-life settings. Our experiences with both—very different—student groups have been very promising. In both groups, the acceptance was high and Care2x provided good insights into the principles of a hospital information system. The medical students learned the principal handling of an HIS, whereas the engineering students had the possibility to go deeper into technical details.

How to prepare both medical and engineering students in the best possible way for their later work with modern HISs is a common question. Whereas students of engineering are rather enthusiastic about IT, students of medicine are skeptical in general about using it. However, HISs are not widely accepted by healthcare professionals; that is, barriers to the use of HIS are primarily sociological, cultural, and organizational rather than technological (Moore, 1996).

It seems plausible to not only give students theoretical background about the structure, functions, and common tasks of an HIS, but to also let them work with a fully functional HIS during lectures. This is essential, particularly if students are required to be able to work with possibly any HIS in practice after only a short period of vocational adjustment. However, it depends on many different factors regarding which HIS to choose. One of the most important is whether it is necessary to teach (with) a particular HIS of a certain vendor, for example, if this system is deployed in a network of local hospitals. Another key factor, especially for noncommercial educational institutions, is the economic impact of the introduction of a commercial HIS at the university. Third, for the education of students of medical informatics, it might also be reasonable to teach the process of developing (parts of) a bigger software engineering project. Hence, the need for an open-source system arises if one does not want to start the development of his or her own HIS. Although there are many more factors to consider in general, we chose Care2x as our primary educational HIS for the following reasons.

CARE2X

Care2x is a generic multilanguage, open-source project that implements a modern hospital information system (the Web page of Care2x is located at http://www.care2x.org/). The project was started in May 2002 with the release of the first beta version of Care2x by a nurse who was dissatisfied with the HIS in the hospital where he was working. As of today, the development team has grown to over 100 members from over 20 countries. Care2x is a Web-based HIS that is built upon other open-source projects: the Apache Web server from the Apache Foundation (http://www.apache.org/), the script language PHP (http://www.php.org/), and the relational database-management system (RDMS) mySQL (http://www.mysql.com/). There exist several source-code branches that try to integrate the option to choose from other RDBMSs like Oracle and postgreSQL. The latter one is already supported in the current version at the time of this writing (Deployment 2.1). For our investigations, we chose the most feature-rich version that was available from the Care2x Web page in early fall of 2004. This release had the version number 2.0.2. Some minor deficiencies that we report later may already be fixed in the current version, Deployment 2.1.

Care2x is a very feature-rich HIS that is fully configurable for any clinical structure. It is built upon different modules, which include, for example, in and outpatient administration, admission, pharmacy, radiology (including DICOM [Digital Imaging and Communications in Medicine] image uploads), laboratories, ambulatories, nursing, medics, DRGs (diagnosis-related groups), and so forth. Online help is available for some clinical paths. See Figure 1 for an example.

REVERSE ENGINEERING

The reverse engineering of existing complex software packages starting at the source-code level has a higher value for practical education than a new development. Bothe (2001) argues that groups of students will rarely be able to develop a project further than to a prototype stage during a single lecture. Access to the source code is not available for most commercial HISs, which is another advantage of using Care2x as an educational system. In our first lecture, the students of HCE were asked to test all functions and paths of Care2x. They had to set up a small virtual clinic and employ doctors, nurses, and technical stuff. Finally, patients had to be admitted, attended to, and dismissed at all stations. In a second lecture in the upcoming semester, our students have the assignment to analyze a fully functional HIS at the source-code level. Since Care2x is built upon a modular structure, small teams of programmers have tasks like finding and fixing bugs in the current version, adding simple modules for special functions not included in the official version, or implementing interfaces to other existing information systems or medical equipment. In the spirit of open-source projects, reasonable additions and modifications can and should be published to the Care2x community Web page.

LESSONS LEARNED

Approximately 100 students from medicine and 25 from HCE participated (Figure 2). The whole lecture was built in the following way:

Figure 1. Help page describing the clinical path for starting a new surgery-operation document

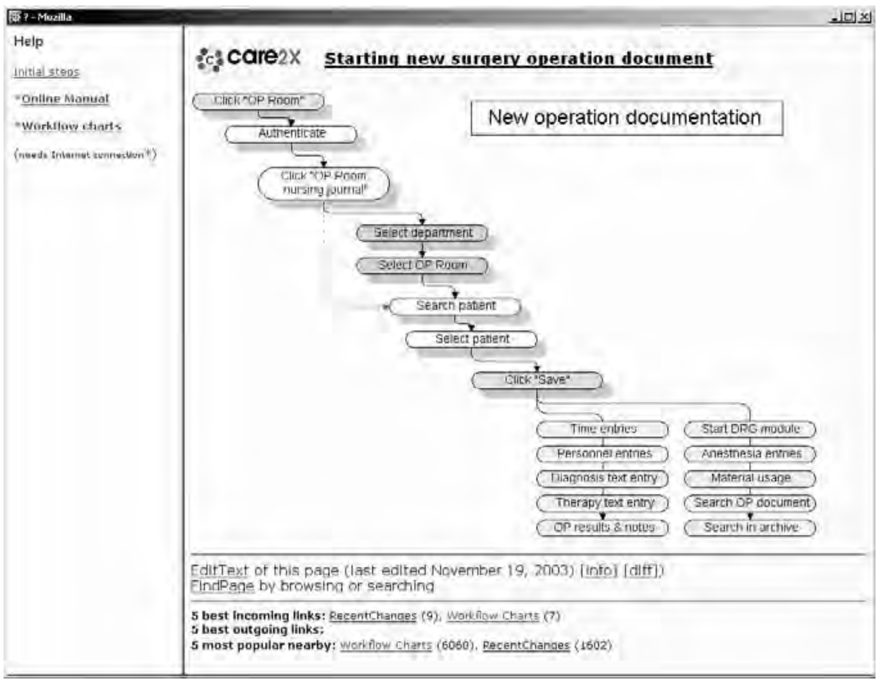

Figure 2. Students at work with Care2x (We assigned groups of 2-3 students with different tasks related to the administration of a virtual hospital)

1. Theoretical foundations of HIS in traditional lectures
2. Principles of Care2x explained (HCE group's lecture was more technology orientated)
3. Familiarization with Care2x in practical sessions
4. Practical work, specific work flows
5. Applying reverse engineering (HCE group only in the second part of the lecture)
6. Examination (both theoretical and practical)

During the education, the students were faced with the following strengths and weaknesses of Care2x.

Strengths:

- Everyone can make his or her own tools
- Work does not have to be done in a strict order
- Very flexible
- Easy to handle
- Continuing design and development
- Open source
- Lots of different languages
- Bg community that takes care of Care2x
- Easy to select the different departments and stations

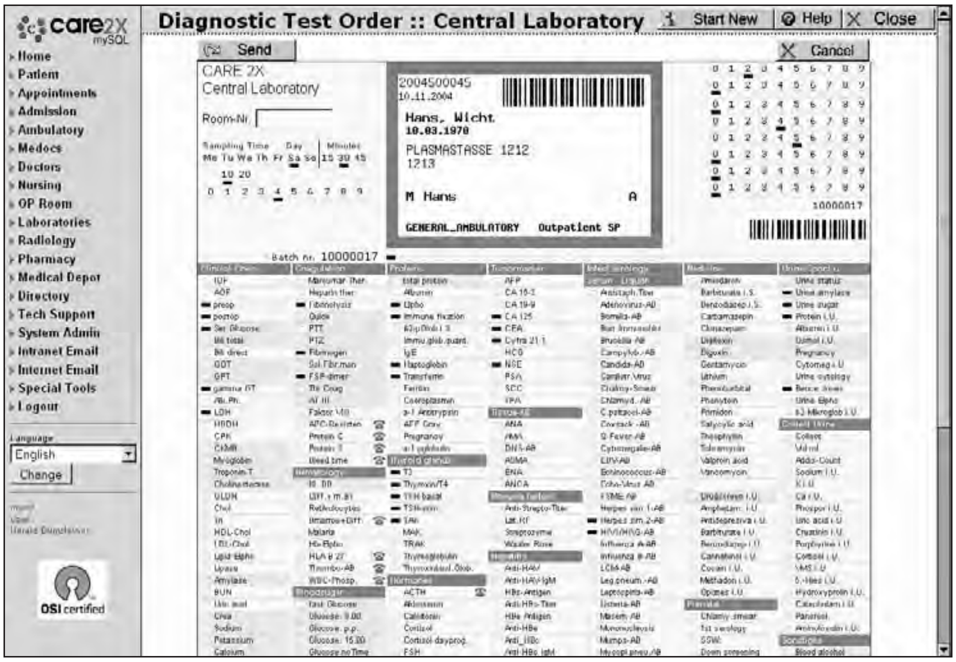
Weaknesses:

- No real standard between the modules
- Documentation is only rudimentary
- A few tools are not really easy to interpret
- Lack of security measures
- Not a state-of-the-art user interface
- There is no global list of patients from which to select one

OBSTACLES IDENTIFIED

During our lectures and trainings, there emerged several problems while using Care2x. There are

Figure 3. Example of a graphically embedded complex form, the diagnostic test order



a lot of small bugs that caused troubles. The biggest problem was that sometimes the browser responded with an "inactivity error" and the session would time out. Most of the time this error message was shown, the last click had not been made but one single minute ago. The next problem with the handling was that sometimes the back button on the Web browser would lead to nowhere because Care2x does not manage this. Much later, we found out that the back button of the browser is unnecessary because the program has included this function. That did not solve the problem completely: Every now and then the integrated back button of Care2x led to nowhere, too. In addition, some pages did not include the Care2x back button (inconsistency), resulting in a blank page. This required the user to restart at the very beginning and click through all the menus once again, which was boring for the students.

The general software problems that did not concern the running process were not severe. However, there is a serious problem when it is possible to admit a patient to more than one station, or when it is possible to alter a patient's record after his or her death.

A severe problem that has to be solved is that patients have to be discharged and then hospitalized again when we just want them to be transferred from the ambulatory to a station.

There are some translation errors and missing notes. For example, if a new patient record is being applied, there are red stars above some properties. Although this is an obvious sign for experienced users, it is not noted anywhere why these stars appear. The students found out that these stars show the minimum amount of data that is required to create a patient record, but how would the students of medicine with little experience in IT know this fact?

It is also sometimes annoying that bits of information are hidden behind a link. For example, if you want to hospitalize a patient, you have to remember the social insurance number because it is not shown in the place it is needed. This is due to the fact that Care2x works with only one window. Sometimes there might just be too little space to provide all the information needed, and then the user has to write this information down or remember it; this cannot be the aim of an HIS.

CONCLUSION

Care2x is flexible open-source software. Although there are some bugs, it has the potential to become functional software to support work flows within a (real) hospital. We think the biggest problems are the documentation and the deduction of treatments. Working with Care2x as a beginner is not very comfortable, and the software is not very intuitive. However, if one trains with Care2x, the work flows become clearer and more logical. The online help of Care2x should be better and more comprehensive. Working with the software was very fun because you really can play with a virtual hospital. Care2x is a very good possibility for training with work flows in a hospital. Further improvement of Care2x will open new areas to work with this software.

KEY TERMS

Care2x: An open-source HIS available from http://www.care2x.org/. Care2x is a quite mature and stable product that can be used at least for educational purposes for both students of medicine and students of medical informatics. Some groups report the deployment of enhanced and adopted versions in real hospitals.

Diagnosis-Related Group (DRG): The DRG system is an inpatient classification system based on several factors: the principal diagnosis, secondary diagnosis, surgical factors, age, sex, and discharge status. Under the Medicare prospective payment system, hospitals are paid a set fee for treating patients in a single DRG category, regardless of the actual cost of care for the individual.

Digital Imaging and Communications in Medicine (DICOM): The DICOM image format is commonly used for the transfer and storage of medical images. Visit Chris Rorden's DICOM page for information about the format and free software to view and manipulate it.

Hospital Information System (HIS): It is the central medical information system in most hospitals in which most healthcare-related data (e.g., personnel, stations, patients and their medical history, etc.) are stored.

Medical Informatics: The rapidly developing scientific field that deals with biomedical information, data, and knowledge: their storage, retrieval, and optimal use for problem solving and decision making. The emergence of this new discipline has been attributed to advances in computing and communications technology, to an increasing awareness that the knowledge base of medicine is essentially unmanageable by traditional paper-based methods, and to a growing conviction that the process of informed decision making is as important to modern biomedicine as is the collection of facts on which clinical decisions or research plans are made (Shortliffe, 1995).

Open Source: The idea of sharing the source code of applications or tools for free. Other people are invited to elaborate on future extensions and improvements. Most open-source projects are committed to one of the Gnu public licenses (see http://www.gnu.org/licenses/licenses.html).

RDBMS (Relational Database Management System): A software package that manages a relational database, optimized for the rapid and flexible retrieval of data. It is also called a database engine.

Reverse Engineering: Taking apart an existing system to analyze smaller or single parts. The reduced complexity simplifies the process of enhancing or understanding its functions.

ABSTRACT

Residency education is the period of clinical education that follows graduation from medical school, and prepares physicians for the independent practice of medicine. The Accreditation Council for Graduate Medical Education (ACGME) is an organization responsible for accrediting residency education programs. The ACGME is increasingly emphasizing educational outcomes in the accreditation process. The authors will discuss the experience of GME programs using ePortfolios for both formative and summative evaluation of residents and the integration of ePortfolios as part of institutions' learning management systems. ePortfolios can be especially useful for evaluating and documenting mastery of educational outcomes such as practice-based improvement, use of scientific evidence in patient care, and professional and ethical behaviors that are difficult to evaluate using traditional assessment instruments. The authors also review the literature describing the use of ePortfolios as a tool that is both powerful and reflective, for the assessment of program outcomes by administrators and faculty.

BACKGROUND

Residency education or graduate medical education (GME) is the period of clinical education that follows graduation from medical school, and prepares physicians for the independent practice of medicine. Depending on the specialty, resident physicians require between three to seven years of full-time experience in a training program to graduate as qualified specialists ready to practice. Resident physicians care for patients under the direct supervision of teaching physicians. The clinical experiences occur in a range of venues from community settings and outpatient practices to institutional environments such as hospitals and long-term care facilities. These clinical experiences are integrated into a comprehensive educational program that includes didactic activities and research.

Keeping track of residents' progress and assuring that all residents acquire the necessary knowledge, skills, and attitudes to become competent physicians in their areas of specialty can be a challenge given this variety of training experiences. Increasingly, accrediting agencies are holding training programs accountable for documenting outcomes. Traditionally, the Accreditation Council for Graduate Medical Education (ACGME) has focused on evaluating the adequacy of the process or structure of the residency programs to educate residents. In 1999, the ACGME introduced a new paradigm, the Outcomes Project, which places greater emphasis on a program's actual accomplishments through an assessment of program outcomes (ACGME, 2004).

In order to accomplish this goal, the ACGME has outlined six competencies: patient care, medical knowledge, professionalism, interpersonal and communication skills, practice-based learning and improvement, and systems-based practice. The rationale for this emphasis on outcomes is the need to ensure that physicians become and remain competent to meet the health care needs of their communities. At the end of their training, physicians must develop competence in lifelong learning strategies, reflective clinical practice, skills, and appropriate attitudes. Achieving these outcomes and documenting the achievement presents challenges for planners of postgraduate teaching, learning, and assessment. Medical educators and trainees must meet these new challenges in the face of dramatic changes in the U.S. health care system. Mounting clinical and academic activities due to changes in health care delivery and advances in medicine have increased demands on academic faculty, resulting in less time for teaching and mentoring (Ozuah, 2002).

To be able to assess this expanded range of competencies, training programs must redefine their current assessment approaches. Graduate medical education programs need to move from an almost exclusive reliance on traditional evaluations such as global subjective ratings of performance and written examinations, towards a competency-based model that requires multidimensional evaluations such as objective structured clinical examinations (OSCEs), standardized patient exams, chart reviews, and peer and patient evaluations. Even these additional assessment methodologies will not enable us to effectively evaluate all of the competencies. The assessment methodologies appear to be more effective in the evaluation of patient care, knowledge, and communication than they are in the evaluation of competencies such as practice-based learning and improvement (Lynch, Swing, Horowitz, Holt, & Messer, 2004), systems-based practice (Ziegelstein & Fiebach, 2004), and professionalism. There is a need for new tools with which to conduct valid and accurate assessments of these competencies. Moreover, these new tools should be compatible with the learner-centered model that emphasizes self-reflection and self-directed learning, critical skills that put learners in control of their own learning.

PORTFOLIOS IN MEDICAL EDUCATION

Portfolios document the evidence that demonstrates a doctor's education and practice achievements (Wilkinson et al., 2002). Medical educators have used portfolios at the undergraduate, graduate, and continuing medical education levels across various medical specialties such as psychiatry (Jarvis, O'Sullivan, McClain, & Clardy, 2004), obstetrics and gynecology (Lonka et al., 2001), internal medicine (Hayden, Dufel, & Shih, 2002), pediatrics (Carraccio & Englander, 2004), and emergency medicine (O'Sullivan & Greene, 2002). Medical education experts advocate the use of portfolios at each level of training to aid these specialties in the evaluation of competencies set forth by accrediting agencies such as the ACGME. Some portfolios focus primarily on assessment and reflect a learner's achievement of competency in specific areas of medicine. These types of portfolios are often used for summative evaluation purposes. Others are more developmental in nature and present evidence of improvements in learning over time. Such portfolios can be used by program directors and by the learners themselves for formative purposes to track progress. Yet other portfolios might showcase a person's best work or achievements in specific areas such as clinical work, research, or education. Most portfolios contain a combination of elements. The table lists some components that have been included in medical portfolios (Carraccio & Englander, 2004; Hays, 2004; Ozuah, 2002).

Portfolios can be tailored to the medical trainee, and the content can be determined by the trainee's learning needs. They can accommodate a diversity of practice and academic evidence. They foster self-directed learning, lifelong learning, critical thinking, and self-reflection (Carraccio & Englander, 2004; Challis, 2001; Hayden et al., 2002; Lynch et al., 2004; Stanton & Grant, 1999).

There are some disadvantages to the use of portfolios. Portfolios are time consuming to complete and assess, and immediate documentation of an experience is not always practical, given competing clinical obligations. Portfolios sometimes lack structure and standardization, making their use in evaluation difficult. Finally, portfolios do not really tell us much about the actual level of performance in many clinical activities (Challis, 2001; Snadden, 1999; Stanton & Grant, 1999).

RATIONALE FOR THE USE OF ELECTRONIC PORTFOLIOS

Electronic portfolios (ePortfolios) can circumvent some of the difficulties with hardcopy portfolios. Portfolios in their traditional written form are difficult to update, store, search, access, and distribute. These problems are compounded by the rotation of residents through different clinical venues. ePortfolios enable program administrators to gather and keep track of all the portfolio components that need to be submitted by residents, supervising faculty, and other contributors, especially when these persons are geographically dispersed. ePortfolios give residents access to their portfolio at all times, so they can document their clinical training in a timely fashion and allow their physician mentors and colleagues to review their progress.

Most ePortfolios are based on Internet technologies that offer multiple useful features such as accessibility, easy updating, learner control, distribution, standardization, tracking, and monitoring. Accessibility refers to the trainee's ability to find in the ePortfolio what is needed, when it is needed. Improved access to ePortfolio content is crucial, as learning is often an unplanned experience. Updating electronic content is easier than updating printed material (Chu & Chan, 1998); ePortfolios allow trainees to revise their content simply and quickly. Learners have control over the content, learning sequence, pace of learning, time, and often media, thereby allowing them to tailor the ePortfolio to meet their own personal learning objectives (Chodorow, 1996). Internet technologies allow the widespread distribution of ePortfolio content to many users simultaneously, anytime and anywhere (Chu & Chan, 1998). An additional strength of ePortfolios is that they may standardize content and delivery. Automated tracking and reporting of a trainee's activity lessens the faculty administrative burden. Moreover, ePortfolios can be designed to include learner assessments to determine whether learning has occurred. Since documentation of outcomes is the new ACGME mandate for residency programs, ePortfolios will likely grow in popularity.

There are some downsides to the use of ePortfolios in medical education, including issues related to computer server space, technical support and maintenance, use of portfolio software, and security and confidentiality. Medical educators considering the use of ePortfolios need to work with their local information technology staff to identify whether the level of expertise is available to develop the electronic platform and have access to dedicated support. There are a variety of commercial products available, but these are generally limited in their ability to meet the specific needs of medical education programs and may not fulfill the needs of learners, faculty, and program administration.

ePORTFOLIOS IN GRADUATE MEDICAL EDUCATION

ePortfolios can be especially helpful in documenting the ACGME competencies for graduate medical education. The ACGME has suggested methods for the evaluation of each competency (ACGME, 2004). Data from these evaluation methods can be effectively captured in the ePortfolio. For example, discipline-specific medical knowledge can be documented in the ePortfolio by including oral, written, or MCQ test results. Most of these tests can easily be administered electronically, which greatly facilitates the inclusion of results in the ePortfolio. The patient care competency can be documented through a variety of information sources, including record reviews, chart-stimulated recall exercises, patient surveys, and results from performance-based competency assessments such as standardized patient exams and OSCEs. The interpersonal and communication skills competency can also be effectively assessed through patient surveys and the performance-based assessments. Some of this data can be gathered electronically. For the other elements it is relatively easy to enter the results in an online template.

ePortfolios offer particular benefits for the remaining competencies, which are more difficult to assess. Aside from the evaluation methods proposed by the ACGME, medical educators can experiment with a wide array of innovative evaluation methods to assess these competencies (Carraccio & Englander, 2004). The practice-based learning and improvement competency requires residents to be able to investigate and evaluate their own patient care practices, appraise and assimilate evidence-based scientific evidence, and consequently improve their patient care. ePortfolios provide an accessible platform where residents can document evidence of their patient care practices, allowing them to reflect upon these experiences, analyze their thought processes, identify strengths and weaknesses, and under the guidance of supervising faculty with access to the same ePortfolio, set up a plan for improvement of overall clinical performance. These reflective activities can also provide evidence for the professionalism competency, as it fosters residents' commitment to ethically perform their professional responsibilities to an increasingly diverse patient population. Finally, the documentation of medical errors, the critical incidents during patient care activities, and the performance of quality improvement projects serve to fulfill the systems-based practice competency where residents must demonstrate an awareness of and responsiveness to the larger health care system, and an ability to provide optimal patient care by effectively mobilizing the health care system resources (Carraccio & Englander, 2004).

There are several examples in the literature of how ePortfolios have been used in graduate medical education to address the above ACGME competencies. Fung et al. (2000) described a learner-driven ePortfolio that was successfully implemented in an obstetrics and gynecology training program. They demonstrated improved self-directed learning and lifelong learning attitudes. Since then, their ePortfolio, called KOALA, has been used successfully with other trainees. Carraccio and Englander (2004) developed a Web-based ePortfolio to evaluate pediatric residents' performance in ACGME competencies. Their ePortfolio consists of self-assessment, a learning plan, tracking features, asynchronous discussion boards, and a system to address critical incidents during pediatrics training. Chisholm and Croskerry (2004) present an ePortfolio entry that can assess the Practice-Based Learning and Improvement competency. An example is of a senior faculty member who describes a medical error that occurred, say "delay in diagnosis." The learner is encouraged to reflect on the system errors and personal errors that might have contributed to the delay in diagnosis. The faculty member can also identify a number of personal learning points. This case study can then be distributed to residents and faculty in an emergency medicine residency. This type of portfolio entry promotes introspection and self-reflection. The authors note that senior-level faculty may need to model the portfolio for novice learners such as students and residents that have little experience with this process.

ePORTFOLIOS IN A GRADUATE GERIATRICS EDUCATION PROGRAM

The Geriatrics Fellowship at the University of Miami Miller School of Medicine is a one- to two-year training program following residency. Currently, nine residents (called fellows at this level) are enrolled in training. The fellowship includes several affiliated institutions with diverse training venues through which the fellows rotate including the nursing home, acute and sub-acute care settings, hospice, geriatric evaluation and management, home care, and outpatient settings. Although the training program is based in Miami, the fellows rotate at locations geographically distant from the home institution.

At the beginning of the 2004-2005 academic year, the fellowship committee decided to incorporate the ACGME recommendations, anticipating the full implementation of the outcome project in 2006. Our technical group, in conjunction with fellowship faculty and fellows, initiated a pilot ePortfolio program to capture the ACGME outcomes. To meet the challenge of reliably measuring all of the six competencies, the committee expanded the assessment of the fellows from global subjective evaluations to a more comprehensive assessment methodology based on multiple assessment tools and multiple raters. One example of a multiple assessment tool is the 360-degree evaluation in which fellows are evaluated by different members of the interdisciplinary teams they work with. A 360-degree evaluation can address aspects of several ACGME competencies, including interpersonal and communications skills, professionalism, patient care, and systems-based practice (ACGME, 2004). These evaluations are integrated with other training materials and self-reflection components as part of an electronic portfolio. Most of these evaluations were previously in written format, which complicated the ongoing evaluation of fellows. The use of an ePortfolio offers the opportunity to enhance documentation and reduce the administrative burden of dealing with nine fellows dispersed across different locations.

The Geriatrics Fellowship relies on a learning management system (LMS) called GeriU: the Online Geriatrics University (http://www.geriu.

org). GeriU is based on the Angel LMS platform, a SCORM (Sharable Content Object Reference Model) conformant LMS which is a database-driven eLearning platform. This LMS offers several collaboration features such as e-mail, chat, and discussion groups. It also serves as a repository for digital materials ranging from digitized text documents to highly interactive multimedia eLearning tutorials. The fellowship homepage was built as an ePortfolio to allow fellows to document the clinical, educational, and research activities they engage in during their fellowship.

DESCRIPTION OF THE GERIATRICS FELLOWS' ePORTFOLIO

The ePortfolio our fellows use is organized into four major sections: toolbox, clinical, education, and research, reflecting the major components of the fellowship training program. A description of each section follows:

Toolbox: This section contains guidelines for completion of the ePortfolio, pertinent articles about ePortfolios, the ACGME competencies, an overview of the assessments used to evaluate each competency, and a frequently asked questions section.

Clinical: This section contains information related to the supervised clinical activities of Geriatrics fellows. For each clinical rotation, the portfolio includes an evaluation of the fellow by the attending physician, an evaluation of the attending completed by the fellow, and a learning objective checklist that allows fellows to check whether they have completed a core set of activities for that rotation. After finishing each rotation, fellows complete a reflective exercise in which they describe some of their key learning experiences. The clinical section of the portfolio also contains a patient log, patient surveys, 360-degree evaluations, chart reviews conducted by the fellows, and an analysis of critical incidents.

Education: The education section comprises fellows' educational activities, products, and evaluations. Fellows conduct teaching and assessment sessions for medical students, residents, their peers, and sometimes other audiences. A list of educational activities conducted by fellows is included in the ePortfolio, as well as any teaching materials the fellows developed such as PowerPoint presentations, journal club reviews, and morbidity and mortality case conference summaries. The education section also contains evaluations of some of these teaching sessions from the learners.

Another aspect included in this section is a list of educational activities the fellows have participated in, as well as results from competency assessment activities. This section also contains a reflective component asking fellows to describe what they learned from each of these experiences.

Research: Each Geriatrics fellow completes a research project under the mentorship of Geriatrics faculty. This section includes the description of the research project with its goals, objectives, research plan, result, discussion, and conclusions. Any abstracts, manuscripts, or presentations resulting from this and other research in which the fellows are engaged are included in this section. Fellows' reflections on their experience with the research project are also included.

Assessment Process: The program director and associate program director are in charge of conducting the ePortfolio evaluation. These two faculty members will review each fellow's portfolio independently following an agreed-upon rubric. After completion of their summative evaluations, they will meet to discuss their evaluations and try to reach agreement. If no agreement is reached, the ePortfolio will be reviewed by the fellowship committee, which will then arrive at a final decision.

Preliminary Indications: The Geriatrics fellows who are currently using the ePortfolio have given some preliminary evaluations. They find the ePortfolio to be a very useful component of their training and describe it as easy to use and navigate. They are very satisfied with the opportunity to analyze their performances and see the milestones during their training clearly documented. The fellows gave mixed evaluations about the reflective exercises for the different sections. A clearer explanation of the rationale for self-reflection may be needed. Fellows indicated they would like to continue having access to their ePortfolio at the end of their training.

CONCLUSION

Medical educators have used portfolios for both formative and summative evaluation of trainees. Portfolios promote self-directed learning, lifelong learning, critical thinking, and self-reflection—important characteristics for competent physicians. The introduction of electronic portfolios offers medical educators advantages over hardcopy portfolios by making it easier to access, update, store, search, and distribute portfolio content. This greatly facilitates the documentation of the training experience. The ACGME is increasingly emphasizing educational outcomes in the accreditation process of graduate medical education programs. ePortfolios can be used to evaluate all six ACGME competencies, but they are especially useful in evaluating practice-based improvement, professional and ethical behaviors, and systems-based practice—competencies that are difficult to evaluate using traditional assessment instruments. The authors described their experience implementing an ePortfolio as part of a graduate medical education program in Geriatrics and provided examples of how their portfolio entries address the ACGME requirements. The ePortfolio can easily accommodate a broad variety of materials and reflect the spectrum of academic activities that medical trainees participate in. Setting up an initial ePortfolio structure that is capable of capturing this broad array of information is time consuming and costly. The authors will refine their existing ePortfolio structure based on feedback from the different stakeholders, with the goal to provide a template that can readily be adapted by other graduate medical education programs to document their outcomes.

KEY TERMS

ACGME: The Accreditation Council for Graduate Medical Education (ACGME) is responsible for the accreditation of post-MD medical training programs within the United States. Accreditation is accomplished through a peer-review process and is based upon established standards and guidelines.

Competencies: Complex set of behaviors built on the components of knowledge, skills, attitudes, and "competence" as personal ability.

Geriatric Fellows: Geriatric fellows are physicians who are first trained in family practice or internal medicine and then complete additional years of fellowship training in geriatrics.

Geriatrics (or Geriatric Medicine): The branch of medicine dealing with the medical management and care of older people.

Graduate Medical Education: Residency education or graduate medical education (GME) is the period of clinical education that follows graduation from medical school, and prepares physicians for the independent practice of medicine.

Resident: A medical resident is a physician who has received a postgraduate medical degree (M.D. or D.O.) and is enrolled in a clinical training program in the United States of America.

Chapter 3.27
Multimedia Computing Environment for Telemedical Applications

V.K. Murthy
University of New South Wales at ADFA, Australia

E.V. Krishnamurthy
Australian National University, Australia

ABSTRACT

This chapter describes the system design for a multimedia telediagnostic computing environment (MMTE) for telemedical applications. Such an environment requires the design of: (i) a wired-in or wireless computing facility based on currently available technology with a high bandwidth for fast, reliable, and efficient communication of data, voice, and image; (ii) a database query system to access data, voice, and medical images from a fixed server to the mobile or fixed hosts; and (iii) suitable audiovisual software communication tools among the cooperating fixed and mobile hosts to help visualize pointer movements remotely (telepointers) and for teleconferencing. Appropriate software and hardware tools for the design of the cooperative environment are described. We also provide an up-to-date bibliography.

INTRODUCTION

Telemedicine (in short, e-medicine) is a means of delivering medical services to any place, no matter how remote, thereby removing the limitations of space and time that exist in today's health-care settings. Computers are indispensable in telemedicine since they provide for efficient, relevant data gathering for large-scale applications. Besides providing immediate feedback of results to patients and doctors, they also can compare past patient records and evaluate relative improvement or deterioration. Further, they are readily available at any time, are fatigue-free, and can be more objective.

Also computers provide for multimedia imaging—ultrasound, digital X-rays, 3D spiral CAT scanning, magnetic resonance imaging, PET scanning, etc.—and can fuse them into a single multipurpose image using fusion software. Adding mobility to computers enhances their role in telemedical applications considerably, especially at times of emergency, since the patients, doctors, and data collecting and retrieval machines, as well as their communication links, can always be on the move.

For instance, very simple, inexpensive mobile communication and computing devices can be of great help in telemedicine, as illustrated below:

- **Low-cost radio:** Even the simplest of mobile devices—such as a low-power radio that can transmit messages to a home computer, from which medical data can be sent through the telephone line and the Internet—can be of great value in saving lives (Wilson et al., 2000).
- **PDA (personal digital assistant):** The simplest of the computers, such as palmtops and PDAs, can assist the doctors for instant nomadic information sharing and looking for diagnoses of different diseases and treatments. PDAs can help the doctors to figure out drug interactions, storing summaries of sick patients and their drug lists. Further, PDAs can provide for downloading suitable programs from the Web and can be programmed for alert, sending and receiving e-mail, jotting down pertinent points, and storing immediately needed clinical results to carry out ward rounds.
- **Internet:** The Internet is an important tool for medical professionals and will completely change the manner in which medical consultations are provided (Coiera, 1997). For minor ailments, Internet-based consultations to doctors can provide prescriptions for medical/pathological examinations by laboratories. The results are then posted on the Internet for subsequent reading of the results by the concerned doctors, who can prescribe medicines that can be posted on the Internet. This prescription can then be handled by a pharmacy to dispense the medicines to the concerned individual. Kim and Hwang (2001) have proposed a password-controlled Internet-based medical system that brings in a variety of services to doctors, patients, pharmacists, and healthcare professionals. It allows people to receive medical examinations and medical advice on the Internet enables examinations that are not possible in the Internet to be treated to have a direct contact with the doctor.

TELEMEDICAL INFORMATICS

The first step in telemedicine is the telemedical diagnosis (or telediagnosis) based on information obtainable from medical images, blood, urine, and other pathological test reports. Usually, for diagnostic purposes, the doctor sends a patient for such examinations. The laboratory assistant takes the required X-ray or ultrasound images or carries out pathological tests and passes these images (or readings) on to a radiologist/pathologist, who then makes an analysis and sends a report to a doctor. These manual actions are totally sequential and slow. This whole procedure can be made cooperative and faster if the images and data are stored in a database and these can be simultaneously retrieved by doctors, radiologists, and specialists in their offices or homes, using personal computers to make a cooperative diagnosis. This is the basis for **telemedical (e-medical) informatics** (Alfano, 1997; Coiera, 1997; Ganapathy, 2001; Gomez et al., 1997; Jameson et al., 1996; Kleinholz et al., 1994; Lauterbach et al., 1997; Mathew et al., 1999; Pham & Yearwood, 2000; Yearwood & Pham, 2000).

Principal Aims

The principal aims of e-medical informatics are to:

i. Provide online services of patient records (medical and pathological databases) to medical practitioners and radiologists.
ii. Provide primary specialist diagnosis, offer a second opinion, and provide pre- and post-treatment advice through e-mail.
iii. Reduce the cost of imaging equipment, reduce delays, and increase the speed and volume of diagnosis.
iv. Aid cooperative diagnosis and provide assistance for remote surgery.
v. Provide student/resident education.
vi. Reduce professional isolation and increase collaboration.
vii. Provide home care.

Advantages

E-medicine offers the following advantages:

i. Provides health care to underserved and isolated areas so that we can make a better allocation and utilisation of health resources.
ii. Since communication cost is much cheaper than the transportation cost, patients in remote areas can outreach physicians quickly.
iii. Increases the speed of diagnosis and treatment, especially when used for teleradiology, cardiology, and psychiatry.
iv. Allows access to speciality care using time-oriented clinical data.
v. Real-time monitoring of public health databases to prepare and respond during epidemics and biological and chemical terrorism.
vi. The Internet can provide the following support:
    a. Health information
    b. Administrative infrastructure
    c. Online health records
    d. Pharmaceutical information and sales outlets
    e. Online training for telemedical professionals

For an excellent treatment on the Internet and telemedicine, see Coiera (1997).

Thus the development of an integrated wireless (mobile) and wired-in networking environment for e-medical informatics can have a wide range of applications in health care for remotely situated areas. Such a computing environment has a particular relevance to vast countries (e.g., Australia, China, and India) with a widely distributed population, as well as to provide emergency medical assistance in areas of natural disasters and war-torn regions.

Prerequisites

The prerequisites for a successful implementation of a telemedical system are:

- **Infrastructure:** A suitable infrastructure of health-care providers, doctors, engineers, computing specialists, communication engineers, information technology professionals, and medical statisticians to analyse outcomes, and suitable outreach clinics with telemedical facilities.
- **Communication network:** A reliable, inexpensive, readily accessible communication network from outreach clinics to hospitals, doctors, patients, and pathological laboratories.
- **Low-cost computers:** Suitable low-cost hardware/software and a good communication bandwidth for transmission of medical data in different modes (radiological images, video images of signals, and text). While using wired-in or wireless mobile devices and monitors, the effect of electromagnetic interference (EMI) and radio frequency interference (RFI) on data collection and transmission, and the side effects on patients (both physiological and psychological

aspects) have to be taken care of so that improper diagnosis does not result.

- **Training facility:** Training of personnel for providing proper maintenance of equipment and safety standards to patients.
- **Security, reliability, efficiency:** Reliability, efficiency, security, privacy, and confidentiality in handling, storing, and communicating patient information.

Economic Necessity

In densely populated countries (e.g., India) if we want to keep the hospital bed to population ratio near the ideal ratio of one bed for every 500 persons, we will require more than 2 million beds. Assuming that we can build 1,000 hospitals with 200 beds every year, it will take 10 years to cater to the needs of the population in India (Ganapathy, 2001). Added to this is the annual rate of growth of population. The rate of growth in hospital beds to cope up with the increasing population is economically unsustainable and technically not viable since the number of medical specialists also cannot grow to meet this demand. It is intractable in reality. Thus in an ideal situation where every citizen needs to have an immediate medical attention unless we have some kind of telepresence of specialists and doctors. The use of telemedicine avoids unnecessary strain involved in travel and associated expenses, provides immediate attention and care, and can avoid hospitalisation and allow the patients to stay home, enjoying family support.

For example, in developing countries, congenital foetal abnormalities are major causes of prenatal mortality and morbidity. Suitable medical attention can be given at an early stage to help women, using the ultrasound imaging technology at remote places and transmitting the image either through telephone lines or the Internet. Chan et al. (2000) describe a real-time tertiary foetal ultrasound telemedical consultation system, using a standard integrated system digital network (ISDN), that operates in Queensland, Australia. This consultation system has gained acceptance from the clinicians and patients.

As another example, consider the home care for the elderly in developed countries.

Here telemedicine and telediagnosis play a different role. An aging population and rising health costs have created the need to care for more patients in their own homes. Hospitals without walls (e-hospitals, or virtual hospitals) provide for continuous monitoring of patients in certain diagnostic categories. The mobile communication and computing technology is vital to transmit information from a home computer through telephone lines and the Internet to appropriate medical professionals. Wilson et al. (2000) describe how to build such "hospitals without walls." The key technology used here is a miniature, wearable low-power radio that can transmit vital and activity information to a home computer, from which data is sent by telephone line and the Internet to the concerned doctors. This system has been experimented in Australia by the Commonwealth Scientific and Industrial Research Organization (CSIRO).

Thus telemedicine and telediagnosis are economic necessities for both the developing and the developed world, and the capital investment on a telediagnostic computing environment is of great benefit to society.

Challenges to Telemedical Service

Although telemedicine has many advantages, the following challenges arise:

- **Reimbursement:** How to charge patients (rationale), who will bear the cost of treatment, and how can the costs be reimbursed from health providers?
- **Costs:** Who will support the ongoing costs?
- **Human factors:** Will telemedicine gain wide acceptance from patients, doctors, governments, and politicians?

- **Liability, malpractice:** Who will be responsible for liability in case of wrong diagnosis and treatment, and how to avoid and eliminate malpractices?
- **Licensing:** How to evaluate telemedical professionals and provide medical licenses?
- **Telecommunication issues:** How to make an appropriate choice of the bandwidth requirement to make telediagnosis cost effective?
- **Interoperability**: Software interoperability is a key requirement in telemedicine since different modalities of patient records are used, running on different platforms. How to achieve this feature?
- **Funding/sustainability:** Setting up a hospital without walls (or a virtual hospital) requires capital expenditure and sustainable running expenses. Thus it is a national issue requiring cooperation of different agencies.
- **Evaluation/outcomes:** The evaluation of the different diagnostic categories suitable for telemedicine and the outcomes of the treatment procedures require monitoring.
- **Confidentiality and security requirements:** Security of patient data during storage and transmission are vital to safeguard confidentiality and privacy of patient information, as it can be abused or tampered to harm the concerned individuals. These criminal threats are more serious than the virus attack, overloading, and network disruption. Biometric authentication, (Nanavati et al., 2002) could be an answer in dealing with patient information. HIPAA (Health Insurance Portability and Accountability Act) has devised certain security measures in handling telemedical information (http://www.hipaadivsory.com / regs/securityoverview.htm).

We will not deal with these aspects as these are beyond the scope of the main theme of this chapter.

MOBILE MULTIMEDIA TELEDIAGNOSTIC ENVIRONMENT

A **mobile multimedia telediagnostic environment (MMTE)** permits users to work remotely on common shared resources and applications and simultaneously communicate both visually and through audio. Such an environment becomes more flexible and useful if it can work in a wireless and wired-in (integrated) environment so that the services can be provided for mobile hosts. As already mentioned, mobility of users becomes very important for many applications in telemedicine, where doctors, specialists, and health-record officials can cooperate and discuss particular medical treatment. In this application we are concerned with a large data set such as radiological images, video images of signals, and text that are transferred to the host from a server. Typically, in this case the communications are asymmetric in the sense that the server transfers a large amount of information, while the mobile host sends only a small amount of information in the opposite direction. Here the users have interfaces of PDA or laptops interacting remotely. In this application we need cooperation among the participants through special communication tools for conversation (Roth, 2001) and e-pointing (MacKenzie & Jusoh, 2001). The conversation can be of conference type, where two or more participants are involved. The e-pointers aid each participant to point out a particular segment of an image or a video image of a signal so that each of the other participants can visualise the movements of the remote pointer. This would provide for greater clarity and effectiveness of discussion about the particular image. Also in telesurgery (e-surgery) where two or more operating rooms are connected by a network, live video signals may require to be transferred from endo-camera (camera for photographing internal organs) and operating room camera to other remote locations for consultancy. This would allow surgeons not only to see but also visualise surgical instrument movements with 3-D models in real time during the surgery.

PREREQUISITES FOR THE DEPLOYMENT OF MMTE

Reliable Communication Network and Equipment

A reliable multimedia communication network that links the remote centres with hospitals is essential. The delivery of multimedia content in a timely fashion is very important. The key is to find a method of delivery that is universally acceptable, easy to use, and reliable. The answer comes from the Internet. The Internet offers a developer the ability to publish information very quickly. It provides a widely used and uniform communications medium to link users together to access or deliver multimedia information. However, while using mobile devices and the Internet as vehicles for multimedia delivery and interaction, the following factors are to be taken into account:

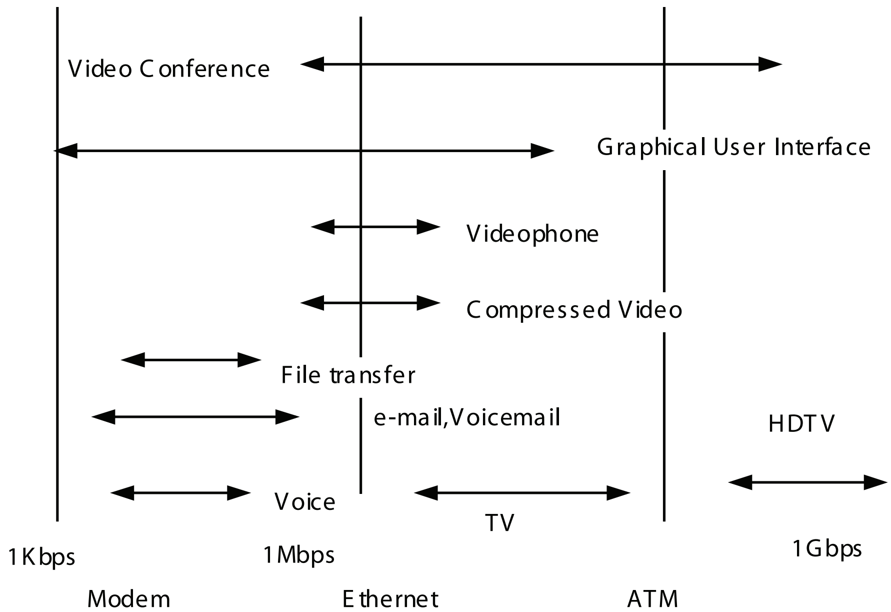
Type of Application

The application requirements can range from a very simple radio to very complex real-time image/signal processing system

Communication Bandwidth Requirements

Text requires the lowest bandwidth, while audio and video data and signals require a significant increase in bandwidth. Specification of bandwidth to be used and compression techniques used are to be laid down so that the data and images that are transmitted are of diagnostic quality. The following issues arise in using networked communication:

Figure 1. Bandwidth (log scale) requirements for applications



i. Choice of equipment and bandwidth management for fast, reliable, and secure transmission of patient data.
ii. Costs involved.

Bandwidth Management

Bandwidth determines the information capacity of a network per unit of time. Wireless networks deliver lower bandwidth than wired networks. Hence software techniques based on compression should be used. Also scheduling communication intelligently can save bandwidth. For use in telemedicine, the techniques should be extremely reliable. Current cutting-edge technologies are yet to develop. Bandwidth requirements along with applications are given in (approximate) logarithmic scale in Figure 1.

Three common technologies used are (bps = bits per second; K= Kilo; M= Mega; G = Giga):

Dial-up mode: Rate 28.8 Kbps
T1: 1.544 Mbps
DS3: 45 Mbps

As an example, standard X-ray transmission takes 30 minutes in dial-up mode, 30 seconds in T1 mode, and 1 second in DS3. It is obvious that the cost goes up as we want to increase the bandwidth to communicate voice, data, and pictures.

As mentioned earlier, even a low-cost dial-up mode can be helpful in telemedicine. Of course the more sophistication we introduce the more complex and costly the system gets, and the system has to be supported by governmental agencies or health insurance providers.

DS3 is a dedicated, private line service designed for point-to-point communication. This service uses fibre-optic cable. One can have the option of tiered DS3 service from lower to higher bandwidth from 5 Mbps to 45 Mbps, depending upon cost considerations and transmission requirements.

Choice of Multimedia Hardware

We need a proper choice of graphics and audio equipment for quality images and audio for diagnosis.

Low-Cost Computing Environment

Low-cost workstations are to be made available at the user's and health provider's end. Suitable software and hardware are to be developed so that the workstations are easy to use by doctors, nurses, and other paramedical staff. For this purpose, suitable training centres are to be made available.

Cost of Consultation

Low cost per consultation, faster diagnosis, faster reply to queries, and quicker medical aid when compared with the conventional method of a direct visit to the doctor.

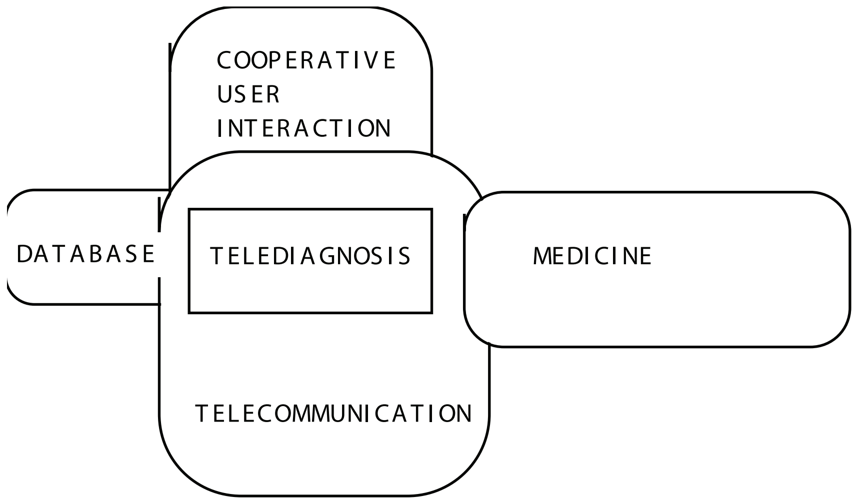
Case Evaluation and Emergency Attention

Quick evaluation of emergency cases and arrangement for transportation to hospitals supported with mobile telemedical personnel and equipment.

FEATURES OF A TELEDIAGNOSTIC ENVIRONMENT

A typical cooperative telediagnostic (e-diagnostic) environment is shown in Figure 2. Yearwood and Pham (2000) and Pham and Yearwood (2000) describe a cooperative telemedicine environment for interactive processing of visual data. This environment consists of databases containing medical/pathological images and textual information, a cooperative interaction facility, and telecommunication. The typical characteristics of such an environment are:

Figure 2. A cooperative diagnostic mobile environment



- **Remoteness of users:** Users work remotely on common shared resources and applications and simultaneously communicate both visually and through audio. This environment becomes more flexible and useful if it can work in an integrated (wireless and wired-in) environment so that the services can be provided for mobile hosts.
- **Cooperation:** Many e-medicine applications require doctors, specialists, and health-record officials to cooperate and discuss particular medical treatment. In this application we are concerned with a large data set such as radiological images, video images or signals, and text that are transferred to the host from a server. Cooperation among the participants requires special communication tools for conversation, e-pointing, and e-surgery.
- **E-pointing facility:** E-pointing is the act of moving an on-screen tracking symbol, such as a cursor, by manipulating the input device. Such a tracker can be placed over text, images, icons, and menu items and is basic to human interaction with graphic interfaces. Such a facility can aid conversation between two or more participants dealing with medical images or signals. The interactive e-pointers (MacKenzie & Jusoh, 2001) aid each participant to point out a particular segment of an image or a video image of a signal so that each of the other participants can visualise the movements of the remote pointer and discuss any abnormality for diagnostic purposes.
- **Facility for Internet link:** Also users should be able to remotely access worldwide knowledge bases/databases, download files from the Internet, and browse the World Wide Web using portable and mobile devices such as laptops, palmtops, and PDAs. Further technological developments are needed to provide the PDA users with facilities to handle text, graphics, and audio messages and access interactive multimedia services.

SYSTEM STRUCTURE OF MMTE

The integrated computing environment consists of fixed host computers and wired-in/wireless mobile client computers (Bates, 1994, Hatfield, 1996; Imielinski & Badrinath, 1994). Fixed hosts (FHs) are connected together via a fixed high-speed network (Mbps to Gbps). The mobile clients (MCs) are capable of connecting to the fixed network via a wireless link. The components in the fixed network are called fixed hosts. Fixed hosts (FHs) provide mobile application services and coordinate tasks to mobile hosts. MCs support query invoking and information filtering from FHs to provide personal information service.

The remote access to image and other related databases may appear like automatic teller machine transactions, but they differ in several respects:

i. They are long-duration transactions requiring the transfer of a large amount of data and require lengthy negotiation, cooperation, pointing, and decisions to reach a final diagnosis and therapy. In this cooperative environment, therefore, we need to sacrifice some of the properties of the traditional transaction model (Krishnamurthy & Murthy, 1992) that enforces ACID properties (atomicity, consistency, isolation, and durability). Note that, in particular, we cannot roll back any transaction in the context of e-surgery. Also isolation implies that the actions of one participant are invisible to another. Therefore, we need to introduce a more realistic model in which the isolation property is removed and intermediate results are made visible so that any catastrophic incidents can be avoided. Also precedence order in execution and context dependencies have to be taken care of. This means we must remove the atomicity constraint that requires "***all or none***" operation and rollback. This model is called "***a workflow model***." More detailed aspects of this model and relevant software design features are described briefly in a later section and in chapter 2 of this book.
ii. A service to permit two users to interact simultaneously with a medical imaging system for cooperative diagnosis. To help diagnosis we need to provide each user with a pointer of a desired identity that can be locally operated and at the same time can be visualised at the remote terminal. This is a concurrent action from two or more users on a read-only image database.
iii. Also an audio conference facility is needed for cooperative diagnosis.
iv. Collaborative multimedia environment allows medical specialists to cooperate in diagnosis. The environment has to support remote database access for medical images, the retrieval of relevant medical cases to support diagnosis, and communication among participants through telepointers and image annotation for freehand drawing.
v. A telepointing device with a very high reliability.

Thus the key elements in the design of a telediagnostic system are:

i. Design of an appropriate workflow model for telemedical applications.
ii. Supporting database access in a mobile cooperative environment for medical images, related text, and video signal images. Also additional support through handheld devices, such as PDAs, for supporting remote information sharing and processing.
iii. Providing a cooperative environment for communication among participants audiovisually through telepointers to visualize movements remotely.
iv. Appropriate hardware/software tools.
v. Implementation of the reliability, fault tolerance, and recovery features.

MOBILE WORKFLOW

Mobility is central to many applications involving telemedicine. This arises due to the fact that the patients, doctors, and data collecting instruments can always be on the move. Hence any transaction that occurs among the clients and servers is a mobile transaction. A mobile transaction is a distributed transaction that can be executed partly within that mobile client (MC) as internal transactions (intran) and partly in other fixed hosts (FHs) as external transactions (extran). Each FH has a coordinator FHC that receives external transaction operations from mobile hosts and monitors their execution in the database servers within the fixed network. Similarly each MC has a coordinator MCC.

In a mobile environment, some of the properties of the traditional transaction model (see Chapter 2 of this book; Krishnamurthy & Murthy, 1992) that enforces atomicity,consistency, durability, and isolation have to be replaced by a more realistic model in which the isolation property is removed and intermediate results are made visible. Also precedence order in execution and other dependencies have to be taken care of; this means we must remove the atomicity restrictions. Such a model turns out to be a workflow model between the MC and FH.

A **workflow** is a collection of tasks organized to accomplish some business activity. Here each task defines some unit of work to be carried out. A workflow ties together a group of tasks by specifying execution dependencies and the dataflow between tasks. Also there could be a constraint that a particular task cannot begin until some other task ends. Such constraints can be specified by event-action systems.

In a workflow model we need to ensure correctness and reliability of workflows. Correctness means that the concurrent execution of transactions and workflows is interleaved in a way that incorrect results such as lost update or inconsistent retrieval cannot occur. Recovery means both the tasks and the transactions are recoverable in the event of a failure arising due to disconnection.

Thus we need to satisfy the following requirements:

i. A programming paradigm to support a combination of transactions that satisfy atomicity, consistency, isolation, and durability (ACID) properties, and workflow tasks that do not have such ACID properties.
ii. A method of managing control flow of workflow and transactions.
iii. A suitable recovery model under failure of the workflow. This recovery is very complex compared to short transactions since it will require re-instantiation and following the control flow of actions strictly.
iv. Contextual information (Henricksen et al., 2002; Mattern & Naghshineh, 2002) that preserves the consistency of databases as well as the local state of the application.
v. Remembering the execution history and path and local states produced in the past.
vi. Externalization of preliminary results: workflow computations need to externalize their results before they are completely done. This implies that unilateral rollback is no longer possible; one needs to specify compensating actions as part of the control flow description.
vii. Concurrency and consistency control: Consistency can no longer be based on serializability only; we must now allow for application-oriented policies of synchronizing access to shared objects.
viii. Conflicts handling: In general, it is not feasible to let some surgical or diagnosis activity wait in case of a resource conflict until a long-duration activity has completed. Nor is it acceptable to roll it back to the beginning. Therefore the control flow description has to specify what should be done if a resource conflict occurs and how it can be resolved using priorities and context. For example,

in an emergency, it is necessary to suspend less critical tasks and postpone them for a later time.

HUMAN-COMPUTER INTERFACE AND SOFTWARE DESIGN

The software and human-computer interface system design consists of the following steps:

i. Design an appropriate transactional workflow model for telemedical applications.
ii. Support database access in a mobile environment for medical images and related video signal images.
iii. Provide a cooperative environment for communication among participants audio-visually through telepointers to visualize movements remotely.
iv. Adapt currently available tools to design the required software for the cooperative multimedia mobile environment.

Two key issues involved in the above steps are:

- Choice of an appropriate software tool to implement mobile workflow.
- Choice of suitable hardware for mobile access and cooperation.

We will now provide some practical aspects on the aforesaid design steps.

Software Tools

Presently, Java (Flanaghan, 1996; Hamilton, 1996; Yourdon, 1996) seems to be the best choice due to the following important features:

- **Portability:** Java is platform independent.
- **Efficiency, power, simplicity:** Java retains the efficiency, power, and simplicity of C++ but is less complex. There is no pointer arithmetic and no memory management. Memory management occurs automatically. Strict rules are enforced regarding variables; this permits detection of mistakes when the program is compiled.
- **Safety:** Java is safer than other low-level languages such as C++ since Java is free from pointer errors and has uniform reference semantics and automatic storage management. Also it provides security.
- **Openness:** It is a de facto standard for platform-independent computing and can run at any level: client, application, or database.
- **Transmission on network:** Java has been developed with the aspect of transmission across the network in mind; Java includes very developed network functionality in its core so that the application developer can concentrate more on users' needs rather than on details of network code.
- **J/SQL and Java Data Base Connectivity (JDBC):** JDBC is a simple call-level library interface. J/SQL provides a seamless integration of Java and SQL. JDBC provides for simultaneous connection to several databases, transaction management, simple queries, manipulation of precompiled statements with bind variables, calls to stored procedures, streaming access to long column data, access to the database dictionary, and description of cursors.

J/SQL is an integration of SQL statements in Java programs. It is more concise than JDBC and more amenable to static analysis and type checking. Use of J/SQL has several benefits:

i. Provides for compile-time type checking.
ii. Runs everywhere.
iii. Extends server: The Oracle database server will store a user's J/SQL program and execute it in its server.

iv. Bridges languages: The J/SQL preprocessor draws a clear distinction between the standard Java language and the supplementary J/SQL clauses, which add functionality to that language by exposing database objects (e.g., tables, cursors) and services (SQL, Persistence) as standard Java objects.

JDBC provides for both automatic commit as well as specific commits from the application before a transaction is committed to the database. JDBC does not support two-phase commit protocol. External support is needed to allow the Java application to have two-phase commits.

Persistent Java (PJava) allows for online transactions. Also the programmer can create new transactional styles. Such styles, as already mentioned, are very important for mobile applications. Transactions in PJava can be launched either synchronously (in the same thread) or asynchronously (in different threads) by invoking the Start () method of the transaction object.

Multithreaded processes are useful for clinical decision support in complicated medical diagnosis involving temporal reasoning for real-time medical data.

Nested transaction enables one to perform updates in a child transaction without affecting the parent transaction. A child transaction that completes successfully passes all its updates (the modified objects) to its parent transaction. If the child transaction aborts, none of its updates are ever reflected in the parent transaction. Also we can spawn parallel independent nested transactions. In this case each of the sibling transactions are isolated from all others and can commit or abort independently.

JetConnect allows real-world applications to be developed using Java by providing data access to any ODBC- or JDBC-enabled database, including DB2 and Oracle. JetConnect augments the Java programming language with easy-to-use, vendor-independent database connectivity that enables transaction-oriented access to corporate data stores from Internet/intranet applications. JetAssist is a GUI-based tool for rapid development of database applets that take advantage of JetConnect's rich set of features. JetAssist employs a wizard-style approach that steps the user through applet creation. Armed with only a casual acquaintance with database principles and a Java-enabled Web browser, an end user can construct and maintain a custom applet using an interface that requires absolutely no programming.

JetExpress provides high-speed connectivity between Java applets and applications and the corporate information resource. JetExpress provides transaction acceleration functionality when accessing DB2 databases, with specific optimization for other DBMSs scheduled in the near future.

To use JetConnect, the system must have these operating systems and software packages installed: either Windows 95/Windows NT or a supported version of UNIX; Java Developer's Kit (JDK); the 32-bit ODBC drivers for the database we want to access. Our experience reveals that Java, the design by contract tool in Java iContract (Kramer, 1998), Java Database Connectivity, JetConnect tools, UML (Gogalla & Kobryn, 2001), and OCL (Warmer & Kleppe, 1999) are eminently suited for our purpose. The type of relaxed transactions we need (subjunctive, or "what-if," programming) requires that we execute hypothetical or pseudo-transactions to test the intention of actions for trial-error design. Such a model uses "virtual copy" and arises in real-time transactions in patient-health monitoring, flight plan, and cooperating information systems.

Lee (2001) describes a Java-applet-based image-guided telemedicine system via the Internet for visual diagnosis of breast cancer. This system automatically indexes objects based on shape and groups them into a set of clusters. Any doctor with Internet access can use this system to analyse an image, query about its features, and obtain a satisfactory performance (http://dollar.biz.uiowa.edu/~kelly/telemedicine.html).

Software Agents

Software agents, which are personalized, continuously running, and semiautonomous objects, can play an important role in cooperative telemedicine. Such agents can be programmed for supporting medical diagnostic intelligence and keep a watchful eye to discover patterns and react to pattern changes that usually occur in epidemics and biological and chemical terrorism. Also agents can help in the appropriate choice of doctors and allocation of hospitals and beds for patients. Since different modalities used for inputting the patient diagnostic data require a heterogeneous computing environment, software interoperability is a major issue. Software agent technology helps to solve this issue; Ganguly and Ray (2000) describe a methodology for the development of a software-agent-based interoperable telemedicine system. This system has been illustrated using a tele-electrocardiography application. Unified Modelling Language, or UML (Gogolla & Kobryn, 2001; Warmer & Kleppe, 1999), has been used for this purpose. O' Hare and O'Grady (2002) describe the use of agents deployed from PDAs and mobile devices. This approach will be useful for online access of a large repository of medical information that is customised and personalised to match the interest profile of an individual. For medical education this will be a very useful tool.

FIPA (the Foundation for Intelligent Physical Agents; http://www.fipa.org) aims to improve agent interoperability by providing standards for protocols and languages. Also the Java 2 Micro Edition (J2ME) is targeted at PDAs. These developments will provide an agent execution environment in PDAs.

Hardware: PCs, Laptops, and PDAs

Presently, portable and mobile devices, such as laptops and personal digital assistants, are not very well suited to remotely access resources in an efficient and reliable manner for reliable telediagnosis (Roth, 2001). For instance, information sharing among doctors through handheld appliances is of limited applicability, except for transmitting small amounts of data, such as heart rate, blood pressure, and other simple monitoring devices. Typical data types for current handheld appliances are: text, data entries, numbers, and tables. None of the applications above can deal with multimedia data such as audio video, which requires considerable bandwidth, sufficient output devices, and a very powerful battery. Also, currently multimedia data are not yet suitable for handheld appliances. Very few applications support graphical data (Roth, 2001).

To provide robustness in the mobile environment, we must overcome different kinds of failures (e.g., radio link failures, mobile host and fixed host failures). Suitable protocols to recover under faults using the recovery mechanisms or rescue clauses are to be developed. WaveLAN radio cards (WaveLAN/AT cards for PCs and WaveLAN/PCMCIA cards for laptops or notebooks) are available (Fogle, 1995; Wong, 1995). WaveLAN is an indoor wireless LAN based on a cellular structure. A cell is the wireless coverage area in which WaveLAN stations can communicate with each other. Also, infrared-based wireless technology is available commercially. Using these devices, PCs are linked.

Telepointers

This is an interaction style for presentation systems, interactive TV, and other systems where the user is positioned at a remote site from the display. Pointing is the act of moving an on-screen tracking symbol, such as a cursor, by manipulating the input device from a remote site. Presently, two devices are commercially available: these are GyroPoint (a product of Gyration Inc., Saratoga, California) and RemotePoint (a product of Interlink Electronics, Camarillo, California).

GyroPoint works in two distinctly different modes of operation: as mouse or as a tracking pointer based on gyroscope principles so that spatial motion can be generated across a screen.

RemotePoint uses infrared for transmission and joystick for motion control. Also telepointers for remote pointing of images and conferencing are not fully developed yet. Currently available tools, such as GyroPoint and RemotePoint(MacKenzie & Jusoh, 2001), lack accuracy and speed. The telepointer technology has yet to mature to provide reliable service for e-medicine and e-surgery. Along with the use of virtual reality, the pointer technology can be useful in teaching surgery and for trial-error planning of operations.

CONCLUSION

Cooperative telemedical informatics will have a direct impact on the rapidly changing scene of information and communication technology (including advanced communication systems) and will provide for greater interaction among doctors, radiologists, and health-care professionals to integrate information quickly and efficiently and make effective decisions at all levels. Some important pilot studies have already taken place in India recently in Apollo hospitals for emergency consultations and remote health care in Indian villages using satellite links (Ganapathy, 2001). Virtual e-hospitals will be a reality in the near future, providing much needed health care that is of great benefit to the human society. Telemedical informatics offers exciting possibilities and is a vastly expanding area of research. For those interested in current developments in these areas in the United States (National Library of Medicine, http://www.nlm.nih.gov/reserch/telemedicinit.html; University of Iowa, Virtual Hospital, http://www.vh.org/index.html) and Australia (CSIRO), reference may be made to several journals in the telemedicine area and also the Web sites provided at the end of this chapter.

ACKNOWLEDGMENT

The authors thank the reviewers for providing valuable suggestions in revising this chapter.

Chapter 3.28
Identifying Optimal Chronic Kidney Disease Patient Education Web Sites:
Assessing E-Health Technology by Content Area Experts

Lisa M. Nanovic
University of Wisconsin, USA

Jonathan B. Jaffery
University of Wisconsin, USA

ABSTRACT

One in nine adults in the United States has chronic kidney disease (CKD). Randomized studies show electronic health (e-health) systems improve health outcomes in chronic disease. This study describes a systematic evaluation of available CKD Web sites. We evaluated Web sites for educating patients with CKD, focusing on three specific design issues: usability, quality, and content. Thirty Web sites were evaluated between April and July 2004. Cohen's kappa and intraclass correlation of quartile rankings for two independent evaluators were calculated. Mean score for evaluator 1 was 7.293 (standard error 0.511) and for evaluator 2 was 8.189 (0.413). Cohen's kappa for the 2 evaluators' total scores for all 30 Web sites is 0.7671, and intraclass correlation is 0.7703. In general, results show that it is possible to identify Web sites more likely to provide a positive educational experience for CKD patients. Further evaluation is needed to investigate the utility of variably ranked Web sites as educational interventions.

INTRODUCTION

Medical informatics has traditionally consisted of applications to improve information exchange, decision-making, and time management for health care professionals. As the fundamental relationship between patients and physicians has changed from paternalistic to partnership, the informatics focus is shifting towards the consumer (Eysenbach, 2000). The objectives of this transition are to empower patients with appropriate medical knowledge, education, and the tools for self-management. This may be particularly effective in enhancing patient and health care provider partnerships in the management of chronic disease (Celler, & Lovell, 2003). According to the Pew Research Center, a nonpartisan organization that provides information on national and global trends, 70% of the health care consumers, who are influenced by online information, report that the Internet affected their decision making about health care (Fox, & Rainie, 2002). Still, very little is known about how patients judge health information obtained on the Internet. Moreover, data suggest that while health care consumers are facile at obtaining answers to directed health questions, they seldom assess the quality or source of the information. Consumers also tend not to remember Web sites from where they acquired the information (Eysenbach & Kohler, 2002). Thus, health care provider-sanctioned Web instruction is needed to help alert and direct patients to information that is valid and accurate.

One in nine adults in the United States has chronic kidney disease (CKD) (Coresh, Astor, & et al. 2003). This creates a tremendous public health burden, with more than $22 billion in spending on the end-stage renal disease (ESRD) program in 2002 (USRDS, 2002). Slowing the rate of loss of kidney function in later stages of CKD by 10-30% could save $5 to $30 billion dollars in health care expenditures over the next decade (Trivedi, & Pang, 2002). Prior to end-stage disease, there may be opportunities to slow progression and delay disease complications, but patient education is vital. Time constraints prevent clinicians from taking on the task of repetitive patient education and counselling. However, customized Web sites available via the Internet may be able to fill this need by providing novel ways to reach patients with CKD.

Randomized studies have found that e-health systems can improve knowledge, self-care, quality of life, coping skills, health care participation, and health outcomes in chronic disease, as well as self-management behaviors, including diet, exercise, medication taking, and health utilization (Gustafson, & Hawkins, 1999a; Gustafson, & McTavish, 1999b). However, very little is known about the selection of e-health Web sites and the assessment of medical information obtained by patients (Eysenbach & Kohler, 2002). There are a number of CKD patient education sites available on the World Wide Web, some of which are sponsored by not-for-profit organizations and some by private industry. Few are written at a level so as to be useful to the general population, and many do not comply with available standards for health Web sites (Calderon, & Zadshir, 2004a; Calderon, & Zadshir, 2004b; Jaffery, & Becker, 2004).

Additionally, as research in the field of e-health expands, it is becoming increasingly clear that in order to capitalize on the potential power of the Internet as an educational tool, innovative methods for communicating with patients is needed. Marill, Miller, and Kitendaugh (2006) report on the ongoing challenges to the National Library of Medicine's Medline Plus, highlighting the dynamic process inherent in health information Web site design.

Although more literature is emerging on optimizing human-computer interactions for specialty clinical areas and the education of chronic disease patients, to date, much of this has been led by the cancer and mental health arenas (Bader, & Strickman-Stein, 2003; Chelf, & Deshler, 2002; Chernecky, & Macklin, 2006; Chou, & Lin, 2004), with limited contribution in the nephrology literature. The purpose of this manuscript is to describe a systematic evaluation of readily available CKD Web sites. A more comprehensive review of these sites revealed significant deficits that are likely to impair their usefulness as educational tools.

METHODS

Based on our previous work, relevant literature in other disease states, and published guidelines for evaluation of e-health Web sites (Kim, & Eng, 1999; Robinson, & Patrick, 1998; Winker, & Flanagin, 2000), a system was developed for evaluating Web sites aimed at educating patients with CKD. Three distinct Web-based design issues were addressed: usability, quality, and content.

1. **Usability:** Defined on the basis of the ease with which a user can access clinically relative material (ease of navigation) and readability (reading level), was assessed with the following tools:
   a. Reading level, which was assessed using the Flesch-Kincaid grade level formula (Kincaid, Rogers, & Chissom, 1975).
   b. Ease of navigation, which was assessed by the number of links needed to get to clinically relevant material. Clinically relevant material is defined as containing information directly related to aspects of CKD management most likely to improve clinical outcomes, as elaborated below. Number of links was defined as the number of mouse-clicks needed to arrive at such material from the home page.
2. **Quality** is a complex measure. Defining and assessing the quality of health education Web sites remains an elusive goal (Gattoni & Sicola, 2005). Various criteria have been used to evaluate the quality of health information on Web sites. These have arisen through expert consensus or arbitrary design. In this study, we defined quality specifically on the basis of adherence to those shared areas that these groups describe as essential when judging the quality of e-health sites (Kim et al., 1999; Robinson et al., 1998; Winker et al., 2000). In this sense, the opinions of area experts are key in judging the quality of relevant CKD Web sites.

Quality questions *(Yes/No)*:

1. Authorship/source: Are the sources of health information mentioned with credentials listed?
2. Quality/best-available evidence: Is it clear whether information is based on scientific evidence (studies), expert consensus, or personal/professional experience/opinion?
3. Privacy: Is there a privacy policy?
4. Updated: Is the date of last modification listed?
5. Contact: Is a link to a valid contact form/e-mail available?
6. Ownership/sponsorship: Are all sources of funding listed?
7. Advertising: Is there an advertising policy?
8. Editorial content: Is there an editorial policy/description of content review?

3. Content had no standard measures to evaluate what information is appropriate to convey to health care consumers visiting a CKD Web site. Evaluations of other e-health education sites for other disease entities have tended to focus on five to eight clinical areas (Croft & Peterson 2002; Impicciatore, Pandolfini, 1997). We judged a CKD Web site's content according to how accurately it addresses six areas. These are based on specific management goals according to the kidney disease outcome quality initiative (K/DOQI) (National Kidney Foundation K/DOQI, 2004), emphasizing aspects of CKD management most likely to improve clinical outcomes. At this point, we focus on each of the areas that are grouped under high blood pressure, CKD complications, and nutrition.
   a. High blood pressure. Hypertension is both a significant underlying cause and

complication of CKD. Blood pressure control is recognized as among the most important factors for slowing the progression of CKD and is associated with other positive outcomes, including the prevention of cardiovascular disease.

Questions *(Yes/No)*:

1. Hypertension: Are specific blood pressure goals addressed?

b. *Complications of CKD.* Among the kidney's functions is the production of two hormones, erythropoietin, a glycoprotein hormone that stimulates the production of red blood cells by stem cells in bone marrow, and 1,25 dihydroxy vitamin D_3, a steroid compound necessary for normal bone growth. Consequently, two of the most common complications of CKD are anaemia and bone disease, or renal osteodystrophy.

Questions *(Yes/No)*:

2. Anemia: Are target hemoglobin/hematocrit goals addressed?
3. Bone disease: Is vitamin D replacement therapy addressed?

c. *Nutrition.* Diet is one of the most modifiable factors that can affect the control of all of the above, thereby offering the potential to have profound effects on both CKD progression and morbidities. Therefore, our content tool evaluates whether CKD Web sites addresses some of the nutritional areas most relevant to CKD, namely sodium, phosphorus, and protein intake.

Questions *(Yes/No)*:

4. Sodium: Are specific dietary sodium goals addressed?
5. Phosphorus: Is appropriate phosphate binder use addressed?
6. Protein: Are specific dietary protein intake goals addressed?

It is important to note that as the appropriateness of CKD Web site content is something that cannot be assumed by the Web site owner nor assessed by the consumer (CKD patient), there is the need for content validation by experts, irrespective of target audience. Therefore, in designing our study, two nephrologists were to perform the Web site evaluation, drawing on their expertise in assessing CKD Web site content. Other aspects of evaluation are objective including "reading level" and "number of clicks," but it was vital that experts in nephrology assess the appropriateness of content.

CKD WEB SITE IDENTIFICATION AND STATISTICAL ANALYSES

CKD Patient Education Web site Identification

Accordingly, the investigators also felt that it was crucial to attempt as exhaustive a search of CKD Web sites as possible, using multiple common search engines. For instrument testing and validation, however, the evaluation was led to exploring the National Kidney Disease Education Program Chronic Kidney Disease Compendium (NKDEP) (2004) for additional relevant Web sites to support instrument testing and validation.

Using five conventional search engines (Excite, Google, HotBot, Lycos, and Yahoo), we entered four search terms (kidney disease, chronic kidney disease, chronic kidney failure, and renal failure) and identified the first 40 uniform resource locators (URLs), the World Wide Web address of a site on the Internet, from each search engine. Of these, 110 were redundant, leaving 90 discrete sites. Twenty-one sites were directed toward the care of animals, 18 were obsolete or pertained to nondisease states, 19 were oriented toward providers rather than patients, and two were focused solely on end-stage renal disease. For the final evaluation, this left 30 Web sites designed for educating patients with CKD.

In the data analysis, we calculated quartile rankings for each of the three areas for two independent evaluators for all 30 Web sites using Microsoft 2000 Excel. Cohen's kappa and intraclass correlation were calculated using the online statistics toolbox of the Department of Obstetrics and Gynaecology at the Chinese University of Hong Kong (Department of Obstetrics and Gynaecology 2005 [accessed 2005 March 23]).

RESULTS

Preliminary Content Validity and Reliability Testing

Initially, five Web sites not among those identified by the search described above were identified using the NKDEP (2004). Two nephrologists from University of Wisconsin-Madison evaluated these sites. Revisions were made based on these pilot evaluations, and this process was repeated with additional Web sites identified in the same manner, allowing for very good correlation among evaluators (r=0.925).

Specifically, revisions to the "usability" construct included the "ease of navigation" concept in addition to "readability." During piloting, readability was assessed using both the Fry readability scale and the Flesch-Kincaid grade level formula. We found these tools to correlate very well (r=0.857), which is consistent with previous correlations between the Flesch-Kincaid formula and other readability scales (Kincaid et al., 1975; Paasche-Orlow, Taylor, 2003). As well, the Flesch-Kincaid formula is significantly easier to use, as it is an embedded tool in Microsoft Word. Therefore the Flesch-Kincaid formula was subsequently chosen for the 30 Web site evaluation. Accommodation for visual impairment was removed as none of the Web sites allowed for this. Content was revised to better reflect specific goals and published guidelines of the National Kidney Foundation, which in turn are based on best evidence or, in the absence of evidence, expert opinion (K/DOQI, 2004). Finally, quality was revised to allow for greater objectivity. All sections were simplified dramatically. Piloting the system in this manner has enabled us to render it a more objective instrument, improving inter-rater reliability and has allowed us to address content validity.

Following piloting of the evaluation system, scoring was weighted to allow each area of evaluation to have similar weight for a median score (Figure 1). Usability scores were the composite of readability and ease of navigation, with readibility, which is key to usability, given greater weight. Because reading grade levels are inversely related to readibility (i.e., the higher the reading grade level, the lower the readibility) and the number of links needed to locate useful material is likewise inversely related to ease of navigation (i.e., the greater the number of links needed, the lower the ease of navigation), the following adjustments were made: the grade level (out of 12) was multipled by a factor of 0.2, and then subtracted from 4. The number of links needed was multiplied by a factor of 0.1, and then subtracted from 1. This formula allowed for the usability score, like the content and quality, to be higher with a lower reading grade level/number of links needed, as well as providing greater relative weighting of readability.

All 30 Web sites were evaluated between April and July 2004. Total scores were calculated for all 30 Web sites for each of the two evaluators. Mean score for evaluator 1 was 7.293 (standard error 0.511) and for evaluator 2 was 8.189 (0.413). Each evaluator's score was assigned scores accordingly to quartiles (i.e., 1 through 4; see Figure 2). Two indices were calculated to assess for interranking reliability.

Cohen's kappa measures concordance between two rankings on the same objects using an ordinal scale. In calculation, differences in scoring are usually weighted according to the differences between the two evaluators. A correlation of 0.6-0.8 is typically considered to be highly significant, with a correlation of 0.8-1.0 almost perfect. The Cohen's kappa for the two evaluators' total scores for all 30 Web sites is 0.7671. Intraclass correlation evaluates the level of agreement between rankings in measurements. The coefficient represents concordance, where 1 is perfect agreement and 0 is no agreement at all. The intraclass correlation for the two evaluators' total scores for all 30 Web sites is 0.7703.

DISCUSSION

The young field of e-health is changing rapidly. As Danaher, McKay, and Seeley (2005) point out in a recent analysis of information architecture design of health behavior Web sites) that despite increasing sophistication, there is as yet no standardized, universally accepted or validated process for designing the structure of health-related Web sites. Despite this, e-health Web sites designed to educate patients with CKD may be a powerful tool in the nephrologists' armamentarium. Currently available and easily accessible, CKD education Web sites present significant limitations as they do not appear to comply with available standards of e-health and are not constructed to be helpful for the majority of end-users who might benefit from them. Despite this, it is possible to identify Web sites that may be more likely to provide a positive educational experience for patient and families.

In previous work, we identified differences in readability and overall e-health Web site quality between nonprofit and industry-owned organizations (Jaffery & Becker, 2004). The present study is the first to our knowledge to attempt an exhaustive evaluation of the quality of CKD education Web sites in multiple realms. Calderon and colleagues identified 12 such sites that fulfilled at least three of six "domains of CKD information" and also found significant limitations of readability (Calderon et al., 2004a, b). While there have been many different criteria used by diverse groups to evaluate Web sites in a variety of specialties and subspecialties, readability is usually included and is nearly universally felt to be too high (high-school level or above) (Berland, Elliott, 2001; Friedman, Hoffman-Goetz, 2004; Griffin, McKenna, 2004; Kusec, Brborovic, 2003). Not surprisingly, Birru, et al. (2004) showed that adults with low health literacy are limited in their ability to gain information from health Web sites.

Our study has several limitations. Only two evaluators performed the Web site evaluations. While correlations were strong, it is possible that different results could be seen with additional evaluations. This study also did not address the issue of languages other than English; this is clearly a potential area for improvement, most notably for Spanish -peaking minorities, a disproportionate number of whom have CKD.

Many of the readily identified sites on the Web are either directed toward health care professionals, rather than consumers, or geared toward specific kidney diseases or distinct CKD complications. Because of this, the present evaluation may be biased against some of the more likely sites to be visited by patients, such as those arising more frequently from common search engines searches, but eliminated from our preestablished exclusion criteria. However, this bias should actually favor the Web sites that were chosen, as they fulfilled criteria more relevant to patients with CKD.

Finally, the present analysis does not specifically address the utility of these sites as educational interventions. While it is tempting to use information such as that found in this evaluation to make recommendations to patients and providers about specific Web site usage, in fact, none of these sites has been proven to enhance patient knowledge of CKD or aid in patient care. Further evaluation will be needed to investigate the relative utility of variably ranked Web sites as educational interventions, as well as strategies for more effectively steering patients and families toward Web sites most useful to them.

ACKNOWLEDGMENT

The authors would like to acknowledge Dr. Arjang Djamali, Dr. Loren Denlinger, and Dr. Bryan Becker for help with manuscript review as well as the anonymous reviewers of IJHISI for their helpful comments and editorial suggestions. Chapter 3.29
Evaluation of a Fuzzy Ontology-Based Medical Information System

David Parry
Auckland University of Technology, New Zealand

ABSTRACT

Evidence-based medicine (EBM) requires appropriate information to be available to clinicians at the point of care. Electronic sources of information may fulfill this need but require a high level of skill to use successfully. This paper describes the rationale and initial testing of a system to allow collaborative search and ontology construction for professional groups in the health sector. The approach is based around the use of a browser using a fuzzy ontology based on the National Library of Medicine (NLM) Unified Medical Language System (UMLS). This approach may provide high quality information for professionals in the future.

INTRODUCTION

Evidence-based medicine (EBM) (Sackett, Richardson, Rosenberg, & Haynes, 1997) has become increasingly important in the modern healthcare industry. Indeed, the concept of basing practice on evidence is even extending to the software engineering domain (Kitchenham, Dyba, & Jorgensen, 2004). Care that is not based on evidence has become increasingly indefensible from professional, safety, and economic points of view. Electronic access to high quality information can improve the professional knowledge of clinicians (Leung et al., 2003), and is very popular (Westbrook, Gosling, & Coiera, 2004). However, there are a number of difficulties associated with providing high-quality information to support EBM.

Assessing and finding appropriate information is difficult and can be time-consuming. This is partly due to the continuing difficulty users have in navigating the interfaces used by various systems and also because of the lack of training available. Indeed, if the concept of just-in-time information retrieval, as an aid to clinical decision-making at the point of care is to be realised (Gardner, 1997), then complex time-consuming strategies performed by trained users are not possible. Recent work, looking at the usage of the Clinical Information Access programme (CIAP) in New South Wales (Gosling, Westbrook, & Coiera, 2003) has emphasised cultural barriers to using online sources of information in a clinical setting, and this includes a perceived lack of skill in information retrieval by clinicians.

In assessing the usefulness of information sources, a framework to identify the aspects that are important needs to be established. Three dimensions have been identified, including information quality, clinical relevance, and clinical usefulness, based partly on the work of Sackett et al. (1997), and some of the limits used in PubMed and other information sources. The aspects of each dimension are outlined in Tables 1 to 3.

Diversity

Both the users and sources of information are characterised by diversity, and existing examples of information portals reflect this. The CIAP system, described by Moody and Shanks (1999), is particularly interesting as a "top-down" approach to providing evidence at the point of care, that is, the project was driven by the funding authority by the New South Wales health department rather than a "bottom-up" approach driven by clinical units. Having multiple database systems with many different interfaces and means of searching can only increase the obstacles to effective use of these tools. Even the CIAP system has over 40 different, searchable, databases available, each with its own interface, not to mention the individual journals, and tools such as Google.

Table 1. Information quality

Aspect	Comments
Peer-review	World wide Web (WWW) sites as well as journals may now have peer-review in place.
Randomised Controlled Trial (RCT)	This is the gold standard for clinical interventions although many interventions have not been subjected to this process. There are also issues of the quality and power of a trial. In some cases meta- analysis can cause smaller trials to lose credibility.
High citation number	This is more of a rule of thumb than an absolute factor. If the source is frequently cited then it indicates that large numbers of authors have found it relevant. It is perfectly possible that a particularly bad study may have a high citation index, or that the index may be inflated for other reasons such as age of the reference. It is possible to infer that references cited in 'good' documents are more likely to be good themselves but this is dangerous to extend too far.
Recent	This depends on the rate of change of the field. Documents in very active research areas are likely to have a shorter useful life than those in inactive areas.
Significant result	A document containing information that a treatment or diagnostic method is effective, and that this effect is large, is likely to be more useful than one that does not. If there is a traditional treatment that is shown to be ineffective then this also is significant.
Authoritative Source	For electronic sources of information the Health on the Net Code of conduct can give some guidance – otherwise, inclusion by indexes or directories e.g. MEDLINE or Cochrane can lend authority. The author affiliation can be an important issue here. An automated system for "authoritativeness" is described by (Farahat, Nunberg, Chen, & Heylighen, 2002).
Usability	Traditional web usability, for example Neilson's heuristics(Neilson, 2000), and also in terms of technical issues such as plug-ins media etc.

Aside from the differences in professional education — which will influence the use of preferred search terms — along with the clinical usefulness indicators, users may also have fundamental differences in their understanding of the meaning of terms. Then to share understanding of the meaning of search terms has been a driver in the use of ontologies (Noy & McGuinness, 2001), and indeed Musen (2001) assigned ontology use and creation as the central role in medical informatics. A general view of a system to support reaching for useful medical information is illustrated in Figure 1. Key elements include the use of multiple information sources accessed through a single browser, an ontology-supported scheme for query expansion and refinement, and the identification of users as members of a professional group with expertise in particular domains and five levels of expertise based on the Dreyfus (Dreyfus, Dreyfus, & Athanasiou, 1986) classification (novice, advanced beginner, expert).

The next section deals with the methods used to construct a system to see if such an approach is valuable. The third section describes the case study and prototype usability testing. The fourth section includes the results of the evaluation, and

Table 2. Clinical relevance

Aspect	**Notes**
Human	Although animal studies, or theoretical ones may be of great use – for example in the case of poisoning or electric shock, human studies are often essential
Correct Sex	Included in this is whether the interventions are safe for pregnant women, and the variation in body sizes and compositions between the sexes, along with other issues related to gender.
Age group relevance	Various age bands are used, or bands that reflect characteristics of the individual rather than his or her age.
Speciality is appropriate	Information designed for one medical specialty may not be appropriate for others, for example between pathologists and other clinicians. Similarly the information requirements of different clinical groups e.g. Physiotherapists and Surgeons treating a patient with an artificial hip may have different needs.
Appropriate language	Is this information in a suitable language for use by clinicians, or is it designed for lay people? The requirements for precision and readability will vary according to the intended audience.

Table 3. Clinical usefulness

Aspect	**Comments**
Appropriate to stage of encounter (e.g. therapy, diagnosis, etc.)	This also excludes information that is purely of a research nature, if better information for the clinical decision is available. However such information can be useful if it casts doubt on current clinical practice, or can help explain otherwise unexpected results.
Deals with available tools	This includes such aspects as whether the drugs or procedures involved are licensed or available in the location, and acceptable in terms of cultural factors and cost.
Suitable format	Are the documents or information sources able to be read by the user; correct language, is a machine reader available. Concrete example of this includes different varieties of microfiche, or PDF files that may require large bandwidths for download.
Available in a timely fashion	Broadly the information may be available immediately (read off the screen- a time period of seconds), quickly (within the library or searching area - a time period of minutes), after a short pause (if documents need to be retrieved from a nearby site- a time period of hours) or after a long time (if the document needs to be specially ordered or generated- a time period of days)
Useful for exclusion	I.e. the information source confirms that a potential diagnosis or treatment is not correct

Figure 1. The overall system

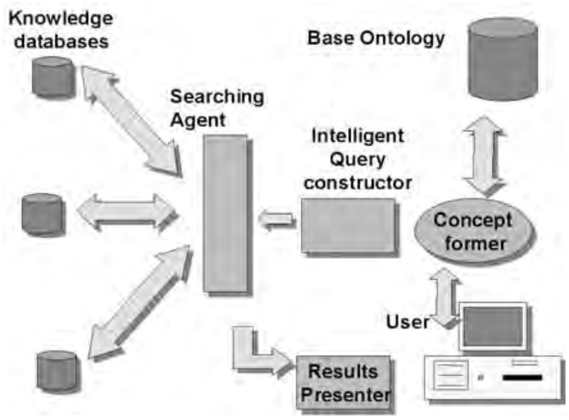

Figure 2. The system components

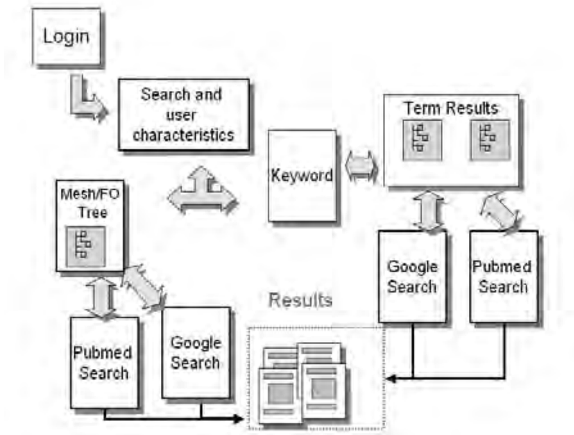

the final section discusses the significance of such an approach.

METHODS

A prototype system was designed, and tested for usability and usefulness.

System Design

The components of the prototype are illustrated in Figure 2. The case study was performed using a prototype version of the system, built in Visual Basic.NET, using an SQL server 2000 as the database (Microsoft). The Google application program interface (Google, 2004) was used along with the entrez eUtilities of PubMed (National Library of Medicine, 2003) to provide two data sources. These are part of an increasing number of Web Services that are being made available via Simple Object Access Protocol (SOAP) that allows XML-based communication and service control over the Internet.

Fuzzy Ontology

Ontologies are extremely important in medical informatics (Musen, 2001), but multiple ontologies (Noy & Musen, 2004) can be difficult to maintain and combine. In addition, terms are often multiplying within ontologies, thus making the mapping between a query term and the intended location in an ontology difficult.

The concept of a "fuzzy ontology" was introduced in Parry (2004b). Effectively, this approach reuses a current ontology, in this case, the MeSH hierarchy (U.S. National Library of Medicine, 2001), and assigns a particular membership value to each multiple-occurring term in each location.

Table 4 demonstrates how these issues arise in existing ontologies. "Pain" occurs in five locations in the MeSH ontology. Because the term is located in a number of different places, query expansion for this term is difficult, because there is a wide range of numbers of "related" terms. For this reason, the MeSH hierarchy was adapted in order to allow users to assign membership values to term, location pairs via a machine learning system described in Parry (2004a). The case study was designed partly to investigate different methods of learning these relations, but all of the searches were performed using the original MeSH hierarchy terms without the use of fuzzy, ontology support.

Many issues arise from the use of multiple ontologies, including the difficulties associated

Table 4. Multiple occurrence examples —"Pain"

Term	Concept ID	Parent	Depth	Root term
Pain	G11.561.796.444	Sensation	4	Musculoskeletal, Neural, and Ocular Physiology
Pain	F02.830.816.444	Sensation	4	Psychological Phenomena and Processes
Pain	C23.888.646	Signs and Symptoms	3	Pathological Conditions, Signs and Symptoms
Pain	C23.888.592.612	Neurologic Manifestations	4	Pathological Conditions, Signs and Symptoms
Pain	C10.597.617	Neurologic Manifestations	3	Nervous System Diseases

with communicating between ontologies and the need for maintenance of large numbers of ontologies. The fuzzy ontology as described is partly suggested in order to allow a common framework, or base ontology, with different membership values associated with different users and groups. It should be noted that because of the learning methods involved, only "is-a" type relations are currently used, based on the currently existing MeSH hierarchy.

Another advantage of this approach is completeness. Rather than impose an arbitrary standard of the importance of a particular location in the ontology, which is required in a crisp ontology to avoid too many examples of a term appearing in the ontology, the term or object can be located in all relevant locations

Most importantly, for searching processes, the use of a fuzzy ontology for the mapping of search terms allows the relative weight of each term in the required output to be calculated. By allowing these weights to be calculated accurately, it removes the bias associated with multiple-located terms being used for searching. If a term is located in multiple locations in a crisp ontology, and is used for query expansion purposes, say by including offspring, then the danger is that the large number of relatively irrelevant expansion terms outweigh those which are useful.

In particular, the use of a fuzzy ontology approach allows the convenient representation of the relationships in a domain according to a particular view without sacrificing commonality with other views; the ontology framework is common, just the membership values are different.

Finally, this approach holds out the possibility that the representation of a potentially very large ontology, can be compressed. If whole areas are not required, the relations to the core can be set to zero. Unwanted intermediate levels can also be removed, with lower-level terms only communicating directly with higher levels. This aspect removes the need to create artificial groupings to avoid orphaned terms. At the limit, a fuzzy ontology, with all membership values = 0 or 1, will have each term or object located in one location only and will behave in exactly the same way as a crisp ontology. A scheme for visually describing the fuzzy ontology is shown in Figure 3.

CASE STUDY

The setting was an academic department of Obstetrics and Gynecology, and only elements of the MeSH tree relevant to this domain were included. Ethical approval was obtained, and eight users were allocated an hour each to use the system. During user number 8's study, the database was corrupted, and the subject was unable to complete

Figure 3. The fuzzy ontology

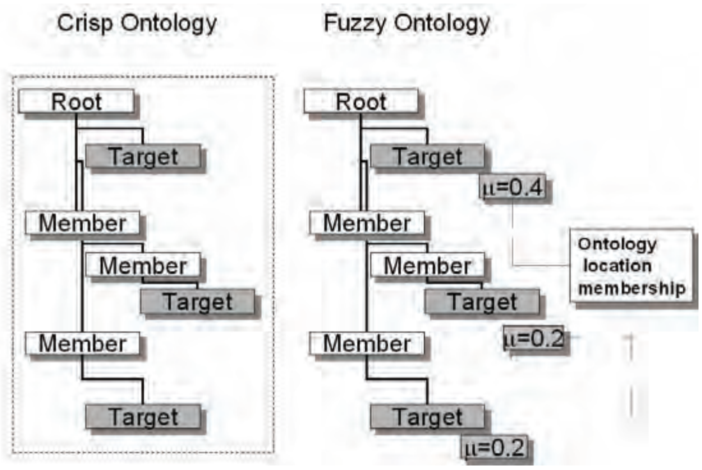

Table 5. Comparison of crisp and fuzzy ontologies

Aspect	Fuzzy ontology	Crisp ontology
Multiply-located terms	Does not occur	Issue for disambiguation
Query expansion	Depends on membership value.	Depends on location only
Customisation	Simple, based on modification of membership values	Requires new ontology and/or ontology sharing.
Intermediate locations for grouping	Unnecessary	Needed for construction – may be useful
Storage required	Depends on the number of terms in the ontology and the membership values of the relations, can be smaller or larger than crisp.	Depends on number of terms in the ontology
Knowledge representation	Related to use	Related to structure.

any testing. As such, the subject was therefore not included in any analysis. This is a small number of users but Neilson (2000) points out that usability testing can often be successful with small groups. In fact, the whole department only comprised less than 10 faculty staff; as with many systems designed for professional use, the pool of users is actually quite small. Results of their searches were presented in the results browser shown in Figure 4.

The users were asked to perform the following tasks:

1. Log into the system and select the appropriate demographic and area of interest.
2. Perform a search using the "obstetric" keyword on the Google interface. This was done mostly to familiarise the users with the system, in particular, the appropriate use of the mouse and the use of the + anchor in lists to expand them, as in Windows Explorer.
3. They then performed another search using terms of their own choosing, again using the Google interface.
4. With the open browser windows, they were asked to rate a number of the pages shown

Figure 4. The results browser

in terms of usefulness via the slider. They were also asked to perform an analysis on pages that they rated highly. In most cases, this amounted to around five pages.

5. They were then asked to perform a similar task using the full MeSH tree.

RESULTS

The results of the study are based around the usability questionnaire responses and user comments. The questionnaire used in the study was adapted from one of those generated from the site provided by Perlman (2001). This questionnaire was originally reported in Davis (1989) and has subsequently been used in a number of studies. This questionnaire focuses on the use of a system for work-related tasks, and the scale runs from -2 to +2, to allow a 0 for neutrality. All of the questions are phrased so that a positive result implies satisfaction with the system. One of the most interesting aspects of this questionnaire is that it specifically links ease of use and usefulness. The original work suggested that increased perceived ease of use has a causal influence on perceived usefulness. However, more recent work (Segars & Grover, 1993) appears to suggest that this analysis is not complete. It is suggested that, in turn, an information system that is perceived as useful must be retrieving useful information.

Overall, the perceived usefulness was rated as X = 1.16 (SD 1.21), and the perceived ease of use at X = 1.53 (SD 0.29). Ease of use could be expected to rate more highly as the situation for testing was somewhat artificial.

Comments about the system were recorded, and general satisfaction seemed quite high. Of particular interest was the ease of use of the analysis system, despite the fact that there were bugs in this version, which allowed duplicate words to occur in the pick list. There was certainly a preference towards identifying positive (very, somewhat relevant) rather than negative (irrelevant, unwanted) words. The users preferred to analyse those documents they found useful, and tended to ignore those they found useless.

One aspect of particular benefit was the presentation of the derived MeSH keywords, which allowed a user to reconsider his or her search before it began. General observations of users included the fact that they found dealing with large numbers of windows a little confusing. By attempting to improve visibility, the use of multiple windows tended to remove the obvious focus. Mouse movement became more uncertain when

Table 6. User group details

Number	Job description	Professional group	Computer experience	Gender	Age Range
1	Senior Academic	Doctor, interest in MFM	Moderate	Male	50+
2	Senior Academic	Doctor interest in MFM	Moderate	Female	50+
3	Junior Academic	Doctor, interest in REI	High	Female	30+
4	Research Midwife	Midwife background, clinical researcher	Moderate	Female	50+
5	New Consultant	Doctor, General Obstetrics and Gynaecology	Moderate	Female	30+
6	Senior Academic	Doctor, interest in Contraception	High	Female	40+
7	Junior Academic	Doctor, interest in Infertility	Moderate	Female	30+
8	New Consultant	Doctor, General Obstetrics and Gynaecology	Moderate	Female	30+

there were overlapping windows, and the users were often uncertain as to the difference between closing and minimising windows. In many cases, the users maximised the active window.

One of the recurring themes was the uncertainty of whether such a system was primarily for medical professionals or for patients. When browsing the documents recovered via Google, the users were sometimes surprised to find what they regarded as legitimate medical pages among the obviously patient-centred ones. This is an unexpected benefit of using multiple search engines — multiple search strategies are used simultaneously. Various meta-engines already use this approach, but they currently do not appear to use non-commercial data sources such as PubMed.

DISCUSSION

Finding and applying appropriate information is one of the key tasks of the knowledge worker (Kidd, 1994). There exists a vast body of knowledge in electronic form for workers and patients in the health sector. However, finding appropriate knowledge is difficult and time-consuming. Fears of inappropriate information being provided abound (Eysenbach, 2002). In order to fully realize the potential benefits of electronic knowledge sources, the sources must be appropriate for their use and usable by the potential beneficiaries. Understanding the knowledge requirements of users in this domain and providing appropriate tools for such users remain great challenges for informatics professionals. This paper has attempted to set up a framework for future research in the area of appropriate knowledge sources based around a user perspective. The importance of delimiting different user groups within the health sector has also been identified. In addition, a prototype system for combining knowledge from different sources in an integrated way has been tested for usability and potential usefulness. The challenges of using diverse information sources from the Web have been raised in Allan et al. (2003), and this area remains a particularly important area of information retrieval research. Other work has

Table 7. Initial group satisfaction

Question	User 1	User 2	User 3	User 4	User 5	User 6	User 7	Mean
Perceived Usefulness								
1 (Quick)	0	2	1	1	1	2	2	**1.26**
2 (Performance)	0	1	0	0	1	2	2	**0.86**
3 (Productivity)	2	1	1	0	1	2	2	**1.29**
4 (Effectiveness)	1	1	0	0	1	2	2	**1.00**
5 (Easier)	1	1	0	1	1	2	2	**1.14**
6 (Useful)	1	1	2	1	1	2	2	**1.43**
Perceived Ease of Use								
7 (Easy to Learn)	2	1	2	2	2	2	2	**1.86**
8 (Easy to Control)	-1	2	1	2	2	1	2	**1.29**
9 (Clear Interact)	2	2	1	2	1	1	2	**1.57**
10 (Flexible)	-1	2	1	2	1	1	2	**1.14**
11 (Skill)	2	2	2	2	1	2	2	**1.86**
12 (Easy to Use)	0	2	1	2	1	2	2	**1.43**

been done recently on the usability of medical information sources (Alexander, Hauser, Steely, Ford, & Demner-Fushman, 2004), and improvements are certainly possible. The results of this study suggest that an integrated knowledge discovery system for a medical professional is desirable and that the prototype represents a useful start in this direction. The results for ease of use compare favourably with similar scores in the technology acceptance model, that is, in Henderson and Divett (2003), dealing with electronic shopping, where ease of use was 1.25 and usefulness was 0.96 when converted to the same scale as used in this work. It is hoped that further research in this area will continue, in particular, in the following areas; the replacement of the executable form of the system with a browser-based client server system that will allow much larger user groups to interact with it and the provision of a substantial base for learning about group preferences. Mobile and wireless information retrieval may be more appropriately integrated into clinical workflow especially by means of "information appliances" (Eustice, Lehman, Morales, Munson, Edlund, & Guillen, 1999), recent work in this area (Burdette, Herchline, & Richardson, 2004) suggests that these devices may be particularly suitable for hospital use. The integration of information sources which provide their data via Web Services is also rapidly becoming accepted in the world of digital libraries (Fu & Mostafa, 2004). Integrating information from diverse sources via ontologies is also becoming increasingly important especially in the context of the "Semantic Web" (Berners-Lee, Hendler, & Lassila, 2001). The Ontology Web Language (OWL) (Smith, Welty, & McGuinness, 2004) could also be modified to support a fuzzy ontology, and it has already been recognised that storage of such ontologies on the Web can allow effective knowledge sharing (Haarslev, Lu, & Shiri, 2004). Finally, more research needs to be undertaken in the use and standardization of aspects of information reliability, usefulness, and relevance to improve research and classification in this area especially from the perspective of the clinical worker.

ABSTRACT

Cognitive screening measures for age-related cognitive impairment have been found to have only fair validity, and the risks of harm even may outweigh the benefits at this time (U.S. Preventative Service Task Force, 2003). A large-scale project designed to assess elder care in Primary Care Physician offices noted that dementia evaluation and treatment was one of the most overlooked aspects of care. Taken together, these studies cited the lack of time and technical expertise in test administration as the most prominent barriers to the accurate detection of dementia in Primary Care Physician offices. It was for these reasons that the Cognitive Screening Test (CST) was created. The CST requires no physician time or training to administer or interpret it. The current study investigated the clinical utility of this cognitive screening system by comparing the results of 102 patients to those of expert geriatricians, using consensus conference methods for diagnosis. Overall clinical utility demonstrated scores at .80 or above for sensitivity, specificity, and positive and negative predictive power. In contrast, the MMSE had only a .38 sensitivity. A Receiver Operating Curve (ROC) analysis indicated a .863 accuracy rating for the predetermined cut score on the CST.

VALIDATION OF A DEMENTIA SCREENING TEST IN GERIATRIC PRACTICE

The growing prevalence of dementia makes it imperative that Primary Care Physicians become more able and more comfortable to diagnose dementia, particularly in its earlier stages. Early diagnosis gives physicians the opportunity to initiate treatment with acetylcholinesterase inhibitors, which have shown to delay cognitive and functional declines (Mohs et al., 2001) and to delay nursing home placement (Schneider, 2000; Turner, 2003), all the while producing infrequent, temporary side effects (Boise, Morgan, Kaye,& Camicioli, 1999). It allows patients and families to plan for future care needs, financial needs, and legal needs associated with a lengthy, debilitating illness (Boise et al., 1999; Knopman, Donohue,& Gutterman, 2000), and families and patients may be given insight into the behavioral and personality changes that may occur and the safety precautions that eventually may be necessary (Knopman, et al., 2000; Sano & Weber, 2003). On the whole, primary care physicians continue to have difficulty detecting the majority of dementia cases among their patients. In previous studies, less than 30% of patients have been correctly identified as cognitively impaired, including even those with poor cognitive performance (Boise, Neal, & Kaye, 2004; Olafsdottir, Skoog, & Marcusson, 2000; Valcour, Masaki, & Blanchette, 2002). In an effort to increase the detection of cognitive impairment and generally to increase the quality of patient care, variables have been identified that impede this process. In a review, Reuben, Roth, Kamberg, and Wenger (2003) identified physician time constraints and a lack of physician technical expertise with cognitive screening administration and interpretation as major factors that impede effective dementia screening. Additionally, compounding the issue is that the standard primary care model of medical practice relies heavily on the patient's symptoms report. However, lack of awareness of symptoms is a common feature of Alzheimer's disease; thus, even when queried directly, patients often deny or minimize cognitive problems (Zanetti et al., 1999).

Conducting and interpreting brief cognitive screening is problematic in Primary Care Practices, even in practices where screening tests such as the Mini-Mental Status Examination (MMSE) are used. It is well established that the MMSE is sensitive to the effects of education and age (Anthony, LeResche, Niaz, Von Korff, & Folstein, 1982; Crum, Anthony, Bassett, & Folstein, 1993; Monsch et al., 1995; Spreen & Strauss, 1998; Tombaugh & McIntyre, 1992; Tombaugh, McDowell, Krisjansson, & Hubbley, 1996; Uhlmann & Larson, 1991). As a result of these findings, normative data have been published that make such considerations (Crum et al., 1993; Tombaugh et al., 1996). However, interpretation that considers age and education rarely occurs in clinical practice. More often than not, single-cut scores are used as a basis to distinguish the impaired from intact patients; for example, a cut score of 23/24 on the MMSE has been suggested to indicate cognitive impairment (Folstein, Folstein, & McHugh, 1975). This cut score also has been found appropriate in population-based studies (Ganguli et al., 1993). However, depending on the age and educational characteristics of the patient, this cut score consistently has demonstrated low sensitivity or specificity (Monsch, et al., 1995; Spreen & Strauss, 1998; Tombaugh & McIntyre, 1996). Due to these test constraints, cognitive screening measures for age-related cognitive impairment have been found to have only fair validity, and the risks of harm even may outweigh the benefits at this time (U.S. Preventative Service Task Force, 2003).

Ideally, a screening device for dementia will contain many memory items, since this is the domain of cognition typically impaired; it will require little in the way of administration and interpretation by those not trained in psychometrics and will be based on normative data that are meaningful to clinical interpretation. In response to both the problematic characteristics of traditional screening measures and the qualities desired in screening devices, a computerized screening battery was created. The Cognitive Screening Test (CST), an Internet-based program, is easily administered and requires no interpretation by the administrator. Conceptually, CST may provide a superior method of screening for cognitive impairment, because it instantly can take into consideration the factors that have shown to significantly affect screening interpretation in order to maximize sensitivity and specificity. Thus, even given equal qualities of the test instrument itself, an Internet-based system has the advantage of being able to utilize corrections for variables such as age and education in sophisticated ways. The purpose of this is to present preliminary data analyses using the CST system in order to compare its validity to other traditional screening devices and to demonstrate other qualities of the CST that lend to its incremental validity over other devices.

Two hypotheses were proposed for the study:

1. The CST will demonstrate a high level of clinical agreement (over .8 on combined indices of sensitivity, specificity, and positive and negative predictive power) with expert physician consensus diagnoses.
2. The CST will demonstrate superior clinical utility data than will the MMSE using a single cut score.

METHODS

Participants and Clinic Procedures

The sample consisted of 102 patients from a specialized geriatric clinic; characteristics of the sample are listed in Table 1. The clinic is located in a suburban setting and typically attracts European American patients who have above-average educational levels. The attending physicians at this clinic are all geriatric fellow trained and board certified. The only patients who were not approached about the study were those who had significant motoric, visual, or cognitive impairments that prevent them from using a computer or understanding directions, and individuals who were not fluent in English.

There are two groups of patients at this clinic, both of which were represented in this study. The first includes those who have established the clinic for primary medical care; the second are individuals who have been referred to the geriatric

Table 1. Sample demographics

	n	Mean/Percent	SD
Age (years)	102	79.3	6.6
Education (years)	102	13.5	2.9
Ethnicity:			
African American	6	5.9%	
European American	96	94.1%	
Gender:			
Male	47	46.1%	
Female	55	53.9%	

memory clinic by their own physicians in order to address specific geriatric issues. Evaluation of all patients is always very thorough. When first admitted to the clinic, there is a comprehensive review of symptoms and a physical examination, including a detailed neurological examination. This would be repeated for primary care patients if cognitive status were in question. Medication review and an informant interview are conducted. Medical, family, social, and occupational histories are taken. Functional assessment, laboratory tests, and neuroimaging are part of the clinical workup for cases of suspected dementia. Included in the screening of patients who are screened for cognitive decline is the Mini-Mental State Examination.

MEASURES

CST Normative Sample and Scoring Rules

The CST norms and cut scores were derived from normative data collected completely independently of the current study. The characteristics of the normative data were a sample size of 105 with a mean age of 73 (s.d.=7) and a mean educational level of 12 years .Seventy percent of the normative sample was made up of non-Hispanic whites, and 30% was minority elders (primarily African Americans).The normative data were employed in developing the cut scores as follows. Multiple regression analyses were conducted for each subtest of interest (learning total, memory total, executive function—total errors and mean response time), with subtest performance as the dependent variable and many potentially significant determinants added as predictors in the equation (e.g., health history variables, demographics, etc.). Of all of the variables included, age, ethnicity, education, and gender alone significantly predicted subtest performance.

Using the normative data beta weights and constants, the significant demographic variables were plugged into the general linear model (a+bx) to derive an expected score for each individual in the current sample. This expected score then was subtracted from the individual's raw score, which was divided by the standard error of the estimate to produce a z-score that describes the patient's deviation from the mean score. An Impairment Index then was derived for each subject as follows: z scores were converted to Impairment Index scores by summing subtest results according to the following: z scores > -2.0 were assigned a subtest score of 0; z scores > -2.5 (but less than -2.0) were assigned a subtest score of .5; z scores < -2.5 were assigned a subtest score of 1. A total score of 1.5 or more (summed across the three subtests) indicates a high probability of cognitive impairment and represents the cut score for impairment in these analyses. See Table 2 for a visual illustration of the translation of z-scores into this impairment index. In summary, the analyses from the cases reported here provide a cross validation of the equations obtained from the normative derivation sample.

Table 2. Translation of z-scores into the cognitive impairment index

Z-Score	Cognitive Impairment Index
-2.0 or greater	0
-2.0 > z > -2.5	0.5
Less than –2.5	1

Cognitive Screening Test (CST)

The CST is composed of several subtests. The following describes each one and explains the rationale for its development. Total administration time is approximately 15 minutes.

- **Keyboard Proficiency Subtests (2 minutes).** The first of these two subtests consists of a green ball presented on the screen. The participant is instructed to press the spacebar repeatedly until the green ball turns red. The second involves a series of numbers appearing on the screen; the participant is instructed to press the number key that corresponds with the number shown. These subtests are administered solely for the purpose of acclimating the patients to the nature of the tests.
- **Learning and Memory Subtests (7-8 minutes).** Individuals learn the placement of nine household objects placed in a virtual cabinet. In the course of three learning trials, they are quizzed about the location of each object. The number of correct responses summed over all three trials is referred to as the Learning subtest. After a delay involving the interpolation of the Executive Function subtest, a final inquiry is made about the location of the objects. This final recall is referred to as the Memory subtest. See Figure 1 for an illustration of this task.
- **Executive Function Subtest (6-8 minutes).** There are two components to this task. For the first, numbers from 0 to 9 are presented one at a time. Individuals are instructed to press the 0 or 1 key when the respective number is presented. Test takers are asked not to respond to other numbers. The second part consists of the numbers again being presented, but the participants are instructed to press the 0 key in response to the appearance of a 1 and to press the 1 key in response to the appearance of a 0. Again, subjects are told not to respond to numbers other than 0 or 1. The second part of this test taps executive function, with its emphasis on self-monitoring, and response inhibition and flexibility (Lezak, 1995). See Figure 2 for an illustration of the Executive Function subtest. Both the number of errors and the mean response time for the second part of this task are used to compute the CST decision.

PROCEDURE

Recruitment and CST Administration

During medical appointments, patients were approached by their physicians about volunteering for the study. Those who agreed to participate then were provided informed consents and ad-

Figure 1. Illustration of the "memory cabinet" used in the memory and learning subtests of the CST

Part 1 of Executive Function Subtest *Part 2 of Executive Function Subtest*

ministered the CST protocol by a graduate student in psychology. Administration typically took 15 minutes. A double-blind procedure was employed, as physicians did not disclose participant diagnoses to the CST administrator, nor did the administrator ever inform physicians about their performance. All participants were administered the CST (n=102).

Consensus Diagnosis Conference

Consensus diagnosis conferences by the attending physicians were conducted, during which clinical impressions, lab record reviews, and the MMSE scores were utilized in order to determine diagnoses; physicians were blinded to the patients' performances on the CST. DSM-IV criteria were utilized for diagnosis of dementia (DSM-IV, 1994); those who were diagnosed with Mild Cognitive Impairment (MCI) met Petersen's consensus criteria (Petersen et al., 1999). Using these criteria and methods of assessment, 35.3% of the sample was determined to be demented, 10.8% to have MCI, and 53.9% to be cognitively intact.

Statistical Analyses

In order to determine the concordance between all of the CST and the consensus diagnoses, scores above and below the cut points were plotted, and accuracy was computed manually.

RESULTS

The demographic characteristics of this sample are presented in Table 1. The final sample of 102 participants administered the CST was examined. An overall 83% concordance was found between the geriatrician consensus diagnosis and the CST predetermined cut score (see previous section titled CST Scoring and Decision Rules). Specifically, there was 80% sensitivity, 87% specificity, 88% positive predictive power (ppp), and 79% negative predictive power (npp) (see Table 3). In order to determine further whether the predetermined cut score (Impairment Index of 1.5 summed across subtests) was the most accurate in predicting cognitive status, a receiver operating characteristic (ROC) curve was examined. The predetermined cut score that had been employed did, in fact, produce the highest overall accuracy among the range of possible scores. The area under the curve (AUC) value for all possible accuracy values as determined by the ROC curve was .861 (SE=.039) (see Figure 3). Thus, there was support for hypothesis 1: clinical accuracy of the CST.

In order to compare the clinical utility of the Cognitive Screening Test to another screening test that utilized a single cut score, comparisons were made between the CST and the Mini Mental State Examination (MMSE). Using the single cut-score method, sensitivity of 37.7%, specificity of 97.6%, ppp of 95.2%, and npp of 55.4% were found for the MMSE. Taken together, these indices demonstrate that a single cut score in this clinic population leads to an unacceptable number of false negatives and very poor sensitivity.

Table 3. Screening device accuracy

	Sensitivity	Specificity	PPP	NPP
CST	.80	.87	.88	.79
MMSE	.38	.98	.95	.55

Table 4. Mean scores on cognitive tests by impairment status

	Impairment Status		
	Intact (n=55)	MCI (n=11)	Demented (n=36)
CST Impairment Index Total*†	.76 (.92)	1.82 (1.03)	1.82 (.98)
MMSE†	28.53 (1.44)	25.73 (3.64)	23.63 (4.30)

*Note. *Signifies that the intact and MCI groups are significantly different. †Signifies that the intact and demented groups are significantly different. No tests were significantly different between the MCI and demented groups.*

Figure 4. Mean IADL scores plotted as a function of the cognitive impairment index scores

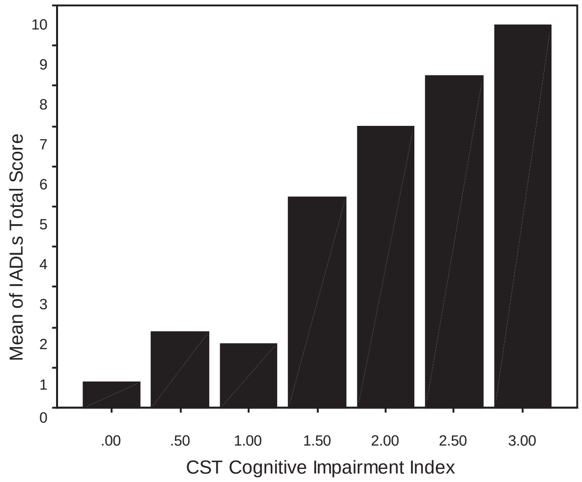

Figure 5. ROC curve for MMSE scores. AUC=.764 (SE=.049), p<.001

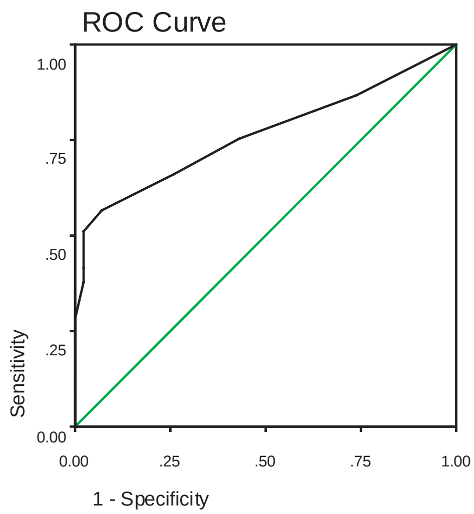


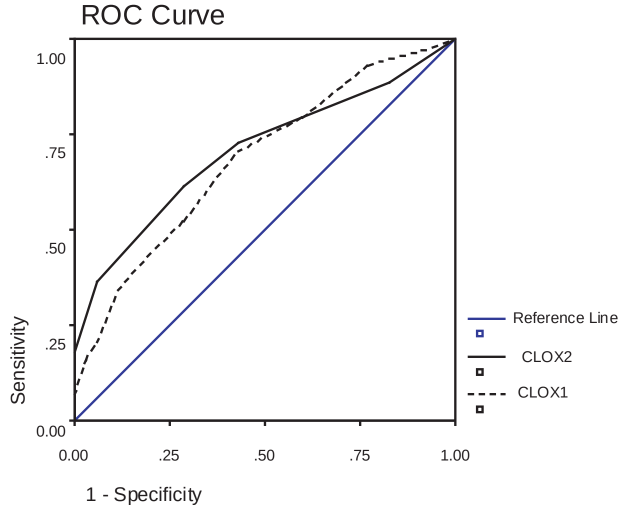
In order to better determine the ability of the CST and MMSE to detect early dementia, an analysis of variance (ANOVA) function was performed among those diagnosed as demented, those diagnosed with Mild Cognitive Impairment (MCI), and those considered cognitively intact by the geriatricians. Significantly different scores were found between those considered intact and those considered demented by all tests. The only test that was significantly different among those who were intact and those with MCI was the CST. A follow-up analysis was conducted among only the MCI patients to determine the effectiveness of the different screens in detecting early dementia. Of the 11 MCI patients, nine (81.8%) were correctly identified by the CST as likely impaired, whereas only three (27.3%) of these were correctly identified by the MMSE.

DISCUSSION

This study demonstrated that the Cognitive Screening Test was administered easily in a physician's clinic setting and had a high rate of concordance with expert geriatrician diagnosis with an overall hit rate of 83%. The exciting implications of these data are related to the use of technology for cognitive screening in a way that reduces clinician burden (i.e., time and expertise) while improving accuracy of the screening tool. As already stated, physicians and other healthcare professionals do not need to be concerned with administering the measure or interpreting results. Studies have reported that physicians may choose not to take part in increased care innovations if they do not feel that they possess the skills to do it correctly (Reuben et al., 2003); thus, a procedure that does not require physicians to learn new skills (i.e., cognitive testing) may more likely be utilized. Additionally, the CST does not take significantly more time than other pencil-and-paper measures and can be administered with little help by a medical technician or other person who can navigate to the Web site and respond to any questions or anxieties of the patient. This translates to little time investment on the part of the physician. Finally, there is no additional equipment to purchase, as the entire system will be available on the Internet. A standard CPU, keyboard, modem, and monitor are used.

There are limitations to this model. The CST is not a diagnostic tool and should not be used for diagnostic purposes. In order to establish a true cognitive impairment, follow-up assessment should be thorough, and diagnoses should use accepted clinical criteria. It is important to note that the major thrust of this study was not to compare the quality of the CST and the MMSE. All cognitive screening tests are affected by variables such as age, education quantity, and education quality. The advantage of the CST is that the inclusion of these variables in a sophisticated way can be brought into the interpretation of a given patient's single test score. This ability is simply not possible with any paper or pencil test, unless the test interpreter is very sophisticated in his or her approach to interpretation. Given these

Figure 6. ROC curve for CLOX1 and CLOX2 scores. .CLOX1 AUC=.683 (SE=.060), p=.005; CLOX2 AUC=.707 (SE=.058), p=.002



advantages of the CST, it was not surprising that the clinical utility of the CST exceeded that of the MMSE when using a single cut score.

Chapter 3.31
The Impact of Information Technology in Healthcare Privacy

Maria Yin Ling Fung
University of Auckland, New Zealand

John Paynter
University of Auckland, New Zealand

ABSTRACT

The increased use of the Internet and latest information technologies such as wireless computing is revolutionizing the healthcare industry by improving services and reducing costs. The advances in technology help to empower individuals to understand and take charge of their healthcare needs. Patients can participate in healthcare processes, such as diagnosis and treatment, through secure electronic communication services. Patients can search healthcare information over the Internet and interact with physicians. The same advances in technology have also heightened privacy awareness. Privacy concerns include healthcare Web sites that do not practice the privacy policies they preach, computer break-ins, insider and hacker attacks, temporary and careless employees, virus attacks, human errors, system design faults, and social engineering. This chapter looks at medical privacy issues and how they are handled in the U.S. and New Zealand. A sample of 20 New Zealand health Web sites was investigated.

INTRODUCTION

Advances in information technology have increased the efficiency of providing healthcare services to patients. Using Web-based technology, the healthcare team can also include the patient, who must be an informed decision maker and active participant in his or her care. These same advances also improve the features, functions, and capabilities of the electronic medical record systems and potentially increase the number of parties, namely hospitals, insurance companies, marketing agencies, pharmaceutical companies, and employers that may have unauthorized access to private medical information. These systems are justifying themselves in terms of cost and life savings. Accessibility to mobile computing devices in the healthcare industry is also evolving. Wireless computing devices enable physicians, clinicians, and nurses to enter patient data at the point of care (Kimmel & Sensmeier, 2002). Disease management systems provide caregivers with information on efficacy of drugs and treatments at various stages of a medical condition. Using bar-coding technology together with decision support, systems can ensure that patients can receive the correct medication or treatment.

Healthcare organizations must manage a tremendous amount of information, from clinical test results, to financial data, to patient tracking information. While most healthcare organizations have policies and procedures in place to guarantee at least minimum levels of privacy protection, they are not core features of most technology systems in the healthcare industry. This is true despite the fact that unauthorized disclosure of an individual's private medical information can affect one's career, insurance status, and even reputation in the community. Without adequate privacy protection, individuals must take steps to protect themselves from what they consider harmful and intrusive uses of their health information, often at significant costs to their health.

Healthcare privacy is an increasingly complex legal and operational issue facing the healthcare industry. For example, in the areas of mental health, HIV, pharmaceuticals, and genetic information, issues of privacy and the appropriate use of health information have already shown themselves to be particularly sensitive. The public has also become increasingly conscious of privacy issues, such as protection of electronic medical records, commercial uses of health information, and insurer and employer access to patient-identifiable information. The increasing use of the Internet also brings a corresponding need for privacy awareness. The very nature of electronic records makes them more easily transportable and thus accessible.

Healthcare professionals face many challenges as they seek ways to deliver quality healthcare while maximizing efficiency and effectiveness and at the same time ensuring privacy. A substantial barrier to improving the quality of and access to healthcare is the lack of enforceable privacy rules. Individuals share a great deal of sensitive, personal information with their doctors. This information is then shared with others, such as insurance companies, pharmacies, researchers, and employers, for many reasons. Yet unlike other personal information, there is very little legal protection for medical records.

This chapter focuses mainly on the impact that information technology has on healthcare privacy and the ways in which privacy can be achieved. We examine this in the context of the situation in the U.S.A. and in New Zealand, which has supposedly the world's strictest privacy legislations in the Privacy Act (1993). Comparisons to other countries are also made where information security technology has been applied in the medical domain.

WHAT IS HEALTH INFORMATION?

The American Health Information Management Association (AHIMA) (The American Health Information Management Association and the Medical Transcription Industry Alliance, 1998) defines health information as:

- Clinical data captured during the process of diagnosis and treatment.
- Epidemiological databases that aggregate data about a population.
- Demographic data used to identify and communicate with and about an individual.
- Financial data derived from the care process or aggregated for an organization or population.
- Research data gathered as a part of care and used for research or gathered for specific research purposes in clinical trials.
- Clinical data and observations taken by trainees in a teaching hospital.
- Reference data that interacts with the care of the individual or with the healthcare delivery systems, like a formula, protocol, care plan, clinical alerts, or reminders.

- Coded data that is translated into a standard nomenclature or classification so that it may be aggregated, analyzed, and compared.

AHIMA further states that healthcare information and data serve important functions, including:

- Evaluation of the adequacy and appropriateness of patient care.
- Use in making decisions regarding healthcare policies, delivery systems, funding, expansion, education, and research.
- Support for insurance and benefit claims.
- Assistance in protecting the legal interests of the patients, healthcare professionals, and healthcare facilities.
- Identification of disease incidence to control outbreaks and improve public health.
- Provision of case studies and epidemiological data for the education of health professionals.
- Provision of data to expand the body of medical knowledge.

WHAT IS HEALTHCARE PRIVACY?

Healthcare is a service industry that relies on information for every aspect of its delivery. Health information is important to the patients, the medical practitioners, the healthcare professionals, and institutions, in addition to society as it directs the health of the population. It must be protected as a valuable asset, and in its primary form as the medical record of a unique individual, it must be safeguarded.

Privacy of health information is a legitimate concern. Such concerns grow as technology is in place to allow confidential medical records and sensitive health information such as: mental illness, HIV, substance abuse, sexually transmitted disease, and genetic information, to be made available to employers, bankers, insurers, credit card companies, and government agencies for making decisions about hiring, firing, loan approval, and for developing consumer marketing.

The application of information technology to healthcare, especially the development of electronic medical records and the linking of clinical databases, has generated growing concerns regarding the privacy and security of health information. The security and integrity of electronic health data must be protected from unauthorized users. However, in the medical field, accessibility for certain authorized functions must overrule any other concerns, that is, when a doctor needs to access the information about a patient in order to provide emergency treatment, it is imperative that the data become available without delay (Ateniese, Curtmola, de Medeiros, & Davis, 2003).

While patients have a strong interest in preserving the privacy of their personal health information, they may also have an interest in medical research and other efforts by healthcare organizations to improve the quality of medical care they receive.

Categories of Healthcare Privacy

In addition to technological revolutions, which are the main cause for privacy concerns, there are three distinct kinds of violations of health information privacy according to the congressional testimony of Janlori Goldman, director of the Health Privacy Project at Georgetown University (Starr, 1999):

- Individual misappropriation of medical records;
- Institutional practices — ambiguous harm to identifiable individuals; and
- Institutional practices — unambiguous harm to identifiable individuals.

Individual Misappropriation of Medical Records

Starr (1999) states that this category involves individuals who misuse medical data, often publicly disclosing sensitive information and typically violating both the policies of the institutions that kept the records and the laws of their state. It is by far the most common type of violation of health information privacy that can be corrected by stronger penalties and more aggressive enforcement of privacy laws and policies. According to *Health Privacy Project: Medical Privacy Stories* (2003), examples include:

- Following the rape accusations against basketball player Kobe Bryant, the alleged victim's medical records were subpoenaed by Bryant's defense lawyers from a Colorado hospital. After a hospital employee released the records to a judge, attorneys for the hospital have asked that judge to throw out the subpoenas and destroy the records already received by him, citing state and federal medical privacy laws. Attorneys for the victim are also attempting to prevent Bryant's defense team from gaining access to her medical records from two other hospitals. However, a number of news stories have published sensitive medical information that reporters allege came from hospital employees (Miller, 2003).
- A hospital clerk at Jackson Memorial Hospital in Miami, Florida stole the social security numbers of 16 patients named Theresa when they registered at the hospital. The hospital clerk then provided the social security numbers and medical record information to a friend, also named Theresa, who opened up over 200 bank and credit card accounts and bought six new cars (Sherman, 2002).

Institutional Practices: Ambiguous Harm to Identifiable Individuals

This category consists of the use of personal health data for marketing and other purposes where the harm to the individual is ambiguous or relatively small. For example, a chemist or pharmacist sells patient prescription records to a direct mail and pharmaceutical company for tracking customers who do not refill prescriptions, and sending patients letters encouraging them to refill and consider alternative treatments. The problem is not so much harmful to the customers, who might have appreciated the reminders; what worries them most is the hands into which such lists might fall. This may also raise the question of the merchandising of health data for purposes unrelated to those for which patients provided the original information.

Institutional Practices: Unambiguous Harm to Identifiable Individuals

This category consists of institutional practices that do cause harm to identifiable individuals. Different from the other two categories, this one raises much more serious privacy issues and needs correction and reform. Starr stresses that the commingling of the insurance and employment functions in the United States has led to serious abuse of confidential medical information; and the development of genetics has made possible a new and insidious form of discrimination. He recommends security measures such as encryption, the use of a universal health identifier, segmentation of medical records, and biometric identifiers for and audit trails of those accessing medical records (Starr, 1999). Examples from *Health Privacy Project: Medical Privacy Stories* (2003) and Starr (1999) include:

- Two hundred and six respondents in a survey reported discrimination as a result of access to genetic information, culminating in loss of employment and insurance coverage or ineligibility for benefits (Science and Engineering Ethics, 1996).

- A survey found that 35% of Fortune 500 Companies look at peoples' medical records before making hiring and promotion decisions (Unpublished study, University of Illinois at Urbana-Champaign, 1996).
- An Atlanta truck driver lost his job in early 1998 after his employer learned from his insurance company that he had sought treatment for a drinking problem (J. Appleby, "File safe? Health Records May Not Be Confidential," *USA Today*, March 23, 2000, p. A1).

TECHNOLOGICAL CHANGES

Information technologies, such as the Internet and databases, have advanced substantially in the past few years. With the adoption of these new technologies, the healthcare industry is able to save billions of dollars in administrative and overhead costs. These savings can be used to discover new drugs or expand coverage for the uninsured. Through these new technologies, patient care will also be improved; for example, telemedicine allows medical specialists to "examine" and "treat" patients halfway around the world. Perhaps most importantly, information technologies help to empower individuals to understand and to take charge of their own healthcare needs. Patients become active participants in the healthcare process through secure electronic communication services. Wilson, Leitner, and Moussalli (2004) suggest that by putting the patient at the center of the diagnosis and treatment process, communication is more open, and there is more scope for feedback or complaint. This enhances and supports human rights in the delivery of healthcare.

The Internet and Patients

The use of Internet in the healthcare industry involves confidential health information being developed and implemented electronically. There are already several applications available on the Internet for caregivers and patients to communicate and for the electronic storage of patient data. These applications include: electronic mail, online conversations and discussion lists (online chat and NetMeeting), information retrieval, and bulletin boards. Caregivers and patients use electronic mail and online chat to communicate. Patients can search the Web for information about symptoms, remedies, support groups, and health insurance rates. They can also obtain healthcare services, such as second opinions and medical consultations, and products, such as prescription drugs, online (Choy, Hudson, Pritts, & Goldman, 2002).

Patient databases are stored on the Internet, with some providers storing complete patient records in Internet-accessible sites. Patients can interact with databases to retrieve tailored health information (selection-based on personal profile, disease, or a particular need such as travel or cross-border healthcare) (Wilson et al., 2004). However, the availability of medical information in an electronic form (whether or not available over the Internet) raises privacy issues.

The Internet and Health Professionals

Through the use of the Internet, health professionals will have the most up-to-date information available at the click of a mouse. Hospitals, clinics, laboratories, and medical offices will be digitally linked together, allowing for the quick, efficient transfer and exchange of information. The test results will be digitized, allowing for a speedy transfer from labs to hospitals while gaining back the valuable time lost in physical transport. For example, Telehealth in Canada will make geography disappear on a large scale (Siman, 1999). It is a new initiative that significantly improves health services, particularly to remote and rural areas. It also allows physicians to do a complete physical examination of the patient via a digital link. Diagnosis can be made over long-distance telephone lines, rather than after long-distance travel, thus saving the patient the strain and cost of travel. Physicians and other caregivers may use the Internet to discuss unusual cases and obtain advice from others with expertise in treating a particular disease or condition (Siman, 1999).

The Internet and Health-Related Activities

The Internet can support numerous health-related activities beyond the direct provision of care. By supporting financial and administrative transactions, public health surveillance, professional education, and biomedical research, the Internet can streamline the administrative overhead associated with healthcare, improve the health of the nation's population, and lead to new insight into the nature of disease. In each of these domains, specific applications can be envisioned in which the Internet is used to transfer text, graphics, and video files (and even voice); control remote medical or experimental equipment; search for needed information; and support collaboration, in real time, among members of the health community (Committee on Enhancing the Internet for Health Applications: Technical requirements and implementation strategies, 2000). For example, the Internet could do the following (Committee on Enhancing the Internet for Health Applications: Technical requirements and implementation strategies, 2000):

- Enable consumers to access their health records, enter data or information on symptoms, and receive computer-generated suggestions for improving health and reducing risk;
- Allow emergency room physicians to identify an unconscious patient and download the patient's medical record from a hospital across town;
- Enable homebound patients to consult with care providers over real-time video connections from home, using medical devices capable of transmitting information over the Internet;
- Support teams of specialists from across the country who wish to plan particularly challenging surgical procedures by manipulating shared three-dimensional images and simulating different operative approaches;
- Allow a health plan to provide instantaneous approval for a referral to a specialist and to schedule an appointment electronically;
- Enable public health officials to detect potential contamination of the public water supply by analyzing data on nonprescription sales of antidiarrheal remedies in local pharmacies;
- Help medical students and practitioners access, from the examining room, clinical information regarding symptoms they have never before encountered; and
- Permit biomedical researchers at a local university to create three-dimensional images of a biological structure using an electron microscope 1,000 miles away.

Also called: "Medicine of the Millennium," telemedicine is connecting geographically separate healthcare facilities via telecommunications, video, and information systems. The purpose of telemedicine is for remote clinical diagnosis and treatment, remote continuing, medical education, and access to central data repositories for electronic patient records, test requests, and care outcomes.

However, the increasing use of the Internet brings a corresponding need for privacy awareness. The very nature of electronic records makes them more easily transportable and, thus, accessible. Privacy on the Internet is becoming more and more of a concern as confidential information transmitted via the Internet may be intercepted and read by unauthorized persons. Some commonly used Internet protocols may allow information to be altered or deleted without this being evident to either the sender or receiver. Patients may be totally unaware that their personally identifiable health information is being maintained or transmitted via the Internet, and worse still, they may be subject to discrimination, embarrassment, or other harm if unauthorized individuals access this confidential information. While technology can and should be used to enhance privacy, it can also be used to undermine privacy.

WHY ARE THERE HEALTHCARE PRIVACY CONCERNS?

Undoubtedly, the Internet is a valuable tool for improving healthcare because of its ability to reach millions of Internet users at little or no additional cost and absence of geographic and national boundaries. Unfortunately, the Internet is also an ideal tool for the commission of fraud and other online crime. Examples of such fraud include healthcare scams such as the selling of misbranded and adulterated drugs, and bogus miracle cures.

Many of the bigger healthcare Web sites collect information by inviting users to create a personalized Web page where they can acquire medical information tailored specifically to their age, gender, medical history, diet, weight, and other factors. Some sites offer alerts on special medical conditions, health and fitness quizzes, and even the opportunity to store one's own medical records and prescriptions online in case of emergency (Medical privacy malpractice: Think before you reveal your medical history, 2001). Other Web sites collect information using cookies. Cookies are small pieces of data stored by the user's Internet browser on the user's computer hard drive. Cookies will be sent by the user's browser to the Web server when the user revisits the same Web site. Hence the user's information such as number of visits, average time spent, pages viewed, and e-mail address will be collected and used to recognize the user on subsequent visits and provide tailored offerings or content to the user.

The California HealthCare Foundation recently examined the privacy policies and practices of 21 popular health sites including: DrKoop.com, Drugstore.com, and WebMD.com (Medical privacy malpractice: Think before you reveal your medical history, 2001). They found that visitors to the sites are not anonymous, and that many leading health Web sites do not practice the privacy policies they preach. In some cases, third-party ad networks run banner ads on the sites that collect information and build detailed profiles of each individual's health conditions.

In New Zealand, no published survey has been previously conducted. In order to examine the privacy policies and practices of the New Zealand health sites, 20 medical related Web sites were chosen from the electronic yellow pages (www.yellowpages.com.nz) and studied for the purpose of this chapter. At this site, the individual listings are arranged such that those that have Web sites appear first. Only unique sites were examined. That is, those with multiple listings or branches were ignored. Those with only a simple banner ad in the electronic yellow pages were also excluded. Of these 20 Web sites, three were medical insurers, or offered a medical insurance policy as one of their services; one was for health professionals to use to support traveling patients; and the rest were medical clinics and hospitals. The result shows that all but one of these Web sites collected personal information, but only one had a privacy statement, and it was very obscure; three used cookies, and none mentioned the purpose for which the information was collected. The New Zealand Information Privacy Principle 3 requires that a well-expressed Web site should have a privacy statement. A privacy statement tells consumers that their privacy right is being considered (Wiles, 1998). The Web sites studied all failed to meet such a requirement. The results of the above studies indicate that healthcare privacy concerns are not just problems in New Zealand, but universal ones.

According to Anderson (1996), many medical records can be easily obtained by private detectives, who typically telephone a general practice, family health services authority, or hospital and pretend to be the secretary of a doctor giving emergency treatment to the person who is the subject of the investigation

Although privacy is a concern as electronic information is vulnerable to hackers and system errors that can expose patients' most intimate data, the most persistent risk to security and privacy is through the people who have authorized access, much more so than the hackers or inadvertent system errors. As medical information systems are deployed more widely and made more interconnected, security violations are expected to increase in number.

WHAT ARE THE CONCERNS?

The American Health Information Management Association (1998) estimates that when a patient enters a hospital, roughly 150 people have legitimate access to that person's medical record, including food workers, pharmacists, lab technicians, and nursing staff, each with a specific authority to view components of the record necessary for their job and each with unique ability to act within a system.

The increasing use of the Internet in the healthcare industry has also heightened concerns on privacy. The CERT Coordination Center at Carnegie Mellon University, a national resource for collecting information about Internet security problems and disseminating solutions (Committee on Enhancing the Internet for Health Applications: Technical requirements and implementation strategies, 1997), lists seven general areas of vulnerability:

- Compromised system administrator privileges on systems that are unpatched or running old OS versions.
- Compromised user-level accounts that are used to gain further access.
- Packet sniffers and Trojan horse programs.
- Spoofing attacks, in which attackers alter the address from which their messages seem to originate.
- Software piracy.
- Denial of Service.
- Network File System and Network Information System attacks and automated tools to scan for vulnerabilities.

In addition to the above vulnerabilities, other concerns are:

- To whom should organizations be allowed to disclose personal health information with and without patient consent? Under what conditions may such disclosures be made?
- What steps must organizations take to protect personal health information from loss, unauthorized editing, or mischief?
- What types of security technologies and administrative policies will be considered sufficient protection?

Additional Common Threats and Attacks

A threat is any of the capabilities, intentions, and attack methods of adversaries to exploit or cause harm to information or a system. Threats are further defined as being passive (monitoring but no alteration of data) and active (deliberate alteration of information). King, Dalton, and Osmanoglu (2001) define four common threat consequences and the sources of threats in the following sections:

- **Disclosure:** If information or data is revealed to unauthorized persons (breach of confidentiality).
- **Deception:** If corporate information is altered in an unauthorized manner (system or data integrity violation).
- **Disruption:** If corporate resources are rendered unusable or unavailable to authorized users (denial of service).
- **Usurpation:** If the corporate resources are misused by unauthorized persons (violation of authorization).

Temporary or Careless Employees

Electronic health records stored at healthcare organizations are vulnerable to internal or external threats. Although with the protection of firewalls, careless employees, temporary employees, or disgruntled former employees cause far more problems than do hackers. As a company's employees have tremendous access to the company's resources, it is possible that the computer system could be hacked into internally, as well as by third parties. For example, an employee attaches a database of 50,000 names to an e-mail and sends it to a business partner who is working on a marketing campaign at another company. It would be very likely that data could be intercepted or harvested by a third party and used for improper or unauthorized purposes (Silverman, 2002).

Human Errors and Design Faults

A serious threat to the confidentiality of personal health information in hospitals and health authorities is the poor design and lax administration of access controls (Anderson, 1996). In many hospitals, all users may access all records; it is also common for users to share passwords or to leave a terminal permanently logged on for the use of everyone in a ward. This causes a breakdown of clinical and medico-legal accountability and may lead to direct harm. Other design errors include improperly installing and managing equipment or software, accidentally erasing files, updating the wrong file, or neglecting to change a password or backup a hard disk.

Insiders

Another source of threat comes from the trusted personnel (the insiders) who engage in unauthorized activities (copying, stealing, or sabotaging information, and yet their actions may remain undetected) or activities that exceed their authority (abusing their access). The insiders may disable the network operation or otherwise violate safeguards through actions that require no special authorization.

Crackers, Hackers, and Other Intruders

While internal threats consist of authorized system users who abuse their privileges by accessing information for inappropriate reasons or uses, external threats consist of outsiders who are not authorized to use an information system or access its data, but who nevertheless attempt to access or manipulate data or to render the system inoperable. Computer break-ins are proven to have occurred in the healthcare industry. The Health Care Privacy Project, a non-profit corporation in Washington DC, reported that a hacker found a Web page used by the Drexel University College of Medicine in Pennsylvania that linked to a database of 5,500 records of neurosurgical patients (*Health Privacy Project: Medical privacy stories*, 2003). The records included patient addresses, telephone numbers, and detailed information about diseases and treatments. After finding the database through the search engine Google, the hacker was able to access the information by typing in identical usernames and passwords. Drexel

University shut down its database upon learning of the vulnerability, and a university spokeswoman stated that officials had been unaware that the database was available online, as it was not a sanctioned university site.

A "2002 Computer Crime and Security" survey conducted by the Computer Security Institute (CSI) with the participation of the San Francisco Federal Bureau of Investigation's (FBI) Computer Intrusion Squad found that the threat from computer crime and other information security breaches continues unabated and that the threat from within the organization is far greater than the threat from outside the organization. Results show that 74% cited their Internet connection as a frequent point of attack than cited their internal systems as a frequent point of attack (33%); 28% suffered unauthorized access or misuse on their Web sites within the last twelve months; 21% said that they did not know if there had been unauthorized access or misuse; 55% reported denial of service; and 12% reported theft of transaction information (*Cyber crime bleeds U.S. corporations, survey shows; Financial losses from attacks climb for third year in a row*, 2002).

Social Engineering

According to King et al. (2001), a social engineering attack involves impersonating an employee with known authority, either in person (disguised) or by using an electronic means of communication (e-mail, fax, or the telephone). For example, an attacker places a phone call to the system administrator claming to be a corporate executive who has lost the modem pool number and forgotten the password. In the hospitals, an outsider places a phone call to an authorized insider, pretending to be a physician in legitimate need of medical information.

Information Warfare

A RAND Corporation study of information warfare scenarios in 1995 suggests that terrorists using hacker technologies could wreak havoc in computer-based systems underlying emergency telephone services, electric power distribution networks, banking and securities systems, train services, pipeline systems, information broadcast channels, and other parts of our information infrastructure (*Committee on Enhancing the Internet for Health Applications: Technical requirements and implementation strategies*, 2000).

Although the above examples do not specifically describe threats to healthcare organizations, they do indicate the growing vulnerability of information systems connected to public infrastructure such as the Internet. As such, the drive for increased use of electronic health information linked together by modern networking technologies could possibly expose sensitive health information to a variety of threats that will need to be appropriately addressed.

Healthcare Privacy Concerns in the United States

According to Ball, Weaver, and Kiel (2004), a national survey of e-health behavior in the U.S. found that 75% of people are concerned about health Web sites sharing information without their permission and that a significant percentage do not and will not engage in certain health-related activities online because of privacy and security concerns. For example, 40% will not give a doctor online access to their medical records; 25% will not buy or refill prescriptions online; and 16% will not register at Web sites. However, nearly 80% said that a privacy policy enabling them to make choices about whether and how their information is shared would make them more willing to use the Internet for their private health information.

A Pew report (2005) documented that 89% of health seekers were concerned about privacy issues, with fully 71% very concerned. When people were made aware of the possibility of the issuance of universal medical ID numbers, a Gallup poll found that 91% opposed the plan; 96%

opposed the placement on the Web of information about themselves held by their own doctor (The Gallup Organisation, 2000). On the other hand, the healthcare administrators are aware of security issues and have many safeguards in place. In a recent survey of healthcare information technology executives, participants ranked the protection of health data as their primary concern (Reid, 2004). Hospitals, for example, indicate that current security technologies in use include anti-virus software (100%), firewalls (96%), virtual private networks (83%), data encryption (65%), intrusion detection (60%), vulnerability assessment (57%), public key infractions (20%), and biometrics (10%). Virtually all respondents expected to use all these technologies to some degree during the next two years (The Gallup Organisation, 2000).

Recent evidence indicates that many medical organizations are lagging behind in their implementation of appropriate security systems. A study of 167 U.S. hospitals conducted by research firm HCPro found that 76% had not conducted an information security audit, and only half planned to do so by April 2001 (Johnson, 2001). Of the hospitals that had performed an audit, 51% said that they would need major improvements to, or a complete overhaul of, their security systems, and 49% claimed that they would have to significantly change or replace their security policies. Alarmingly, only 5% said they had an annual budget for HIPAA compliance.

The inadequacy of some medical providers' security systems was recently underscored by the hacking of the University of Washington Medical Center (UWMC) computers (*Thomson Corporation and health data management*, 2005). SecurityFocus.com reported that an intruder was able to break into the UWMC computers and view the name, address, and Social Security number and medical procedures of over 4,000 cardiology patients. Theoretically, the UWMC could face potential lawsuits by distressed patients.

Healthcare Privacy Concerns in New Zealand

A survey was conducted in 1998 to study the practice and plans in New Zealand for the collation and retention of health records about identifiable individuals, with particular reference to the implications for privacy arising from the increased use of National Health Index Numbers (NHI) (Stevens, 1998).

What is NHI? The NHI provides a mechanism to uniquely identify healthcare users. It was developed to help protect personally identifying health data held on computer systems and to enable linkage between different information systems whilst still protecting privacy. The NHI database records contain information of each person to whom an NHI number has been allocated, their name, date of birth, date of death, address, gender, ethnicity (up to three entries allowed), residence status, and other names by which they may be known (Stevens, 1998). It, however, does not contain any clinical information, and its availability for research purposes tends to be limited chiefly to a peripheral role in cohort studies and clinical trials (Stevens, 1998).

Alongside the NHI database is the Medical Warnings System (MWS) database, which can only be accessed via the individual's NHI number. The MWS is designed to warn healthcare providers of the presence of any known risk factors that may be important in making clinical decisions about individual patient care.

The MWS database records contain individuals' NHI numbers, donor information (e.g., heart or kidney), contact details for next of kin (name, relationship, and phone number), medical warnings (typically allergies and drug sensitivities, classified as "danger" or "warning" or unverified "report"), medical condition alerts (such as diabetes), and summaries of healthcare events (so far these have been limited to hospital admissions, showing dates of admission and discharge, hospital, and diagnosis or procedure code).

These two databases are maintained by New Zealand Health Care Information Services (NZHIS) formed in 1991, a division of the Ministry of Health. NSHIS is responsible for the collecting, extraction, analysis, and distribution of health information.

In this survey, it is found that a statement on the Ministry Web site states that access to the MWS is "restricted solely for the use of providers in the context of caring for that individual." However, it is estimated that there are some 20,000 people who have direct access to the MWS and a further 70,000 who potentially have access to it, so that in practice, the security of the system probably relies heavily upon the difficulty of getting a hold of the NHI for the individual subject of an unauthorized enquiry (Johnson, 2001).

The survey further reveals that the same Web site document states, in respect of the NHI and MWS systems, "The Privacy Commissioner will be continuously involved in ensuring that the very highest possible standards of integrity and probity are maintained." Yet NZHIS do not appear to have taken any steps either to check with the Privacy Commissioner before making that statement or, having made the statement without the Commissioner's knowledge or agreement, to involve him/her at all in checking arrangements for operation of these databases. At the least, therefore, the statement is misleading in suggesting a form of endorsement by the Privacy Commissioner.

During the survey, more than one doctor contacted admitted that they use a different name for transactions involving their own healthcare, because they do not trust the security of records held by hospitals, laboratories, and other healthcare agencies with which they deal. This implies that the more health records that are to be integrated, the more users that must be concerned about the possibility of security breaches in any one part of the larger system. This also implies that the functions of an information system can be subverted if it does not gain and keep the confidence of both users and subjects.

WHO HAS ACCESS TO THE HEALTHCARE INFORMATION?

There are a variety of organizations and individuals who have an interest in medical data, and they are both within and outside of the healthcare industry. Usually access to the health information requires a patient's agreement by signing a "blanket waiver" or "general consent forms" when the patient obtains medical care. Signing of such a waiver allows healthcare providers to release medical information to employers, insurance companies, medical practitioners, government agencies, court orders or legal proceedings, direct marketers, medical institutions, hospitals, and newsgroups/chat rooms on the Internet.

Employers

Employers have an interest in an employee's fitness to work and fitness to perform particular tasks such as flying airplanes, controlling air traffic, and driving trains, buses, trucks, and cars. Some self-insured businesses establish a fund to cover the insurance claims of employees, which requires employees' medical records to be open for inspection by employers instead of an insurance company.

Insurance Companies

Insurance companies seek to combat rising costs of care by using large amounts of patient data in order to judge the appropriateness of medical procedures. They may also have an interest in healthcare data about a person's injuries and illnesses in relation to medical claims.

In New Zealand, the Accident Rehabilitation and Compensation Insurance Corporation (ACC), whose accident records are used for calculating workplace premium, will be shared with healthcare organizations. For example, to be eligible for weekly compensation, an injured person must be (a) incapacitated through injuries and (b) an earner at the time of the incapacity. ACC obtains medical opinion to clarify incapacity. It also obtains information from Inland Revenue, employers, and accountants to satisfy the second criteria.

Medical Practitioners

The medical practitioners have an explicit statutory obligation to disclose information on patients who have a serious physical condition, notifiable disease, or impairment that the doctor knows is likely to result in significant danger to the public (Clarke, 1990). In some cases it may be important that sensitive health data to be conveyed as part of information provided about a referral, in particular if the patient has been diagnosed as HIV-positive.

Government Agencies

In the U.S., government agencies may request citizens' medical records to verify claims made through Medicare, MediCal, Social Security Disability, and Workers Compensation. In New Zealand, government agencies such as Inland Revenue Department may share the information with healthcare organizations and ACC for tax and benefits purposes.

Medical Institutions and Clinical Researchers

Medical institutions such as hospitals or individual physicians require health information for evaluation of quality of service. This evaluation is required for most hospitals to receive their licenses. Clinical researchers and epidemiologists need health information to answer questions about the effectiveness of specific therapies, patterns of health risks, behavioral risks, environmental hazards, or genetic predisposition for a disease or condition (e.g., birth defects).

Direct Marketers

Drug companies want to know who is taking which drug so that they can conduct post-marketing surveillance to develop marketing strategies. Direct marketers use health-screening tests to collect medical information and build up data banks of businesses for promoting and selling products that are related to the information collected.

Court Orders/Legal Proceedings

In the U.S., medical records may be subpoenaed for court cases for people who are involved in litigation, an administrative hearing, or workers' compensation hearing. In the (less litigatious) New Zealand context, this is more likely to involve the granting of powers of attorney to make decisions on medical matters for patients who are not capable of making such decisions.

Internet Service Providers/Users

The Internet is available for individuals to share information on specific diseases and health conditions. While the Web sites dispense a wide variety of information, there is no guarantee that information disclosed in any of these forums is confidential.

MECHANISMS FOR ADDRESSING HEALTHCARE PRIVACY

Today, healthcare organizations are confronting the challenge of maintaining easy access to medical/clinical data while increasing data security. Technology is only part of the solution. Many healthcare organizations have deployed, to varying degrees, mechanisms to protect the security and integrity of their medical records, such as the use of strong enterprise-wide authentication, encryption, several levels of role-based access control, auditing trails, computer misuse detection systems, protection of external communications, and disaster protection through system architecture as well as through physically different locations. Among other strategies, databases are also used to address security and access control. One database will have consumer identification (ID) geographic information linked to an ID number. The second database will have actual clinical information indexed by patient ID number but no personal data (Ball et al., 2004). However, there are obstacles to the use of security technologies which are yet to be resolved.

Technological Solution

Technological security tools are essential components of modern distributed healthcare information systems. At the highest level, they serve five key functions, as seen in Table 1 (Committee on Enhancing the Internet for Health Applications: Technical requirements and implementation strategies, 1997): availability, accountability, perimeter identification, controlling access, and comprehensibility and control.

However, these types of controls focus more on protecting information *within* healthcare provider institutions and do not address the problems of unrestricted exploitation of information (e.g., for data mining) after it has passed *outside* the provider institution to secondary players or to other stakeholders in the health information services industry (Committee on Enhancing the Internet for Health Applications: Technical requirements and implementation strategies, 1997). In New Zealand, the Health Intranet, a communications infrastructure that allows health information to be exchanged between healthcare providers in a secure way, defines six key elements that any security policy must address (New Zealand Health Information Service, 2001): confidentiality, integrity, authenticity, non-repudiation, auditing and accountability.

Security Architecture

The primary goal of a security architecture design in the healthcare industry is the protection of the healthcare provider's assets: hardware, software, network components, and information resources.

Healthcare Finance Administration (HCFA) (CPRI toolkit: Managing information security in heath care, 2005) suggests that technical protection measures are traditionally grouped into three high level categories:

Table 1. Functions of technological security tools

Principles	Implementation
Availability	Ensuring that information is accurate and up to date when needed
Accountability	Ensuring the access to and use of information is based on a legitimate need and right to know
Perimeter identification	Knowing and controlling the boundaries of trusted access to the information system, both physically and logically
Controlling access	Ensuring the access is only to information essential to the performance of jobs and limiting the access beyond a legitimate need
Comprehensibility and control	Ensuring that record owners, data stewards, and patients understand and have effective control over appropriate aspects of information privacy and access

- **Confidentiality** measures provide the mechanism to ensure that the privacy of information is maintained. Mechanisms include encryption (e.g., virtual private networks, end-to-end, and link level encryption).
- **Integrity** measures enhance the reliability of information by guarding against unauthorized alteration. Protection measures include: digital signature and strong authentication using certificates provided through the Public Key Infrastructure (PKI) initiative.
- **Availability** measures seek to ensure that information assets are accessible to internal and external users when needed and guard against "denial of service" attacks. Protection measures include: firewalls and router filters for mitigating availability risks created by denial of service attacks.

While developing guidelines for the clinical security system for BMA (British Medical Association), Ross Anderson (1996) identified a few shortcomings of the NHS (UK National Health Services) wide network, which are useful for any security architectures to be built for the healthcare industry:

- The absence of an agreed common security policy enforced by all the systems that will connect to the network.
- The lack of confidence in the technical security measures such as firewalls.
- Many of the NHS wide network applications are unethical, which make personal health information available to an ever-growing number of administrators and others outside the control of both patient and clinician. Such availability contravenes the ethical principle that personal health information may be shared only with the patient's informed and voluntary consent. For example, the administrative registers will record patients' use of contraceptive and mental health services, while the NHS clearing system will handle contract claims for inpatient hospital treatment and contain a large amount of identifiable clinical information.
- Item of service and other information sent over existing electronic links between general practitioners and family health services authorities. While registration links are fairly innocuous, at least two suppliers are developing software for authorities that enables claims for items of service, prescrip-

Table 2. Key elements of a security policy

Principles	Implementation
Confidentiality	Ensuring that the message is not readable by unauthorized parties whilst in transit by applying strong encryption tools, such as Digital Certificates
Integrity	Ensuring that the message is not damaged or altered whilst in transit by using secure private networks and Digital Signatures
Authenticity	Ensuring that the user is a trusted party by using user ID/password and/or Digital Certificates
Non-repudiation	Ensuring that the sender cannot claim the message is counterfeit, or deny sending and receiving it by using secure private networks and Digital Signatures
Auditing	Recording user connectivity and site access for audit purposes
Accountability	Identifying clear responsibilities of organizations and individual users through compliance with Legislation and Security Policies

tions, and contract data to be pieced together into a "shadow" patient record that is outside clinical control (Advanced information system, Family Health Services computer unit, 1995; Data Logic product information at http://www.datlog.co.uk/).

Table 3 is a typical security architecture, the components of which are formed based on the ten basic security services (physical security; firewalls; intrusion detection; access control; authentication; privacy and integrity (encryption); electronic signature/non-repudiation; virus protection; audit trail creation and analysis; and database security) identified by HCFA and a list of application-specific baseline requirements for the healthcare industry proposed by King et al. (2001). Some of the components and guidelines are also adopted from the Anderson's UK NHS model.

Encryption

There is an increasing number of health practitioners transferring patient health information

Table 3. Security architecture principles and guidelines

Principles	Security Services	Mechanisms
Confidentiality	Encryption is required over all communications channels (e.g., Internet, ISP-based connections, dial up etc.). Confidential data must be kept encrypted on user laptops and workstations. Such information is to be disclosed only to named individuals on a need-to-know basis.	• Firewalls—Use at connection to Internet and boundary points. • Physical Control—Central office and Data Center continued physical security; integrated smart card access control. • Encryption—Application-specific, primarily DES-based and PKI-based key mgmt; SSL. • Database Security—Proprietary, DBMS-specific; DAC, PKI-enabled; RBAC (role-based access control) integrated; DAC.
Integrity	Business unit managed change control is required. Field-level change history must be maintained. Rollback functionality is required.	Encryption—Application-specific, primarily DES-based and PKI-based key management; SSL (Secure Socket Layer).
Availability	Virus scanning and redundant and high availability solutions are required. Strong system configuration, change control, and regular backup/restore processes are required.	Virus Prevention—Workstation-based and server-based program; signed applications.
Identification and authentication	Strong authentication (encrypted username and password, token, certificate).	Authentication—User ID and password-based with limited smart card pilots; Private key-based with multi-factor identification.

Continued on following page

using electronic mail across wide area networks, for example, using mailbox systems to transfer registration data and item of service claims to family health services authorities, links between general practitioners and hospitals for pathology reports, and the use of Internet electronic mail to communicate with patients that require continuing management. Anderson (1996) suggests that the problem may be tackled using cryptography: encryption and digital signatures can protect personal health information against disclosure and alteration, whether accidental or malicious, while in transit through a network.

Encryption is a tool for preventing the possibility of attack and interception during transmission and storage of data, for assuring confidentiality and integrity of information, and for authenticating the asserted identity of individuals and computer systems by rendering the data meaningless to anyone who does not know the "key." Information that has been cryptographically wrapped cannot be altered without detection. For example, the integrity of a health message is destroyed by removal of personal identifiers or by encryption of crucial pieces of the message. At the destination, the receiver decrypts the message using the same key (symmetrical encryption) or a complementary but different key (asymmetrical encryption) (New Zealand Health Information Service, 2001). Pretty Good Privacy (PGP) and GNU-PGP are commonly used third-party encryption software, which are available free for most common makes of computer.

There are two types of encryption systems: Public-key encryption and private-key encryption. The most commonly used and secure private-key encryption system is the Data Encryption Standard (DES) algorithm developed by IBM in the 1970s, which is gradually replaced by the newer and more efficient algorithm, the Advanced Encryption Standard (AES), which was chosen by the U.S. government after a long, open contest.

Table 3. (continued)

Principles	Security Services	Mechanisms
Authorization and access control	Authorization by business unit or function and detailed role-based access control are required.	Access Control—Platform-specific access control lists; RBAC-based, centrally managed access.
Non-repudiation	Strict change controls are required. Field-level file change history must be maintained. Digital signatures for creator and the checker are required.	Electronic Signature—FIPS 140-1 digital signature; Escrow for encryption keys (not signing keys).
Auditing and monitoring	System-level for user-access, file changes, failed login attempts, alarms.	• Audit Trail Creation & Analysis—Logs generated on a platform-specific basis; Consistent log content, directive data reduction and analysis. • Intrusion Detection—Automated monitoring of limited entry/exit points; Pro-active with integrated action plan.
Compliance with regulations	Compliance with Legislation.	For example, HIPAA in the U.S., European Union Data Protection Directive or the Health Information Privacy Code 1994 in New Zealand.

According to Wayner (2002), the basic design of DES consists of two different and complementary actions: confusion and diffusion. Confusion consists of scrambling up a message or modifying it in some nonlinear way. Diffusion involves taking one part of the message and modifying another part so that each part of the final message depends on many other parts of the message. DES consists of 16 alternating rounds of confusion and diffusion.

Public-key encryption is quite different from the DES. The most popular public-key encryption system is the RSA algorithm, developed in the late 1970s, which uses two keys. If one key encrypts the data, then only the other key can decrypt it. Each person can create a pair of keys and publicize one of the pair, perhaps by listing it in some electronic phone book. The other key is kept secret. If someone wants to send you a message, only the other key can decrypt this message, and only you have a copy of that key. In a very abstract sense, the RSA algorithm works by arranging the set of all possible messages in a long loop in an abstract mathematical space (Wayner, 2002). Public key cryptography is the underlying means for authenticating users, securing information integrity, and protecting privacy. For example, New Zealand North Health is planning to use encryption to encrypt the patients' NHI number and to deposit the information in a database. As such, information about any individual can only be retrieved by means of the encrypted identifier.

In the wide area networks, both secure socket layer (SSL) encryption and IP security (IPSec) should be deployed to allow the continued evaluation of different modes of securing transactions across the Internet. SSL is used to transport the encrypted messages on a communication channel so that no message could be "intercepted" or "faked." It provides authentication through digital certificates and also provides privacy through the use of encryption. (IPSec) protocol, a standards-based method of providing privacy, integrity, and authenticity to information transferred across IP networks, provides IP network-layer encryption.

Virtual Private Network (VPN)

Virtual private networks (VPNs) are standard secure links between companies and their resource users, which allow a company's local networks to be linked together without their traffic being exposed to eavesdropping. It can reduce the exposure to interception of international network traffic. With the increasing use of Internet in the healthcare industry, VPNs play a significant role in securing privacy. VPNs use tunneling and advanced encryption to permit healthcare organizations to establish secure, end-to-end, private network connections over third party networks. Some practical applications that will be used include accessing and updating patient medical records, Tele-consultation for medical and mental health patients, electronic transfer of medical images (x-ray, MRI, mammography, etc.), psychiatric consultations, distance learning, and data vaulting (ScreamingMedia, 1999).

The Hawaii Health Systems Corporation (HHSC) has created a Virtual Private Healthcare Network and Intranet solution that allows for collaboration between its 12 hospitals, 3,200 employees, and 5,000 partners located worldwide. By creating a sophisticated healthcare network that supports high speed, broadband data connectivity, doctors, specialists, and administrators can collaborate throughout the State of Hawaii just as if they were together at the same hospital. This scalable solution also allows existing and future partners, clients, and suppliers to connect to the HHSC network to collaborate and share data. By using a unique subscription profile concept, the network provides impenetrable security and allows for the free and secure flow of mission critical data (ScreamingMedia, 1999).

Firewalls

When private networks carrying confidential data are connected to the Internet, firewalls must be utilized extensively to establish internal security boundaries for protecting the internal private network, computers, data, and other "electronic assets" from tampering or theft by outsiders. Firewalls are a collection of network computing devices such as routers, adaptive hubs, and filters working in tandem and configured to ensure that only expressly permitted packets of data may enter or exit a private network. Firewalls will screen all communication between the internal and external networks according to directives established by the organization. For example, Internet access to an internal patient data system should be entirely prohibited or limited only to those people authenticated by a password or security token (Committee on Enhancing the Internet for Health Applications: Technical requirements and implementation strategies, 2000).

Communications security is also important. Some general practices have branch surgeries, and many hospitals have branch clinics, so the possibility of access via a dial up modem from branches is often raised (Anderson, 1996). In such cases, the main additional risk is that an outside hacker might dial up the main system and gain access by guessing a password. In order to avoid that, Anderson (1996) suggests that there should be no direct dial access to the main computer system. Instead, the main system should dial back the branches. Extra effort should also be made to educate users to choose passwords with care, and all incidents should be investigated diligently.

Audit Trails and Intrusion Detection Monitoring

Transaction logs and audit trails are important, as changes to the patient data can be closely monitored and traced. Audit trails record who and when alterations are made to particular files. The use of audit trails is invaluable, as they can be used as evidence in a court of law. The HCFA information systems create audit logs that record, in a centralized repository, logon and logoff; instances where a role is authorized access or denied access; the individual acting in that role; the sensitivity level of the data or other asset accessed; what type of access was performed or attempted (e.g., whether the nature of the requested action was to create, read, update, execute a program, or delete). Anderson (1996) suggests that periodic audits should be carried out, and from time to time these should include penetration tests. For example, a private detective might be paid to obtain the personal health information of a consenting patient. In this way, any channels that have developed to sell information on the black market may be identified and closed off.

Intrusion detection is primarily a reactive function that responds as attacks are identified. HCFA recommends the use of intrusion detection software to monitor network and host-based assets and employ a computer emergency response team to report and respond when incidents occur.

Biometric Systems

New technology called "biometric authentication" is being used to replace passwords and other security measures with digital recognition of fingerprints or other unique attributes. Biometrics uses individual physiological (finger-scan, iris scan, hand-scan, and retina-scan) or behavioral characteristics (voice and signature scans) to determine or verify identity. The most commonly used is the physiological biometrics. Because biometric security is based on a unique feature of an individual's body, for instance, a fingerprint, it is very difficult to copy, steal, or replicate this information (The Independent Research Group, 2002). Iris-scan is very suitable for use by healthcare institutions. Iris-scan can verify or identify a person based on the unique characteristics of the human iris. The strengths of iris-scan include its high resistance to false matching, the stability of the iris over time, and the ability to use this biometric to provide access to healthcare information or entry into physically secure locations, such as a medical record-keeping or information technology department.

A study done in Albuquerque, New Mexico indicates that the most effective technologies currently available for identification verification (i.e., verifying the claimed identity of an individual who has presented a magnetic stripe card, smart card, or PIN) are systems based on retinal, iris, or hand geometry patterns (Stevens, 1998). On the other hand, single-sign-on technology enables users to log on via user IDs and passwords, biometrics, or other means to gain immediate access to all information systems linked to a network (Clarke, 1990). Single sign-on (SSO) is the capability to authenticate to a given system/application once, and then all participating systems/applications will not require another authentication (King et al., 2001). Both technologies are designed to provide increased security in an unobtrusive manner (Clarke, 1990). St. Vincent Hospital and Health Care Services, Indianapolis had implemented a combined biometric and single-sign-on system in one of its acute care departments using different types of biometric readers to identify physicians and nurses.

Smart Cards

Internet commerce interests are pushing forward aggressively on standards for developing and deploying token-based cryptographic authentication and authorization systems (e.g., the Mastercard-Visa consortium and CyberCash Inc.) (Siman, 1999). Smart Card Token is a smart card about the size of a credit card and has a liquid crystal display on which a number appears that changes every minute or so. Each user card generates a unique sequence of numbers over time and, through a shared secret algorithm for which the user has been assigned access privileges, can generate the corresponding sequence of numbers. The number can be used as a session password. The write-controlled internal memory supports services such as user-specific information storage, authentication, and cryptographic certificate management. Some even have biometric access control features. Employees and appropriate contractors will be issued smart cards or tokens that store a private key and other essential authentication information.

Access Control

A serious threat to the confidentiality of personal health information in hospitals and health authorities is the poor design and lax administration of access controls (Anderson, 1996). Anderson stresses that, in particular, the introduction of networking may turn local vulnerabilities into global ones if the systems with ineffective access controls are connected together in a network, and then instead of the data being available merely to all staff in the hospital, they might become available to everyone on the network.

However, access controls must also be harmonized among networked systems, or moving information from one system to another could result in leaks. The solution for this is to have a common security policy that clearly states who may access what records and under what circumstances. Anderson emphasizes that the following are important to the implementation of effective access controls:

- A senior person such as a hospital manager or partner in general practice must be responsible for security, especially if routine administration is delegated to junior staff. Many security failures result from delegating responsibility to people without the authority to insist on good practice.
- The mechanisms for identifying and authenticating users should be managed carefully. For example, users should be educated to

pick passwords that are hard to guess and to change them regularly; and terminals should be logged off automatically after being unused for five minutes.

- Systems should be configured intelligently. Dangerous defaults such as maintenance passwords and anonymous file transfer access supplied by the manufacturer should be removed. User access should be restricted to departments or care teams as appropriate. With hospital systems that hold records on many people, only a few staff should have access to the files of patients not currently receiving treatment.

Password Management

In many hospitals all users may access all records and often share passwords and leave terminals permanently logged on for the use of everyone in a ward. Such behavior causes a breakdown of clinical and medicolegal accountability and may lead to direct harm: one case has been reported in which a psychiatric patient changed prescription information at a terminal that was left logged on (Anderson, 1996).

It is important for administrators to educate all users that passwords issued to an individual should be kept confidential and not be shared with anyone. When a user ID is issued to a temporary user who needs access to a system, it must be deleted from the system when the user has finished his or her work. All passwords should be distinctly different from the user ID, and ideally they should be alphanumeric and at least six characters in length. Also, passwords should be changed regularly, at least every 30 days. Rittinghouse and Ransome (2004) suggest that it is a good security practice for administrators to make a list of frequently used forbidden passwords. Standard passwords that are often used to get access to different systems for maintenance purposes are not recommended.

Database Security

Database authentication and access control will be public key enabled and role-based. This means that a user will employ a multi-factor authentication procedure based on knowledge of his/her private key to obtain access to a database. Once authentication is complete, access, sometimes down to the record level, will be granted or denied based on the user's roles and associated privileges. Database security will be implemented on a discretionary access control (DAC) basis.

Social Engineering and Careless Disclosure Safeguards

The weakest link in security will always be people, and the easiest way to break into a system is to engineer your way into it through the human interface (CPRI toolkit: Managing information security in heath care, 2005). The main threat to the confidentiality of clinical records is carelessness in handling telephone/e-mail/fax inquiries, instant messaging and on-site visits, and inadequate disposal of information.

According to King et al. (2001), social engineering safeguards consist of non-technical (procedural) means that include: security training for all corporate users; security awareness training for all system administration personnel with well-documented procedures, handling, and reporting; and security awareness training for personnel responsible for allowing outside visitors into restricted areas (such as assigned escorts).

With regard to careless disclosure, Anderson (1996) developed a set of common sense rules that the best practices have used for years and that are agreed by the UK NHS Executives. Whether records are computerized or not, these rules of best practice can be summed up as clinician-consent-call back-care-commit:

- Only a clinician should release personal health information. It should not be released by a receptionist or secretary.

- The patient's consent must be obtained, except when the patient is known to be receiving treatment from the caller or in the case of emergency or the statutory exemptions. In the latter two cases the patient must be notified as soon as reasonably possible afterward.
- The clinician must call back if the caller is not known personally, and the number must be verified, for example, in the Medical Directory. This procedure must be followed even when an emergency is claimed, as private investigators routinely claim emergencies.
- Care must be taken, especially when the information is or may be highly sensitive, such as HIV status, details of contraception, psychiatric history, or any information about celebrities.
- The clinician must commit a record of the disclosure to a ledger. This should have the patient's name; whether consent was sought at the time (and, if not, the date and means of notification); the number called back and how it was verified; and whether anything highly sensitive was disclosed.

In addition, the guidelines for disclosure by telephone should also apply to faxes. Verifying the identity or, failing that, the location of the caller is just as important as it is when disclosing personal health information over the telephone. It is important, and it is the BMA's established advice that personal health information should be faxed only to a machine that is known to be secure during working hours.

Equipment Theft, Loss, and Damage

Anderson (1996) considers the most serious threat to the continued availability of computerized clinical information in general practice to be theft of the computer that has been experienced by over 10% of general practices surveyed. Data can also be destroyed in other ways such as by fire, flood, equipment failure, and computer viruses. He suggests that physical security measures must be taken; hygiene rules to control the risk of computer virus infestation must be applied together with a tested recovery plan.

Since most organizations do not perform realistic tests of their procedures, with the result that when real disasters strike recovery is usually held up for lack of manuals and suppliers' phone numbers, it is important that a drill based on a realistic scenario, such as the complete destruction of a surgery or hospital computer room by fire must be carried out, and a full system recovery to another machine from back up media held off site must be performed. Another measure is to keep several generations of back ups in cases of equipment failure and virus attacks that it may take time to notice that something has gone wrong. A typical schedule in a well run establishment might involve back ups aged one, two, three, four, eight, and twelve weeks, as well as daily incremental back ups.

Limitations of Security Technologies

Despite an aggressive move toward computerized healthcare records in recent years and ongoing parallel technological improvements, there are still limitations of the security technologies to achieve usable and secure systems (Gillespie, 2001).

Firewalls

Firewalls do not offer perfect protection, as they may be vulnerable to so-called tunneling attacks, in which packets for a forbidden protocol are encapsulated inside packets for an authorized protocol, or to attacks involving internal collusion (Gillespie, 2001). One of the concerns with firewalls is that most firewalls pass traffic that appears to be Web pages and requests more and more, as it is the way to get things to work through the firewall. The solution is to re-implement the whole as Web services (Webmail being a good example). These pressures continually erode the effectiveness of firewalls (Ateniese et al., 2003). For example, the NHS Network in Britain is a private intranet intended for all health service users (family doctors, hospitals, and clinics — a total of 11,000 organizations employing about a million staff in total). Initially, this had a single firewall to the outside world. The designers thought this would be enough, as they expected most traffic to be local (as most of the previous data flows in the health service had been). What they did not anticipate was that as the Internet took off in the mid-1990s, 40% of traffic at every level became international. Doctors and nurses found it very convenient to consult medical reference sites, most of which were in America. Trying to squeeze all this traffic through a single orifice was unrealistic. Also, since almost all attacks on healthcare systems come from people who are already inside the system, it was unclear what this central firewall was ever likely to achieve (Ateniese et al., 2003).

Cryptography

The basis for many of the features desired for security in healthcare information systems depends on deploying cryptographic technologies. However, there are limitations to the use of cryptography. One problem is that security tools based on cryptography are still largely undeployed. One general weakness is poor usage of the system by individuals that includes: easily guessed passwords to the cryptographic system are chosen, or even written down on a sticker and stuck on the notebook, or people use the same password across different systems. The password then becomes as safe as the weakest system that is using it (which will often be something like a Web browser that has been told to remember the password) (Anderson, 2005; Gutmann, 2005). The other problem is that cryptography does not solve the security problem, that is, cryptography transforms the access problem into a key management problem, including authentication, digital signatures, information integrity management, session key exchange, rights management, and so on. It is observed that as the scope of key management services grows, trust in the integrity of key assignments tends to diminish, and the problems of revocation in the case of key compromise become much more difficult (Gillespie, 2001). Although public key infrastructure can help deal with the problem, it has also introduced complexities of its own. This has led to organizations effectively misusing cryptographic keys, as managing them appropriately has become too complex. The simplest example is that everyone in the organization really does get the same key.

Biometrics

The deployment of biometrics is proven to be advantageous to the healthcare providers because it provides added security, convenience, reduction in fraud, and increased accountability. It increases the level of security by providing access to health information to authorized individuals and locking out those with nefarious intent. However, there are drawbacks to the technology. For example, when performing an iris-scan, individuals must remain perfectly still during enrollment and presentation, or the system will not be able to scan the iris, therefore causing false non-matching and failure-to-enroll anomalies to occur. Reid (2004) further identified a few drawbacks to biometrics: hardware costs, user perception, placement, and size. For example, iris-scans require specialized cameras with their own unique light source that can be very expensive. The user perception on having infrared light shined into the eye is quite disconcerting. To get the iris in the proper position can be quite time consuming. Some cameras can use eye recognition techniques to try to auto-pan and focus the camera, but such solutions do increase the cost of the camera and may still require some user coordination. The current size of the camera, which has been reduced to that of a desktop camera on steroids, is still very large. It needs further reduction to be able to work efficiently on a desk.

Hardware and Software Costs

The costs of putting secure technologies in place can be tremendous. Very often the implementation of secured systems requires procurement of new software and hardware as the legacy system becomes obsolete. Unfortunately, there are not many commercial tools readily available in the market to integrate legacy systems into modern distributed computing environments. Furthermore, such integration will involve many database content inconsistencies that need to be overcome, including patient identifier systems, metadata standards, information types, and units of measurement.

Overall the lack of standards for security controls and for vendor products that interoperate between disparate systems will hinder the implementation and enforcement of effective security solutions.

Legislation

The importance of assuring the privacy and confidentiality of health information has always been acknowledged. However, up until recently the legal protection for personal information has been patchy and disorganized (ScreamingMedia, 1999).

U.S. Legislation

The healthcare industry is currently going through an overhaul to meet government-mandated regulations stemming from HIPAA to ensure patient confidentiality, privacy, and efficiency. HIPAA, which was passed in 1996 and effective in 2001, gives consumers the right to their medical records, to limit disclosure, and to add or amend their records. Providers must have complied by April 2003. Entities covered include health insurers, physicians, hospitals, pharmacists, and alternative practitioners such as acupuncturists.

HIPAA requires all healthcare providers, health insurers, and claims clearinghouses to develop and implement administrative, technical, and physical safeguards to ensure the security, integrity, and availability of individually identifiable electronic health data. Failure to comply with HIPAA can result in civil fines of up to $25,000 a year for each violation of a standard. Because HIPAA encompasses dozens of standards, the fines can add up quickly, and wrongful disclosure of health information carries a criminal fine of up to $250,000, 10 years imprisonment, or both (King et al., 2001).

N.Z. Legislation

In New Zealand, the Privacy Act, which came into force on July 1, 1993, provides a measure of legal protection for all personal information, including health information, and applies to the public and private sectors and to information held in both paper and electronic formats.

The Health Information Privacy Code 1994, which is consistent with the provisions of the Privacy Act 1993 (s.46), was issued by the Privacy Commissioner specifically to protect the privacy of personal health information. While the code protects personal health information relating to an identifiable individual, it does not apply to statistical or anonymous information that does not enable the identification of an individual.

The Medicines Act 1981 was issued by the Ministry of Health to penalize any unauthorized sale of prescription medicines, publication of advertisements containing insufficient information about precautions and side effects, and advertising the availability of new medicines before their approval for use in New Zealand. Under Section 20, the maximum penalty for an individual is up to six months imprisonment or a fine not exceeding $20,000. Sections 57 and 18 have a maximum penalty for an individual of three months imprisonment and a fine not exceeding $500.

The Privacy Commission also considered the application of the Privacy Act to the process of caching (Anderson, 2001). Caching occurs when a Web page accessed by users is temporarily stored by the user's computer (client caching) or by the network server that provides the user with Internet access (proxy caching). It also considered that the Privacy Act applied to the use of cookies within New Zealand and offered sufficient protection. It is proposed that using cookies for the purpose of collecting, holding, or giving access to personal information would be an offence unless the Web site indicated such information would be gathered. However, the Privacy Commissioner did not support the creation of such an offense.

European Union Data Protection Directive

International action may further affect the ways in which personal health information is transmitted over the Internet. The EU Data Protection Directive, which went into effect on October 25, 1998, requires EU member states to block outbound transmissions of data to countries that do not have laws providing a level of privacy protection similar to that in the country where the data originated (Siman, 1999). The directive affords the people to whom the data refer a host of rights, including the right to be notified of data collection practices, to access information collected about them, and to correct inaccuracies (Stevens, 1998). In 1998, New Zealand addressed three aspects of the Privacy Act to ensure it is adequate for the purposes of the EU directive. This is important for New Zealand businesses dealing in personal data originating from Europe because the directive limits the exportation of data to third countries (countries outside the EU) that do not have an adequate privacy protection (Wiles, 1998). The three aspects are:

- The channeling of data from Europe through New Zealand to unprotected data havens;
- Limits on who may exercise rights of access and correction under the Privacy Act; and
- The complaints process. "With a long queue of complaints awaiting investigation, the EU may have concerns that our complaints system is not sufficiently resourced to provide timely resolution of complaints."

In view of the above, the Privacy Commissioner addressed that the Privacy Act is built upon a desire that the collection, holding, use, and disclosure of personal information should be carefully considered and that all activities in this area should be as open as possible.

FUTURE TRENDS

The growth of wireless computing in healthcare will take place for two reasons (The Independent Research Group, 2002):

- For all electronic medical record systems to work, physicians cannot be tied down to wired PC workstations. They will need to use some type of wireless device that allows them access to the relevant hospital databases.
- As the cost of healthcare continues to rise, many individuals are being treated on an outpatient basis. To keep track of an outpatient's vital statistics or signal when the patient needs immediate medical attention, many pervasive devices, such as toilet seats, scales, smart shirts, smart socks, and pacemakers, are being developed that collect relevant patient information. Collected data can then be transmitted via a wireless device using a wireless or mobile network to the patient's physician, who can then decide on possible interventions.

In the recent years, the technological advancements in sophisticated applications and interoperability has increased the popularity of wireless LAN (WLAN) and the use of wireless technology in healthcare. Also with the faster connection speeds of broadband LANs, the healthcare providers have developed a number of applications to improve patient safety and the healthcare delivery process. According to Kourey (2005), the use of personal digital assistants (PDAs) has become increasingly popular. It is because, "PDAs provide access to data and e-mail, store and retrieve personal and professional information and facilitate communication in wireless environments, their use among healthcare professionals has skyrocketed. Industry experts predict the trend to continue. In 2001, 26% of American physicians used handheld devices for tasks related to patient care. While some experts predict this number to reach 50% by 2005." Increasingly, clinicians can check on patient data or order treatments through secure wireless networks from anywhere in the hospital. For example (Hermann & Norine, 2004):

- A nurse is automatically notified on a handheld wireless device that a patient's blood pressure is falling.
- A doctor on rounds receives the results of an important blood test on a wireless PDA instead of having to call the lab for the information.
- A telemetry system records the vitals signs of dozens of patients in critical care and sends them wirelessly to a central control station for continuous, around-the-clock monitoring.
- A surgeon completing a procedure writes after-care orders while still in the operating room and transmits them to the clinical information system, making them instantly part of the patient's electronic record.

Rittinghouse and Ransome (2004) stress that employees who have not been properly educated about wireless security may not realize the dangers a wireless network can pose to an organization, given wireless computing is still a very new technology. They classify WLAN security attacks into two types:

- **Passive attacks** — An unauthorized party simply gains access to an asset and does not modify its content (i.e., eavesdropping). While an attacker is eavesdropping, he or she simply monitors network transmissions, evaluating packets for specific message content. For example, a person is listening to the transmissions between two workstations broadcast on an LAN or that he or she is running into transmissions that take place between a wireless handset and a base station.
- **Active attacks** — An unauthorized party makes deliberate modifications to messages, data streams, or files. It is possible to detect this type of attack, but it is often not preventable. Active attacks usually take one of four forms (or some combination of such):
    1. *Masquerading*: The attacker will successfully impersonate an authorized network user and gain that user's level of privileges.
    2. *Replay*: The attacker monitors transmissions (passive attack) and retransmits messages as if they were sent by a legitimate messages user.
    3. *Message modification*: It occurs when an attacker alters legitimate messages by deleting, adding, changing, or reordering the content of the message.
    4. *Denial-of-service (DoS)*: It is a condition that occurs when the attacker prevents normal use of a network.

When patient information is sent wirelessly, additional security measures are advisable, although a well-defined wireless utility basically protects confidentiality and restricts where the signal travels (Hermann & Norine, 2004). Tabar (2000) suggests that the growth of new technology also creates a unique security threat and requires user authentication protocols. For example, PDAs, laptops, and even mobile carts can fall into unauthorized hands; the electronic ID must be stored elsewhere. Vendors are working on solutions such as: hardware ID tokens that are inserted into the mobile devices before use and radio transmitter-tracking devices. Other browser-based only applications on the mobile computing device are also used such that the patient data resides only on the server and cannot be accessed by the mobile computing device once it is outside the WLAN coverage area. Turisco and Case (2001) argue that while vendors are responsible for code sets, encryption, privacy, and audit trails, user organizations need to manage the device with extreme care or cautions. Physical security is of paramount concern in the wireless communications. The device needs to be turned off when not in use and be kept in a safe place. Tabar (2000) concurs that the greatest hurdle in information security still rests with the user, and no technology can make up for slack policies and procedures. "Changing perceptions, culture and behavior will be the biggest challenges," says Monica Summers, IS Director at Beaufort Memorial Hospital, Beaufort, S.C. "It's not just the technology. You could slap down $5 million in technology, and it won't stop people from giving out their password." (Tabar, 2000).

CONCLUSION

Privacy is not just about security measures, but is at least as much about what information is collected and collated and practically recoverable. Health information has always been regarded as highly sensitive, which must be protected by medical ethics and privacy legislations. The emergence of new technology and new organizational structures in the healthcare industry has opened up the means and the desire to collect and collate such information in ways never previously considered.

The increased use of the Internet and latest information technologies such as wireless computing are revolutionizing the healthcare industry by improving healthcare services, and perhaps most importantly, empowering individuals to understand and take charge of their own healthcare needs. Patients become involved and actively participate in the healthcare processes, such as diagnosis and treatment through secure electronic communication services. Patients can search healthcare information over the Internet and interact with physicians. This enhances and supports human rights in the delivery of healthcare. The same technologies have also heightened privacy awareness. Privacy concerns include: healthcare Web sites that do not practice the privacy policies they preach, computer break-ins, insider and hacker attacks, temporary and careless employees, virus attacks, human errors, system design faults, and social engineering. Other concerns are the collection, collation, and disclosure of health information. Healthcare providers and professionals must take into account the confidentiality and security of the information they collect and retain. They must also ensure that their privacy policies or secure technologies meet the public expectation and abide by the law. Such policies and technologies must also be implemented to ensure the confidentiality, availability, and integrity of the medical records. If this is not done, resources could be wasted in developing secure systems, which never reach fruition, and the new systems will never gain the confidence of the public or of the health professionals who are expected to use them.

Technology is, to a large extent, both the cause of and the solution to concerns about the protection of personal health information. However, there are limitations to the secure technologies that need on-going research and development. Technologies, if coupled with physical security control, employee education, and disaster recovery plans, will be more effective in securing healthcare privacy. Further advances of new information technologies, if designed and monitored carefully, will continue to benefit the healthcare industry. Yet patients must be assured that the use of such technologies does not come at the expense of their privacy.

Section IV
Utilization and Application

This section introduces and discusses the ways in which information technology has been used to shape the medical and biomedical sectors and proposes new ways in which IT-related innovations can be implemented within organizations and in society as a whole. These particular selections highlight, among other topics, the implementation of telehealth and the evolution of new, computerized systems in hospitals. Contributions included in this section provide excellent coverage of today's medical environment and insight into how medical informatics impacts the fabric of our present-day global village.

Chapter 4.1
Successful Health Information System Implementation

Kristiina Häyrinen
University of Kuopio, Finland

Kaija Saranto
University of Kuopio, Finland

INTRODUCTION

A Standish Group (1994) study showed that only 16% of all information technology projects come in on time and within budget. The situation is not better concerning health information systems. Many health information system implementations are less than completely successful (Berg, 2001; Giuse & Kuhn, 2003; Lorenzi & Riley, 2003). In this article, the health information system means "a system, whether automated or manual, that comprises people, machines and /or methods organized to collect, process, transmit, and disseminate" data that represent user information in healthcare (Kuhn & Giuse, 2001, pp. 275). What is successful implementation and whose success is measured? Successes can be measured in many ways. Delone and McLean have been finding out the success factors of management information system which are also applicable to health information system. The success factors are: system qualities, *e.g.*, the ease of use or time savings, information quality, *e.g.*, completeness or data accuracy, usage, *e.g.*, the frequency of use or the number of entries, user satisfaction, *e.g.*, user-friendliness or overall satisfaction, individual impact, *e.g.*, changed work practices or direct benefits and organizational impact, *e.g.*, communication and collaboration or impact on patient care. Furthermore, user involvement during system development, implementation and organizational culture have been identified as possible factors measuring the success. However, the need for further research to determine which attributes are the most useful ones in measuring success has also been revealed. (van der Meijden, Tange, Troost & Hashman, 2003).

The different phases in implementation process are, in general, user needs and requirements analysis (specification), system design, initial system implementation and testing (Ahmad, Teater, Bentley, Kuehn, Kumar, Thomas & Mekhjian, 2002; Schuster, Hall, Couse, Swayngim & Kohatsu, 2003; Souther, 2001). The system requirements analysis includes workflow analysis, and the initial system implementation includes the technical installation of the information system, integration of the information system to other information systems and users' training. Project management is an important factor in every phase of the implementation project.

The purpose of this article is to highlight the health information system implementation process from end-user perspective. Which factors are crucial in the implementation process from the point of view of the end-users? How does project management contribute to the implementation process, what is the role of the end-user in system designing and how does training effect the information system implementation?

BACKGROUND

The lack of financial support was the most significant barrier to successfully implementing information technology in healthcare from both clients' and vendors' perspective. The vendors' inability to deliver products, and difficulties in achieving end-user acceptance or use were the other barriers from the point of view of the clients. (HIMSS, 2002.) Costs are often underestimated because the cost of the software is only the beginning of other expenditures, *e.g.*, person-hours for training and support have been forgotten (Ash, Stavri & Kuperman, 2003).

The social and organizational issues, not only the technical ones, are the critical issues in the implementation of information systems. The health information systems do not effectively support the health processes, and terminology for the healthcare environment is needed. (Ahmad et al., 2002; Berg & Toussaint, 2003; Berg, 2001; Giuse & Kuhn, 2003; Kuhn & Giuse, 2001; Littlejohns, Wyatt & Garvican, 2003).

Human-computer interaction is also perceived as unsatisfactory. The human-computer interaction indicates the means by which humans interact with computers, *e.g.*, users enter and retrieve data. To optimize the design of the human-computer interaction, concepts are needed (Berg, 2001; Kuhn & Giuse, 2001). Technical issues, *e.g.*, integration with other information systems and the need for open systems are also issues which must be solved (Giuse & Kuhn, 2003; Kuhn & Giuse, 2001).

The reasons for failures were that the complexity of healthcare tasks and social and professional cultures of healthcare organizations was not taken into account and, furthermore, the education of the users was insufficient and the timing of the education was wrong (Littlejohns, Wyatt & Garvican, 2003). Lorenzi and Riley (2003) report that the failures of the implementation of the health information system can be classified into four categories: technical shortcomings, project management shortcomings, organizational issues and information explosion. The technical failures contain, *e.g.*, the old system maintenance and staff training. Project management issues are, *e.g.*, project management skills. Organizational issues are concerned with constant changes. Information explosion means that knowledge has increased exponentially and new technical tools have been developed to cope with the information. Berg (2001) notes that it is important to notice that the implementation is not only a technical installation, and also that the project is not only a technical project but also an organizational development project.

The three major reasons that a project will succeed are user involvement, executive management support and the clear statement of requirements (Standish Group, 1994). Doolan, Bates and James (2003) reported that the factors associated with successful implementation are unusually strong leadership, a clearly defined long-term commitment, clear focus on improving clinical processes and gaining clinical involvement and support improving productivity. Lorenzi and Riley (2003) included technical skills, project management skills and people and organizational skills to the success factors. The skills mean knowledge, experience and abilities in each area. Ahmad et al. (2002) stated that success factors are a continuous executive support, engagement of physicians, an effective implementation team, a consistent user-friendly interface and on-going user support.

User involvement during system development, implementation process and organizational culture may explain the failure of the information system. The attributes assigned to system development were the extent of user involvement, redesigning work practices and the reconstruction of content and technical limitations. Communication, training and technical support were attributes addresses to implementation process. Organizational aspects attributes were organizational culture, *e.g.*, control and decision-making, management support, professional values as well as support and maintenance. (van der Meijden, Tange, Troost & Hashman, 2003.)

THE ROLE OF THE PROJECT MANAGEMENT

A project approach is the most common way to implement health information systems. Project management is the process of planning for organizing and controlling projects. From the end-users' point of view, the objectives of health information system projects must make explicit, *i.e.*, improve patient care or efficiency. It is recommendable to set a stage for improvements, *e.g.*, reduce the number of phone calls or move manual files to on-line files. The objectives of the project must also improve workflows and work practice, in other words the hospital managements and also clinicians involved in the project must also upgrade their work performance. The implementation of information system must add value for the end-user. Clear objectives motivate the end-users for implementation. (Ash, Stavri & Kuperman, 2003; Berg, 2001; Berg & Toussaint, 2003; Doolan, Bates & James, 2003, FitzHenry & Snyder, 1996; Giuse & Kuhn, 2003; Littlejohns, Wyatt & Garvican, 2003; Lorenzi, Riley, Blyth, Southon & Dixon, 1997; Nikula, Elberg & Svedberg, 2000; Lechleitner, Pfeiffer, Wilhelmy & Ball, 2003)

The information system implementation process must be seen as an organizational change process (Anderson & Stafford, 2002; Berg, 2001; Lorenzi, Riley, Blyth, Southon & Dixon, 1997). Change management, which means "the process of assisting individuals and organizations in passing from an old way of doing things to a new way of doing things" (Lorenzi & Riley, 2003 pp.200), should be taken into account from the start of the implementation process. Organizational resistance always occurs during the implementation of new information systems. The change management is one reason why the leader has an important role in projects. (Lorenzi & Riley, 2003; Lorenzi, Riley, Blyth, Southon & Dixon, 1997; FitzHenry & Snyder, 1996) Furthermore, the implementation process itself requires effective leadership (Ash, Stavri & Kuperman, 2003;Lorenzi & Riley, 2003; Souther, 2001). Leadership is needed at multiple levels in organizations; high-level leadership was considered the single most important factor. It was demonstrated by the long-term commitment of resources. (Ahmad et al. 2002; Doolan, Bates & James, 2003; Littlejohns, Wyatt & Garvican, 2003). At the executive level, leadership is needed to promote a shared vision the purpose of health information system, which is e.g. to improve patient care. At the project management level, the leadership is needed to make practical, effective and useful decisions (Ash, Stavri & Kuperman, 2003). The need for bottom-up participative and top-down authoritarian approaches are also useful when changing organizational behavior. (FitzHenry & Snyder, 1996; Souther, 2001). External consults can also be used as change agents. (FitzHenry & Snyder, 1996; Lechleitner, Pfeiffer, Wilhelmy & Ball, 2003; Souther, 2001)

There is a need for different people, and many types of skills, both technical and medical, in implementation process. The persons who are assigned to the projects must be influential and knowledgeable and they must represent significant organizational groups and professionals. The challenge is to find the right persons. The multidisciplinary team approach has proven advantageous in health information system implementation.(FitzHenry & Snyder, 1996; Lechleitner, Pfeiffer, Wilhelmy & Ball, 2003; Littlejohns, Wyatt & Garvican, 2003; Souther, 2001) There must be different levels of teams: an executive steering team, a project steering team and a project work team. The end-users are representatives in different levels of teams. It is important that physicians and nurses belong to the project steering team, which makes major policy decisions based on user needs and requirements, organization infrastructure and general implementation strategies. The end-users also belong to the project work team, whose focus is training, user-interface, testing, security policy and pilot implementation. (FitzHenry & Snyder, 1996; Souther, 2001) The end-users' participation to the project enhanced their involvement.

The organizational readiness for information system innovation could also be assessed in advance. The information about the organizational readiness could be used in planning implementation strategy (Nikula, 1999; Snyder-Halpern, 2001; Yetton, Sharma & Southon, 1999), *e.g.*, in what order to engage different parts of the organization or in which phase of implementation process managerial influence must be at its highest. The healthcare organizational readiness for information system innovation could be assessed by the validated eight sub-dimensions of knowledge, end-users, technology, administrative support, management structures, processes, resources, values and goals. The end-user readiness themes include, *e.g.*, skills to use computers or involvement in the change process. The information about the end-user readiness could be used in planning their training. (Snyder-Halpern, 2001)

THE END-USERS' ROLE IN DESIGNING INFORMATION SYSTEM

For the design of information systems, the conventional approach has been to model a system completely before implementing it (Berg, 2001; Kuhn & Giuse, 2001; Lorenzi, Riley, Blyth, Southon & Dixon, 1997). Prototyping has proven a successful project (Ahmad et al., 2002; Doolan, Bates & James, 2003; Lechleitner, Pfeiffer, Wilhelmy & Ball, 2003; Lorenzi, Riley, Blyth, Southon & Dixon, 1997; Schuster, Hall, Couse, Swayngim & Kohatsu, 2003). Prototyping requires an iterative approach, in which information system analysis, design, implementation and evaluation merge. It is evident that the information system changes work practices and vice versa. Therefore, the first step is to model the environment of the system. A socio-technical approach is suitable for system design. It means that the work practices in which information systems will be used are the starting points for design and implementation of the information systems. This means defining the core actors, their core tasks, the flow of work and the flow of data. The present workflows are analyzed, the future workflows described and documented. (Berg & Toussaint, 2003; Berg, 1999; FitzHenry & Snyder, 1996; Schuster, Hall, Couse, Swayngim & Kohatsu, 2003; Souther, 2001) The interactive model increases end-user involvement. The need for optimally adapting information systems to the work practice in the healthcare organizations and the users' terminology are important, as well as reducing workload and simplifying the workflow (Anderson & Stafford, 2002; Berg & Toussaint, 2003; Doolan, Bates & James, 2003; Giuse & Kuhn, 2003, Kuhn & Giuse, 2001; Lechleitner, Pfeiffer, Wilhelmy & Ball, 2003; Lorenzi, Riley, Blyth, Southon & Dixon, 1997). Health professionals must develop the information system together with the vendors. The interaction between the vendor, the teams installing the information system and the users is a crucial point. Representatives must include all different health professionals and administrative personnel (Anderson & Stafford, 2002; Berg & Toussaint, 2003; Doolan, Bates & James, 2003; Kuhn & Giuse, 2001; Lechleitner, Pfeiffer, Wilhelmy & Ball, 2003; Lorenzi, Riley, Blyth, Southon & Dixon, 1997 Nikula, Elberg, Svedberg, 2000; Schuster, Hall, Couse, Swayngim & Kohatsu, 2003; Sleutel & Guinn, 1999)

TRAINING AND SUPPORT

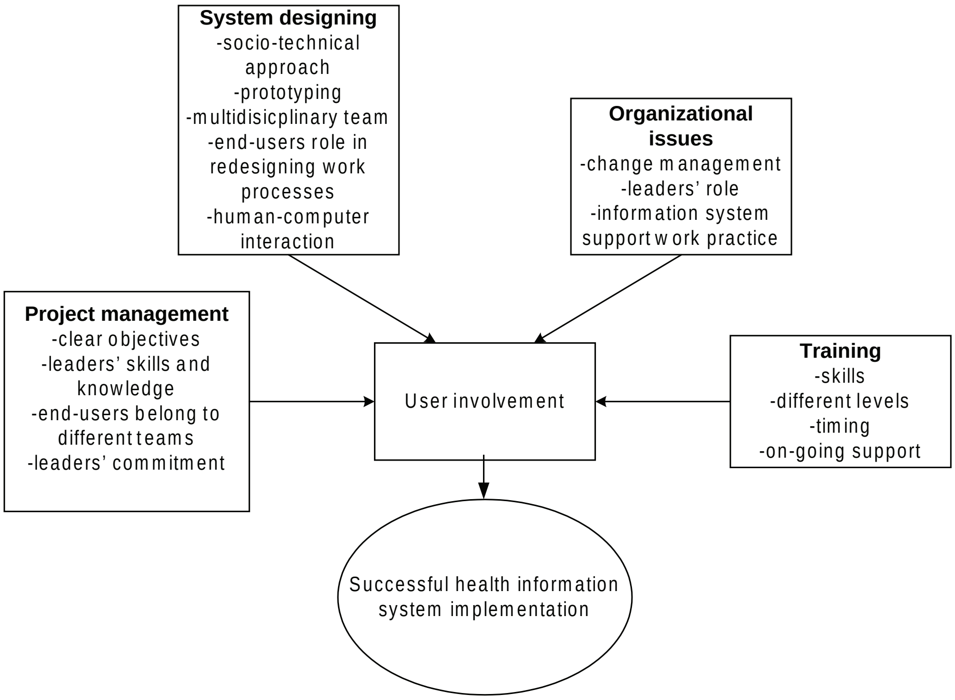
The proper training and support are an essential part of the health information system implementation process (Ahmad et al., 2002; Anderson & Stafford, 2002; Ash, Stavri & Kuperman, 2003; Doolan, Bates & James, 2003; Littlejohns, Wyatt & Garvican, 2003; Lorenzi, Riley, Blyth, Southon & Dixon, 1997; Schuster, Hall, Couse, Swayngim & Kohatsu, 2003; Souther, 2001). An implementation of the health information system requires extensive support and training in order to achieve user acceptance. The training plan must be completed before the initial implementation and it should also include intensive support at the time of the implementation. In the most successful implementation the end-users have more support after initial implementation than before it (Ash, Stavri & Kuperman, 2003).

There are also differences between computer literacy within healthcare professionals. (Saranto & Hovenga, 2004; Souther, 2001). Computer literacy means basic skills in computers use, *e.g.*, read and write. Information literacy consists of computer literacy, information retrieval abilities and communication skills. (Saranto & Hovenga, 2004) Therefore, the skills of the users, as well as their needs, must be taken into account when planning the training of a new information system. The quality of user training has a key role for a good user acceptance of information system (Anderson & Stafford, 2002; Quinzio, Junger, Gottwald, Benson, Hartmann, Jost, Banzhaf & Hempelmann, 2003). Disagreement on the efficiency of the system training has occurred (Lechleitner, Pfeiffer, Wilhelmy & Ball, 2003; Quinzio et al., 2003). The well-trained users were significantly more satisfied with the information system in routine use. A three-step training strategy has been recommended. First, the employees should be informed of the planned information system. The second phase includes general on-job training, and the third phase includes the opportunity to work on the individual problems of each user. (Quinzio et al., 2003) Whitman, Hamann & Vossler (1997) have also introduced a training plan. The strengths of the training plan are the contract that identified the roles and responsibilities of staff, management, and information services and staff development. Peer trainers have proven useful. Everyone must also have their own computer during training sessions. A competency test has been suggested as improvement to training plan. Ahmad et al. (2002) report a formalized training program for all users which precedes the implementation by two or four weeks. In addition, extensive on-site training occurred during the implementation period. The traditional help-desk phone has been found inadequate for user support.

FUTURE TRENDS

From the end-user perspective, the critical issues concerning the health information system implementation are project management, system designing, organizational issues and training and support. First of all, the project must have clear objectives. The teams must consist of different types of healthcare professionals, vendors, management and so on. It is important to find the right people to engage in the project. Project management task and responsibilities must be clear for each level of the teams and the interaction between the teams will also be efficient. The teams must work actively with the vendors. The management must also commit to the implementation process so the end-users notice that the project is important. The project

Figure 1. The factors of successful implementation process- end-users perspective



management aids the change management, which is one of the critical issues of information system implementation process. The leaders can use the information about the organizational readiness in planning the implementation strategy.

It is crucial that both representatives from the future users and leaders are involved in the design process. They are the experts of their work. The iterative development process will be used and the information systems adapting to workflows is important. When the information systems' requirements and future workflows are modeled properly it becomes evident that the work processes change, because the healthcare professionals must consider what they do and why they do it.

The training plan must be designed carefully. The information literacy of the end-users will be taken into account. A multilevel approach is good. First, the vendor can present the main functions of the information system. After that the tutors teach the users to use the information system and the users can train the system themselves. The users are also supported, they can ask questions. After that the users themselves can practice and also contact the tutors if they have any problems using the information system.

CONCLUSION

In the first stages the point of view in health information system implementation was only technical. The implementation process paid no attention to workflow patterns prior to the implementation, or to the computer experience among personnel or aspects of the organizational culture. Strategies for the successful management of health information system implementation must be planned carefully. The personnel of an organization must learn to use the information system and also change their working processes. Education is the critical point of the implementation process. Knowledge about end-user attitudes and skills prior to computerization is useful. The training will be tailored to meet the varying needs of user groups. There is a need for research in the area of evaluating health information system implementation.

KEY TERMS

Change Management: Change management is the process of assisting individuals and organizations in passing from an old way of doing things to a new way doing things.

Health Information System: Health Information System is the system, whether automated or manual, that comprises people, machines and /or methods organized to collect, process, transmit and disseminate data that represent user information in health care.

Implementation: The implementation of information system includes different phases: user needs and requirements analysis (specification), system design and initial system implementation and testing. The system requirements analysis includes workflow analysis; the initial system implementation includes technical installation of information system, integration the information system to other information systems and users' training.

Information Literacy: Information literacy consists of computer literacy and information retrieval abilities and communication skills. Computer literacy means basic skills in computers use, *e.g.*, being able to read and write with computers.

Project Management: Project management is the process of planning for organizing and controlling projects. The multidisciplinary team approach in project management means that there are different levels of teams: the executive steering team, the project steering team and the project work team. Different teams have their own tasks.

Prototyping: Prototyping is the development approach in which prototypes are produced. It is an iterative approach to the developing of the information system. The distinctions of the different phases of development of the information system, *e.g.*, analysis, design, implementation and evaluation are not clear.

Socio-Technical Approach: Socio-technical approach means that the work practices in which information systems will be used are the starting points for design and implementation of the information systems.

Chapter 4.2
Perceived Level of Benefits and Risks of Core Functionalities of an EHR System

Diane C. Davis

Minal Thakkar
Southern Illinois University-Carbondale, USA

ABSTRACT

The need to adopt an electronic health record (EHR) system in United States (U.S.) hospitals seems to be more and more obvious when evaluating the benefits of improved patient safety, quality of care, and efficiency. The purpose of the study was to identify the status of EHR systems in U.S. hospitals in regard to the core functionalities implemented (as identified by the Institute of Medicine) and to determine if there was a significant relationship between perceived level of benefit and risk with the use of each core functionality, as well as if there was a significant relationship between the status of the EHR system and size of hospital. A national survey of U.S. hospitals was conducted to answer the research questions. The results showed that 37% had some components in **all** of the core functionalities of an EHR system, while 27% were using at least **some** functionalities. Health information and data, administrative processes, and results management were the three core functionalities that a majority of hospitals had as a part of their EHR system. A significant positive correlation between perceived benefits and risks was found in all of the eight core functionalities. There was no significant relationship found between status of EHR system and size of hospitals.

INTRODUCTION

With the growing need to provide the right information to the right person anywhere at anytime in today's global interconnected world, the U.S. healthcare industry has been moving toward an electronic health record (EHR) system. The need to adopt an EHR system in U.S. hospitals comes primarily from concerns regarding the quality of healthcare. Results of two studies of large samples using 1984 and 1992 data "imply that at least 44,000 and perhaps as many as 98,000 Americans die in hospitals each year as a result of medical errors" (Kohn, Corrigan, & Donaldson, 2000, p. 26). According to Aspden (as cited in Rippen & Yasnoff, 2004), universal availability of healthcare information and decision support through the national health information infrastructure can bring substantial improvements in patient safety and quality of care. The EHR, which is defined as "a secure, real-time, point-of-care, patient-centric information resource for clinicians" (HIMSS, 2003) is designed to provide this point of access to patient health information where and when it is needed by medical professionals.

EHR systems could save up to $81 billion in healthcare costs annually and improve health care quality (Hillestad et al., 2005). Financially sound hospitals and physician offices are leaping into adopting EHR systems (Goldschmidt, 2005). At the same time, some small hospitals and small physician offices are lagging behind in the use of EHR systems creating a digital divide (Goldschmidt, 2005). This may be due to lack of significant return on investment (ROI) in the short term, considering the high costs associated with the adoption of EHR systems.

Currently there are various initiatives carried out by governing agencies and healthcare associations in the area of promoting EHRs. David Brailer, national coordinator for health information technology, emphasized the important role EHR systems play in improving quality, increasing patient safety, increasing operational efficiency, and reducing costs. In his report on "The Decade of Health Information Technology: Delivering Consumer-centric and Information-rich Health Care: Framework for Strategic Action," Brailer said that reimbursing physicians for using EHR systems and reducing their risk of investing in them should accelerate the adoption of EHR systems in physicians offices (as cited in Mon, 2004).

At a conference in Baltimore on April 27, 2004, President Bush announced that most Americans will have EHRs within the next 10 years to allow doctors and hospitals to share patient records nationwide. To build upon the progress already made in the area of health information technology standards over the last several years, he proposed the FY2005 budget to include $100 million for demonstration projects (Cassidy, 2004). This will help test the effectiveness of health information technology and establish best practices for more widespread adoption in the healthcare industry (Administration Unveils 10 Year Health Information …., 2004).

Many organizations are working to develop initiatives and goals to help meet the needs of the healthcare industry. One initiative is Electronic Health Information Management (e-HIM) by the American Health Information Management Association (AHIMA). E-HIM goals are to: (1) promote the migration from paper to an electronic health information infrastructure, (2) reinvent how institutional and personal health information and records are managed, and (3) deliver measurable cost and quality results from improved information management ("AHIMA Mobilizes to Meet the e-HIM Call," 2003).

The Department of Health and Human Services (DHHS) charged a committee established by the IOM in May 2003 to:

- Provide guidance to DHHS on a set of "basic functionalities" that an electronic health record system should possess to promote patient safety.

The IOM committee considered functions, such as the types of data that should be available to providers when making clinical decisions (e.g., diagnoses, allergies, laboratory results); and the types of decision-support capabilities that should be present (e.g., the capability to alert providers to potential drug-drug interactions) (Institute of Medicine, 2003, p. 4).

Core functionalities of an EHR system and its components at that time as identified by the Institute of Medicine (IOM) committee were health information and data; results management; order entry/management; decision support; electronic communication and connectivity; patient support; administrative processes; and reporting and population health management. See the Appendix for a description of each of these functionalities.

PURPOSE AND GOAL OF THE STUDY

The overall goal of this study was to identify the core functionalities (as defined by IOM) being used by hospitals throughout the U.S. and the perceived level of benefits, costs, and risks associated with each of the functionalities. In order to meet this goal, a national survey was conducted to answer the following research questions:

- **RQ1:** What are the EHR core functionalities (such as health information and data, results management, order entry/management, decision support, electronic communication, patient support, administrative processes, reporting and population health management) utilized by healthcare systems?
- **RQ2:** Is there a significant difference between the status of the EHR system utilized and the size of the hospital (as measured by number of beds in the hospital)?
- **RQ3:** Is there a relationship between the perceived level of benefit and risk with the use of each of the core functionalities of an EHR system?

RELATED WORK

The status and the effects of using an EHR system are topics of growing interest to researchers. The most comprehensive study on the trends and usage of EHR has been conducted on a yearly basis by the Medical Records Institute (2005). The major role of the largest number of the 280 provider respondents of the 2005 study was information technology (IT) managers and professionals (42%) of which 11% were health information managers or MIS/CIS managers (p. 3). The motivating factors or driving forces for implementing EHR systems that were marked by 75% or more of these respondents were the need to (1) improve clinical processes or workflow efficiency, (2) improve quality of care, (3) share patient record information with healthcare practitioners and professionals, and (4) reduce medical errors (p. 6). The only major barrier to implementation marked by a majority of respondents (57%) was lack of adequate funding or resources (p. 22).

In regard to specific applications or functions, the ones used by a majority of respondents were in the Administrative and Financial Application; the Data Capture, Review, and Update Capabilities; and E-mail categories. Those used by 50% or more in the Administrative and Financial category were in billing and accounts receivable (66%), claims processing (63%), scheduling (61%), patient appointments, (59%), registration/admissions (59%), and charge capture and/or coding (53%) (MRI, 2005, p. 11). In Data Capture, Review, and Update Capabilities, demographics (67%), laboratory results (52%), medications being taken (50%), and allergies (50%) were the ones used by the majority of respondents (p. 13). In the e-mail category, only e-mail between practitioners was used by a majority of respondents (57%).

A study conducted in 2004 by AHIMA showed the industry is continuing to see more movement toward the EHR. The study (as cited in Zender, 2005) was conducted by Healthcare Informatics in collaboration with AHIMA at their 2004 national convention. It included 284 responses from respondents who primarily (80%) worked in clinical settings. Of these, 55% worked in hospitals while smaller groups worked in ambulatory care, long-term care, behavioral health, and others. A total of 83% of the respondents indicated they were HIM professionals (most having titles of director or manager). The study found that when organizations were asked to describe progress toward an EHR, 17% of respondents indicated extensively implemented; 26% indicated partially implemented; 27% said they were selecting, planning, or minimally implemented, and 21% indicated they were considering implementation and gathering information about it (Zender, 2005).

Medical personnel at the Adult Primary Care Clinic at the Medical University of South Carolina in Charleston, South Carolina, conducted a study to identify if the direct entry into the EHR system in the examination room by physicians had an effect on the physician-patient relationship as perceived by the patients themselves. They found the "use of the EHR had no negative impact on patients' perceived level of satisfaction with their physicians' interpersonal skills, the quality of the visit, or the perceived outcome of the care received" (Wagner et al., 2005, p. 38-39).

In a study conducted during the summer of 2004 by the American Academy of Family Physicians (AAFP), nearly 40% of respondents indicated they either completely converted to EHRs or were in the process of doing so and 24% with EHRs had purchased the system within the first half of the year (Carol, 2005). Cost seemed to be the primary barrier to EHR systems for physicians in small and medium-sized practices. According to Barbara Drury, an independent consultant of Pricare, a national consulting firm in Larkspur, CO (as cited in Carol, 2005), the median cost of implementing an EHR system was in the range of $30,000 per physician and could easily increase to $50,000 when including hardware, training, network upgrades, and IT services.

Previous research on EHR systems identified reducing medical errors, improving quality of care, conserving physician time, sharing patient information among healthcare practitioners, and workflow efficiency as the main benefits (Berman, 2004; Hier, Rothschild, LeMaistre, & Keeler, 2005; Valdes, Kibbie, Tolleson, Kunik, & Petersen, 2004). In regard to risks, privacy, security, and ROI were identified as major concerns (Bates, 2005; Hersh, 2004; Swartz, 2005). Few other studies conducted in the area of EHR reported the status of EHR systems in U.S. hospitals and physician offices (Gans, Kralewski, Hammons, & Dowd, 2005; "Small practices report success with EHRs," 2005; Valdes et al., 2004). These studies and other previous research conducted in the area of EHR systems studied the benefits, risks, and the extent of the usage of EHR applications and functions in U.S. hospitals and physician offices. They did not study the perceived level of benefits, risks, and costs associated with each of the core functionalities of an EHR system.

METHODOLOGY

In order to gain a better understanding of electronic record systems used in healthcare systems and terminology related to electronic health systems, the researchers conducted interviews at three hospitals within a 65-mile radius. Seven healthcare and information systems professionals from the three hospitals were interviewed. After these interviews and a thorough review of the literature, a draft of a survey instrument was developed. It was designed to gather answers to the research questions stated above. The survey instrument was reviewed by a panel of experts, which included an additional group of medical personnel and information systems personnel in local hospitals. Revisions were made to the survey instrument based on the comments of the reviewers. The survey was then approved by the Human Subjects Committee at the university employing the researchers prior to pilot testing. Next, the survey was sent to eight randomly selected hospitals from a national list of hospitals for pilot testing. Comments from these experts were reviewed and used as feedback for final revision of the instrument.

A database of randomly selected 1000 member hospitals of the American Hospital Association was purchased from Third Wave Research. A mailing including a cover letter, survey instrument, and drawing describing the core functionalities as identified by the IOM, and self-addressed return envelope was mailed in February 2005 to the Director of Health Information of these 1000 randomly selected hospitals. A follow-up mailing was sent in March. The response rate was slightly less than 10% and the findings described on the following pages are based on the 90 usable surveys that were returned. Responses to this study were coded onto Scantron sheets and analyzed using SPSS, version 14.

FINDINGS

Demographics of Respondents and Hospitals Surveyed

Fifty-eight percent of the respondents had 20 years or more of experience in the field; only 16% had less than 10 years. The mean for experience was 20 years. The majority of the respondents (61%) indicated their job title was health information manager or director of health information as seen in Table 1.

The specific titles in the miscellaneous "medical titles" category were Executive Director Physician Practice Network, Sr. VP Quality and Medical Staff Affairs, Transcription Coordinator, Coder in HIM, Patient Health Education Coordinator, and RN/DON. The titles in the miscellaneous "information systems" category were Systems Coordinator, Accounts Receivable /IT, Manager Patient Accounts/MIS, and Network Administrator. The "other" category contained respondents that indicated they had a title such

Table 1. Job titles of respondents

Title	Number	Percent
Director (or Manager) of Health Information	54	61.36
Director (or Manager) of Medical Records	13	14.77
HIM Manager/Director and Privacy Officer	3	3.41
Chief Information Officer/VP of Information Systems	3	3.41
Miscellaneous Medical Titles	6	6.82
Miscellaneous Information Systems' Titles	4	4.55

Table 2. Number of beds in facility

Beds	Number	Percent	Percent from AHA Statistics*
Less than 100	30	34.88	47.46
100 – 199	24	27.91	23.86
200 - 299	12	13.95	12.75
300 - 399	7	8.14	7.13
400 - 499	7	8.14	3.51
500 or more	6	6.98	5.29
Total	86	100.00	100.00

**Based on AHA 2003 statistics of 4,895 U.S. community hospitals.*

as Chief Financial Officer, Operations Manager, Team Leader, or Resource Manager.

The average (mean) for the number of beds in the facility was 209. The smallest hospital had 12 beds and the largest had 1460 beds. Table 2 shows the number of beds per facility as grouped according to the groupings used by the American Hospital Association (AHA). The average for the number of beds in the entire healthcare system was 546, with the smallest containing 20 beds and the largest containing 6000 beds.

The average number of hospitals in the healthcare system was 14 with a range from 1 to 172; 48% of the systems had only one hospital; 43% had 2 to 28 hospitals. The remaining 9% had more than 50 hospitals in their entire healthcare system.

Research Question #1

During the literature review and the interviews with healthcare and IT professionals, it was found that an EHR system could be purchased with some or all of the core functionalities depending on the funds available to purchase the software system. In an attempt to determine where hospitals were in regard to the use of EHR systems, the respondents were asked two questions. First, they were asked to mark the status of their facility in regard to the use of an EHR system from a list of options as shown in Table 3. The largest number of the respondents (37%) indicated they currently used some components in all of the eight core functionalities and 27% used only some of the eight core functionalities of an EHR system. Table 3 shows the number of responses and their corresponding percentages.

Second, they were asked to mark the core functionalities of the EHR system that their facility had or planned to have within the next five years (Research Question #1). Health Information and Data, Results Management, and Administrative Processes were the only core functionalities that were currently part of or interfaced with the EHR system in more than 50% of the respondents' facilities. The responses are shown in Table 4.

Research Question # 2

To answer the second research question, which was to determine if there was a relationship between the status of the EHR system and the size of the hospital as measured by the number of beds in the hospital, a one-way ANOVA was conducted. The overall F did not reveal any significant differences among the groups as seen in Table 5 (the groups are the levels of EHR status as listed in Table 3). In other words, there was no relationship between

Table 3. Status of facility in regard to use of EHR system

Status of Facility	Number	Percent
Currently using some components in all the core functionalities of an EHR system	33	37.08
Currently using some functionalities of an EHR system	24	26.97
Currently using some electronic records systems and plan to interface these into an EHR system within the next two years	9	10.11
Currently using some electronic records systems and plan to interface these into an EHR system sometime between 2 and 5 years from now	13	14.61
Not currently using any electronic records systems, but plan to use an EHR system sometime in the future	10	11.24
Total	89	100.01

Table 4. Status of the core functionality within facility

Core Functionality	Already a part of the EHR system or it is interfaced with the EHR system	Plan to interface within the next 5 years	Do not plan to interface or Not sure
Health Information and Data	64%	32%	4%
Results Management	56%	35%	9%
Order Entry/Management	46%	46%	7%
Decision Support	35%	39%	26%
Electronic Communication and Connectivity	48%	36%	16%
Patient Support	21%	36%	42%
Administrative Processes	57%	25%	17%
Reporting and Population Health Management	39%	27%	34%

the status of the EHR system and the size of the hospital. The significance of the results was assessed at the 0.05 alpha level.

General Benefits and Risks

The respondents were asked to evaluate the benefits, risk factors, and cost justification of the core functionalities for which they currently had interfaced or planned to interface into their EHR system within the next five years. They were to evaluate the core functionalities in regard to (1) the degree each one had benefits related to the delivery and quality of healthcare, (2) the degree each had risk factors in relation to cost, cultural change, security of information, dependency upon information, computer downtime, etc., and (3) the degree to whether or not each one was cost justifiable in regard to general terms such as whether the benefits in the long run outweighed the problems, risks, etc., and the anticipation that there would be some ROI in the future. The core functionality the respondents indicated as the most beneficial (one with the highest mean) was "health information and data," closely followed by "electronic communication and connectivity." The functionality with the greatest risk (highest mean for risk factors) was "electronic communication and connectivity," closely followed by "results management." The two functionalities that the respondents found to be the most cost justifiable were "health information and data" and "results management." The means for all three factors for each of the functionalities can be seen in Table 6.

Research Question #3

To answer the third research question, to determine if there was a relationship between perceived level

Table 5. Status of EHR system compared to size of the hospital

Status of EHR	Sum of Squares	df	Mean Square	F	p-value
Between Groups	364250.21	4	91062.553	2.011	.101
Within Groups	3622448.1	80	45280.601		
Total	3986698.3	84			

Table 6. Mean of benefits, risks, and costs associated with each of the core functionalities

Functionality	Benefits	Risk Factors	Cost Justification
Health Information and Data	8.83	6.71	7.84
Results Management	8.64	6.96	7.74
Order Entry/Management	8.49	6.77	7.59
Decision Support	7.71	5.95	6.45
Electronic Communication and Connectivity	8.69	7.03	7.21
Patient Support	7.71	6.67	6.83
Administrative Processes	8.25	6.59	7.46
Reporting and Population Health Management	7.58	6.23	6.83

of benefit and risk, a Pearson correlation was conducted. First, it was determined if an overall correlation existed between benefits and risks for each core functionality. Then the correlation was calculated again for each of the groups separately to test where the significance occurred and which group had a higher correlation between benefits and risks (those who had the functionality or with those who did not currently have it, but planned to within the next five years). Those who indicated they did not plan to have the core functionality or were not sure, were not included.

There was a significant positive correlation between benefits and risks for all eight core functionalities. The correlation was significant at the 0.01 alpha level. This positive correlation indicated that the respondents associated high benefits with high risks. For three of the eight core functionalities--Health Information and Data, Administrative Processes, and Reporting and Population Health Management--there was a significant positive correlation for both groups (those who already had it and those who planned to have it). For the other five functionalities, the significance existed only in the group that planned to have it. Therefore, for the group of hospitals who already had the core functionalities of an EHR system, the respondents did not seem to associate as high a risk with the benefits as those who were just in the planning stages.

In the area of Health Information and Data, the correlation was 0.544 between perceived benefits and risks. When looking at each group individually (those who had this functionality in their EHR system and those who planned to have it within the next five years), the correlation was twice as much for the group who planned to have this functionality (0.742) compared to those who already had it (0.361).

In the area of Results Management, there was again an overall high positive correlation between benefits and risks (0.578). However, this time when looking at the groups individually, a significant positive correlation (0.681) existed only in the group who planned to have this functionality (and not those who already had it). These results and those for the other core functionalities can be seen in Table 7.

DISCUSSION

The majority of the respondents (61%) indicated their job title was health information manager or director of health information. This is a much larger percent than the 11% of respondents to the 2005 Medical Records Institute's Survey of EHR trends and usage (which included physicians as well as those in other roles), but slightly less than

Table 7. Correlation between perceived benefit and risk for each functionality (overall and individual correlation for groups respectively)

Core Functionality	Overall Correlation for Both Groups	Calculated p value	Correlation for Group that Already Had Functionality	Calculated p value	Correlation for Group that Planned to Have Functionality	Calculated p value
Health Information and Data	.544*	.000	.361*	.011	.742*	.000
Results Management	.578*	.000	.247	.120	.681*	.000
Order Entry/ Management	.597*	.000	.134	.444	.738*	.000
Decision Support	.694*	.000	.205	.337	.816*	.000

**p = 0.01*

the 83% from the AHIMA study which indicated they were HIM professionals. The average (mean) for the number of beds in the facility's surveyed was 209; 35% of the hospitals had less than 100 beds. The most recent American Hospital Association statistics for bed size of hospitals in the U.S. was consulted to determine if the study sample provided a qualitative representation of U.S. hospitals. Thirty-five percent of the hospitals responding to the survey reported 1 to 99 beds while the 2003 AHA statistics reported approximately 47% hospitals in the category of less than 100 beds. Therefore, this study had responses from fewer small hospitals than there were in the actual population of hospitals. However, for all the other categories of hospitals by bed size, it was pretty comparable, varying only 2 to 5% within each bed size category (AHA, 2003). See comparisons in Table 2.

The largest number of the respondents (37%) indicated they currently used some components in all of the eight core functionalities and 27% used only some of the eight core functionalities of an EHR system. The study conducted by AHIMA, although worded slightly differently, found that 17% of organizations indicated they had extensively implemented EHR systems and 26% indicated partially implemented (Zender, 2005). These two studies had a slightly different focus and way of analyzing the status of the EHR system. The AHIMA statement asked respondents to describe their organization's progress toward implementation of an EHR, and this study sought to discover the status of their facility in regard to the use of the EHR system by looking at how many of the core functionalities were used or interfaced into the EHR system.

The overall F in this study did not reveal any significant differences among the status of the facilities' use of an EHR system in relation to the size of hospital. However, other research indicated that some small hospitals and small physician offices were lagging behind in the use of EHR systems creating a digital divide (Goldschmidt, 2005). In order for EHR systems to be seamlessly used and offer the intended benefits, they must become more affordable and see some return on investment (ROI).

Health Information and Data, Results Management (lab test results, radiology procedures, and other results reporting), and Administrative Processes were the only core functionalities that were currently part of or interfaced with the EHR system in more than 50% of the respondents' facilities. This seems to correspond fairly closely to the MRI Survey which found that specific applications or functions used by at least a majority of respondents were in the Administrative and Financial Application; the Data Capture, Review, and Update Capabilities; and E-mail categories. Laboratory results, which fell under the category of Data Capture, Review, and Update Capabilities, of the MRI survey were used by over 50% of respondents.

There was a significant positive correlation between perceived level of benefits and risks for all core eight functionalities. For the majority of the core functionalities, the positive associations were stronger for those in the group that planned to have it (than the group that already had it). Since all the overall correlations between risk and benefits were positive, we can conclude that the respondents associated high benefits with high risks. For the group of hospitals who already had the core functionalities of an EHR system, the respondents did not seem to associate as high a risk with the benefits as those who were just in the planning stages. This may imply that once the functionality is implemented the perceived level of risk decreases.

LIMITATIONS

The study may have some limitations. First, the low response rate may make it difficult to generalize the findings to the total population. Second, although the study identified that a correlation existed between the risks and benefits for each of the core functionalities among the groups, it did not identify any specific risks or benefits for each of the functionalities.

CONCLUSION AND FUTURE WORK

Each of the eight core functionalities can be adopted by hospitals individually or as an entire EHR system. This study identified the majority of the core functionalities used in the hospitals, as well as the correlation between the benefits and risks associated with these core functionalities. Other hospitals that are in the planning and information gathering stages can use this information to prioritize the core functionalities that they plan to adopt.

Based on the findings of this study, it is suggested that some of the high risks associated with EHR systems may be misconceptions by professionals in the field who have not yet adopted an EHR system. The benefits have been stated over and over again. However, little research has been done on the risks associated in using these systems. Future work in the area of EHRs should identify risks associated with the use of each of the core functionalities of an EHR system and ways to avoid these risks or come to the realization that they may not be as problematic as once thought.

This study identified a perceived level of cost associated with the benefits and risks in adopting each of the core functionalities. Since ROI is a barrier to adoption of EHR systems, future study of cost-benefit factors related to each of the core functionalities is recommended. An implication of this would be that hospitals and physicians will gain a better understanding of the cost factors related to each of the functionalities and be able to prioritize and procure the functionalities of an EHR system as needed.

APPENDIX A.

1. **Health Information and Data:** A defined dataset that includes medical and nursing diagnoses, a medication list, allergies, demographics, clinical narratives, and laboratory test results for access by care providers when needed.

2. **Results Management:** A feature to manage the lab test results, radiology procedures results, do results reporting, results notification, and multimedia support—images, waveforms, pictures, sounds.

3. **Order Entry/Management:** Computerized provider order entry (CPOE) for such areas as electronic prescribing, laboratory, microbiology, pathology, XR, ancillary, nursing, supplies, consults. Even with little or no decision support, they can still improve workflow processes by eliminating lost orders and ambiguities caused by illegible handwriting, generating related orders automatically.

4. **Decision Support:** A computerized decision support system, which enhances clinical performance by providing drug alerts, other rule-based alerts, reminders, clinical guidelines, and pathways. It also helps in improving drug dosing, and drug selection. It can be used for chronic disease management, clinician work lists, diagnostic decision support, and automated real-time surveillance.

5. **Electronic Communication and Connectivity:** Electronic communication can be between provider-provider, patient-provider, trading partners such as pharmacies, insurers, laboratory, radiology, and among team members for coordination. Electronic connectivity includes integrated medical record within facility, within different facilities of the same healthcare system, and among different healthcare systems.

6. **Patient Support:** Patient support includes patient education, family and informal caregiver education, data entered by patient, family, and/or information caregiver such as home monitoring

7. **Administrative Processes:** Administrative processes include electronic scheduling systems for hospital admissions, inpatient and outpatient procedures, and identifying eligible or potential eligible patients for clinical trials.

8. **Reporting and Population Health Management:** This feature would report patient safety and quality data, public health data, and disease registries. It makes the reporting process less labor-intensive and time-consuming (Institute of Medicine, 2003).

Chapter 4.3
Virtual Reality Simulation in Human Applied Kinetics and Ergo Physiology

Bill Ag. Drougas
ATEI Education Institute of Epirus, Greece

ABSTRACT

Virtual reality is today an excellent tool for a full simulated experience in a modern environment where any researcher or any individual scientist may work with vital experimental environments or use parameters that sometimes does not really exist. It is already a vital step for the future of science and for the modern experiment. Ergo physiology today has many applications for research. We can find new unknown parameters for the human body searching biokinetics and ergo physiology, and it is time to use modern technologies and applications. The vital issues discussed in this chapter may offer many applications for human kinetics and movement and may also discuss biokinetics research using the physical laws and parameters in various biokinetics and physiology fields.

INTRODUCTION

Virtual reality is today an important part of modern scientific methodology and research, using modern high-speed computers of lately designed technologies for research and simulation in various scientific fields such as ergo physiology and biokinetics. This is a new field in contemporary science, methodology, and experimentation, and we can recognize that during the past years, it has continued with great success. An important field using this new way of research is the simulation of human movement in ergo physiology and applied biokinetics science. Virtual reality is very useful for researchers in these fields because they can have simulations of the physical human body at any time they want for study or experimentation.

BACKGROUND

One of the first authors who wrote about virtual reality was Howard Rheingold (1991), who wrote about data visualization and 3-D CAD (computer-aided design) in which someone may use his or her hands and fingers. Many applications can be found from the middle war period by the U.S. Air Force to create flying simulations.

Myron Krueger, during the '60s, worked on the affiliation of human and computer with special research in computer-controlled responsive environments, which were named by him artificial reality (Krueger, 1993). He also designed the video place, a system that contains a projection screen and a video camera that is controlled by a computer. By this method, human movements in each activity are transferred to computer graphics in software (Boudouridis, 1994).

So, there can be a connection between human and technical things in space with computer graphics. This was one of the first methodologies in human-kinetics research and applications.

Tom Furness was another scientist who designed the Super Cockpit for the U.S. Air Force after many years of research. In a small place, a human could use computers and a HMD (head-mounted display) to understand vital secrets of the flight without any danger (Furness, 1991).

But the man who is the father of the terms virtual reality and reality engine is Jaron Lanier, an informatics scientist who, with another young man named Tom Zimmerman, established the Visual Programming Language Research Inc in 1980 (Boudouridis, 1994). This company was the first to make important tools for virtual reality programs and applications, such as data gloves and HMDs.

ISSUES

In the beginning, many other scientists worked with computer data for virtual reality applications in various fields with very big success.

Today, there are many different fields and applications of virtual reality technology. Table 1 summarizes some of the virtual reality applications similar to those of ergo physiology.

Especially in the fields of ergo physiology and biokinetics, virtual reality is used in many applications. Some of the characteristics of human movement, the human body, and parameters such as space, geometry, color, and sound may help virtual reality programs become more effective in various methodologies of research and virtual applications.

The importance of this is to find a methodology for using virtual reality and a way to recognize the results, such as some of the official physiology results that can give to researchers many new discoveries in existing science and theory, or future science research in finding new signals from the human body during simulations.

Today we have all the modern technology to make better simulations for the human body and to see new fields that had not previously existed. This is, of course, the future of research.

For example, it is not possible for anyone to fly at high speeds without any danger so that scientists can see the behavior of the human body or parameters such as blood pressure, the behavior of the heart, muscle energy, signals or other problems in the eyes, and so forth. But with virtual reality simulations, we can today register

Table 1. Summary of the virtual reality applications similar to those in ergo physiology fields

- Time
- Sound frequency
- Color frequency
- Wave length
- Velocity
- Pressure
- Area
- Energy
- Power

many of these parameters and standards, see how they change after the experimentation, and see it is used in our theories.

The very best aspect of this method is that we can stop the experiment when we must or when we want to begin the experiment again from the last step, or, if we want, we can design another model with new parameters. So, we can always put something new into our experimentation and theory, and this is important because every person is different from every other. By this methodology, we can register statistical effects or make a very good mathematical analysis of the problem to continue with advanced research and measurements or to make other project experiments.

So many past methodologies or past technologies will be changed after these experiments. Ergo physiology and applied human kinetics today use many important laws of physics, physiology, mathematics, statistics, and, of course, medical data, and it is important to continue to grow using new technologies like virtual reality. Table 2 summarizes some of the parameters that are important in virtual reality simulation for the human body and movement.

In some experiments, all of the parameters in Table 2 can be used, and in some others, only a few of them can be used. However, the parameters in the simulations are very near to those of physics, and the philosophy is about the same in similar experiments.

Table 3 summarizes some of the fields in which virtual reality can help to recognize and study the physical parameters of Table 2.

In every subject of the study of human abilities, there are various techniques and methodologies. However, the philosophies of all methodologies are about the same and have similar directions.

So it is important to understand that with virtual reality simulations in ergo physiology, we may simulate human models in an environment that does not really exist physically. In this way we can find new and unknown parameters of the basics of human biokinetics and ergo physiology. In the same way, a researcher can establish new models of experiments and fields for research using many parameters of the modern population and all the modern kinetic problems that appear in people. Researchers can include these problems in the data of the simulation and study the methodology or the effects within the simulation. For example, the influence of a brain problem on human kinetics ability can be registered from various kinetics parameters and/or kinetics behavior and movement in various daily skills. Many years before, this was not so clear, and many of these problems seemed like they didn't exist. In simulations, we have two bodies: the virtual and the real.

It is important to understand that two human bodies in the same experiment are the same but

Table 3. Summary of the fields of the physical parameters in virtual reality

- Kinetics conception
- Space-creation parameters
- Relative-movement creation
- Color-conception studies
- Sound-conception studies
- Kinetics-parameters registration
- Study of velocity
- Study of frequency
- Study of space parameters
- Study and registration of time

also different.

We have two human bodies during the experiment that we can use, or many more if it is possible with the program. Virtual reality biokinetics research programs must have both human bodies: the real and the virtual one. The parameters and simulations must be very close between these two categories. These two bodies are different persons, but closely exhibit the same movements. It is very important to recognize the abilities of the bodies. The information about kinetics behavior or any other information from any data structure that defines the behaviors of the movement and kinetic parameters of one virtual human can be passed directly to all the other virtual humans if there is more than one human in the program of the experiment. In this way, we can have parameters and measurements from various kinetic models at the same time and study many different behaviors. This is the philosophy of a multiple experiment.

Two or more students or researchers can work with two or more models at the same time and give different conclusions and different theories. Virtual humans are real models that can be used many times for the same work and for the same or a different research. This is very good for the physiology studies and medicine experiments for human biokinetics and behavior, and, of course, for education programs for researchers or students at the graduate or postgraduate levels.

Table 4 summarizes some of the simulated and virtual applications to human abilities.

Many of the methodologies that exist today began first in front of a computer screen and, with the help of modern programs of simulation in physiology, biology, and mathematics, they continue to establish some of the new theories.

Today, electronic methods give us the opportunity to continue our research in a safer work environment; in the past, various experimental problems in the physical environment were impossible to avoid. Virtual reality and its development are currently underway in a number of organizations such as NASA, IBM, Boeing, and so forth, and also in many official research programs of famous university laboratories and technological educational institutes. In many of these institutes, there exist many new international programs of human study and ergo physiology research.

Table 4. Summary of some of the simulated and virtual applications

- Simulation of ergonomic environments
- Simulation-based training
- Rehabilitation and modern orthopedics
- Virtual patients and human organs for surgery
- Psychotherapy and applied physiology
- Sports simulations
- Physiological behavior with various phobias
- Biomechanical walking
- Virtual training for balance

CONCLUSION

Virtual reality is today an excellent tool for a fully simulated experience in a modern environment where the researcher or simple scientist may work with vital experimental environments or use any parameter that sometimes does not really exist. This is important for people who are researching the abilities of the human body. The vital issues discussed in this article may offer many applications for human kinetics and movement, and biokinetics research using physical laws and parameters. In the same philosophy, any researcher may propose or design new models for informatics scientists. Ergo physiology today has many applications for research, and the modern computer systems for simulations and virtual reality give us many applications and the opportunity to work in easier experimental environments to make and design experiments using real and unreal parameters without any danger for us or any other human. This is already a step toward the future of science and the experiments.

KEY TERMS

Biokinetics: A scientific division of ergo physiology for the research and recognition of physical laws, standards, and existing parameters of human movement and kinetics, or the changes from any external or internal effect that can change any physiological movement. The creation of a physical model helps researchers to understand the problems of movement and kinetics and their relation with various pathological problems.

Ergo Physiology: A division of physiology that searches physiological and physical parameters, constants, and standards for the creation of energy, power, balance, velocity, and other physical changes in the human body. This division includes a vital search for the physical and physiological laws related to various kinetics problems for humans.

Kinetics Behavior: A number of characteristics of human movement including the physical behavior of the human body in movement and kinetics. These characteristics draw a behavior model for the physical body and offer the opportunity to researchers in the area of physiology and biokinetics to search the behavior of humans and to create scientific programs for rehabilitation.

Physical Biokinetics Parameters: A number of different parameters, laws, and measurements that are recognized from a physical model from physiology and human movement. We can use this model in various applications recognizing human behavior and movement.

Rehabilitation: A scientific methodology using physical methods, especially applied movements, kinetics, and modern psychology applications, to change the human body and mind behavior, helping people to recreate their energy levels and their physical ability, or to use the near environment in the best way to live with their problems for a better life.

Simulation: A number of presentations of different parameters for things, models, or environments designed from physical standards and laws. In this virtual presentation, one can use his or her experience to have an interactive participation and use this virtual environment for personal training, education, rehabilitation, and so forth.

Virtual Human: A virtual human body in a 3-D immersive, interactive simulation, created by computer software, for the parallel presentation of reality in the virtual using any influence from the real environment.

Virtual Reality: An immersive, interactive simulation for real and unreal environments. We can also use this term for simple interactive models that cannot offer to a user any immersive presentation in a virtual environment. Virtual reality is the most useful tool in medicine today, with many applications in various fields, especially in rehabilitation, education, and so forth.

Visualization: A medicine application using a 3-D human body model that has been made from a number of different 3-D scans from a medical computed tomography.

Université de la Méditerranée, France

ABSTRACT

Teleradiology, sending of x-rays, is the most common application of telemedicine in use today. Mobile telemedicine is the latest area of research where the patient can be monitored remotely by a doctor. In this paper, we propose a teleradiology system whereby the communication is established via cellular networks and cell phones. Since the data is sent over a wireless channel, it is more prone to data loss due to the mobile environment. To prevent data from getting lost due to noise in the wireless channel, an error-coding scheme is applied. Turbo code is a powerful error coding technique employed nowadays in communication systems. In this paper we apply turbo codes to an x-ray image and an ECG image and simulate the transmission system by adding Gaussian noise to the image. The performance of Turbo codes, in terms of bit error rate is better than other error coding schemes even in the region where the signal strength is very low. The Quality of the image is retained in the receiving end by proper design of the error-coding scheme. An analysis has been done on various parameters considered in the design of turbo codes. The images obtained

after decoding are found to be suitable for recognition and diagnosis by the doctors in their mobile phones. This novel technology will enhance the health care in rural area where the opinion of a specialized doctor is not available.

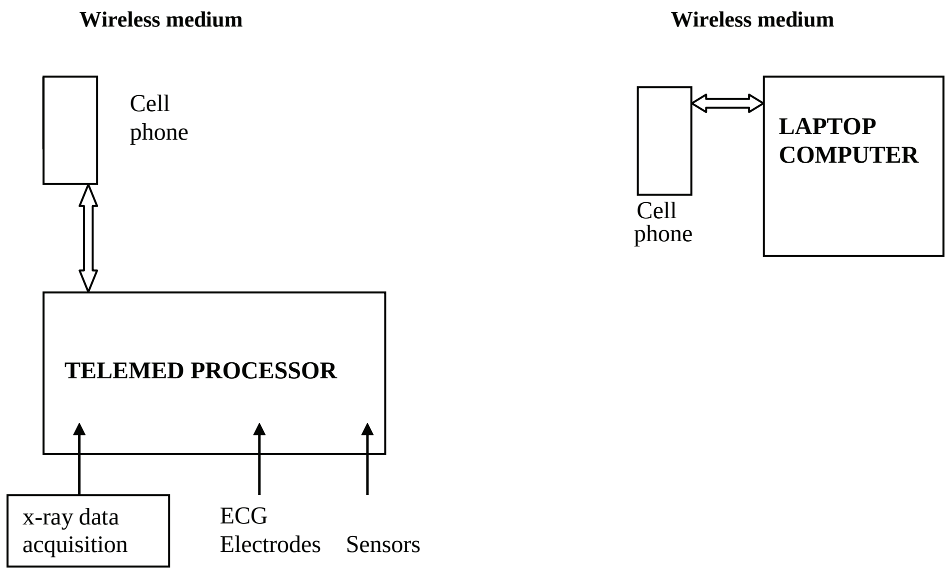
INTRODUCTION

Mobile telemedicine is a new research area that takes advantage of the cellular technology to provide highly flexible medical services that are not possible with standard telephony. Conventional telemedicine systems using public switched telephone network (PSTN) land lines are already available to enable a doctor to monitor a patient remotely for home care or emergency applications as mentioned by the authors Rezazadeh and Evans (1990), Patel and Babbs (1992), Clarke, Fragos, Jones, and Lioupis (2001), Coyle, Brown and Boydell (1995). Systems using satellite communications are dealt by the authors Pierucci and Del Re (2000); Murakami, Shimizu, & Yamamoto (1994). Teleradiology is the term used when any digital image is moved outside the local environment. Teleradiology involves the transmission of digitized radiological signals to a remote site for medical diagnosis. The transmission site is a hospital. The remote site is the location of the specialized doctor. Since the doctor may not be available at all times in a hospital, it becomes difficult to attend to trauma patients. With teleradiology, the territory of a doctor is expanded by being able to receive the images over his cellular phone. The doctor will make an initial diagnosis and communicate to the hospital. For further diagnosis, the doctor will attend to the patient at his own convenience. The global system for mobile communications (GSM) has been applied along with signal processing for transmission of ECG signals by Woodward, Istepanian, and Richards (2001). In GSM, the error-coding scheme used is Convolutional coding. The limited bandwidth of GSM (9.6kbps) restricts potential mobile telemedical services. Turbo coding is the error-coding scheme used nowadays in wireless transmission since it almost reaches Shannon limit. In this article, the images are coded using Turbo encoder and decoded using the Turbo decoder. The noise signal is simulated and added to the image after encoding the data. While decoding, the algorithm efficiently removes the noise and the image quality is analysed. These images will be made available in the cellular phones. The doctor can diagnose based on that image or can download the image into a computer to do a detailed analysis. The QoS (Quality of Service) parameters of Turbo coding are modified to make the transmission of images more efficient with better quality. The paper is organized as follows. In section 1, the existing Teleradiology system is discussed and the proposed system is explained with a diagram. The second section explains the operation of the Error coding scheme .The optimal design of the QoS parameters used in Turbo coding for this application is discussed in detail in the third section. The fourth section gives the simulation results. Conclusion and future work is given in the fifth section.

TELERADIOLOGY SYSTEM

Teleradiology system is a system used for sending raw data from a complete patient study to a remote location for a radiologist to make a final decision. A teleradiology system consists of an image acquisition system, an image server to compress, and a telecommunication network to transmit the images. The network could be a Local Area Network (LAN) or a broadband internet connection. LAN cannot be applied for far distances. Broadband internet connections are not easily accessible in all areas. In this paper, we propose a system by means of which the images could be sent over the easily available cellular network, which is very economical. The system consists of two segments, one for sending, and

Figure 1. Teleradiology system



the other for receiving. The functional block diagram is shown in Figure 1. The function of the processor is to store, compress, frame, and multiplex the data. The input signals are analog data from electrocardiogram (ECG) acquired from conventional chest electrodes, x-ray data from x-ray data acquisition systems, or digital data from other types of physiological sensors. The processor is a computer that can have any amount of memory. Since the signals are from many channels, multiplexing is done to send the desired signal based on a priority scheme in a particular time instant. Since the data size is large, it is necessary to compress the data before transmission. To have a secure transmission, encryption algorithms are applied. The processed signals are then fed to a mobile telephone via a standard infrared (IrDA) port or a bluetooth enabled device. Signals from the telephone are transmitted at the standard Universal Mobile Telecommunications system (UMTS) rate to the base station. The rate of transmission supported by UMTS is 384 kbps and it is targeted at reaching 2 Mbps. The signals would be received by another mobile cellular phone carried by a medical specialist equipped with a laptop computer, without being at a hospital. The receiving segment demodulates the data and then decodes the data to get back the original data that was transmitted. There are lot of systems to view picture efficiently. Some researchers have begun to develop PDA (Personal Digital Assistant) applications that drive larger picture archiving and communication system (PACS) displays or act as digital image capture stations. Laptop-based systems have been used by Reponen, Illkko and Jyrkinen (1998), but are not as portable as a PDA-based system and have much longer start-up times. Laptops and touch-screen input–based Tablet PCs (personal computers) are also limited by their relatively short battery life, whereas PDAs can function for days between charges. If image quality were sufficient, a handheld teleradiology system would be very useful for practicing radiologists, especially for those who provide emergency and other time-critical services.

The communication between the two segments is via the wireless media. Since the data is more prone to error, it is necessary to implement a suitable error correction scheme to reduce the noise in transmission. In this paper an error correction scheme has been applied to a chest x-ray and ECG data. The simulation model is shown in Figure 2. The input image gets corrupted when transmitted. Hence, the data is encoded by means of Turbo coder. The noise signal is simulated for any Signal to noise ratio level (SNR) and is added to the encoded signal. The decoder algorithm is applied to get back the original image without much loss in the information.

Having the ability to view radiologic images any time, any place, whether in a hospital or off-site could reduce time to diagnosis and increase the efficiency of the daily workflow, possibly reducing costs and improving patient care.

ERROR-CODING SCHEME

Telemedicine takes advantage of telecommunications to offer medical care at any time and at any place. The 2G mobile technology, GSM (global system for mobile communications), has been used by Woodward, Istepanian, and Richards (2001), Kyriacou, Pavlopoulos, Koutsouris, Andreou, Pattichis, and Schizas, (Oct.2001), and Elena, Quero, Tarrida, and Franquelo (2002), which has enabled remote diagnosis in mobile environments and to areas, which cannot be reached by fixed networks. GSM is used to carry circuit switched data at a maximum bit rate of 9.6 kbps. For multimedia applications where images have to be transmitted, GSM cannot be applied due to low bit rate. Universal Mobile Telecommunications system (UMTS) overcomes these limitations as it can support up to 2 Mbps with different quality of service (QoS). A complete performance analysis of transmission of medical data over UMTS channel has been done by Jose, Hernandez, Maria, Lafuente,Valdovinos, and Fernandez (2005). In this paper, we adopt the UMTS standards and make the error-coding scheme adapt to the desired QoS. Turbo codes emerged in 1993 and been implemented by Berrou, Glavieux and Thitimajshima (1993), Berrou, and Glavieux (1996), Benedetto and Montorsi (1996a), Branka and Jinhong (2000) and have since become a popular error-coding scheme in the area of wireless transmission. The important characteristics of turbo codes are the small BER achieved even at low

Figure 2. Simulation model

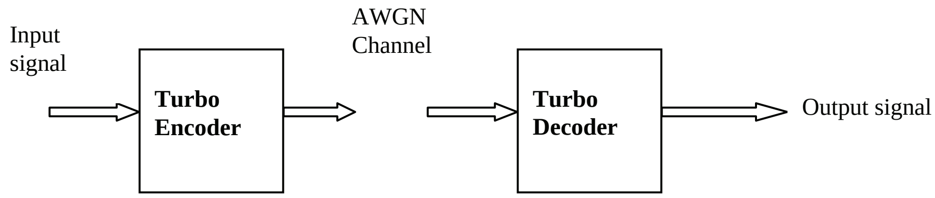


Figure 3. Structure of turbo encoder

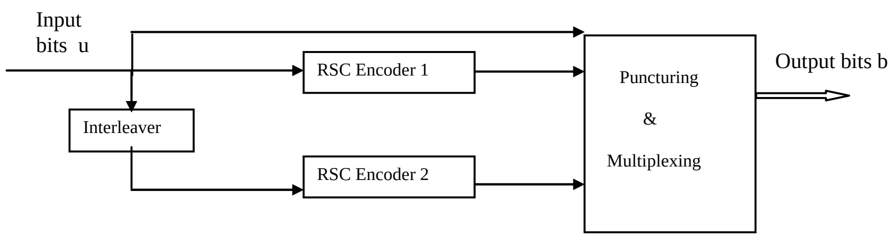

Signal to noise ratio (SNR) and the flattening of the error rate curve (i.e., the error floor at moderate and high values of SNR). The performance of turbo codes is due to the randomness created by the interleaver and the iterative decoding. Turbo codes consist of two binary recursive systematic convolutional (RSC) encoders with small constraint lengths usually set between 3 and 5 which are concatenated in a parallel fashion by using a Turbo code interleaver and a puncturing and multiplexing device as shown in Figure 3. The basic role of an interleaver is to construct a long block code from small memory convolutional codes, as long codes can approach the Shannon capacity limit. There are two main algorithms to decode the data. One of the algorithms is called Soft Output Viterbi Algorithm (SOVA) and the other one is Maximum A Posteriori Algorithm (MAP) implemented by Benedetto, Divsalar, Montorsi, and Pollara (1996b).

OPTIMAL CHOICE OF PARAMETERS

In mobile telemedicine, the transmission is more prone to error due to the high speeds of the mobile doctor. Users moving at high speeds have worse channel conditions and thus require higher signal to noise ratios for the same QoS constraints. Turbo codes, the latest error-coding scheme is adaptable to the needs of different QoS. The different parameters of turbo codes are designed to achieve the required QoS.

Choice of Constituent Code in Encoder

The code design criteria depends on the region of SNR's where the code is used. A turbo code performing well in the region of high SNR's may not perform well in the region of low SNR's, or vice versa. Hence, the design of constituent codes is made, based on the range of SNR's where the code is used. One of the parameter involved in the encoder design is the effective free distance defined as:

$$d_{free,eff} = 2 + 2z_{\min} \quad (1)$$

where $z_{\min}$ is the lowest weight of the parity check sequence in error paths of RSC component encoders generated by an information sequence with weight 2. The binary rate r=1/2 RSC code is shown in Figure 4. The generator matrix of this coder is represented by:

$$G(D) = \left[1 \frac{g_2(D)}{g_1(D)} \right] \quad (2)$$

where $g_1(D)$ and $g_2(D)$ are the feedback and feedforward polynomial. The design criteria for constructing good turbo codes is to maximize the effective free distance which has been done by Benedetto and Montorsi (1996b). Based on this design objective, turbo encoder has been designed by choosing a primitive feedback polynomial to be used in the RSC component encoder. Based on the design, the generator matrix is [111,101] where g_1(D) is 111 and g_2(D) is 101. The input is d_k and the outputs are u_k and v_k which is the parity bit. The states of the encoder are represented by a_k, a_{k-1}, and a_{k-2}. Since the encoder is a recursive systematic coder, ak is recursively calculated as:

$$a_k = d_k + \sum_{i=1}^{K-1} g_{1i} a_{k-i} \quad (3)$$

The output pair of this RSC code is v_k, d_k where v_k is given by:

$$v_k = \sum_{i=0}^{K-1} g_{2i} a_{k-i} \quad (4)$$

The interleaver length and the memory of component codes have to be trade off according to the system requirements. In fact, increasing the

Figure 4. Structure of RSC encoder

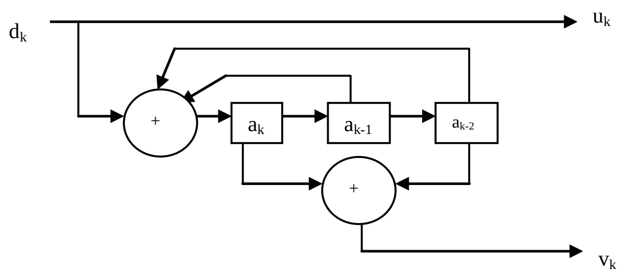

Figure 5. Performance analysis for different types of interleavers

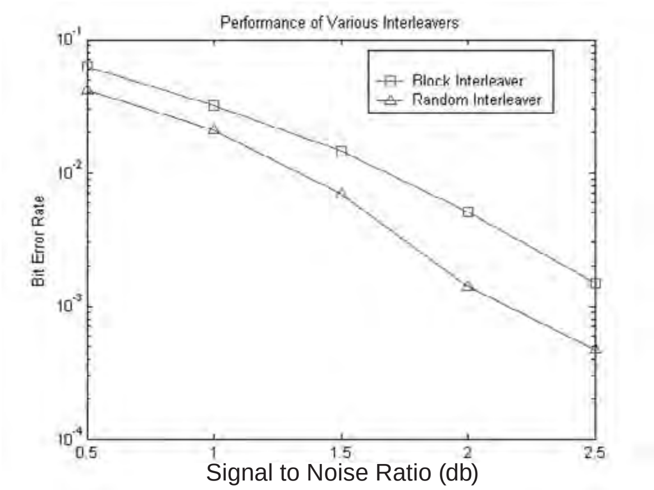

interleaver size increases the decoding delay at almost no expense in complexity, whereas increasing the memory increases the complexity with only slightly increasing the decoding delay. Hence, the memory size chosen for the encoder is 2.

Choice of Interleaver

The proper design of interleaver plays a major role in the performance of turbo codes. The design criterion at high SNR or low BER is to maximize the code effective free distance. At low SNRs or high BER, the performance of the code is determined by its distance spectrum. At low SNRs the interleaver size is the only important factor as it can increase the interleaver gain and enhance the code performance. At high SNRs both the structure and size play an important role in maximizing the code effective free distance, thus enhancing the performance of the turbo code. Random and block interleavers are the most commonly used interleavers. Block interleaver formats the input sequence in a matrix of m rows and n columns, such that $N=m\times n$. The input sequence is written into the matrix row-wise and read out column-wise. In the random interleaver a block of N input bits is read into the interleaver and read out randomly. Based on simulations shown in Figure 5, random interleaver is found to be the best as the error rate is less compared to the block interleaver.

At low SNR's, the turbo code performance is dominated by the interleaver size. Turbo codes have been shown to exhibit remarkable performance when the frame size is large. The size of the interleaver is same as the size of frame. However, the latency in a turbo-coded system is directly proportional to the frame size. Thus, there is a direct tradeoff between latency and bit error rate (BER) based on the choice of interleaver size. Thus, the frame size has to be chosen based on the required QoS.

Latency is given by:

$$t_d = \frac{K_f}{R_b} N_i \qquad (5)$$

where R_b is the bit rate, K_f is the frame size and N_i is the number of decoding stages. From the formula we are able to conclude that latency is directly proportional to the frame size. Larger the frame size, larger is the latency or the delay. For applications where delay is a major constraint, the frame size should be reduced to get less delay or fast transmission.

The bit rate considered is 384 kbps. The number of decoding stages is 5. We are able to see that for larger frame size of 1000 bits, the latency is 13ms and for smaller frame size of 500 bits, the latency is 6.5ms. But on the performance analysis given in Figure 6, we are able to see that the error rate curve is very high for smaller size frame. To achieve the desired bit error rate of 10^{-3}, there is a gain in .3db for a frame size of 1000 compared to the frame size of 500. Hence we optimally choose 1000 as the frame size or the interleaver size.

Design of Decoder

There are two main algorithms used in the decoding of turbo codes. One is the MAP algorithm and the other is SOVA. Both the algorithms can be used as an iterative algorithm. SOVA is less complex compared to MAP but the performance of MAP is better compared to SOVA in terms of the bit error rate. In SOVA, a branch metric is assigned to each state transition for every state and for each decoding cycle. The path with the best path metric is selected. The path metrics are accumulated for the different time instants. Based on the history of the best path, the values of the data are taken from a memory available in the decoder.

In the MAP decoder, for each transmitted symbol, an estimate is made on the received bit by means of a posteriori probability on the basis of the received sequence r. The decoder computes a log-likelihood ratio given by

$$\Lambda\left(c_t\right) = \log \frac{P_r\left\{c_t = 1 \middle| r\right\}}{P_r\left\{c_t = 0 \middle| r\right\}} \qquad (6)$$

for $1 \le t \le n$ where n is the received sequence length and compares this value to a zero threshold to determine the hard estimate The estimate of c_t is taken as 0 if the log-likelihood ratio is lesser than 0, otherwise c_t is taken as 1.

Based on the performance analysis of both the decoders, MAP algorithm proves to be better as shown in Figure 7. In this article, iterative MAP algorithm is applied as performance is better when the number of iterations are increased. The iterative MAP decoder is shown in Figure 8. It consists of two component decoders serially concatenated via an interleaver. The first MAP decoder takes as input the received information sequence r_0 and the received parity sequence generated by the first encoder r_1. The decoder then produces a soft output, which is interleaved and used to produce an improved estimate of the a priori probabilities of the information sequence for the second decoder. The other two inputs to the second MAP decoder are the interleaved received information sequence r_3 and the received parity sequence produced by the second encoder r_2. The second MAP decoder also produces a soft output, which is used to improve the estimate of the apriori probabilities for the information sequence at the input of the first MAP decoder. The feedback loop is a distinguishing feature of this decoder. After certain number of iterations, the soft outputs of both MAP decoders stop to produce further performance improvements. Then the last stage of decoding makes a hard decision after deinterleaving.

The number of iterations lead to more latency but increased performance.

SIMULATION

The images are divided into frames and are sent to the encoder. The coded sequence is the information and the parity sequences. This coded data is added with Gaussian noise. Adding noise involves generating Gaussian random numbers, scaling the numbers according to the desired energy per symbol to noise density ratio E_s/N_0, and adding the scaled Gaussian random numbers to the coded sequence. The energy per symbol is given by

$$E_s/N_0 = E_b/N_0 + 10\log_{10}(k) \qquad (7)$$

where k is the code rate and E_b/N_0 is the signal to noise ratio in db. The variance of the noise which is added is given by σ^2 which is equivalent to $N_0/2$ and

$$\sigma = \sqrt{\frac{1}{2(E_s/N_0)}} \qquad (8)$$

Gaussian random numbers of the above variance which relates the SNR is generated and added to the coded sequence. The data, which reaches the decoder is the corrupted data (i.e., the coded sequence added with the Gaussian variable). The aim of the decoder is to get back the original information. But practically, it is not possible to achieve transmission without any loss. The MAP decoder is run for five iterations inspite of the extra latency since the image quality is better after five iterations.

The following parameters have been chosen based on the analysis done:

Figure 6. Performance analysis for different frame sizes

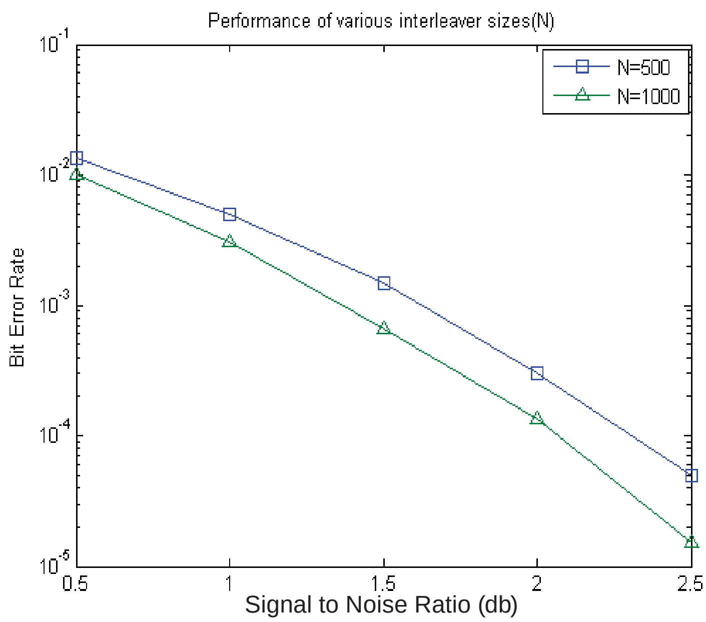

Figure 7. Performance analysis of Turbo codes with different types of decoders

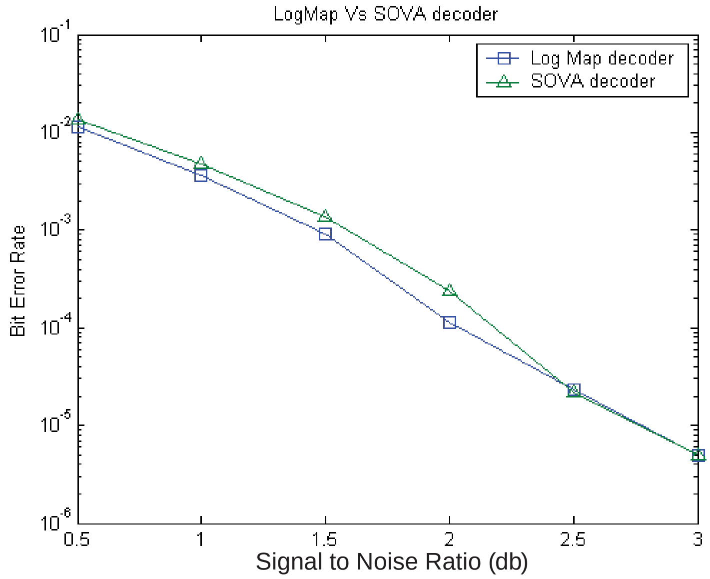

- Frame size: 1000 bits.
- Interleaver choice: Random interleaver.
- Generator Polynomial: g_1= 111 and g_2=101.
- Decoding algorithm: MAP algorithm.
- Noise level added: 1.0db AWGN noise.

A chest x-ray image and an ECG has been simulated for 1.0db noise level. The images after decoding are shown in Figure 9 and Figure 10. The error metrics used to analyse the quality of image is the Peak Signal to Noise Ratio (PSNR) and Mean Squared Error (MSE). The MSE is the cumulative squared error between the reconstructed and the original image, whereas PSNR is a measure of the peak error. The mathematical formulae are:

$$MSE = \frac{1}{N}\sum_{i=1}^{N}\left[\text{Image}_{original}(i) - \text{Image}_{reconstructed}(i)\right]^2 \quad (9)$$

where N is the total number of pixels in the original image.

$$PSNR = 20\log_{10}\left[\frac{255}{\sqrt{MSE}}\right] \quad (10)$$

A lower value for MSE means less error. A higher value of PSNR is desirable because it means that the ratio of Signal to Noise is higher. Here the signal is the original image. The PSNR values are shown in Figure 11 and Figure 12. The decoding algorithm is run for five iterations. In each iteration, the PSNR value increases. For images with noise, a PSNR value of 30 is acceptable. For ECG, the PSNR is higher than 30 and for chest x-ray, it will approach 30 with another iteration. The images are sent to a bluetooth enabled cellular phone to visualize the image quality. The photographs of the images are shown Figure 13 and Figure 14.

CONCLUSION AND FUTURE WORK

Teleradiology is an upcoming technology in the field of telemedicine. Most of teleradiology is done using dedicated links, which is costly. Cellular networks are the cheapest and easily available wireless networks. It has also reached all parts of the world. The UMTS networks offer high rate of transmission and hence this scheme is reliable and cheaper. The image quality is an important factor in wireless links. In this paper, we have implemented an error coding technique with optimal parameters to offer the necessary Quality of Service. Future work can be to incorporate streaming technology for EEG and transmit EEG signals.

The complete teleradiology system can be implemented in real time and the performance analysis can be done. Incorporation of compression algorithms and encryption techniques for secure transmission could be another interesting area of future work

Chapter 4.5
Methods and Applications for Segmenting 3D Medical Image Data

Hong Shen
Siemens Corporate Research, USA

ABSTRACT

In this chapter, we will give an intuitive introduction to the general problem of 3D medical image segmentation. We will give an overview of the popular and relevant methods that may be applicable, with a discussion about their advantages and limits. Specifically, we will discuss the issue of incorporating prior knowledge into the segmentation of anatomic structures and describe in detail the concept and issues of knowledge-based segmentation. Typical sample applications will accompany the discussions throughout this chapter. We hope this will help an application developer to improve insights in the understanding and application of various computer vision approaches to solve real-world problems of medical image segmentation.

INTRODUCTION

The advances in medical imaging equipment have brought efficiency and high capability to the screening, diagnosis and surgery of various diseases. The 3D imaging modalities, such as multi-slice computer tomography (CT), magnetic resonance imaging (MRI) and ultrasound scanners, produce large amounts of digital data that are difficult and tedious to interpret merely by physicians. Computer aided diagnosis (CAD) systems will therefore play a critical role, especially in the visualization, segmentation, detection, registration and reporting of medical pathologies. Among these functions, the segmentation of objects, mainly anatomies and pathologies from large 3D volume data, is more fundamental, since the results often become the basis of all other quantitative analysis tasks.

The segmentation of medical data poses a challenging problem. One difficulty lies in the large volume of the data involved and the on-time requirement of medical applications. The time constraints vary among applications, ranging from several tens of milliseconds for online surgical monitoring, to seconds for interactive volumetric measures, to minutes or hours for off-line processing on a PACS server. Depending on the application, this puts a limit on the types of methods that may be used. Another major hurdle is the high variation of image properties in the data, making it hard to construct a general model. The variations come from several aspects. First, the complexity of various anatomies maps to the large variation of their images in the medical data. Second, the age, gender, pose and other conditions of the patient lead to high inter-patient variability. Last, but not the least, are the almost infinite variations in an anatomy due to pathology or in the pathological structures. On the other hand, medical applications usually have a strong requirement of robustness over all variations. Beside the above challenges, system issues exist for the major modalities, such as noise, partial volume effects, non-isotropic voxel, variation in scanning protocols, and so forth. These all lead to more difficulties for the medical segmentation problem.

Knowledge-Based Segmentation

Medical image segmentation has the advantage of knowing beforehand what is contained in the image. We also know about the range of size, shape, and so forth, which is extracted from expert statements. In other fields of computer vision, such as satellite image analysis, the task of segmentation sometimes contains a recognition step. Bottom-up strategy is usually used, which starts with the low-level detection of the primitives that form the object boundaries, followed by merging. One sophisticated development is Perceptual Organization (Sarkar & Boyer, 1994; Guy & Medioni, 1996; Mohan & Nevatia, 1989), which attempts to organize detected primitives into structures. It is regarded as the "middle ground" between low-level and high-level processing. In 3D medical data, grouping is much more difficult due to the complexity of medical shapes. Because of this, top-down strategies prevail in 3D medical image analysis.

Knowledge-based segmentation makes strong assumptions about the content of the image. We use prior knowledge to find and tailor a general segmentation method to the specific application. Global priors are applied when the local information is incomplete or of low quality. It is a top-down strategy that starts with knowledge or models about high-level object features and attentively searches for their image counterparts.

The past several decades witnessed dramatic advances in the fields of computer vision and image analysis, from which the area of medical image analysis is derived. Various methods and frameworks for segmentation have been proposed, and many are driven by the needs of medical image analysis. These provide valuable theoretical thoughts as the basis of knowledge-based segmentation, but only at a high level. Typically, such a method is shown to be generic as it works on a number of cases from various applications with reasonable successes. This is quite different from the requirement of medical image segmentation in the real world, which depend heavily on the specific application—the workflow of the medical procedure, the anatomy and pathology of interest, the performance and accuracy requirements and the user inputs. Given all the priors and conditions of a medical application, we need to design the algorithm that will be the best compromise between accuracy, speed, robustness and user inputs. The resulting system will be specific to the given application; not only the algorithm, but also the parameter settings. A medical image analysis algorithm will be put to tests on thousands of data sets before it can be made into a clinical product. Hence, even if it is application specific, such an algorithm is general in that it has to cover all possible variations of the application.

A developer in this field not only needs to master the various methods in computer vision, but also understand the situations each of them may be applied to, as well as their limitations. In the next sections, we will focus on real world issues of medical image segmentation. We will first give an overview of the relevant low-level methods with examples. We will then discuss the popular frameworks for incorporating global priors and their limitations. We will present the principles of a novel strategy that was developed recently (Shen, Shi, & Peng, 2005) for an sample application. Finally, we will conclude the chapter with an outlook on the future trends in this field.

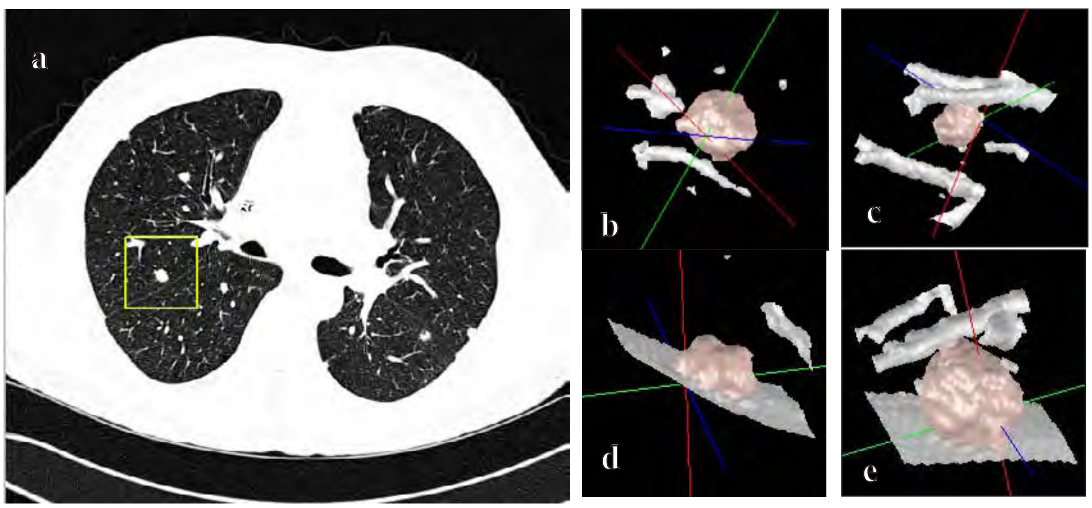
APPLICATIONS USING LOW-LEVEL SEGMENTATION METHODS

In this section we will give 3D medical application examples that use low-level segmentation methods. We define low-level methods as those that do not incorporate global shape priors of the object to be segmented, but mostly rely on local image properties. Many surveys and textbooks (Sonka, Hlavac, & Boyle, 1998) give detailed descriptions of all the segmentation methods, and this short chapter will not serve as a duplication of these efforts. Instead, we will give examples to show where each category of low-level method is adequate, and also review the recently developed methods.

Segmentation Using Regional and Morphological Methods

Region-based methods group together voxels that have some common properties. They are applicable when there is high contrast between object and background and intra-object variation is minimal. As shown in Figure 1, in a chest CT data, the lung area maps to dark regions, while the chest wall, the vessels, the airways and nodules map to bright regions of the same intensity range. A typical application is the segmentation of a lung nodule given a click point in the nodule. Since there is high contrast between object and background, a simple 3D region grow (Sonka et al., 1998; Adams & Bischof, 1984) is the best method to obtain the foreground voxels that are above a clear-cut threshold. The challenges are as follows: First, the nodule can be connected to a vessel and/or the chest wall, which has the same intensity range as the nodule. Second, it is required that the segmentation result be com-

Figure 1. Lung nodule segmentation from multi-slice chest CT data



pletely independent of the click point as long as it is within the nodule. Last, but not the least, is the high expectation from the user of success rate on a large number of cases due to the fact this looks like an easy problem.

These challenges are met by incorporating prior knowledge about the application. First, the click point is guaranteed to be in the nodule. Second, the nodule size range is known. Third, the nodule is known to be compact, while a vessel is assumed to be of elongated shape, and the chest wall is mostly a smooth surface. Given the click point and size range, we define a cubic volume of interest (VOI) centered at the click point, and hence isolate out the object and its immediate neighbors. In this VOI, methods such as mathematical morphology are applied to consistently find the nodule center and separate the nodule from the connected structures.

Mathematical morphology utilizes local shape information (Sonka et al., 1998; Haralick, Sternberg, & Zhuang, 1987). Although grayscale operations are also defined, this type of method is mostly used in binary images that are generated from an earlier process such as region grow. As illustrated in Figure 1(c), the foreground object contains a nodule connected to a vessel. The basic operators such as dilation, erosion, opening and closing can be used for boundary modifications and to separate two connected objects. However, the more effective separation techniques are based on the important concept of geodesic distance. A geodesic distance of a point inside the foreground object is the shortest travel distance to the background by any path that is completely inside the object.

Using a geodesic distance map, the vessel voxels can be removed from the nodule since their distance values are relatively small. Again, the knowledge about relative sizes between the nodule and the vessel are used to determine the distance thresholds. We could use more sophisticated watershed algorithms (Vincent & Soille, 1991) to find and separating distance basins, if the over-segmentation issue can be overcome (Meyer & Beucher, 1990).

The region-based methods are based on the similarity or connectivity of voxels, therefore they can be extended to more general situations by redefinition of the similarity or connectivity. Recently, the concept of fuzzy connectivity has been introduced (Udupa, Saha, & Lotufo, 2002; Herman & Carvalho, 2001), which is defined between every possible pair of voxels. All objects are initialized with a reference point and then grow by competition to acquire voxels according to the strengths of fuzzy connectivity.

Overall, region-based segmentation is robust, simple to implement and fast when the object is small. In some cases, region merging and splitting is necessary to the grown region according to other criterions (Sonka et al., 1998; Chang & Li, 1994). However, the more heuristics that have to be applied in order to get a decent result, the less reliable the algorithm will become. The bottom line is that region-based, low-level methods should be applied to regions with relatively homogenous intensities.

Segmentation Based On Primitive Detection

Image primitives are local properties such as edges, ridges and corners. Instead of looking for properties of all voxels inside the region, primitive-based methods look for the region boundaries. There are many recent developments in primitive detection, especially edge detection, which is the basis of most segmentation schemes. The detected primitives are usually fragmented, and the challenging problem of linking edges and lines into boundaries was the focus of many works in the early and middle 90s (Basak, Chanda, & Majumder, 1994; Wu & Leahy, 1992).

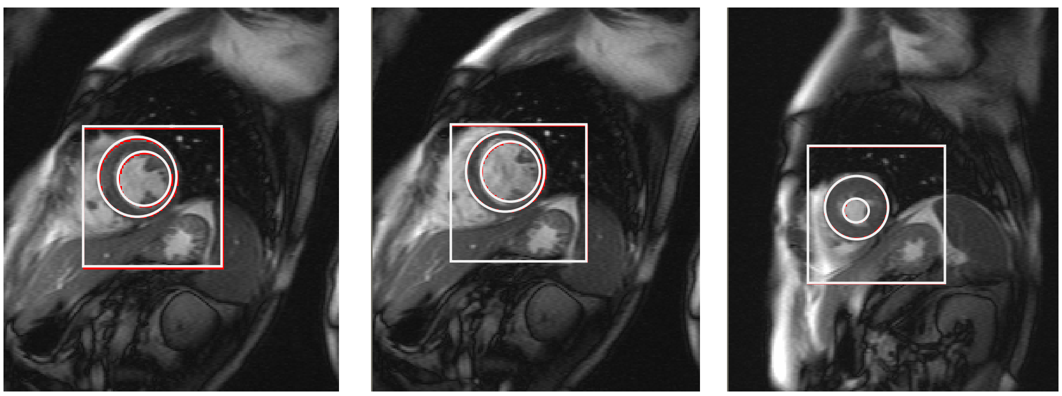
Basic edge detection is achieved by applying an edge operator (Sonka et al., 1998) followed by non-maxima suppression. A systematic treatment of edge detection was provided by Canny (1986), which is an optimal detector for step edges, and can be adapted to detect other features when different filters are selected. Recently, Brejl and Sonka (2000) invented a 3D edge detector that is particularly fit for anisotropic situations, which are typical in 3D medical data. Freeman and Edward (1991) proposed a method of systematically detecting all linear primitives, including step edges, ridges and valleys, as well as their orientations. They designed a basis of filters from which an arbitrarily-oriented filter can be generated to selectively detect the primitives of a specified orientation. This is particularly useful for high-level feature detection. For instance, if we know beforehand there should be a long ridge at a certain orientation and location, a ridge filter of that direction can be applied.

As a special type of primitive-based method, Hough Transform (Sonka et al., 1998; Shankar, Murthy, & Pal, 1998) utilizes a very powerful scheme for noisy medical images—voting. It is applicable when the object roughly fits a simple parametric model, such as a rectangle. Although in medical applications precisely regular shape is rare, some are roughly spherical or with a circular cross-section. For instance, shown in Figure 2 are the segmentation results of the left ventricle from cardiac MR data. The outer and inner boundaries approximate a circle, which has three free parameters in its parametric equation. Edge detection followed by non-maxima suppression is performed within the region of interest, and each edge pixel casts one vote for every circle equation it satisfies. The circle with the highest vote is taken as the object boundary. To achieve good results, the parameter space needs to be carefully divided into cells. Sometimes the vote can be weighted by edge strengths.

The power of this algorithm comes from its strong assumption. It works in spite of noise, weak boundaries and even occlusions, as long as the good edges can form a majority over the outliers. Certainly, the parametric model has to be simple before the algorithm becomes too complex. However, in some cases even when the object shape is not regular, we may still use it to find at least the correct centroid of the object.

The Hough Transform is a type of robust estimation method. Its principle of utlizing the majority of pixels can be widely applied. In the presence of abnormality, noise and high complexity, the robustness of a segmentation algorithm is usually determined by the number of voxels the decision is made upon.

Figure 2. Segmentation of the left ventricle wall from cardiac MRI data. The white circles mark the inner and outer boundaries of the left ventricle.



Statistical Segmentation Methods

Statistical methods treat the intensity of each voxel as an event, and model the local intensity variations by the estimation of probabilistic distributions. The goal is to use classification frameworks to determine whether a voxel belongs to a certain object. The set of voxels that are labeled as object points forms the segmented object. A simple scheme is to estimate the probability density functions (pdf) of different objects or background by computing the frequency of histograms from sample data. The estimated pdfs can then be applied to the test data. Each voxel can be classified using conventional classification methods, such as Bayesian classification or maximum likelihood decision. A more sophisticated algorithm would estimate the joint pdfs of the voxels in the neighborhood to capture the spatial local interaction properties between image labels. The most popular method is the Markov Random Field (MRF) framework, in which the pdfs are estimated with advanced algorithms such as EM algorithm. The segmentation is often obtained using a MAP estimator (Sun & Gu, 2004).

These type of methods can be applied when there is little knowledge about object shape and the intensities are nonhomogenous. A typical case, as shown in Figure 3, is the segmentation of ground glass nodules (GGN) from chest CT volume data, which has strong clinical significance due to the high malignance rate of GGNs (Zhang, Zhang, Novak, Naidich, & Moses, 2005). Due to large inter-nodule variations, an iterative approach is applied to gradually capture the local image properties. A rough intensity model is generated from training data and applied to the first round of classification. The resultant segmentation is then used to estimate a more specific distribution for the current nodule, which is in turn applied to the next round of classification. Several iterations combined with other heuristics give consistent segmentation results with respect to different user clickpoints. The same iterative strategy was used by Marroquin, Vemuri, Botello, and Calderon (2002) in the segmentation of brain MRIs. The establishment of pdfs is a learning process that requires large sample sets for each object, which may not be available for medical image segmentation. Further, large variations in

Figure 3. Segmentation of ground glass nodules (GGN) from chest CT data using Markov Random Field. Top row: Slices of volumes of interest (VOI). Bottom row: Slices of segmented GGN from the VOI above it.

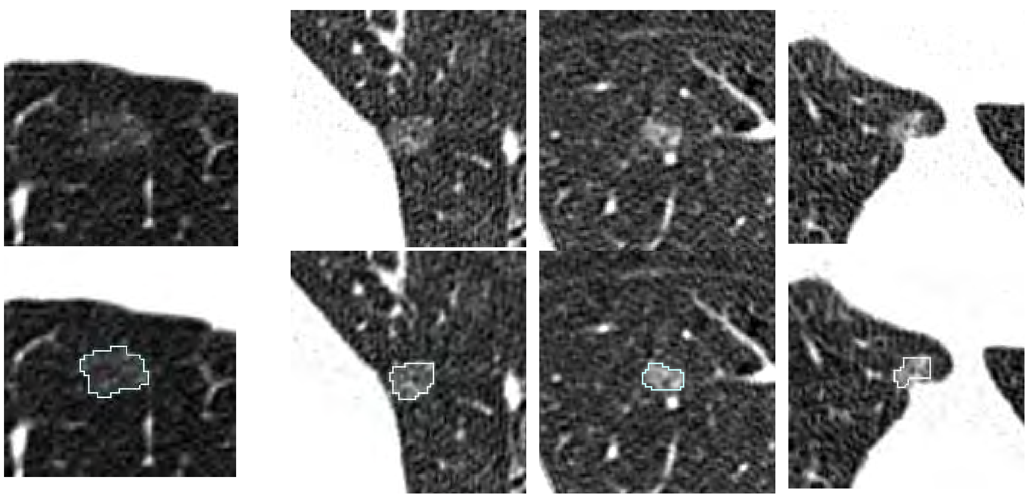


image properties often lead to overlapped pdfs. Usually, heuristics have to be combined to achieve a decent result.

SEGMENTATION INCORPORATING GLOBAL PRIORS

For more complex situations, low-level methods will not be successful. This is because the objects to be segmented in a medical application usually have high internal nonhomogeneity and strong internal edges. In these cases, a global prior is needed.

We first give as intuitive examples two special applications that utilize the global priors of object shapes—the tracing-based segmentation of tube-like structures. As shown in Figure 4, 3D tracing algorithms were developed for the segmentation of neurons from laser-scanning confocal image stacks (Al-Kofahi et al., 2002), and of rib structures from chest CT data (Shen, Liang, Shao, & Qing, 2004). A tracing algorithm uses the global prior knowledge that the object has piecewise linear shapes with smooth surfaces. First, seed points are automatically detected for all objects by techniques such as sparse grid search or 2D cross-section analysis. From each seed, tracing proceeds iteratively along each object, using edge information to determine the tracing directions. Carefully designed stopping criteria are applied to terminate a trace.

This approach has the advantage of obtaining object centerlines and boundaries simultaneously, and all tube structures are naturally separated. Another significant advantage is the low computational cost. This type of algorithm is exploratory. Only the voxels on or near the objects are processed, which is a small portion of the image data.

Deformable Models

The deformable models provide a framework that allows the incorporation of global priors. It is widely applied to medical data, and the potential is far from fully explored. Before global prior is introduced, a deformable model is a unified ap-

Shown are the rib contours and centerlines. They are naturally separated. A graphical surface reconstruction algorithm can be applied to obtain the rib surfaces.

proach to the capture of local image properties through front evolution, without the need of local primitive grouping. Further, by the constraints that a smooth shape is to be maintained during evolution, the frontier points move with interaction rather than independently. Figure 5a and 5b show the two example segmentations using the level set method, which is one popular deformable model.

Kass, Witkin, and Terzopoulos (1988) proposed one of the first deformable models—snakes—in which they introduced the energy minimizing mechanism. By using gradient decent and variational approach, the 2D contour is attracted to the local energy minimum. Through contour or surface evolution, a deformable model integrates three factors to jointly determine the segmentation. First, the smoothness requirement of the shape constrains the relative motion of frontier points. These points are only allowed to move such that a smooth front is maintained. Second, the surface actively adapts to the local image primitives, such as edges, ridges, etc. Finally, it is possible to impose global geometrical constraints on the shape. In the initial treatment of snakes, these three factors are integrated as energy terms in the partial differential equation (PDE).

Accordingly, three issues are to be addressed when designing a deformable model. First of all, we need to decide how to represent a shape or surface. The other two major issues are the design of local image forces and the incorporation of global priors to constrain the front evolution.

The issue of shape representation becomes more challenging in a 3D situation. Pentland and Sclaroff (1991) used an approach based on finite element method (FEM) to establish a parametric model of shapes. Lorenz and Krahnstover (1999) used a 3D mesh to represent the vertebra shape. Recently, Slabaugh and Unal (2005) developed a more general deformable mesh for surface evolving.

The Level Set Method for Shape Representation and Evolution

In the past decades, the level set methods (Malladi, Sethian, & Vemuri, 1995; Adalsteinsson & Sethian, 1995) received much attention. The surface is represented implicitly. Typically, for a close surface, a signed distance function is defined in a volume that contains that surface. The value of each voxel is the geodesic distance of that voxel to the closest point on the surface. Since this value on the surface is zero, the set composed of all surface points is named the zero level set of the signed distance function. The distance values of voxels in and outside the surface are set to be negative and positive, respectively. This implicit representation of the surface by the zero level set of the signed distance function provides great simplicity at the cost of an increase in dimension. The implementation is relatively simple, and provides a flexible platform to design various algorithms. Further, level set is transparent to dimension, which makes it much more desirable than some other methods that are hard to adapt to 3D.

Until recently, most level set researchers focused their efforts on the problem of surface evolving under local image properties, such as defining local image force or speeds, either edge-based or region-based (Chan & Vese, 2001; Chakraborty, Staib, & Duncan, 1996). A recent survey by Suri, Liu, and Singh (2002) gave a systematic summary of all the important efforts that address in depth the local surface evolvement. Without a prior shape model, however, a deformable model such as level set only reacts to local properties. For edge-based force, the surface will converge at local edges. For region-based force, the surface will converge when the average intensity of voxels in the object and background differs the most. A medical structure usually has complex local image properties, such as incomplete boundaries, noise, nonuniform internal intensities, etc. Therefore the most common problems for low-level segmentation methods also bother a deformable model—the

Figure 5. Surface evolving in the level set segmentation. The left column shows initialization, and the right column shows converged boundary.

leaking at weak boundaries or being caught by internal edges. The surface will truthfully conform to whatever local information it encounters. Even with the most advanced local constraining schemes, these problems persist.

Statistical Model as Global Prior Representation

Cootes, Taylor, Cooper, and Granham (1995) proposed the popular active shape models (ASM). Cootes, Edwards, and Taylor (2001) later proposed the active appearance models (AAM). Both of the two methods used statistical models to represent prior knowledge. The surface was represented by a point distribution model (PDM), which was a set of landmark points that were distributed on the object boundaries. For a given shape, the locations of all the landmarks were concatenated to form long vectors as the representation. The success of a PDM depends on correspondence of landmarks, which is challenging in 3D. Overall, the PDM models are difficult to implement in 3D. It is a very active field that attracts many contributions to solve these difficulties (Hill & Taylor, 1994; Walker, Cootes, & Taylor, 2002; Horkaew & Yang, 2003).

On the other hand, this was among the first systematic efforts to introduce statistical representation of global shape priors into a deformable model. Sample vectors were extracted from a set of registered training shapes and principal component analysis (PCA) is performed on the set of sample vectors. The dimension of the covariance matrix equals that of the sample vectors, but only the eigenvectors with the largest eigenvalues are taken to form the basis of the linear model space. The segmentation process first transforms the mean shape to the data, and then finds the correspondence of the mapped model landmarks by searching for strong edges in the contour's normal direction. Subsequently the shape vector computed from the correspondent points is projected onto the model basis to find the best matched model. This means a large number of residual components are discarded. The matched model is again matched onto the image data for next iteration. In a PDM, the representation of surface and the incorporation of global priors are combined and a shape is only allowed to vary within the model space. The local surface evolution is limited and for the only purpose of finding the matched model.

For the level set framework, recently Leventon, Grimson, and Faugeras (2000) introduced the similar PCA model. PCA analysis is performed on a set of registered training samples, each represented by a signed distance function defined in a volume. Compared to the PDM, the linear PCA model on signed distance function is only valid within the limited space centered at the mean shapes, which is clearly a disadvantage.

Limitations of the PCA Statistical Model

The PCA statistical models have limitations both in the representation and application of global priors. The representation is incomplete, especially when the structure is complex and with high variations due to age, gender, race and almost infinite types of pathological abnormalities. Coverage of these variations requires a large number of modes, in addition to the need for high-valued coefficients. Setting up such a large and high-dimension model space is impractical due to the limited size and coverage of the training set, in which every sample needs to be obtained by arduous manual segmentation. Further, searching in such a complex model space is also impractical if any reasonable performance is desired. Therefore, any practical PCA model space will be restricted to that of a relatively low dimensional, and the model shape can only vary in the neighborhood of the mean shape.

The established PCA model is applied to segmentation as follows. In an iteration of surface evolution, a model is identified from the PCA model space such that it has the minimum shape difference from the current surface. The difference is then used as a penalty term and added to the evolving force. In such a scheme, how to determine the relative strengths of model and local force is a critical issue. In a PDM, the local image force is only used to evolve the surface to its best model, and the shape residues not covered in the limited model space will be ignored. A level set scheme better understands the limitations of a model, and allows the surface to converge to a shape not covered by a model under local image force. The high-level model force and the local image force are added together, with a multiplier on one of the two terms to adjust the relative strength.

For a PDM, precise segmentation of a complex structure is obviously not possible, since the object is completely restricted to an inaccurate model space. In the literature, PDM showed its success mostly in 2D cases. Mitchell et al. (2002) extended it to 3D segmentation of a left ventricle from cardiac MR and Ultrasound images, in which the object of interest has a relatively simple shape and hence the issue of inaccurate model space is not severe. In some applications, such as ultrasound, the shape is not well defined. Even humans cannot consistently delineate the object boundaries. The goal is then to find a shape that best fits the visual clues of boundaries. This is where PDM is useful but, strictly speaking, it is geometric modeling rather than precise segmentation. On the other hand, geometric modeling sometimes is the best we can do since validation of results is not possible. Depending on application, geometric modeling may be a satisfactory solution even if it does not represent the actual object boundaries. When there is consistent ground truth from human, precise segmentation should be achieved.

In comparison, the level set scheme is fit for precise segmentation, since surface evolution is allowed to converge to local image primitives. However, the PCA model (Tsai et al., 2003; Yang, Staib, & Duncan, 2004) introduced the same-level competition scheme between global prior and local image forces. Because of the inaccurate model, the global prior term will often disagree with the local image term. In a situation where the shape is not well defined, the model term can be made very strong by adjusting the multiplier, and the resulting surface boundaries will be very close to that of a model shape. A example is shown in Figure 5c and 5d, in which a prior shape model was applied. In such a case, the user has only vague visual clues to identify the actual object boundary, therefore the boundaries suggested by a model shape are well accepted. Much work in the literature follows these types of strategies.

In a situation where an object shape is well defined, the user would expect a precise segmentation. A good example is the human vertebra in high-contrast data, such as multi-slice CT images, as shown in Figure 6.

This 3D complex structure has a relatively well-defined shape, at least for a human observer, who can perform consistent delineation of the object boundaries on 2D slice images. However, there are many places where local boundaries are weak, diffused and have gaps. Further, such a structure is adjacent or even connected to a neighboring structure that has similar image properties. This is the typical case where we cannot afford an accurate model, and the inaccurate model will compete with the local image forces. If we make the model strong, the surface will not converge to some of the strong local features and abnormal shapes that are out of the model space. On the other hand, if we reduce the strengths of the model, then level set will leak out at places where local primitives are weak and hence need guidance. Obviously, this is a dilemma that cannot be completely addressed by adjusting the multiplier. In the work in which Leventon et al. (2000) defined this competition scheme, an attempt was made to segment the human vertebrae. The training shapes are from the vertebrae of the same data set, leaving the middle vertebrae out as the test data. The problem manifested itself. The not-well-fit model shape competes with local primitives to pull the evolving surface away from these strong features and the abnormal shapes. From the published result, the convergence was quite far from the object boundaries that can be easily delineated by a human observer.

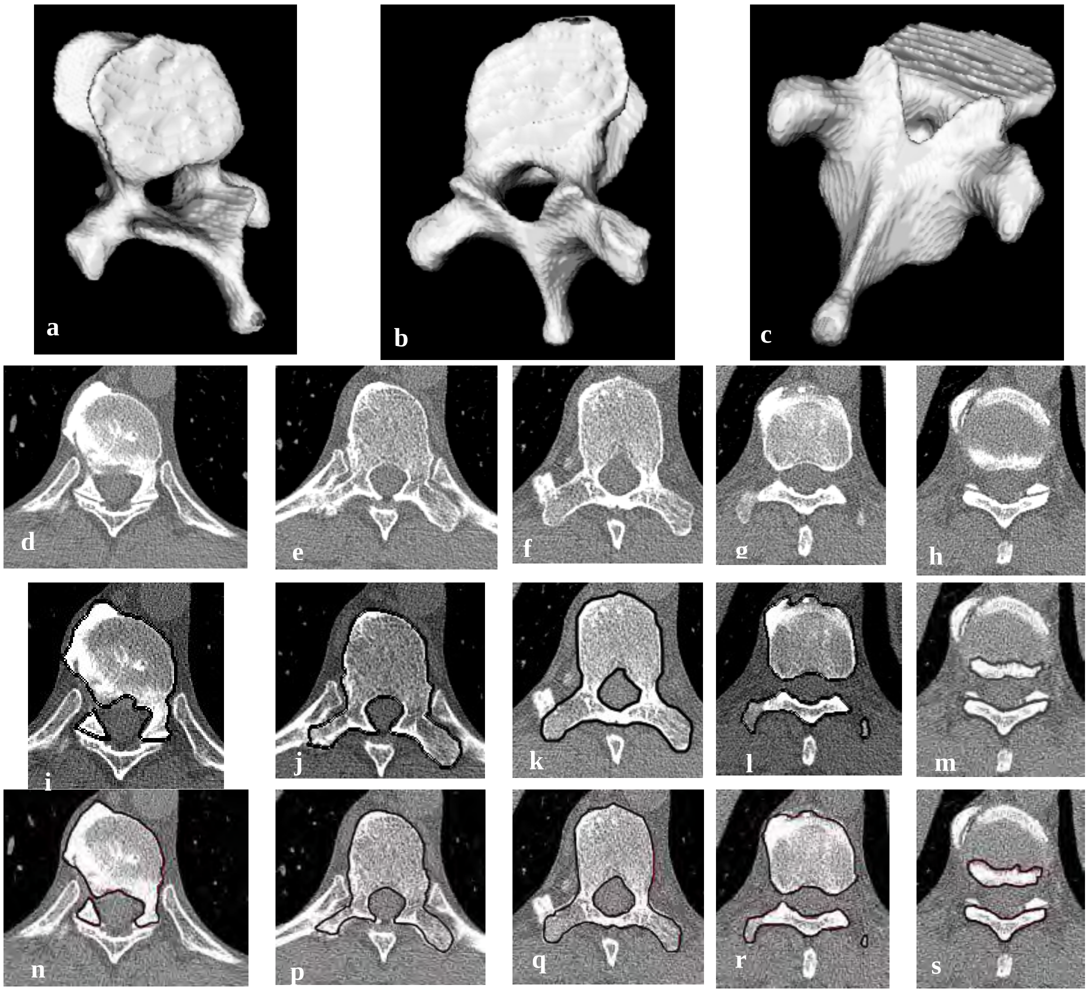
A Better Strategy

The limitations of the PCA models for representing global prior knowledge can be understood from an alternative point of view. Mathematically, the PCA models are based on the moment average of the training samples, and hence high frequency information will not be preserved. On the other hand, human observers to identify a complex structure most effectively use high frequency information, such as abrupt ridges, corners, etc. These are singular points, lines or planes where derivatives do not exist. A surface model represents smooth surfaces well, but does not incorporate these singular features. In other words, this important portion of the prior knowledge has to be represented more explicitly rather than implicitly embedded in the shape model.

Further, global prior knowledge, such as surface models, should not be put in competition with local image properties at the same level. When simply added to the local image force, a global prior loses it “global” status and degrades into a local factor. A global prior should act as a high level guidance to local evolution, so that the surface will converge to the “correct” local primitives, hence avoiding the problems of local minima and leak-out.

To determine what global priors are needed, we want to find out what causes the failure of the surface evolution when no global prior is applied. As shown in Figure 6, the internal intensity of the vertebra is very nonhomogenous, and there are

Figure 6. 3D level set segmentation of the vertebra



(a)-(c): 3D view of the complex structure of a vertebra shape. (d)-(h): Vertebra on selected axial slices, with its neighboring vertebra and rib structures. While the shape looks well defined for a human observer, local boundaries are far from clear. Also notice the pathology induced abnormal shape on the top-left of (d). (i)-(m): The 2D boundaries delineated by a human observer. Regions outside the contours belong to the neighboring vertebras and rib structures. (n)-(r): Converged 3D level set surface of segmented object projected onto selected axial slices.

many internal edges. A level set front when initialized inside the vertebrae will ensure converge to these internal edges. The only way to prevent this from happening is to keep these internal edges away from the evolution path. Since the convergence of level set depends on the initial front, a major effort is to design the initial front such that it is close to the boundaries but outside of the vertebrae. The surface will then converge to the outside boundaries before it even encounters the internal edges. Another problem is the weak boundary locations, from which the surface will leak out. We can carefully design the speed map according to the various local properties to avoid this problem. For instance, we can use region based speed at locations where edges are weak. Next, a more challenging issue is the adjacent, or even connected, ribs and vertebrae that have the same image properties. To separate them from the vertebrae of interest, we need to explicitly detect the high-level features formed between the vertebrae and its neighboring structures.

From the above, global priors should then include a surface model as a general description of shape, augmented by a set of known high-level features. The surface model is constructed as follows: First, a small number of vertebrae, roughly covering the spectrum of shape variations within the normal range, are selected and their surfaces are manually segmented. These surfaces are transformed into a common coordinate system using similarity transformation such that the spinal channel and inter-vertebrae planes are registered. We do not intend to match the surfaces themselves, since that is unnecessary and will require nonlinear warping of the surfaces. Afterwards, the registered surfaces are represented as a set of signed distance functions. We then compute the mean signed distance function, whose shape is shown in Figure 7a. It has the basic look and structure that belong to and characterize a vertebra. The mean shape model is used as a rough guide or template and hence does not need to cover the large variations. This low requirement allows a small sample size.

Using the mean shape as a reference system, we define planes that divide the volume into regions. For each region, the proper speed design is applied, which varies in the type of speed and the constants. The region division is shown in Figure 7b and 7c.

The mean shape representation is augmented with a set of high-level features, which are formed by linear primitives including intensity edges, ridges and valleys. If the locations of the strong and same-type primitives in a local neighborhood roughly fit to a simple parametric model, such as a plane, that plane is recorded as a high-level feature. There are two types of high-level plane features, and both are recorded with reference to the common coordinate system. If fitted by the ridge or edge primitives from the object boundary, it is named a high-level boundary feature. A high-level context feature, on the other hand, is fitted by valley primitives located at the interface between the object and a neighboring structure. Plane is the simplest parametric model, which can be extended to piecewise linear models. Examples of high level boundary and context features are shown in Figure 7d and 7e.

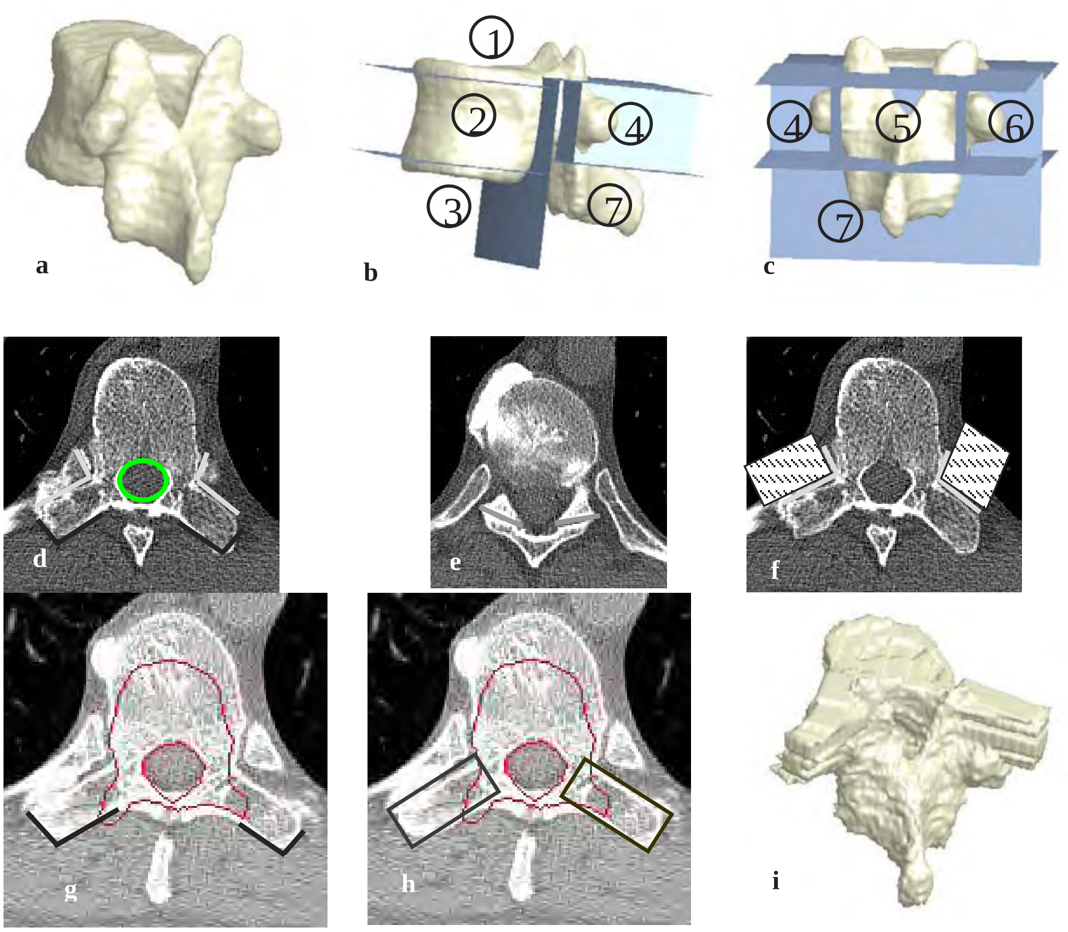
Application of Global Priors in Surface Evolution

Similar to the registration process of training samples, the mean shape is mapped to the image data using the estimated similarity transformation, as shown in Figure 7g. This is, of course, specific to this application. However, a transformation can be estimated with other more general methods to map the initial shape, and we have seen examples in the literature (Baillard, Hellier, & Barillot, 2001). The boundaries of the mapped mean shape are usually close to the boundaries of the object, except that the surfaces at the two transverse processes are too far inside. Such an initial front will be captured by local minima and not converge to the outside true boundaries. It therefore needs to be modified, and we use the high level features to achieve this.

The high-level feature models are also mapped to the neighborhood of the features in the image data. The detection of high-level boundary and context features uses mainly parametric model-fitting techniques, such as Hough Transform. This is a typical knowledge-based strategy, which fits known models to local image data, rather than estimate models from detected image primitives. The detected high-level features have impacts on the correct convergence of the surface, as described below.

As shown in Figure 7g, the high-level boundary features at the two transverse processes are detected, and we use them to modify the mean shape into a good initial front. We place two rectangular parallelepipeds in connection with

Figure 7. Representation and application of prior knowledge



(a) The mean shape. (b)(c) The plane division of the volumes into regions. Each region has its specific speed design. (d)-(e) High-level boundary features and context features which are marked with black and gray, respectively. A context feature is not on object boundary, but is on the object interfaces. (f) Blocker speed regions. (g) Mean shape mapped to the image. Two high-level boundary features are detected. (h) The mean shape is augmented to make it close to the object boundaries. (i) 3D structure of the augmented mean shape to be used as the initial front for level set surface evolving.

the mean shape to form the initial front, as shown in Figure 7h and 7i. This is a general idea that is applicable to many applications: If we are given a true knowledge of a partial boundary, we can use it as part of an arbitrary shape to augment the initial front. After the modification, the initial front is pulled to the actual boundary, which helps in avoiding the internal local minimums.

The high-level context features, as shown in Figure 7d and 7e, are used for the introduction of a new type of speed to affect level set evolution—namely the blocker speed. The blocker speed serves as an energy potential that prevents the surface from evolving beyond the detected context feature. With this we can prevent the leakage to neighboring objects. As shown in Figure 7f, the two plane context features divide the space into two regions. Using the center of the spinal channel as the reference, we can determine the region which the surface should not evolve into. For that region, the speed terms are made negative, which prevents the surface from evolving beyond the context features. Note that the high-level context features do not belong to object boundary; rather, they belong to background. The surface will not converge to the context feature, but will converge to the object boundary that is on the inner side of the context feature.

From the above, the leakage and local minimum issues that frequently bother a level set surface evolution are principally addressed. Finally, the separation planes associated with the mean shape are also mapped to the image data. Local primitive detection is performed to generate the speed terms specially designed for each region. Careful design of the speed is also an important part of this knowledge-based segmentation scheme.

As shown in Figure 6n-6s, after iterations of surface evolution, the level set surface converges to the correct object boundaries despite the internal inhomogeneity, the weak boundaries and the presence of neighboring structures. From this example we showed the power of prior knowledge when it is well represented, organized and applied to medical image segmentation. We only presented high level concepts in this example, and the reader is referred to the work of Shen et al. (2005) for a detailed treatment including mathematical deductions.

CONCLUSIONS, DISCUSSION, AND OUTLOOK

We have made an attempt in this chapter to give an intuitive introduction to the various methods and frameworks that are useful in 3D medical image segmentation. We also discussed the concepts of our approach of knowledge-based segmentation, in which the effective representation and application of prior knowledge is most important. From the discussion, the most prominent high-level features are of most value and need to be intensively explored before other image properties come into play.

The state-of-the-art medical image segmentation methods still leave much to be desired. Other than the difficulties of the segmentation problem itself, the relatively short time in which the 3D medical data become available is also one factor. The earlier scanners produced data in which the axial resolution is much lower than the other two directions. Therefore 3D correlation between two adjacent axial slices is weak, and a 3D segmentation method is not particularly more beneficial than 2D segmentation on each slice image. In the past two years, multi-slice CT scanners have achieved true isotropic voxels. With the development of medical instrument technology, 3D medical image segmentation will become increasingly popular. 3D methods are inherently better for the segmentation of complex structures, in that they implicitly involve the 3D structural information that is difficult to capture in 2D methods. On the other hand, it will still take time for people to have full awareness of the properties of these data and develop insights.

Medical imaging applications have now become an important driving force for the advance of computer vision. On the other hand, medical image analysis needs to address real-word issues that have been outside the realm of computer vision. These issues come largely from the fact that the end systems are mostly used by the physician. The human factor is essential, since any successful solution will have to be accepted by a physician and integrated into one's medical procedural workflow. This put strong constraints on the type of applicable methods. Because of this, there has been a discrepancy between the advanced frameworks presented in computer vision and the low-level and ad-hoc methods used by researchers working on real medical application solutions. Recently, we have seen the hope of practically applicable frameworks which are relatively simple in implementation, and reasonable in performance and robustness. In this respect, we foresee several trends. First, existing and coming frameworks from computer vision will improve themselves to be more practical and compete for their prevalence in medical image analysis. Second, more medical imaging researchers will make use of these frameworks, with their efforts focused on the incorporation of application-specific priors. Third, more efforts from the computer vision community will be attracted to solving real-world problems, and, hence, lead to the invention of more general methods for prior knowledge incorporation. As a byproduct, general frameworks will also be invented for the incorporation of user interaction into difficult segmentation problems.

ACKNOWLEDGMENTS

I would like to thank my colleagues at Siemens Corporate Research: Dr. Gozde Unal, Dr. Greg Slabaugh, Dr. Leo Grady, Dr. Li Zhang, Dr. Zhizhou Wang, Zhigang Peng, Dr. Marie-Pierre Jolly, Ludek Hasa and Julien Nahed for their support in writing this chapter. Gratitude also goes to Dr. Khalid Al-Kofahi from Thomson Legal & Regulatory and Yonggang Shi from Boston University. They have provided useful images and references, and most importantly, insightful discussions, without which this chapter would not be possible.

ABSTRACT

Information technology (IT) has changed our lives and many applications are based on IT. IT can be helpful for remote mental health care education. Because there are very few mental health care specialists, it is very important to decrease their moving time. But it is not easy to use the conventional TV conference systems for ordinary people, mental health care specialists, and their students because they are not computer specialists. For this reason, we have developed a WWW conference

system. Our system can communicate between the mental health care specialists and their students by using the live video on WWW browser. In this paper, we show the implementation and the evaluation of proposed system. The experimental results over the Internet show that our system can be used for real time communication between Fukuoka, Ishikawa, and Iwate prefectures.

INTRODUCTION

Recently in Japan, mental health care has become a very important issue because there are many people suffering from mental problems. Also, there are only a few specialists and researchers to deal with these problems. For example, bullying at school is one of the big problems worrying teachers in Japan today. Also, there are other problems such as refusal to go to school and school violence. However, there are few counselors in Japanese schools. It should be noted that many of these specialists are also doing other works. In general, one mental health care specialist should take care for many patients and they want to see their face. They should take care of not only the counseling but also the individual aftercare.

Information technology (IT) has changed our lives. People can communicate between themselves and students can study various courses at anywhere and anytime using the Internet. IT can be helpful for mental health care, education, aftercare, and counseling for patients and their families. Because there are very few mental health care specialists, it is very important to decrease their moving time. Also, it is very important to see the facial expression and to talk to people for mental health care education, aftercare, and counseling. For this reason, the video and voice are needed.

Recently, because of the use of ADSL and FTTH (NTT West, 2004) many people can use several Mbps on the Internet. Therefore, many people can use the streaming live video and TV conference. For example, the streaming live video is used for the tourist attractions broadcasting (Fuji-shi, 2005; Kumamoto-shi, 2001; Sapporo-shi, 2004), assembly broadcasting (The House of Councilors, 2005; The House of Representatives, 1999;), and public information broadcasting (The ministry of public management, 2004). In these live streaming video methods, the image refreshed at regular intervals over WWW (Fuji-shi, 2005; Kumamoto-shi, 2001; Sapporo-shi, 2004) and RealPlayer or Windows Media Player (The House of Councilors, 2005; The House of Representatives, 1999; The Ministry of Public Management, 2004) are used.

Some TV conference systems are used as special hardware (NEC Engineering, 1996; Polycom, 2004; SONY, 2004; VTEL, 2004) and in other systems are used as application software or PC connected to the existing cameras (Advanced Solutions, 2001, 2002; Hitachi Hybrid Network, 2004; Microsoft, 2004; Visual Nexus, 2004). When using the special hardware, the users need to connect to the Internet and set up the hardware in each spot before using the system. But, it is difficult to use the special hardware in counseling because the users are usual people. While, when using the application software and PC is connected to the existing camera, the users need to connect the PC and camera, setup the PC, and install the application software in each spot before using the system. Also, it is difficult to introduce these systems for mental health care because the mental health care specialists and their student are not computer specialists.

In order to realize a remote mental health care education, we have developed a WWW conference system. Our system is able to support the communication between the mental health care specialists and their students. Also, our system can provide the communication between the mental health care specialists, patients, and their families by using the live video on WWW browser, point to point communication, point to multi-point communication, and multi-point to multi-point communication.

The organization of this article is as follows. In the next section, we will introduce the related works. Next, we describe the WWW conference system and explain system architecture. The conference types are treated in the following section. After that, we show the connection management for each conference type and the flow of WWW conference system. Then, we show implementation of our proposed system by using Macromedia Flash and Macromedia Flash Communication Server and provide the experimental results. Finally, we give some conclusions and future works.

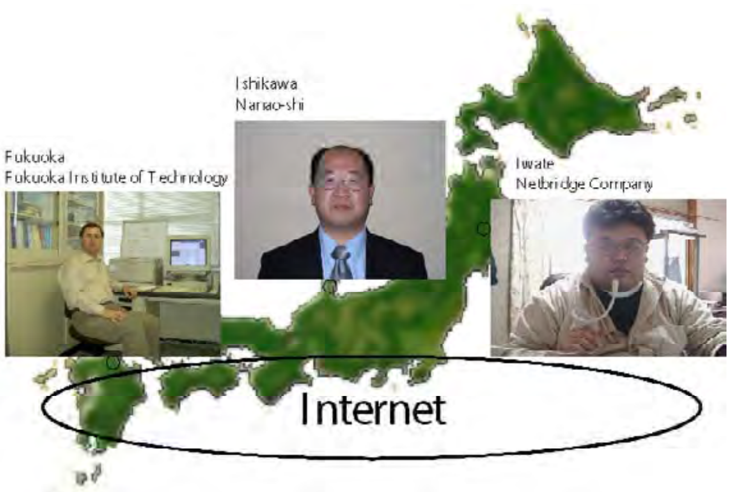
RELATED WORK

Existing communication systems are usually realized on the LAN environment and leased lines. Many remote education systems are proposed in Inoue, Okada, and Matsushita (1997), Mori, Oyabu, Nomura, and Oshita (1992), Sakiyama, Ohono, Mukunoki, and Ikeda (2001), and Wakahara (1998). In Inoue et al. (1997) and Wakahara (1998), the multi-point to multi-point communication is used. While in Sakiyama et al. (2001), a video stream selection according to lecture context is proposed. In these systems, the remote users can communicate between them using the live video.

Recently, the live video communication systems have become very popular and the network speed is increased very fast. Therefore, the video conference systems can be applied in the medical field. There are many video conference systems such as the medical tele-consultation support system using super high definition imaging system (Yamaguchi et al., 2001), remote medical support system using the transcoding function (Kawamura, Maita, Hashimoto, & Shibata, 2003), and care communications service between hospitalized patients and their families (Abiko, Iijima, Koyama, Kamibayashi, & Narita, 2003). In these studies, the system was implemented only for intranet or leased lines.

Some other communication systems using live video for remote learning systems (Maeda et al., 1997; Miyoshi, Okanaga, Kou, & Kondo, 2000) and streaming video (Kato, Jiang, & Hakozaki, 2003) has been proposed. In the multimedia communication environment for distance learning proposed in Maeda et al. (1997) are given

Figure 1. WWW conference



the experimental results for remote learning using intranet and Internet environments. In this study is shown that an efficient remote learning can be achieved by using 600 Kbps bandwidth. Now, Internet users can have more bandwidth by using ADSL and FTTH. And the live video over the Internet is possible. In Kato et al. (2003), the authors propose a streaming video system for best-effort networks using adaptive QoS control rules to improve the satisfaction of streaming video services.

However, these systems can't be used by usual people and they need special hardware and software. These systems use point to point communication, so they can not be used for multi-point to multi-point communication. In order to overcome these problems, we have developed a WWW conference system, which uses multi-point to multi-point communication and can transmit live video over the Internet.

PROPOSED WWW CONFERENCE SYSTEM

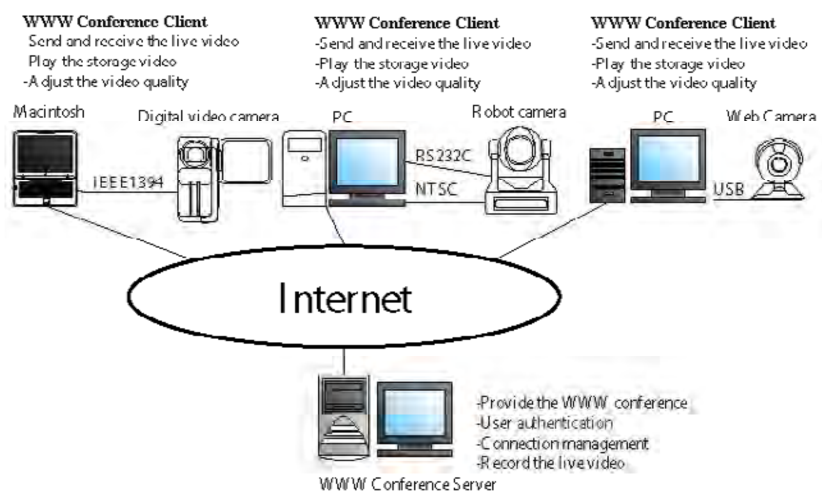
The proposed WWW conference system is shown in Figure 1. If the user has a video camera and PC connected to the Internet, the user can communicate to the remote users by using live video on WWW. Using our system, the user does not need to install and setup the application software. He just only needs to access the WWW conference server by using the WWW browser.

The concept of WWW conference is shown in Figure 2. The user can use various cameras such as the WWW camera, digital video camera and robot camera. But, the camera should be identified and connected to the PC. Our system is composed of the WWW conference client and the WWW conference server. When the user accesses the WWW conference server by using a WWW browser, the WWW conference client is downloaded to the PC. After downloading the WWW conference client, the system provides the following functions:

1. User authentication
2. Live video function
3. Video record function
4. Quality setting function

The user authentication function is provided by user ID and password. When the user enters

Figure 2. WWW conference system



into the WWW conference server, the user inputs its user ID and password. The user ID and password are compared with the registered ones in the WWW conference server. When the user ID and password do not match, the user login fails and the user needs to input again its user ID and password. It should be noted that the user login may fail when the WWW conference server has already logged on the maximum number of users.

The live video function provides the video data and voice data. The video data and voice data are sent and received by the video stream. They are encoded by H.263. Our system provides three types of conference using this function. In order to realize the live video, the WWW conference client has the connection management function, the video encode function, and the video decode function. The WWW conference server has the connection management function.

The video record function records the live video stream and plays the recorded video stream on the WWW conference server. The user can record the live video stream and play the recorded video stream by using the WWW conference client. The recorded video stream is stored in the WWW conference server. The recorded video stream is used for learning the existing cases of counseling and replaying the instructions for mental health care.

The quality setting function modifies the video quality for local WWW conference client and remote WWW conference client. The local WWW conference client can modify the video size and frame rate. But, the remote WWW conference client can modify only the frame rate. When the PC does not have enough CPU power or network bandwidth, the voice data are delayed and video data experiences frame loss and frame delay. However, our system can guarantee the quality of service such as "Frame rate is high and video size is small" and "Frame rate is low and video size is large" when the user modifies the video quality using this function.

SYSTEM ARCHITECTURE

In order to implement our system, we propose a system architecture, which is organized by the WWW conference client and the WWW conference server as shown in Figure 3.

WWW Conference Client

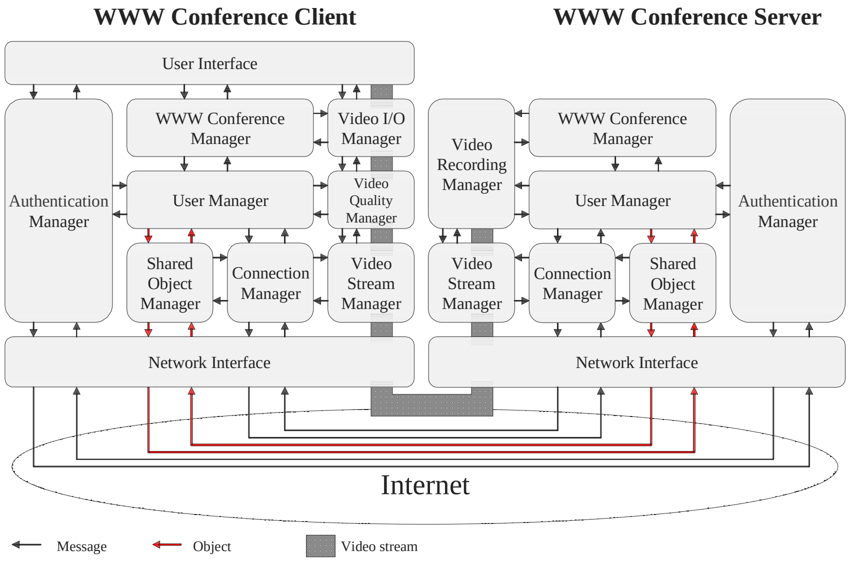
Presently, various network environments exist, such as broadband network and narrowband network. The bandwidth varies from 10 Kbps to 100 Mbps. In order to realize the communication between various network environments, the WWW conference client is organized by User Interface (UI), Authentication Manager (AM), User Manager (UM), WWW Conference Manager (WCM), Connection Manager (CM), Shared Object Manager (SOM), Video I/O Manager (VI/OM), Video Quality Manager (VQM), and Video Stream Manager (VSM).

The UI provides the following functions:

1. Insertion of user ID and password
2. Setup of video input and output device
3. Display of live video
4. Modification of video quality

The AM authenticates the user ID and password by using the registered user ID and password on the WWW conference server. When the AM fails for the authentication, the AM requests the user ID and password to the user again. When the AM authentication is a success for the authentication, the AM sends the user ID to the UM. The UM manages the system users, the video quality for each video stream and the name of the recorded video stream. When maximum number of users has been logged in to the WWW conference server, the UM rejects other users. The WCM sets up the number of maximum users and provides the user interface. The maximum number of users and the user interface are decided by the conference type. The CM manages the connections of

Figure 3. System architecture



the other WWW conference clients participating in the WWW conference. The CM converts the number of maximum users to the number of maximum connections. The SOM gets the shared object from the WWW conference server. The recorded video stream is played by using the video name. We use the shared object to record the name of video stream on the WWW conference server. When the user wants to record the live video stream through the UI, the SOM adds the name of video stream as the shared object to the WWW conference server. The VI/OM inputs the video data and sound data from the camera and the video stream is selected by the WCM. The VI/OM displays the video data and sound data from the video stream and the camera. Also, the VI/OM sends the video data and sound data to the VQM. The VQM decides the frame rate and the size of video by using the identified video quality. The VSM sends and receives the video data and voice data as the video stream to the WWW conference server. The other WWW conference clients operate in the same way.

WWW Conference Server

In order to realize the WWW conference and record the live video stream, it is needed to manage the video stream including live video stream and recorded video stream. So, the WWW conference server is organized by the AM, WCM, UM, CM, SOM, Video Record Manager (VRM), and VSM. The AM manages the user ID and password. It compares the user ID and password with the registered user ID and password when the AM requests the authentication from the WWW conference client. The UM manages the users inside the system, the video quality for each video stream and the name of the recorded video stream. The WCM manages the user and video stream based on type of conference. The CM manages the connection of the WWW conference clients. Then, it decides the number of maximum connections by using the number of maximum users. When the WWW conference server has already the maximum number of users, the CM rejects the new connection. The SOM stores the shared object, which is the name of video stream on the WWW conference server. The shared object remains even after disconnecting the WWW conference client. The VRM records and manages the video stream on the WWW conference server. The VSM manages the video stream between the WWW conference clients and the WWW conference server.

TYPE OF CONFERENCES

For the remote mental health care education are needed various conference types. We introduce three conference types because our system is used for the counseling, aftercare, and education.

Point to Point Conference

The point to point conference is used for counseling the patients. The point to point conference provides functions for point to point communication as shown in Figure 4. This type displays the local live video stream and the remote live video stream. The user can record the local live video stream and play the recorded video stream. Using the point to point conference, the patient can take the counseling at home.

Multi-User Conference

The multi-user conference is used for aftercare. The multi-user conference provides functions for the multi-point to multi-point communication as shown in Figure 5. In the multi-users conference, the users can communicate in a distributed way at the same time. This is why the local video stream and the multiple remote live video streams can be display at the same time. By using the multi-user conference, the patient and their family members can talk together with psychology specialists even if they are not at the same place.

Figure 4. Point to point conference

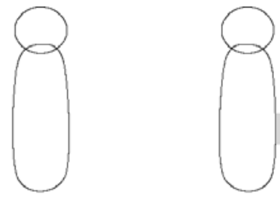


Figure 5. Multi-user conference

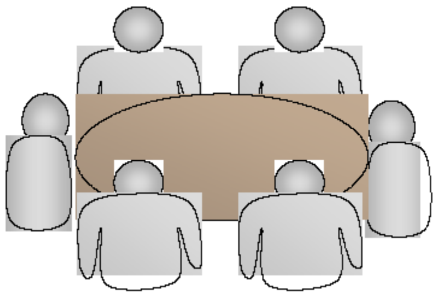

Figure 6. Broadcast conference

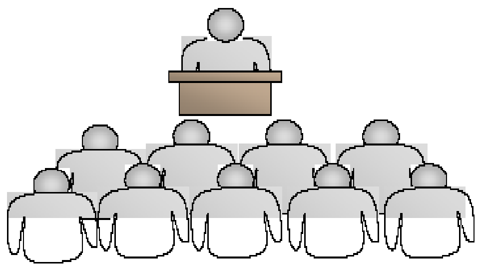

Broadcast Conference

The broadcast conference is used for health care education. It provides broadcast functions to broadcast the live video to many users as shown in Figure 6. This method is used for live broadcast (The House of Councilors, 2005; The House of Representatives, 1999). The broadcast conference uses two types of WWW conference clients: the sender and receiver clients. The sender client displays the local live video, selects the sending channel, sends the live video stream to receiver client, and records the local live video stream. The receiver client selects the receiver channel, receives and displays the video stream and plays the recorded video stream. Using the broadcast conference, the students can learn the clinical psychology, the family and patient can learn the mental health care at home.

CONNECTION MANAGEMENT

In order to provide the live video for distributed users, the video data and voice data are transmitted in the video streams. The number of video streams is decided based on the type of conference and the number of users. The WWW conference client can be connected to the remote WWW conference client via WWW conference server to create the video stream. Our system uses the channel to create and manage the video stream. Each channel has a channel number. The channel number is used for the clients connection and selection of the video stream. In the point to point conference and multi-user conference, the channel numbers are assigned based on the connection order. While, in the broadcast conference, the channel numbers are selected by the user.

An example of the relation between the video stream and channel number in the point to point conference is shown in Figure 7. This conference uses two video streams in each WWW conference client. One is used for the sender client and another for the receiver client. The sender video stream and receiver video stream have different channel numbers. After allocating the channel number, the WWW conference client creates the video streams by using the channel number.

In this example, the user 1 is connected to the WWW conference server before the user 2. For this reason, the channel number starts from 1. The channels 1 and 2 are shown in Figure 7. In the channel 1, the user 1 is the sender and the user 2 is the receiver of the video stream. While, in the channel 2, the user 2 is the sender and the user 1 is receiver.

The relation between the video stream and channel number in the multi-user conference is shown in Figure 8. In this type, each user has its own video stream. The channel number is assigned the same as type one. After allocating the channel number, the WWW conference client creates the video stream for each receiver.

In this example, four users are connected to WWW conference server. In the channel 1, the user 1 is the sender and the users 2, 3 and 4 are receivers. Each WWW conference client creates the video streams by using these channel numbers.

The relation between the video stream and channel number in the broadcast conference is shown in Figure 9. The user can select the sender channel number using the sender client. Then, the video stream is created based on the selected channel number. Also, the user can select the receiver channel number using the receiver client. It should be noted that a user can not send the video

Figure 7. Connection management for point to point conference

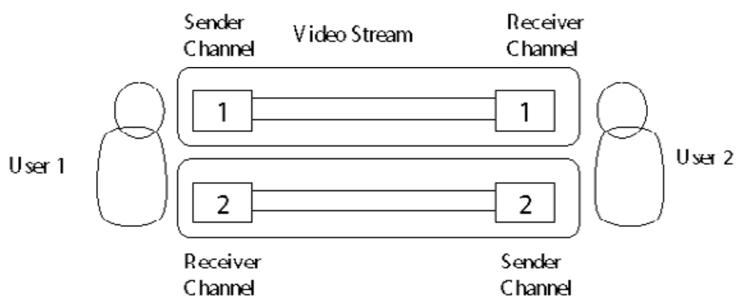

Figure 8. Connection management for multi-user conference

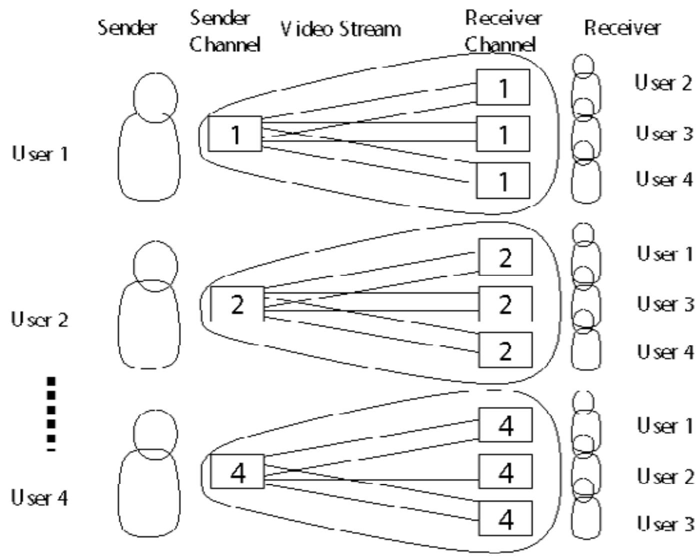

Figure 9. Connection management for broadcast conference

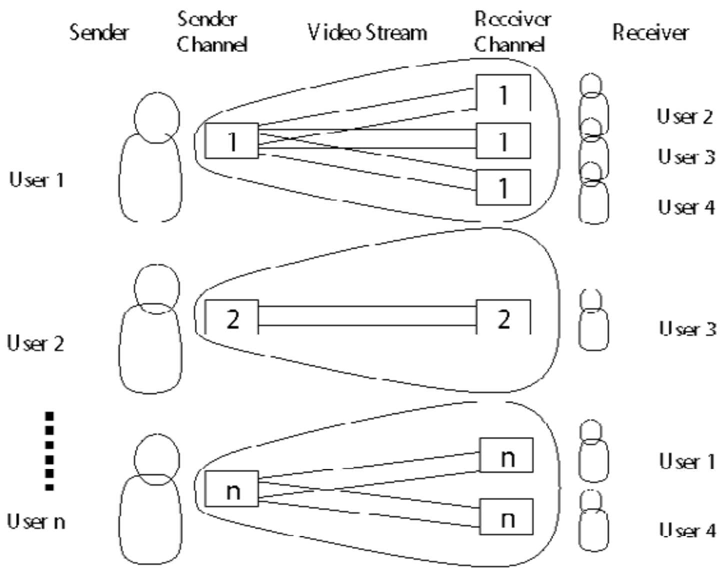
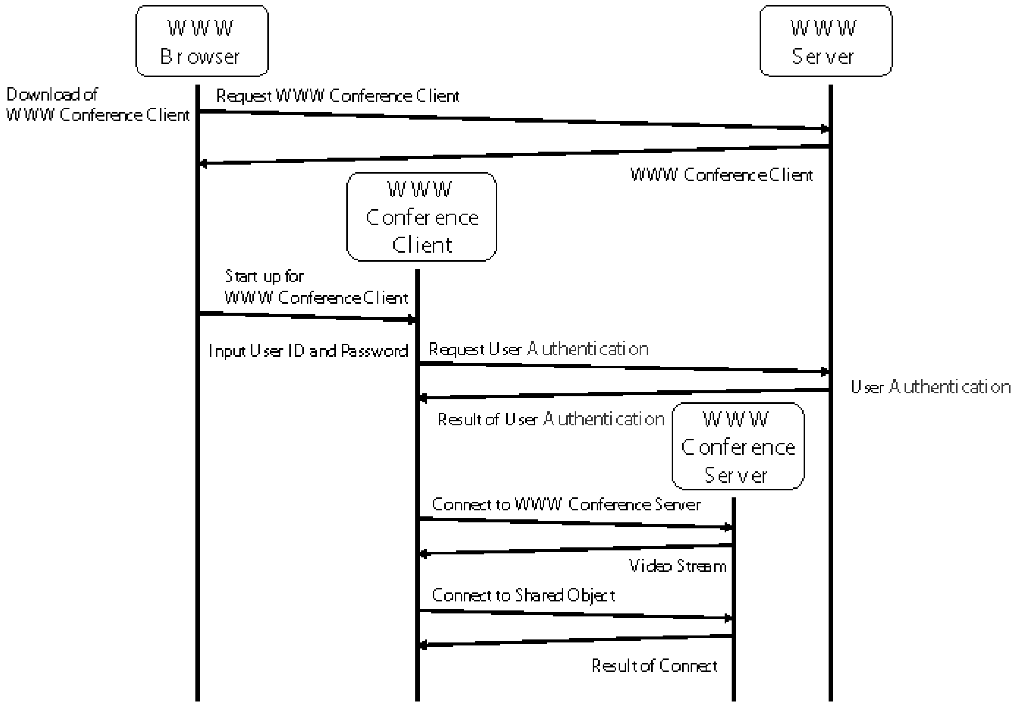


stream in a channel when this channel is used by another user. But, the receivers can get the same channel at the same time. When the sender channel number has already been used, the WWW conference client displays this message: "This channel number has already been used."

WWW CONFERENCE OPERATION

The WWW conference operation has two phases: the start up phase and live video communication phase. In the start up phase, the WWW conference client is downloaded and the user enters into the WWW conference server using the WWW

Figure 10. Startup phase



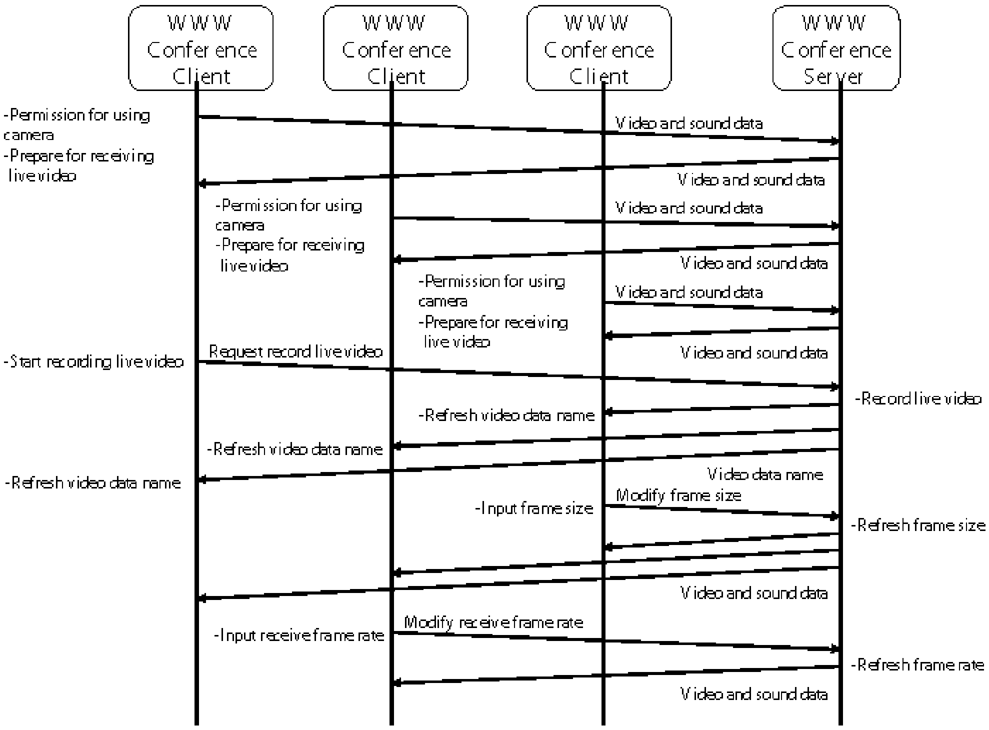
browser. The live video communication phase consists of camera setup, video quality modification, and sending and receiving the live video.

The start up phase is shown in Figure 10. First, the user downloads the desired type of the WWW conference client from the WWW conference server. After that, the WWW conference client starts up automatically and requires the user ID and password. When the user inputs the user ID and password, the WWW conference client sends this information to the WWW conference server to authenticate the user. When the authentication fails, the WWW conference client requests the user ID and password again. When the authentication is a success, the WWW conference client creates the video streams. Then, the WWW conference client connects to the shared object to share the name of recorded video stream with other WWW conference clients.

The live video communication phase is shown in Figure 11. First, the WWW conference client asks the user for the permission to use the camera. Next, the WWW conference client allocates the channel number to send and receive the live video stream. When the WWW conference client finishes the channel allocation, it starts to send/receive the live video streams to/from other clients via WWW conference server. When the user requests to record the live video stream, the WWW conference client sends this request to the WWW conference server.

The WWW conference server adds the new name of live video stream to the shared object. Then, the name of live video stream is added to the connected WWW conference clients. When the user inputs the frame size, the WWW conference client updates the frame size, modifies the captured frame size and sends the modified frame size to the WWW conference server. When the WWW conference server receives the modified frame size, it updates the new frame size and sends the live video stream to the WWW conference

Figure 11. Live video communication phase



clients using the new frame size. Also, the frame rate is updated the same as the frame size.

IMPLEMENTATION

The implemented system structure is shown in Figure 12. The WWW conference client is implemented by using the Macromedia Flash Studio MX1.5. The WWW conference server is realized by using the Apache1.3.29 and the Macromedia Flash Communication Server MX1.5. The Apache1.3.29 is used to provide the WWW conference client to the users. The Macromedia Flash Communication Server MX1.5 is used for sending and receiving the video data and voice data. The live video streams are encoded by H.263. We implemented three types of applications for each type of conference. When the user downloads the desired type of application, the WWW conference client displays the authentication interface. The user can take part in the WWW conference after authentication.

The point to point conference application is shown in Figure 13. The bottom side of interface shows the remote live video, recorded live video, and local live video from left to the right side. The list box and play button are shown below the recorded video. The list box is used to select the name of video stream and play button is used to play the recorded live video stream. The stop button is shown in the left side below the local live video stream. This button is used to stop the recorded live video stream. The record button is shown in the right side below the local live video. The user can record and play the live video stream by using these buttons. The main video display can be selected by clicking one of the videos shown in the bottom side. The video quality setup is shown in the upper side of the interface. The interface also has in the bottom side some list boxes, which are

Figure 12. Implemented system structure

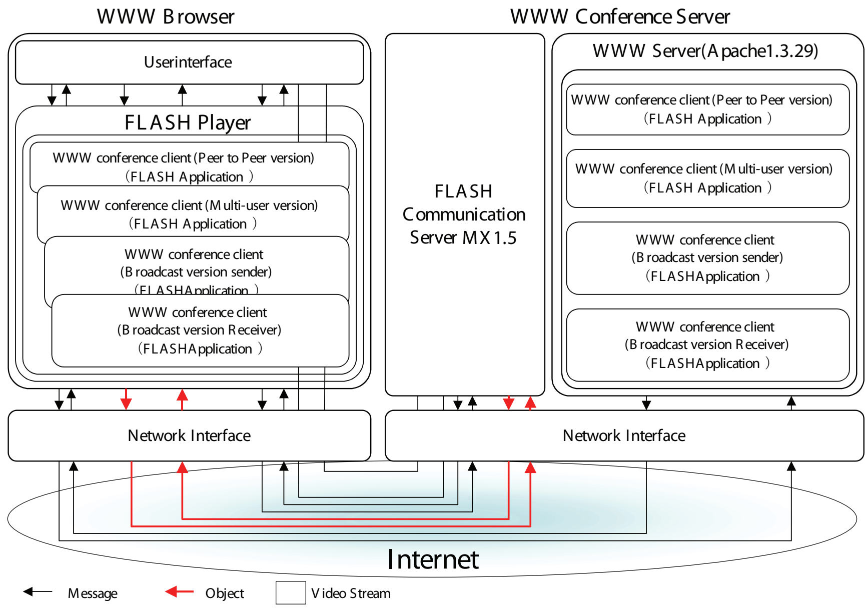


Figure 13. Point to point conference application

Figure 14. Multi-user conference application

used to change the frame size and frame rate. The frame size can be changed only at the local live video. But, the frame rate can be changed in both: the local live video and remote live video.

The multi-user conference application is shown in Figure 14. In the bottom side of interface are shown the remote live videos and local live video. The right side displays the local live video. The user can modify the frame rate for each remote

Figure 15(a). Broadcast conference sender application

Figure 15(b). Broadcast conference receiver application

live video using the list box. Also, the user can modify the frame rate and frame size for the local live video using the list box.

The broadcast conference applications are shown in Figures 15(a) and (b). These applications include the channel select interface, video quality set up interface and video display interface.

The sender client interface is shown in Figure 15(a) and the receiver client interface is shown in Figure 15(b). The main video in the center of the display shows the snap shot of the live video captured from the video camera. In the bottom side of interface are shown the text box, stop button and play button. The text box displays the name of recorded video stream. On the right side of the interface are shown the sender channel select buttons. The user can select the channel number from 1 to 12. Also, the user can input the name of live video stream and record the live video on the WWW conference server. When the user pushes the channel select button, the sender client starts to send the live video stream and the name of live video stream using the selected channel number. The video quality set up interface has the list box shown below the video. The user can modify the frame size and frame rate by selecting the values in the list box. The video display interface displays the live video and interface select buttons. The receiver client interface is almost the same with sender client interface, but the sender client interface can record the live video while the receiver client interface can play the recoded video.

EXPERIMENTS

Experimental Results

In order to evaluate our system for remote mental health care education, we used our system in a real Internet environment between Fukuoka, Ishikawa, and Iwate prefectures. Our evaluation environment is shown in Figure 16. The LANs are connected to the Internet environment by leased line (1 Gbps), FTTH (100 Mbps) and ADSL (12 Mbps). The experiment showed that the live video quality is good enough for communication. But it should be noted that sometimes the live video quality deteriorates because the bandwidth is not enough to send and receive the live video. In such cases, the frame rate is decrease and voice data is delayed about 1 second. Also, we evaluated the performance of our system on the LAN environment (100 Mbps) to analyze the possibility of realization of remote mental health care. We analyzed the throughput and load average for the multi-user conference. In this experiment, we use low performance computers because usual people use in general low performance computers. We used five PCs in this experiment. One PC is used as WWW conference server and four other ones are used as the WWW conference clients. The PC characteristics are shown in Table 1.

From these results, we conclude that the bandwidth of the LAN environment is enough for our system. But, the PCs should have more power to send, receive and display the live video.

The relation between the frame rate and load average at client side is shown in Table 2 and the relation between the frame rate and throughput is shown in Figure 17. We see that the load average and throughput are affected by the frame rate at client side. But, we found that the throughput is not changed more than 12 fps. This is because the PCs have not enough CPU power and the load average is close to 100%. After that, the throughput remains the same. In this case, the frame is delayed and the load average becomes high.

The relation between the frame size and load average at client side is shown in Table 3 and the relation between the frame size and throughput is shown in Figure 18. We see that the load average is affected by the frame size at client side. But, we found that the throughput is not affected by frame size.

The relation between the number of clients and load average at client side is shown in Table 4 and the relation between the number of clients and throughput is shown in Figure 19. We see that the load average and throughput are affected by the number of clients. Especially, the data sent from the server are affected by the number of clients because each client needs to receive all of live videos except for the own live video. But, the data sent from the client remain the same.

Comparison of Proposed and Conventional Systems

In Table 5 we compare our proposed system with conventional systems considering network environment, implemented platform, hardware/software, installation and setup, and communication service.

Some of conventional systems can be used not only in LAN environment/leased line, but also in Internet environment. However, these systems don't run in the multi-platform OSs. Using these systems, each user needs to install and setup the special hardware or software. In some of them is needed only the setup, but each user needs to make installation of special hardware or software. Furthermore, there are few systems, which can be used for point to point, multi-point to multi-point, and broadcast communication.

Table 1. PCs characteristics for performance evaluation

	CPU	Memory	OS
Server	Pentium4 (1.6GHz)	1G	WindowsXP
Client 1	Pentium3 (450MHz)	128M	Windows2000
Client 2	Pentium3 (667MHz)	128M	WindowsXP
Client 3	Pentium3 (664MHz)	128M	Windows2000
Client 4	Celeron (700MHz)	192M	WindowsXP

Figure 16. Evaluation environment

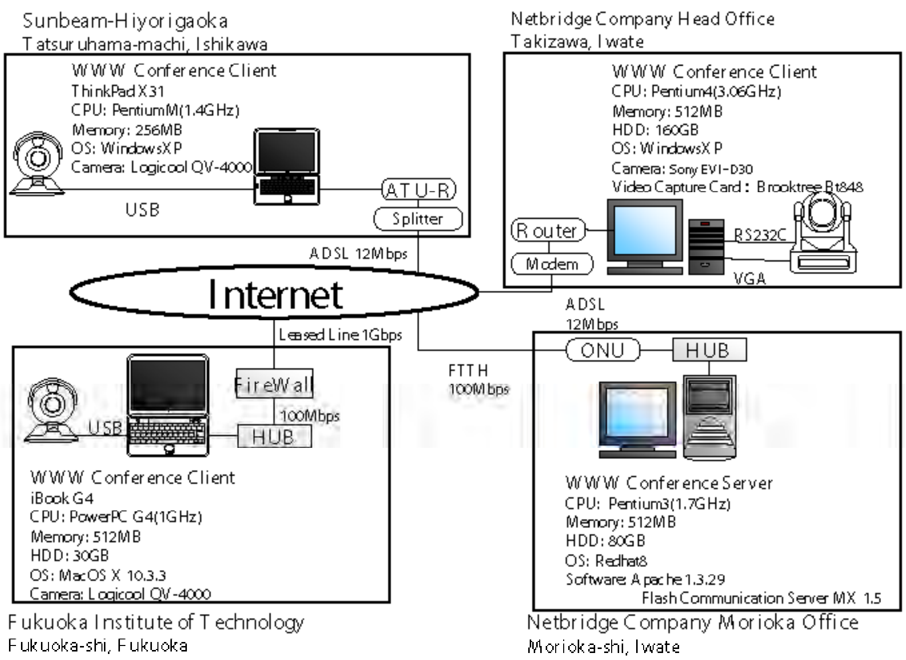

Figure 17. Relation between frame rate and throughput

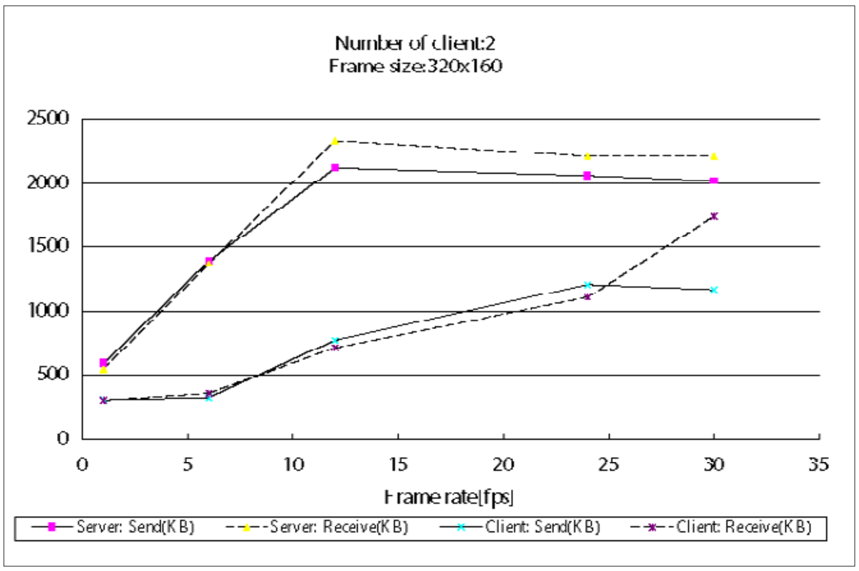

While, our proposed system can be used in real Internet environment, and Windows, Macintosh and Linux OSs. In order to use our system, the user needs only to access the WWW conference server by using the WWW browser. After that, the system is installed and set up automatically. Also, the proposed system supports point to point, multi-point to multi-point and broadcast communication.

Table 2. Relation between frame rate and load average

Frame Rate	1	6	12	24	30
Load Average	40	69	87	93	94

Frame Size	160x120	320x240	640x480
Load Average	30	69	92

Figure 18. Relation between frame size and throughput

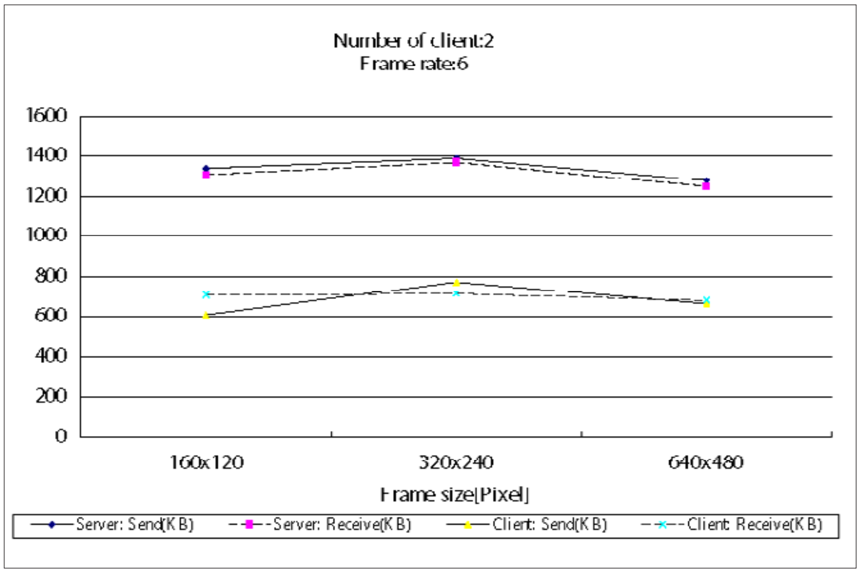

Table 4. Relation between number of clients and load average

Number of Clients	2	3	4
Load Average	69	76	87

CONCLUSION

In this article, we proposed a WWW conference system for supporting remote mental health care education. We showed the conference types and connection management methods for realizing each type of conference. We presented the WWW conference operation. Finally, we discussed the implementation and evaluation of our proposed system. From experimental results, we conclude as the follows:

1. The proposed system can provide the same communication between Fukuoka, Ishikawa, Iwate prefectures over the Internet.
2. The WWW conference client can send and receive the live videos for four users in the LAN environment.
3. The WWW conference client needs a high CPU power to send, receive, and display the live video.

Now, we are evaluating the proposed system for different kind of networks and number of hops. In the future, we would like to use the proposed system for mental health care education and counseling.

Chapter 4.7
ICT in Medical Education in Trinidad and Tobago

Marilyn Lewis
The University of the West Indies, Trinidad and Tobago

INTRODUCTION AND BACKGROUND

Information and communication technology (ICT) allows users to access information without taking geographic position into account. These users are also unconstrained by time, volume, or format of the information. ICT applications have enormous potential as a tool for aiding development in countries such as Trinidad and Tobago. Telemedicine, which can provide medical services to persons in isolated places, in emergencies, to the homebound, or the physically challenged, is but one example. Mansell and Wehn de Montalvo (1998) noted that "ICT applications facilitate telemedicine" (p. 85), and that "economic development can be fostered by tele-working and tele-services in some developing countries" (p. 83).

The twin-island nation of Trinidad and Tobago lies at the southern end of the Caribbean chain of islands, approximately seven miles off the northeast coast of Venezuela. The area covers 1,864 square miles (5,128 sq. km.), with a population of approximately 1.5 million. The economy of this small nation state is based mainly on petroleum and gas-based industries, but there is a growing service sector. PAHO figures (2002a, b) show a highly literate population with an overall adult literacy rate of 98.5% (males at 99.1% and females at 97.9%).

Transshipment and telecommunications facilities contribute to this country's position as the most industrialized in the Caribbean. The country's technical capacity and access to information have grown enormously in recent years. Telecommunication tools extend to the vast majority of the population. Per capita GDP stands at US$8,500.

There is a shortage of medical staff in general, with the ratio of doctors to inhabitants at 7.5 per 10,000. Shortages in primary health care are more acute than in other areas and have resulted in the employment of retired nurses and the recruitment of professional staff from other countries, particularly from Nigeria, India, and more recently, from Cuba. Trinidad and Tobago therefore stands poised to benefit from further development by fully embracing ICT, especially in the areas of education and medicine.

MEDICAL EDUCATION IN TRINIDAD AND TOBAGO

Medical education in Trinidad and Tobago engenders self-directed, lifelong learning through the use of the problem-based learning (PBL) method of teaching. The Faculty of Medical Sciences (FMS) of the University of the West Indies opened in St. Augustine, Trinidad and Tobago, in 1989, and has utilized PBL from its inception. Students' relative independence has been noted (Donner & Bickley, 1993) in students following PBL programs. Donner and Bickley noted that "they differ markedly from those following traditional medical programmes… [becoming] more skilled at an eclectic style of learning" (p. 297). These students show particular personal characteristics that encourage them to take a proactive role in their own learning, making them lifelong learners.

Research has also shown that PBL students make maximum use of library resources and that librarians taught the use of technology as a means of accessing, organizing, and managing information (Marshall, 1993). Library instruction is therefore a required part of the curriculum. Librarians become not just providers of books and other materials but also instructors in the use of modern technology. The library, therefore, prepares medical students for wider use of other applications and technologies to support their future information needs. This has implications for how these students will operate when faced with adverse conditions such as rural health offices and hospitals with limited resources, and for development in the community generally; these students in their homes, in their practices, and in the wider community will generate a multiplier effect.

INSTRUCTIONS IN THE USE OF MODERN TECHNOLOGIES IN THE MSL

From its inception, the Medical Sciences Library (MSL) has embarked on a program of information literacy for undergraduates and other categories of users. From as early as 1993, topics such as "MEDLINE: basic and advanced"; "International Pharmaceutical Abstracts (IPA)"; "MedCarib—health literature for the Caribbean"; "ProCite"; "Introduction to Computers"; and later, "EPI Info"; "Introduction to the Internet" and "PubMed" have been taught. In facilitating this training, the library equips its clientele with survival skills for the 21st century.

The Trinidad and Tobago Ministry of Health also recognized a need for retraining, because new demands were being placed on practitioners by health care transition, health care reforms, increased public and patient expectations, and advances in medical sciences and technology. The Ministry found that medical practitioners required additional skills. This was part of the rationale for the introduction in 2000 of a new postgraduate diploma in Primary Care and Family Medicine being offered by dual mode, face-to face initially, and thereafter, through distance education.

The library component of this course focused on skills such as "Locating and evaluating health information"; "Skills base for managing health information resources"; "Innovations in health information practice"; "Effective search and retrieval principles"; "MEDLINE on the Internet"; "Finding biomedical information on the Internet"; "Evaluating information resources"; and "Managing bibliographic references". Assessment tasks included:

- Joining and leaving an electronic discussion group

- Subscribing and unsubscribing to a mailing list
- Posting to a discussion group
- Locating an electronic serial and printing an article or abstract
- Executing a search on MEDLINE or PubMed and printing the results
- Creating a small database and generating a bibliography

Each session represented distinct skills requirements and supported the utilization of applications to manage the efficient exchange of information among health professionals.

ICT IN EDUCATION: PRIMARY, SECONDARY, AND TERTIARY

Primary and secondary schools in Trinidad and Tobago are also embracing the technology. Many secondary schools have computer science as a subject on the curriculum and typically have computer laboratories. More than 35% of the 78 primary and 120 secondary schools listed in the telephone directory for 2003–2004 have computers with Internet access facilitated by Telecommunication Services of Trinidad and Tobago (TSTT), the only telephone company on the twin islands. Additionally, there are 22 Internet cafes listed in the yellow pages of this directory. Some of these Internet cafes are located in rural areas such as Enterprise, in Central Trinidad, and Penal in the south of the island. Eighteen Internet Service Providers are listed as well.

Other initiatives to produce a computer literate society in Trinidad and Tobago include the government making computer loans available to all public servants. In 2002, the government also launched an initiative, the National Information and Communications Technology Plan (2004), that aims "to connect people, communities, business, government and educational institutions through an integrated technology network. It will also examine the policy, financial and skills development requirements that will be necessary to ensure sustainability and to ensure that the benefits of connectivity continue to grow, and accelerate, as new technologies, innovation and thinking emerge."

A survey (NIHERST, 2002) designed to provide empirical data on the penetration of ICT in private households reflects the varying penetration of ICT in private homes of varying socioeconomic status. Data were collected from a representative sample of 2,812 households throughout Trinidad and Tobago. Thirteen percent (13%) of the households in Trinidad and Tobago (approximately 44,600 households based on national statistics for 2000) had a home computer as of June 2001. By comparison, more than 30% of the households in a number of Organisation for Economic Co-operation and Development (OECD) countries were equipped with computers in 1997, and more than half (54%) of the households in Australia had computers in May 2000. Other important findings of the survey were that affordability was the major constraint in 56% of all households without computers; ranging from 43.9% in the City of Port of Spain to 78% in the Borough of Point Fortin. Also, 53% of households purchased computers from private savings; 13% accessed government loans. Households (20%) with gross monthly incomes of $6,000–$7,999 had the largest proportion of home computers, followed by 15% of households with incomes of $4,000–$5,999. Only 5% of households with monthly incomes of less than $2,000 had computers. In 2000, 27% of the computers were acquired compared with 6.7% in 1997. Almost three out of four persons (73%) in each household used the computer. The proportion of male (51%) to female (49%) computer users was generally similar. Approximately 16.6% of computer users were between 15 and 19 years of age, 16.3% between 30 and 39 years and 14.5% between 40 and 49 years. Of computer users, 50% had acquired secondary level education, and only 3.8% had a university level education in computer studies. Approximately 50% of computer users were employed and self-employed, and 39% were students. In private enterprises, 59.8% of employees used the computer compared with 29.7% in government. Windows 98 and 95 were the main operating systems in 74.4% of households. Most households (70.8%) used the computer daily between two and five or more hours. Only 11.8% of households were engaged in software development, and 20.2% accessed distance learning/education compared with other activities such as games (78.4%), Microsoft Office (66%), e-mail (62.4%), and Web searches (61.5%).

Apart from the Faculty of Medical Sciences, the university as a whole is also involved in programs to implement ICT applications. The UWI, St. Augustine, in its latest strategic plan (2003–2007) identified student-centeredness as one of its strategic objectives. The campus libraries, of which the MSL is a branch, determined that promoting the use of ICT in delivery of service and products was one way of meeting this objective. Additionally, an increasingly complex print and digital environment was emerging, and people began to expect certain services without coming to the library. Facilitated by the technology, the libraries were able to accomplish one of their main missions by launching a valuable new campus-wide online course, "Foundations of Information Literacy" on March 2, 2004. It is a modular course covering the following seven topics:

1. Basic computer literacy
2. Basic research skills
3. Using the OPAC (online public access catalogue)
4. The Internet as a research tool
5. West Indiana and Special Collections
6. Online databases
7. Managing references

There were tutorials on how to use each of the databases to which the libraries subscribe, as well as a quiz and online feedback, discussion board, and on-campus WebCT server.

In its quest to keep abreast of technology, the St. Augustine campus libraries is looking at further ways to implement applications in ICT in its ongoing program of work. Initiatives such as a digital reference service are also being considered. This project aims to answer students' reference queries in real time and will enable persons needing live human assistance while using the Web to immediately get the help they need from librarians who can quickly provide the answers. Speed and responsiveness are critical to this initiative, which will radically change the way we serve and support our clientele.

A TOOL FOR COMMUNITY DEVELOPMENT

Based on our epidemiological circumstances, where the Caribbean is second only to Southern Africa in the proliferation of HIV/AIDS and other STDs, ICT can indeed be seen as an effective tool for development. The toll of HIV/AIDS is heaviest on young persons between the ages of 18 and 45, who form the majority of the workforce. CAREC figures indicate that in Trinidad and Tobago, 5,000 persons have died of AIDS since 1985. The nature of the response to these diseases has to do with preventive education, capacity building, and treatment, care, and support.

ICT can play a role in the way people connect with information. Through ICT, people in remote areas can have access to the same information as many of the people in developed countries. With an infusion of ICT learning, people in underdeveloped countries such as Trinidad and Tobago can access and share critical health information that can help in the fight against HIV and AIDS, and its related morbidity and mortality. Ideally, health education should begin in primary schools. When this occurs, the transformative nature of ICT on the epidemiological status of affected countries can become visible.

CONCLUSION

The type of medical education available in Trinidad and Tobago, the campus libraries' program of instruction in the use of ICT, the government's initiatives to make computers available to public servants, the provision of computers in primary and secondary schools, the burgeoning economy, and the developing infrastructure all signal that this country is capable of embracing fully ICT applications that can enhance community development. Additionally, the postgraduate course has been viewed as an investment in the health care of Trinidad and Tobago nationals, in terms of an enhanced quality of health care that will be rendered by the practitioners involved. Healthy individuals contribute to a more productive economy. The course is ongoing, therefore, there will need to be an increment to those receiving training, as well as those receiving enhanced care. Three further cycles of the postgraduate course have been held, resulting in at least 60 primary care physicians who have already been exposed to and benefited from the postgraduate training provided by the MSL.

By teaching the core competencies of information literacy, identifying the information needs, accessing information, and understanding the legal and other issues in the use of information, the St. Augustine campus libraries aim first to increase the competitiveness of the student. However, not only have the libraries supported the academic enterprise, but they have also made available resources for knowledge creation and capacity building. At the Medical Sciences Library, we assisted in the retraining of primary care physicians to make them comfortable with the new technologies. This has resulted in more effective, efficient high-quality health care for the national community and has contributed to development.

Today's information consumer wants seamless access whenever and wherever they want it. They are comfortable with Web-based information. In this complex and rapidly changing, increasingly interconnected environment, ICT can be an effective tool for community development.

KEY TERMS

Digital Reference Service: A human-mediated, Internet-based service in which users' queries are answered in real time.

Discussion Group: Any system that supports group messaging, e.g., a shared mailbox, Usenet, bulletin board system, or possibly a mailing list, used to publish messages on some particular topic (FOLDOC, 2004).

Information Communications Technology (ICT): The study of the technology used to handle information and aid communication. The phrase was coined by Stevenson in his 1997 report to the UK government and promoted by the new National Curriculum documents for the UK in 2000 (FOLDOC, 2004).

Listserv: An automatic mailing list server, initially written to run under IBM's VM operating system by Eric Thomas. Listserv is a user name on some computers on BITNET/EARN which processes e-mail requests for addition to or deletion from mailing lists. Examples are listserv@ucsd.edu, listserver@nysernet.org. Some listservs provide other facilities such as retrieving files from archives and searching databases. Full details of available services can usually be obtained by sending a message with the word HELP in the subject and body to the listserv address. Eric Thomas has recently formed an international corporation, L-Soft, and has ported Listserv to a number of other platforms including Unix. Listserv has simultaneously been enhanced to use both the Internet and BITNET. Two other major mailing list processors, both of which run under Unix, are Majordomo, a freeware system, and Listproc, currently owned and developed by BITNET (FOLDOC, 2004).

MedCarib: A database of the health literature of the Caribbean.

MEDLINE: A CD-ROM database of medical literature in journals produced by the National Library of Medicine, United States.

Problem-Based Learning (PBL): A concept in which students focus from the beginning of their course on a series of real professional issues, where the knowledge of the various academic disciplines that relate to these issues is integrated.

PubMed: An online database of over 14 million citations of biomedical articles from 1950 to the present time. This database is available free over the Internet.

WebCT: Software that provides electronic learning in a flexible integrated environment.

Chapter 4.8
Telehealth Organizational Implementation Guideline Issues:
A Canadian Perspective

Maryann Yeo
University of Calgary, Canada

Penny A. Jennett
University of Calgary, Canada

ABSTRACT

The current status of policies, guidelines and standards related to the organizational context of clinical telehealth practice were investigated. The directions these should take to meet the healthcare needs of Canadians also were outlined. An environmental scan approach was employed, consisting of a literature review, stakeholder survey questionnaire, and 12 key informant interviews. The literature review resulted in 260 sources related to organizational leadership issues, of which 176 were abstracted. The stakeholder survey questionnaire response rate was 64% (156/245), with 55% (84/154) completing the organizational context section. All (100%) key informants who were selected for interviews participated. Findings were categorized into four key organizational themes: organizational readiness, quality assurance, accountability, and continuity. Organizations need to review existing policies, standards, and guidelines in order to determine whether telehealth is covered and, if not, revise them or develop new telehealth-specific policies. Telehealth policies and procedures should be integrated with those in existence for face-to-face services.

INTRODUCTION

In Canada, there are 14 health jurisdictions; all are engaged in deploying telehealth applications. Telehealth, as defined in this project, is "the use of information and communications technology to deliver health and healthcare services and information over large and small distances" (Picot, 1998). Clinical telehealth applications are now operational in tertiary and community healthcare settings. As the number of telehealth projects, programs, and services has increased steadily, greater attention is being focused on policy and quality issues related to the delivery of telehealth services. There is increasing interest among healthcare professionals and administrators, healthcare institutions, organizations, businesses, government agencies, and regulatory bodies to develop and adopt policies, procedures, guidelines, and standards for use within provinces across Canada.

The National Initiative for Telehealth Guidelines (NIFTE) was established in order to develop consensus on a national, interdisciplinary framework of guidelines for use by health-sector organizations (National Initiative for Telehealth Guidelines, 2003). The guidelines were designed by telehealth providers for use by health professionals in developing their specific standards and as benchmarks for standards of service and by accrediting agencies in developing accreditation criteria. A major activity of the project was an Environmental Scan designed to examine four content areas related to telehealth: Organizational Context, Technology and Equipment, Clinical Standards and Outcomes, and Human Resources (National Initiative for Telehealth Guidelines Research Consortium, 2003).

The organizational context team investigated the status of policies, guidelines, and standards as they related to the organizational or administrative context of clinical telehealth practice in Canada. In addition, this component also explored the directions that telehealth administrative policies, guidelines, and standards should take in order to meet the healthcare needs of Canadians. The purpose of this article is to synthesize the findings of the environmental scan and to summarize the organizational issues and recommendations related to clinical telehealth implementation within organizations.

LITERATURE REVIEW

There is a recognized need for national standards for healthcare professionals and guidelines for the accreditation of healthcare organizations and facilities that provide telehealth services. This lack of standards and guidelines has been considered to be a barrier to the successful integration of telehealth into healthcare facilities. Standards are requirements that an organization must meet in order to earn accreditation and are important, because they provide a benchmark for measuring quality. At present, there are no existing Canadian telehealth accreditation standards. A variety of policies and guidelines were found in the literature review. Although many published papers, reports, and documents were reviewed, few provided insight into organizational policies, standards, or guidelines with respect to the provision of telehealth services nationally or internationally. The majority of the documents reviewed on the subject of organizational policies, guidelines, and standards for telehealth and telemedicine tended to focus on technical aspects. Standards need to be established for the administrative management of telehealth services. In addition, national standards need to be established for the management of privacy, confidentiality, and security, as well as for the documentation of policies and procedures.

The Advisory Committee on Health Infostructure (2001) asserted that several ingredients must be in place if the national health infostructure is to be implemented in an effective manner, including strong leadership; a clear and comprehensive strategy and detailed plan; and a common understanding of federal, provincial, and territorial initiatives. Jennett and Andruchuk (2001) stated that the successful implementation of telehealth services in Canada depends on several key factors: (1) the readiness of the environment; (2) systematic needs analyses, strategic business plans, and diverse, collaborative partnerships; (3) adequate equipment and IT vendors; (4) staged implementation; and (5) evaluation. Jennett and Siedlecki (2001), in a paper looking at the issue of policy development in telehealth, concluded the following:

The success of the telehealth venture is contingent on the development of policy to support and enable the use of technology in delivering quality care and equal access to stakeholders. A successful system is seamless, ubiquitous, and integrated. It supports a single point of access to stakeholders and incorporates clinical, administrative, educational, and transactional functions. The policy enabling this success ensures that privacy, confidentiality, and security are ensured; equality of appropriate access is provided; jurisdictional boundaries are not an impediment to optimal care; cultural diversity and human dignity are respected; stakeholder needs are met; and the telehealth service is timely, cost-effective, and patient-centered.(Jennett & Siedlecki, 2001, p.57–58)

There is a recognized need to develop telehealth policies, guidelines, and standards, but few policies, guidelines, or standards actually were found to exist in practice within Canada. Those policies, guidelines, and standards that do exist are specific to a particular organization, program, or project and are not integrated.

RESEARCH METHODOLOGY

An environmental scan approach was used to address the following research questions: (1) What is the status of policies, guidelines, and standards as they relate to the organizational or administrative context of clinical telehealth practice in Canada? (2) What direction should telehealth administrative policies, guidelines, and standards take to meet the healthcare needs of Canadians? As illustrated in Figure 1, the organizational context environmental scan framework methods included a literature review, stakeholder survey questionnaire, and key informant interviews.

Literature Review

The purpose of the literature review was to (1) identify key issues that need to be explored in the stakeholder survey, specific to the organizational context; (2) help to formulate the survey questions. The literature search was limited to English only, with an emphasis on Canada. The search of articles explicitly dealing with the organizational context (and similar keywords) of telehealth and policy issues, such as standards, guidelines, and protocols, resulted in 260 papers and documents being obtained and reviewed. Of these, 176 references met the review criteria (dealing with organizational context of telehealth and policy issues, such as standards, guidelines, and protocols) and were abstracted. The number of articles explicitly dealing with the organizational context of telehealth and policy issues was minimal. The majority of the literature obtained was related to the topics of organizational readiness, accountability, quality assurance, and continuity within the context of telehealth and/or health technology.

Stakeholder Survey Questionnaire

A mailed survey questionnaire was used to collect the more structured and quantitative information about the organizational context from telehealth stakeholders. Questions were asked about readiness for telehealth, leadership of telehealth programs, quality assurance, policies, processes, accessibility, and coordination of services. The semi-structured questionnaire was developed specifically for the environmental scan survey, using the knowledge gained from the literature review. Face and content validity were established by pilot testing the questionnaire with a sample of nine stakeholders that were representative of telehealth practice in Canada.

A total of 245 questionnaires were mailed to all the individuals listed in the Telehealth Stakeholder Database, a mailing list of individuals and organizations compiled and maintained by a Canadian Secretariat. To facilitate a quality response rate, an e-mail reminder (two weeks after initial mailing) and a second questionnaire mailing (two weeks after the e-mail reminder) were employed. Questionnaires were coded so that the second mailing could be targeted to non-responders. Of the 156 (64%) returned questionnaires, 84 (55%) completed the organizational leadership section of the survey. These 84 were coded and analyzed. Descriptive statistics were calculated using SPSS (Statistical Program for the Social Sciences) Version 11.0. The respondents' open-ended survey responses were transcribed and content analyzed by the research team. The largest portion (36%) of respondents completing the organizational leadership section were nurses (n=30), while administrators (n=18) accounted for 21%, physicians (n=11) accounted for 13%, allied healthcare professionals (n=6) accounted for 9%, and other professions (n=18) accounted for 21%.

Key Informant Interviews

The specific objectives of the 12 key informant interviews were to determine directions that telehealth polices, guidelines, and standards should take, and how they should evolve in order to meet the healthcare needs of Canadians. Organizational key informants were defined as individuals who frequently used telehealth (delivering or receiving telehealth services) within an organization in order to provide care or information related to care and who held management or administrative leadership positions within their organizations. The organizational key informants were selected by the researchers from individuals listed in the Telehealth Stakeholder Database to be representative of organizations offering clinical telehealth services across all Canadian provinces and territories. All (100%) key informants selected for interviews participated. Six physicians, three nurses, two administrators, and one psychologist participated in the interviews.

Semi-structured, open-ended questions were developed and asked during a telephone interview. The interviews were tape recorded with key informants' consents. The key informants were asked to provide their thoughts and opinions about what key organizational factors should be in place for the successful implementation of clinical telehealth services. The tape-recorded interviews were transcribed. The transcriptions and handwritten notes were summarized and analyzed independently by two researchers. Analysis was a multi-step process involving each researcher independently reviewing the transcriptions; becoming familiar with the content; and extracting significant comments, themes, phrases, or ideas. The researchers then met and discussed the independently reviewed transcripts in order to reach consensus on the common themes, phrases, or ideas.

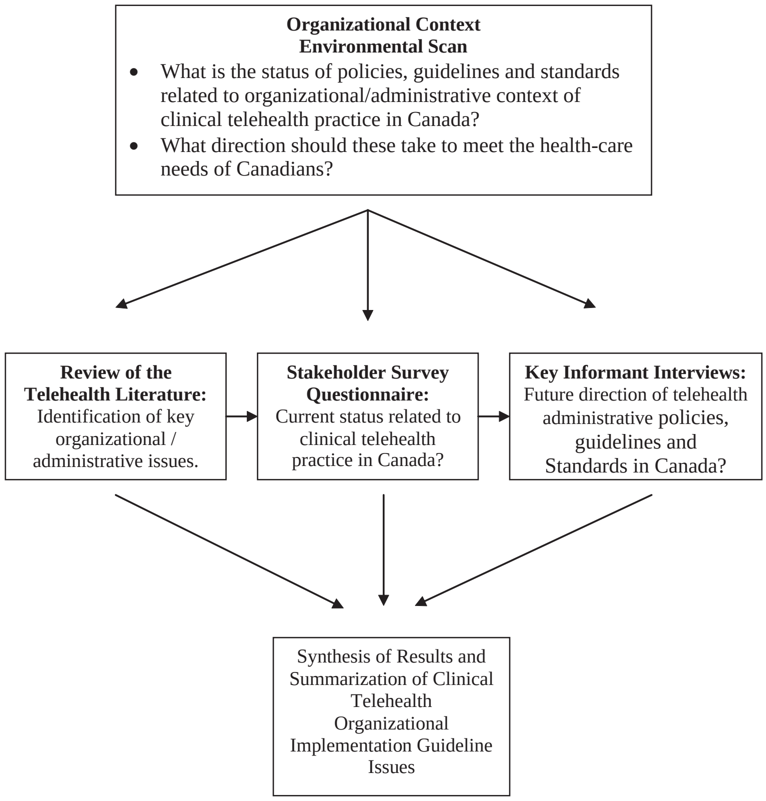
RESULTS

The following summaries synthesize and describe the four key organizational themes identified during the environmental scan: Organizational Telehealth Readiness, Accountability, Quality Assurance, and Continuity.

Organizational Telehealth Readiness

The need to systematically assess an organization's readiness to use telehealth technology was identified. Overall, the survey findings and key informants' responses support the literature, stressing the importance of organizational readiness in ensuring the long-term success of telehealth programs and services. Organizational readiness

Figure 1. Organizational context environmental scan framework



for telehealth is a multi-faceted concept consisting of planning, workplace environment, healthcare systems, and technical readiness.

Planning Readiness

An important component of an organization's telehealth readiness is planning readiness (Advisory Committee on Health Infostructure, 2001; Jennett & Andruchuk, 2001). Planning readiness involves organizations being able to demonstrate that the organizational leadership has completed required upfront work in terms of planning for the implementation and sustainability of telehealth (Alliance for Building Capacity, 2002). Planning readiness includes (1) a telehealth strategic plan, including a needs assessment and analysis, business plan, marketing plan (internal and external), communication plan, and evaluation plan; and (2) leadership, including program champions and collaborative partnerships. The dynamics of the planning process and order in which the steps in the planning process are conducted are very important. A phased approach to implementing the strategic plan was identified as important by the key informants.

A needs assessment and analysis was identified as an important factor in the successful implementation of telehealth. The majority (73%) of survey respondents reported that their healthcare organization or facility had conducted a needs assessment for its telehealth services. All 12 key informants (100%) noted that a needs analysis is a critical component of a healthcare organization's telehealth readiness and that there are several components to a needs analysis, including an assessment of community readiness and provider readiness. The rapidly changing status of telehealth services suggests that an almost ongoing approach to needs assessment should be in place. Organizational policies and guidelines should reflect this unique aspect of telehealth. A strategic business plan is an important component of organizational telehealth readiness. Indeed, the majority (83%) of survey respondents reported that their telehealth services were part of their organizational business plan, or that the business plan was in development. These findings are an indication that telehealth services are becoming recognized as a part of routine healthcare services. A telehealth strategic business plan needs to take into account research and evaluation of telehealth as an innovation. Given the rapidly changing nature of telehealth, the needs assessment and business plan must remain open to change and revision on a regular basis. Two subthemes—cost-benefit/cost effectiveness and financial readiness for sustainability—were identified. An indicator of sustainable funding would be that new investment dollars are put forth by the organization in order to address service gaps that use telehealth.

The survey findings indicated that the marketing of telehealth services is in an evolving phase. Only three of the 84 respondents reported that their organizations had a marketing plan in place or in development. Healthcare organizations currently are marketing primarily internally among healthcare providers within their institution or region or to their partners rather than to external audiences. A need was recognized for an open communication plan and for all stakeholders to be kept informed during the planning and implementation stages. It was felt to be critical for achieving buy-in and support for the planned programs, facilitating the change process, and team building. Since telehealth involves communication between organizations, a good working relationship between them is needed, as well as a sense that the receiving organization is a trusted authority.

Leadership Readiness

One of the key informants used the term *leadership readiness* to refer to the need to have program champions and collaborative partnerships in place and informed prior to beginning a telehealth program (Ash, 1997). Survey respondents (36%) indicated that there is a move toward the involvement of multiple advocates in senior positions or telehealth committees. Different types and levels of program champions and/or primary advocates are needed, based on their ability to influence. Within organizations, two types are needed: a clinical or provider champion and a senior-level administrative champion. At the community level, someone from within the community is required to promote what telehealth can provide (Alliance for Building Capacity, 2002). Senior management support is critical for the success and sustainability of telehealth services in healthcare organizations. All 12 key informants (100%) indicated that collaborative partnerships are an important component of organizational readiness. These partnerships should be in place before beginning and should include a variety of partnerships with different groups. The types of partnerships developed depend on the scope and application of the telehealth services. Partnerships need to be revised over time. Collaborative partnerships demonstrate that an organization has the ability to partner.

Workplace Environment Readiness

Findings also noted that organizations need to take into account the impact that telehealth services have on the workplace environment and work routines (Aas, 1999). The workplace environment should be ready to implement telehealth services (Aas, 2001). The identified components of workplace environment readiness include awareness of legislation; professional, and regulatory requirements; structural readiness; administrative support for telehealth; along with change management, human resources, healthcare system, and technical readiness. Healthcare organizations ready to use telehealth technology are aware of all legislation and professional regulations that may impact the delivery of telehealth services (e.g., health information protection laws that mandate policies and procedures to be in place in order to protect the privacy and confidentiality of sensitive information) as well as regulatory specific policies to determine telehealth coverage.

The workplace environment must be ready for the required telehealth technology and equipment (Kaplan, 1997). An organization with structure, capacity, means, and resources to implement telehealth is required because of the large amount of coordination needed to deliver and to receive requests for services. The workplace setting should have telehealth equipment in locations where it is convenient for providers and where it can facilitate the delivery of patient care (i.e., structural readiness). Support needs to be established for clinical decision making, functioning, and the process of using the telehealth system. These administrative support policies and procedures include mechanisms for the transfer of patients; a standardized, well-defined, easy-to use referral system; a standard and consistent method of recordkeeping at both the receiving and referring sites; and definitions for who gets privileges to use telehealth both at the receiving and referring sites. The introduction of telehealth services into an organization is often disruptive to the work environment (Aas, 1999; Ash, 1997). Readiness also means that the organization's leadership understands this impact and has a change management plan in place (Garside, 1998; Southon, Sauer & Dampney, 1997).

Human Resources Readiness

Human resources readiness involves having adequate and dedicated human resources in order to implement the strategic plan. Clarification of roles and responsibilities provides the required policies and procedures that are related to user characteristics, such as training and specialty. Six key informants (50%) stressed that an organization that is ready to use telehealth technology would have an education or learning plan in place for those individuals who provide care via telehealth.

Healthcare System Readiness

Healthcare system readiness for telehealth involves the healthcare system being ready in terms of providing strategic support and expertise and having policies, guidelines, and procedures in place at provincial/territorial and/or national ministry levels related to the required infrastructures, funding, remuneration, support for innovation, and diffusion processes (Olsson & Calltorp. 1998-1999).

Technical Readiness

Four key informants (33%) stated that the technical requirements and feasibility of providing telehealth services were essential components of organizational readiness with respect to such things as network and local site technical readiness and interoperability, technical feasibility, bandwidth, verification of fidelity of data transmission, and procedures to make sure that it is checked regularly. Technical support must be in place. Two key informants (17%) representing rural and remote telehealth services stressed that the technology support aspect of telehealth equipment requires consideration, particularly related to the maintaining of equipment in communities that do not have easy access to technology support services.

Quality Assurance

The literature review indicated a need to determine whether or not telehealth does improve the quality and accessibility of care (Jennett, Gao, Hebert & Hailey, 2000; Kangarloo, Dionisio, Sinha, Johnson, & Taira, 1999; Office of Health and the Information Highway, 2000; Yawn, 2000). All 12 key informants (100%) and survey respondents reported that telehealth quality assurance is important. Nearly all respondents (83%) indicated that their organizations were collecting some data or had such activities in development. Telehealth services evaluation is evolving; however, there is still a lack of sophistication in data collection. Evaluation of telehealth services currently focuses on the collection of system utilization, technical performance data, patient/client satisfaction, and provider satisfaction data. The more challenging areas related to the provision of telehealth services, such as access to care/services (Jennett, Person, Watson, & Watanabe, 2000), patient/client outcomes, cost-benefit/cost effectiveness, the impact on workflow, team relationships, provider roles, and responsibilities need to be evaluated more frequently. In addition, all aspects of the telehealth encounter should be evaluated, including a patient's physical and psychological comfort, technical quality of the service, quality of communication between caregivers and patients, duration of the consultation, timeliness of the care delivery, degree of confidentiality, and the costs (Hailey & Jennett, 2004; Sisk & Sanders, 1998). Informed, evidence-based evaluation of quality of care and cost effectiveness is still mainly in an early stage. However, the need to have baseline data to show that quality of care and patient safety are at least equal to face-to-face encounters is becoming recognized. The collection of both qualitative and quantitative data to evaluate telehealth services is needed (Lee, 1997). Four key informants (33%) indicated that telehealth services should be evaluated in a continuous and ongoing process. All key informants (100%) expressed that regular review of telehealth services should be part of an organization's overall evaluation process. It was suggested that they be done quarterly for the first year and then semi-annually.

The survey findings indicated that a wide range of organization or program-specific indicators and measures are being used to evaluate telehealth services. Standardization of data collection tools, common measures, and key indicators for telehealth applications are needed. Key performance indicators for telehealth should be defined in order to ensure consistency in how they are monitored, reported, and evaluated. Four key informants (33%) responded that standardized quality indicators, defined at both the program level and the organizational level, are needed related to system utilization, patient and provider satisfaction, and technical performance.

At the organizational level, a condition of accountability is the requirement of monitoring what is occurring through the development of an ongoing evaluation plan. Part of this accountability for quality assurance involves organizations having mechanisms in place in order to make the necessary adjustments to services, based on evaluation results.

Accountability

For each accountability issue, strengths and areas for improvement were identified. Key informants indicated that strengths can be demonstrated by the policies and procedures that organizations have in place and by the accountability mechanisms and structures present to address key requirements. Eight topics were identified: governance framework; privacy, confidentiality, security, and ethics; cultural awareness; document and storage of patient/client telehealth records; liability and risk management; licensure; cross-jurisdictional services and other liability issues; and remuneration/reimbursement.

Governance Framework

Organizations need to develop a governance framework that focuses on the roles and responsibilities of all individuals involved in telehealth activities (Industry Canada, 2001). Two issues related to the governance structure of the organization were identified:

1. Where telehealth is positioned in the organizational structure as well as the lines of accountability for telehealth services were reported to be important by both key informants and survey respondents. The person to whom telehealth is accountable should be at a high senior administrative level and positioned in the organization to make a strategic impact.
2. Administrative processes should be in place in order to support the governance structures and to help those individuals responsible for telehealth to assume accountability. Telehealth services ultimately should be accountable to a board or some other body that would provide governance with the appropriate administrative steps to support that structure: technical, personnel, supervisory, and managerial. To whom and for what telehealth is accountable needs to be defined and documented in writing. There are three levels of accountability: the health system itself, including health regions; the organization (administrative and clinical accountability); and the Privacy Commission (consent, confidentiality, and privacy).

Privacy, Confidentiality, Security, and Ethics

The literature indicated that privacy, confidentiality, and security must be considered when implementing telehealth services (Committee on Maintaining Privacy and Security in Health Care Applications of the National Information Infrastructure, 1997; Privacy Working Group, 2000). The practice of telehealth does not appear to raise any new policy issues regarding confidentiality. Traditional confidentiality policies should be applied in this new context with consideration for the specific technical issues involved in applying these polices for telehealth applications. In 2001, COACH, Canada's Health Informatics Association, published Guidelines for the Protection of Health Information (Canada's Health Informatics Association, 1997) as a framework to assist health organizations in the development and implementation of comprehensive privacy and security programs.

Protection of privacy requires organizational-level policies (Committee on Maintaining Privacy and Security in Health Care Applications of the National Information Infrastructure, 1997; Privacy Working Group, 2000). Most organizations have corporate privacy policies, and thus, 70% of questionnaire respondents and all key informants (100%) felt that a separate privacy policy specific to telehealth was not needed. However, existing privacy policies will have to accommodate the crossing of organizational and facility boundaries and the sharing of highly personal information. Organizational policies are required to govern who can be present during a videoconferencing session and who must declare themselves.

Confidentiality is an important issue that requires organizational-level policies around the protection of health information and the consenting process (American Medical Association, 1996; Privacy Working Group, 2000). Confidentiality is protected under the Health Information Act or similar provincial legislation, and the principles must be reflected in writing in the organization's policies (Canada's Health Informatics Association, 1997). The policies must reflect the impact of the human, organizational, and technical aspects of telehealth.

All key informants (100%) identified security as an important organizational policy issue, an area in which additional policies and standards related to telehealth were needed. Telehealth has some unique aspects that require special mention in the organization's security policies, guidelines, and procedures (Canada's Health Informatics Association, 1997). These policy and procedures issues are similar to those around electronic health records, and key informants believed that in the near future, these would be integrated. In addition, two informants (17%) stated that there should be an educational component in order to deal with the security issues related to human behavior. This was felt to be of particular importance in the remote regions of Canada due to the use of lay healthcare providers and lay telehealth coordinators.

The majority of survey respondents (65%) stated that their organizations did not have telehealth-specific codes of ethics and appeared to rely on their organizations' existing codes of ethics and/or legal guidelines. However, there are several ethical aspects related to telehealth concerning informed consent, protection of confidentiality, privacy and security, handling of confidential electronic information, and so forth that are unique to this method of delivering health services (Iserson, 2000). Respondents' suggestions on what should be included in a telehealth code of ethics support the need to review existing codes of ethics to determine if they include telehealth-specific ethical considerations. All 12 key informants and 13% of questionnaire respondents believed that the same ethical principles that apply in face-to-face care should be applied to telehealth encounters. Existing provincial/territorial policies, standards, guidelines, and procedures should be used. The issue of consent for healthcare via telehealth is one area that was identified as needing special consideration (Joint Interdisciplinary Telehealth Standards Working Group. 1998; Stanberry, 1998). Organizations should have procedures in place to have patients/clients give informed consent before they agree to the telehealth consultation. In addition, policies need to be in place that outline what information needs to be given to patients/clients for informed consent. Two key informants (17%) reported that special ethical needs must be taken into consideration in policies, standards, guidelines, and procedures when providing telehealth services to First Nations and Inuit communities in the more isolated and remote areas of Canada.

Documentation and Storage of Patient/ Client Telehealth Record

Although 56% of survey respondents reported that there was a protocol in place in their organizations or facilities for the documenting and storing of patient information for telehealth, the wide range of survey responses to the location of the patients' medical records (18% referring site; 18% consulting site; 24% copies at both sites; 12% other) indicated that there were no uniform standards that everyone could follow. Record-keeping and documentation for telehealth care was identified as another accountability issue that requires organizational policies to be in place so that what is going on can be tracked and so that two institutions can generate a record for the same patient and same encounter (Huston, 1999). With the coming age of the electronic health record, three key informants (25%) felt that standards should be developed in keeping with the total electronic communication environment.

Liability and Risk Management

The literature review indicated that there are several types of liability relating to the health professionals involved, the technology, the organization or institution, the human resources and training, and the telehealth application (Canadian Nurses Association, 2000; Saltzman, 1998). Organizations should have a written policy statement regarding whether healthcare providers need to be certified or not in order to potentially cover liability issues related to credentialing and privileging. It is recommended that established risk management policies be followed and that new telehealth-specific policies be created for anything not covered under existing policies (Switzer, 2001).

Licensure, Cross-Jurisdictional Services, and Other Liability Issues

Licensure was felt to be an important policy issue (Blum, 2000; Jacobson & Selvin, 2000). However, there was lack of agreement among the survey respondents and key informants as to whether or not it was necessary to require health professionals to be licensed in order to practice telehealth.

A number of policy issues need to be resolved with respect to the provision of cross-jurisdictional telehealth services (Pendrak & Ericson, 1996). Four key informants (33%) and 39% of survey respondents indicated that a common Canada-wide level of agreement should be in place with respect to cross-jurisdictional services. Also, policies regarding other cross-border liability issues need to be established at the national level by professional associations or regulatory bodies before healthcare organizations can put in place their organizational policies and procedures. Until national policies are developed, interim policies and agreements are required in order to address these issues.

Remuneration/Reimbursement

The issue of reimbursement, as it relates to physicians and other healthcare professionals in private practice, is unique to telehealth due to its borderless and cross-jurisdictional nature (Hogenbirk, Pong & Liboiron, 2001; Pong & Hogenbirk, 2000). All key informants (100%) felt that the development of policies in order to address reimbursement for health professionals paid on a fee-for-service basis is not an organizational-level issue and would have to be handled at the provincial level.

Continuity

Overall, the findings indicated that organizational leaders are just beginning to integrate telehealth into healthcare organizations and facilities as a service.

Integrated Telehealth Delivery Model

Organizations have to ensure that they do not develop policies and procedures that are different from existing policies and procedures for a regular visit. An integrated telehealth delivery model should be developed that positions telehealth as a strategic resource, which makes it possible to continuously improve the organization's capacity to deliver services and information across distances. One key informant indicated that a high accreditation rating should be given to an organization in which healthcare providers, during the course of the day, move easily from one medium to another as seamlessly as talking on the phone, going to a meeting, or sending an e-mail.

Administrative Interoperability

Telehealth services should be integrated into existing administrative policies, guidelines, and procedures. There are clearly the following well defined policies and guidelines that need to be in place for telehealth: technical interoperability; clinical practice, including liability; protection of privacy; freedom of information; and financial issues (Jennett & Siedlecki, 2001; Lemaire, 1998-2000). An integrated system of information and communication technologies rather than a focus on just videoconferencing is required in order to enable continuity of care, particularly in the remote areas of Canada. Scheduling of telehealth services is a unique administrative interoperability issue that requires standardization. Two key informants indicated that administrative policies should be put in place that allow all providers access to information about teleconsultations. As telehealth applications become more complex (e.g., homecare, preoperative care at a distance, regionalization of health facilities), some central coordination of telehealth communications will be required. A standard for coordination and linkages should be developed along with administrative structures to facilitate these standards. How do we make it work in a practical sense? How much is centralized? How much is a function of existing administrative structures, and how much needs to be new? Telehealth can provide coordination and linkages to facilitate the continuity of care without physically having to move patients. Telehealth can facilitate a different way of linking together virtually rather than physically, but the coordination has to come from the providers or organizations.

Coordination of Multiple Telehealth Services

Key informants suggested that organizations should look at how they currently deliver several services and deliver multiple telehealth services in the same manner and try as much as possible to integrate into routines that are already in place. The organization of outpatient services was proposed by one key informant as a useful model. A small-core telehealth group is needed to look after and manage the equipment and physical space. Macro-level organizational policies should be in place that are relevant to all telehealth applications (e.g., what has to happen in the event of a failure; maintenance standards; how booking is done; considerations of privacy, ethics, and informed consent). Coordination of multiple telehealth services should be the responsibility of a telehealth management committee, with site coordinators or network coordinators responsible for day-to-day operations. Setting priority criteria and guidelines for use of the services would be an administrative responsibility. The site coordinators would be coordinating the clinical services, using the developed criteria and guidelines.

Strategies and Policies to Ensure Sustainability

Business plans, regular reviews, and reliable, long-term funding strategies were identified as mechanisms around which policies and guidelines should be developed in order to ensure accountability and sustainability of telehealth services within organizations. One key informant stated that the extent to which an organization has demonstrated continuity would be evident by how much telehealth is in place. The majority of survey respondents (83%) and all 12 key informants (100%) recognized the importance of long-range business plans in terms of sustainability of telehealth services within an organization. However, they tended to believe that five years was too long of a period for a telehealth business plan to be in place, as it is difficult to do a long-range business plan with such a vibrant, growing technology. Program-related infrastructure supports need to be developed in order to ensure sustainability (e.g., bridging, scheduling, information repositories, telehealth information repositories, and directories). The budget for telehealth should be an integrated part of the complete budget, not an add-on. Long-term funding was identified by all key informants (100%) as being critical to the sustainability of telehealth services. A sustainability policy with funding to sustain it needs to be in place across Canada.

DISCUSSION AND CONCLUSION

This organizational environmental scan established that there are a number of organizational-level items that require consideration when developing policies, standards, and guidelines for telehealth services (see Table 1). These include the human, physical, and environmental infrastructures required for telehealth; organizational telehealth readiness; the business case specific to telehealth services; the governance framework for telehealth; provincial, territorial, national, and international policy-related activities; different policies, guidelines, and procedures for different types of telehealth activities; quality

Table 1. Summary of clinical telehealth organizational implementation guideline issues

Key Themes	Issues
General Organizational Issues	Concept of a Virtual Organization Integration of Telehealth Policies Telehealth-Specific Policy Issues Flexibility and Sensitivity to Innovation Multiple Types of Clinical Telehealth Applications and Technologies

Accountability	Governance Framework Privacy, Confidentiality, Security, and Ethics Documentation and Storage of Patient/ Client Telehealth Records Liability and Risk Management Licensure Cross-Jurisdictional Services Remuneration/Reimbursement
Continuity	Integrated Telehealth Delivery Model Administrative Interoperability Coordination of Multiple Telehealth Services Strategies and Policies to Ensure Sustainability

assurance, including safety and required processes and indicators; and the integration of telehealth services with existing non-telehealth services. In addition, telehealth quality assurance, accountability, and continuity policies, standards, guidelines, and procedures should be integrated as much as possible with those in existence for face-to-face services.

These findings are a demonstration of the current status of telehealth in Canada and are reflective of the organizational implementation issues related to clinical applications in 2003.

The pan-Canadian funding and jurisdictional priorities and envelopes at the time of this work focused considerable attention on telehealth readiness and evaluation. Thus, it is not surprising that the majority of the findings relate to the areas of organizational readiness and accountability. Attention had not yet been directed to telehealth clinical outcomes, quality of care, or patient safety at the time of this study. This may be why less input was provided in these areas.

Telehealth is an innovation with rapidly changing characteristics and is a new alternative way of providing services. Therefore, organizations must move beyond site-specific focus to network considerations. The recommendations arising from these findings provided the groundwork for the development of the Organizational Context sections of the NIFTE framework of guidelines (National Initiative for Telehealth Guidelines, 2003). These sections are Organizational Readiness, Overarching Organizational Leadership Issues, Accountability, Quality Assurance, and Continuity. These are now being operationalized and considered in the organizational hospital accreditation processes.

ACKNOWLEDGMENTS

The Health Telematics Unit (HTU) expresses its gratitude to the Richard Ivey Foundation for funding. The HTU researchers appreciate the collaborative insights and efforts of the NIFTE Research Consortium members, the NIFTE Secretariat, and the NIFTE Advisory and Steering Committees. Appreciation is expressed to all stakeholders who participated in the survey questionnaire and key informant interviews. The research team also would also like to thank the HTU staff, researchers and student research assistants for their work on this project.

APPENDIX A. ORGANIZATIONAL FOCUS SURVEY QUESTIONNAIRE

The questions in this section ask about your organization's or facility's readiness for telehealth, leadership for your telehealth program, quality assurance, policies, processes, accessibility, and coordination of services.

1. Did your organization/facility conduct a needs assessment for its telehealth services?
   - ❑ Yes
   - ❑ No
   - ❑ Uncertain (***Please explain***):

2. ***If yes,*** when was this needs assessment done?
   - ❑ Less than one year ago
   - ❑ Between 1 year and 2 years
   - ❑ Between 2 years and 3 years
   - ❑ Greater than 3 years ago

3. Are your telehealth services a part of your organization's overall business plan?
   - ❑ Yes
   - ❑ To be considered in the near future
   - ❑ No
   - ❑ Uncertain (***Please explain***):

4. Do your telehealth services operate on a remuneration basis (e.g., cost-recovery or fee-for-service basis)?
   - ❑ Yes — ALL
   - ❑ Yes — PARTIALLY (***Please explain***):

     What is?

     What is not?
   - ❑ No
   - ❑ Uncertain (***Please explain***):

5. Do you market your telehealth services?
   - ❑ Yes
   - ❑ No
   - ❑ Uncertain (***Please explain***):

6. What is the location of your telehealth services (e.g., large hospital, small hospital, walk-in clinic, physician's office)?
   - ❑ On-site location (***Please specify***):
   - ❑ Off-site location (***Please specify***):
   - ❑ Other (***Please specify***):

7. Do your telehealth services have a program champion (i.e., primary advocate)?
- ❑ Yes ➔ **Go to question 8**
- ❑ No ➔ **Go to question 9**
- ❑ Uncertain (***Please explain***):

8. ***If yes,*** who acts as the telehealth program's primary advocate? What position does he or she hold in your organization/facility (e.g., physician, administrator, etc.)?
Please specify:

9.Do you collect data to evaluate your telehealth services?
- ❑ Yes — all services ➔ **Go to question 10**
- ❑ Yes — some services
- ❑ No ➔ **Go to question 11**
- ❑ Uncertain (***Please explain***):

10. ***If yes,*** how do you evaluate your telehealth services?
Please specify:

10a. Does your organization/facility collect data to determine the impact that telehealth services have on the following?

	Yes	In Development	No	Uncertain
The quality of care/service	❐	❐	❐	❐
System utilization	❐	❐	❐	❐
Patient/client outcomes	❐	❐	❐	❐
Cost of care/service vs. its benefit	❐	❐	❐	❐
Patient/client access to care/service	❐	❐	❐	❐
Provider's satisfaction with care/service	❐	❐	❐	❐
Patient's/client's satisfaction with care/service	❐	❐	❐	❐
Technical performance	❐	❐	❐	❐
System integration with established services	❐	❐	❐	❐
Workflow	❐	❐	❐	❐
Health team relationship	❐	❐	❐	❐
Provider roles and responsibilities	❐	❐	❐	❐
Other (***Please specify***): ________________________	❐	❐	❐	❐

11. Are there baseline data available so that the impact of telehealth services can be compared to data prior to telehealth?
- ❑ Yes
- ❑ No

❑ Uncertain (***Please explain***):

12. The following are some telehealth policy issues that have been identified in the literature. Does your organization/facility have written policies in place for the following areas as they relate to telehealth? ***Please check yes, no, or uncertain for each.***

	Yes	In Development	No	Uncertain
a) Reimbursement	❑	❑	❑	❑
b) Security	❑	❑	❑	❑
c) Privacy	❑	❑	❑	❑
d) Confidentiality	❑	❑	❑	❑
e) Liability	❑	❑	❑	❑
f) Cross-Jurisdictional Services	❑	❑	❑	❑
g) Ethics	❑	❑	❑	❑
h) Other (***Please specify***):				
______________________	❑	❑	❑	❑

13.Does your organization/facility or province/territory have a policy developed for dealing with cross-border licensure and other liability issues?

❑ Yes
❑ In development
❑ No
❑ Uncertain (***Please explain***):

Ethics, Privacy, Confidentiality and Security

15. In your organization, is there a telehealth-specific code of ethics for telehealth personnel?

❑ Yes
❑ In development
❑ No
❑ Uncertain (***Please explain***):

16. What telehealth-specific items would you suggest for inclusion in a code of ethics for telehealth personnel? (***Please specify)***

17. Are there policies regarding the role of non-clinical staff during confidential telehealth activities within your organization? For example, do you have a policy that requires non-medical staff to sign non-disclosure agreements?

❑ Yes
❑ No
❑ In Development
❑ Uncertain (***Please explain***):

18. Does your organization/facility conduct security assessments/audits of its telehealth services?
- ❑ Yes
- ❑ No
- ❑ Uncertain (***Please explain***):

19. Does your organization/facility have procedures in place for dealing with breaches of client/patient privacy or confidentiality?
- ❑ Yes
- ❑ In Development
- ❑ No
- ❑ Uncertain (***Please explain***):

20. Does your organization/facility have a risk management strategy in place for its telehealth services?
- ❑ Yes
- ❑ No
- ❑ Uncertain (***Please explain***):

21. In your organization, which of the following methods are used to ensure patient confidentiality for a telehealth encounter (***Choose as many as apply***):
- ❑ Physical security measures (e.g., locking away equipment when not in use)
- ❑ Confidentiality clauses in employees' contracts
- ❑ Training of employees regarding confidentiality
- ❑ Secure storage of telehealth medical records (e.g., passwords, encryption, etc.)
- ❑ Following the standards for health information privacy developed by the Canadian Institute for Health Information for maintaining patient confidentiality
- ❑ No protocols/procedures to ensure confidentiality for telehealth encounters
- ❑ Other (***Please specify***):

22. In your organization/practice, when is it necessary to obtain consent (verbal or written) for a telehealth encounter?
- ❑ Consent is implied by the patient arriving and participating in a telehealth encounter ➔ ***Go to question 26***
- ❑ Consent is necessary for all telehealth encounters
- ❑ Consent is necessary only under certain conditions

23. In your organization what type of consent is required for the following telehealth parameters? (***choose one of the following options for each parameter by placing a check mark (,) in the box***)

Telehealth Parameter	Verbal Consent Required	Written Consent Required	No Consent Required	N/A	Uncertain
Telehealth as a medium for service delivery					
Diagnosis and treatment recommended					

A permanent videotape is to be kept					
There is a surgical procedure involved					
The patient is part of a research study					

24. In your organization, what information is included in a written informed consent form? **(*Choose as many as apply*)**

- ❑ Potential risks, consequences, and benefits
- ❑ Description of procedures that will be followed
- ❑ Who has case responsibility and their obligations
- ❑ Who has access to patient information (privacy and security measures)
- ❑ Where patient health record will reside
- ❑ How and what information will be transmitted
- ❑ Whether session is to be photographed or videotaped
- ❑ No written consent form is obtained
- ❑ Other (***Please specify***):

25. In your organization, please indicate who is responsible for obtaining consent (verbal or written) for each of the following telehealth parameters. **(c*hoose one of the following options for each parameter by placing a check mark (,) in the box*)**

Telehealth Parameter	**Telehealth Coordinator**	**Referring Physician/ Health Professional**	**Consulting Physician/ Health Professional**	**Both Physician/ Health Professional**	**Other Staff**	**No Consent Required**	**N/A**	**Uncertain**
Telehealth as a medium for service delivery								
Diagnosis and treatment recommended								
A permanent videotape is to be kept								
Surgical procedure is involved								
The patient is part of a research study								

26. In your organization, is there a protocol for documenting and storing patient information for telehealth?

- ❑ Yes
- ❑ No ➔ **Go to question 28**
- ❑ In development
- ❑ Uncertain ➔ **Go to question 28**

27. In your organization, where is the patient's medical record stored, or where will it be stored for a telehealth encounter? (***Choose one***)

- ❑ The referring site (i.e., where the patient is located)
- ❑ The consulting site (i.e., where the consultant is located)

- ❑ Copies of the patient's medical record should be stored at both sites
- ❑ Other (***Please specify***):

28. Do you have additional observations and/or comments regarding the standards and/or guidelines pertaining to the organizational/leadership component of telehealth?

Thank you for your participation!

APPENDIX B. ORGANIZATIONAL FOCUS KEY INFORMANT INTERVIEW QUESTIONS

We are interested in your thoughts and opinions about what the key organizational factors are for the successful implementation of telehealth services. We will be addressing four content areas: (1) Organizational Readiness; (2) Accountability; (3) Quality Assurance; and (4) Continuity.

Organizational Readiness

➢ **Telehealth readiness is defined as "the degree to which users, health-care organizations, and the health system itself are prepared to participate and succeed with telehealth implementation" (The Alliance for Building Capacity, 2002, p. 2).**

1. In your view, what policy and procedures need to be in place to be able to say that an organization is **ready to use telehealth technology**?
2. What do you view to be **key components** of administrative or organizational leadership readiness?

Accountability

➢ **Being accountable is defined as being "responsible; required to answer for conduct, tasks, or activities. This responsibility may not be delegated" (Canadian Council on Health Services Accreditation, 2001, Glossary, p. 1).**
➢ **A number of content areas come under the Accountability heading, including liability and risk management; credentialing and privileging; ethics, governance, and leadership; privacy, confidentiality, and security.**

3. From your perspective, what **written policies/standards/protocols/guidelines** need to be in place in order to ensure accountability in an organization providing telehealth services?
4. What written policies **should be** in place for telehealth?

Quality Assurance

➢ **Quality is defined as "the degree of excellence; the extent to which an organization meets clients' needs and exceeds their expectations" (Canadian Council on Health Services Accreditation, 2001, Glossary, p. 15).**
➢ **Quality Assurance is defined as "strategies to verify that a product, process, or service conforms to and meets specifications or requirements" (Canadian Council on Health Services Ac-**

creditation, 2001, Glossary, p. 16).

5. In your opinion, what policies and procedures specific to quality assurance are needed for organizations that are providing telehealth services?
6. What are various **components of quality assurance** that would **require policies and procedures** (e.g., ongoing data collection)?
7. If yes, **what type of telehealth data** should be collected?

Continuity (coordination, linkages, and administrative interoperability)

➢ **Continuity is defined as "the provision of unbroken services that are coordinated within and across programs and organizations, as well as during the transition between levels of services, across the continuum, over time" (Canadian Council on Health Services Accreditation, 2001, Glossary, p. 5).**
➢ **The continuum is defined as "an integrated and seamless system of settings, services, service providers, and service levels to meet the needs of clients or defined populations" (Canadian Council on Health Services Accreditation, 2001, Glossary, p. 5).**

8. In your opinion, what are the **policies, guidelines, and procedures** that need to be in place in order **to enable coordination** of an organization's telehealth services?
9. If an organization offers **more than one telehealth service** (e.g., telepsychiatry, telehomecare, telelearning), **how should they be coordinated**?
10. In your opinion, what strategies, policies, or procedures need to be in place in order to ensure the

Chapter 4.9
Tele-Medicine:
Building Knowledge-Based Tele-Health Capability in New Zealand

Nabeel A. Y. Al-Qirim
Auckland University of Technology, New Zealand

ABSTRACT

This chapter reviews the strategic planning of health information systems in New Zealand. This step is deemed necessary to identify the main accelerators and/or impediments that influence technology adoption and diffusion in health organisations in New Zealand. This research introduces the tele-medicine technology as one possible solution to provide continuous, quality, and immediate medical care to rural patients and to encourage networking among the different hospitals in New Zealand. This research suggests that in order to realise tele-medicine benefits in health care delivery in New Zealand, certain issues need to be addressed such as implementing comprehensive cost-benefit analysis and identifying the benefits sought from adopting the tele-medicine technology. The New Zealand context is unique and this perspective with respect to tele-medicine adoption and success is addressed in this research.

INTRODUCTION

Information systems (NZHIS, 1995a; NZHIS, 1995b; NZHIS, 1996; Neame, 1995; Austin, Trim & Sobczak, 1995; Conrad & Shorttel, 1996), information technology (IT) (Bomba, Cooper & Miller, 1995) and technology (Little & Carland, 1991) have been emphasised as strategic tools for enhancing health care delivery and for improving performance, leading to optimised services and efficiencies. However, the New Zealand studies (NZHIS, 1995a; NZHIS, 1995b; NZHIS, 1996; Neame, 1995) indicate that the sector is "relatively devolved," with purchasing contracts being the main mechanisms to drive sector-wide change at the provider level. Much of the information needed is unavailable in the form needed or at the time that it is needed most. This in part is related to gaps in the conceptual understanding of service delivery, which is in this sector is a very complex business, spanning what has been an extensive range of relatively autonomous functional areas. But it is also due to a lack of reliable information about outcomes, effectiveness and actual costs on which improvements can be based. Because of this lack of empirical data, the tools for dealing with this complexity, and understanding what happens and why, are deficient (NZHIS, 1996). Various organisational issues and the lack of coordination at the national level were also identified. Expertise in health information management and systems is limited. Currently few health and disability sector personnel have the knowledge and skills to understand the issues or to make informed judgements about the validity of the advice they obtain.

New Zealand is not alone in this situation and different countries are facing similar difficulties although the severity of this situation varies from one country to another (Austin, 1992; Bakos & Tracy, 1986; Shortell, Morrison & Friedman, 1990; Topping & Hernandez, 1991; Conrad & Shortell, 1996). This literature points to different organisational, technological, and environmental impediments in adopting and in making use of IS/IT in organisations (Austin, 1992; Austin, Trimm & Sobczak, 1995; Ward, Griffiths & Whitmore, 1990). The 23 Health and Hospital Services (HHSs)[1] that exist all over New Zealand are no longer in competition with each other or paid in principal according to the number of people they care for. The competition from the few private hospitals has no effect on them. Ever-lacking government funds (Neame, 1995) are faced with further reduction on the medical portfolio by reducing or eliminating less priority and less life threatening services for the sake of introducing important new ones. The various gaps that exist between the various stakeholders and the lack of a leader (e.g., the government) to coordinate between the different HHSs result in having 23 different information systems that eventually do not interact with one another.

Diminishing funds from the government and cost control mechanisms have led to the need for alternative and more cost-effective means of providing care (Edelstein, 1999; Neame, 1995). In many cases, this has become necessary for survival (Edelstein, 1999) in order to sustain the increased competition among health care providers. The business of health care has become so competitive in different countries that many small rural hospitals are trying to align themselves with larger tertiary care centres in a community health-information network, a tele-medicine network, or some other type of partnership in order to survive and to retain their local patients (Huston & Huston, 2000). Within these challenges, tele-medicine emerge as one possible solution to New Zealand health providers in reaching out to rural patients (Charles, 2000; Harris, Donaldson & Campbell, 2001), to areas where patient volumes for certain services are limited (Edelstein, 1999), to conduct administrative and clinical meetings, and to conduct different training courses to patients (smoke treatment centres), doctors, nurses, and other medical staffs (Perednia & Allen, 1995; Wayman, 1994).

Tele-medicine means medicine from a distance where distant and dispersed patients are brought closer to their medical providers through the means of telecommunication technologies (Charles, 2000; OTA, 1995; Noring, 2000; Perednia & Allen, 1995; Wayman, 1994). Noring (2000) provided an interesting comparison between the former definition for tele-medicine and tele-health. This researcher defined the term tele-health as expanding the capacity of tele-medicine to provide the full continuum of care, from health promotion and disease prevention through curative treatment and terminal care. This term also implies including non-physician-based health care providers.

Tele-medicine covers a wide spectrum of benefits through the use of video conferencing (VC) technology in areas such as consultations, diagnostics, therapeutic, transfer of patient-related records, case management, training, and meetings. Researchers envision tele-medicine to be an important building block in the strategic plan of many health care organizations (Charles, 2000). In a rural setting, tele-medicine could help New Zealand health providers in supplying quality, fast, and economical medical services to rural patients and hence save doctors and patients valuable time wasted in commuting long distances. Specialists could utilise this extra time in seeing more patients at the main hospital.

Thus, this research is interested in introducing the tele-medicine technology as one of the strategic building blocks of Health and Disability Information Systems (HDISs) integration across the different health care providers in New Zealand. This research is interested in achieving the following objectives:

1. Highlight the status of tele-medicine in New Zealand.
2. Highlight the importance of tele-medicine to health care providers in New Zealand and elsewhere. Identifying the accelerators and/or the impediments that influence tele-medicine success could assist health care providers in New Zealand and elsewhere in planning their adoption and use of tele-medicine. This research utilises the technological innovation literature as a guiding theoretical framework in highlighting these factors.

Before expanding on the potential benefits of tele-medicine to health care providers, the following section examines the status of tele-medicine in New Zealand.

TELE-MEDICINE IN NEW ZEALAND

One of the early initiatives that emerged in 1993 within Northland HHS was transmitting radiology images between two hospitals using leased telephone lines. Tele-medicine has been investigated by most of the health providers in New Zealand. The entire crown-owned hospitals in New Zealand are managed by regional organisations known as Health and Hospital Services (HHS)[2]. Some HHS regions have one hospital and others have more than one. In the North Island, Waitemata Health has three video teleconferencing systems. Two of those systems are used in psychiatry and the third one is used in administrative and training purposes (ADMN). Health Waikato has two VC systems. Two of these systems are used in dermatology and the third one is used in ADMN. Northland Health Ltd (Whangarei) has two VC systems and another two PC-based VC. These systems are used in psychiatry and ADMN. Starship Children's Hospital (part of Auckland Healthcare Services) is in the process of establishing a national tele-paediatric network across the 23 HHSs and already started with a pilot project. Middlemore Hospital (South Auckland Health) has one group VC system for ADMN. Auckland University School of Medicine has one group VC system for training purposes and for conducting regular clinical meetings with other CHEs in New Zealand. Lakeland Health, LTD has two group video-teleconferencing systems for ADMN purposes.

In the South Island, Coast Health Care, LTD has three VC systems used in paediatrics, psychiatry, and ADMN.—HYPERLINK "canterburyhlth.html"—Canterbury Health, Ltd (Christchurch) has one video-conferencing system for paediatrics and for ADMN purposes. Healthlink South, LTD (Christchurch) has two group systems for psychiatry and ADMN. –HYPERLINK "hlthsthcant.html"—Health South Canterbury, Ltd (Timaru), Healthcare Otago, LTD, –HYPERLINK "nelsonmarlboro.html"—Nelson-Marlborough Health Services, LTD, and Southern Health, LTD each have one group system. Otago University in Dunedin is using it for training in their school of medicine. It is interesting to know that there is a level of cooperation among CHEs in the South Island in the areas of psychiatry and paediatrics.

A stock-take of the VC technology in these hospitals reveals that medical schools in New Zealand were among the early adopters and users of the technology. Out of the 23 HHSs in New Zealand, only 12 have actively adopted tele-medicine. The adopted systems ranged between one and four tele-medicine systems with the majority of HHSs adopting one system only. Those HHSs that adopted one tele-medicine system use it mostly for general purposes such as managerial meetings, case discussions and occasionally for clinical training. Such initiatives were described as being initial and experimental. Where an HHS owned more than one tele-medicine system, it was oriented for clinical purposes such as psychiatry, paediatric, and dermatology areas. Hence, an attempt is being made to adopt tele-medicine to provide prompt, inexpensive, and quality medical care to geographically dispersed patients, which was otherwise not possible.

TELE-MEDICINE: A BACKGROUND

The first tele-medicine initiative employing interactive television sessions for medical purposes emerged in 1959 by using a microwave link for tele-psychiatry consultations between the Nebraska Psychiatric Institute in Omaha and the state mental hospital 112 miles away (Perednia & Allen, 1995). In the late 1980s tele-medicine was being used routinely to deliver general health services to remote regions of Norway (Noring, 2000). In the US, interest in tele-medicine was initially focused on use in the military, in space programs, on off-shore oil rigs, in prisons, and in rural areas (Noring, 2000). It seems the opportunities provided by tele-medicine inspired many innovative ideas. For example, BMI British Midland has become the first airline to install tele-medical technology on planes making long-haul flights to the US Virgin Atlantic has also purchased the system and will start installing it in long-haul aircraft this year. The device monitors blood pressure via a wrist cuff, pulse rate, temperature via an ear probe, electrocardiogram, blood oxygen and carbon dioxide levels. Using a modem, this data is sent to physicians who can advise the crew on what action to take (Anonymous, 2002).

Since tele-medicine's inception in the 1950s, Perednia and Allen (1995) reported limited growth and pointed to the fact that only few tele-medicine projects were instituted in the 1970s and 1980s at several sites in North America and Australia. They confirmed that none of the programs begun before 1986 has survived. Although data is limited, the early reviews and evaluations of these programs suggest that the equipment was reasonably effective at transmitting the information needed for most clinical uses and that users were for the most part satisfied. However, when external sources of funding were withdrawn, the programs disappeared, indicating that the single most important cause of their failure was the inability to justify these programs on a cost-benefit basis. Other issues, such as limited physician acceptance, played a less significant role in their downfall (Perednia & Allen, 1995).

The views about tele-medicine effectiveness in the medical area vary from one adopter to another. Depending on one's viewpoint, tele-medicine can be seen as a valuable tool for providing immediate specialty care services to rural areas, a more efficient use of existing medical resources, a way to attract patients living outside a hospital's normal service area, a way of bringing international health care dollars. On the other hand, others could see it as a serious misallocation of increasingly scarce health care dollars (Perednia & Allen, 1995). This challenge needs to be resolved by highlighting the importance of the tele-medicine technology in a rural setting specifically.

In review of the literature it was observed that despite the rapid growth and high visibility of tele-medicine projects in health care (Grigsby & Allen, 1997), few patients are actually being seen through tele-medicine for medical purposes. In almost every tele-medicine project, tele-consultation accounts for less than 25% of the use of the system (Perednia & Allen, 1995). The majority of the online time is used for medical education and administration (Wayman, 1994; Perednia & Allen, 1995; Hassol, 1996). The low level of usage can be explained in part by the federal government's position on reimbursement for tele-medicine consultations (Hassol, 1996). However, this author did not find any association between reimbursement and tele-medicine utilisation in this research. Other issues need to be resolved first before the different benefits of tele-medicine can be realised. These unresolved important issues revolve around how successful tele-medicine can be in providing quality health care at an affordable cost and whether it is possible to develop a sustainable business model that could maintain profitability over time. This depends on (Perednia & Allen, 1995): (1) clinical expectations, (2) matching technology to medical needs, (3) economic factors like reimbursement, (4) legal (e.g., restrictions of medical practices across state lines (licensure) and issues of liabilities), and social (e.g., changing physician behaviours and traditional practices and workflow) issues (Anderson, 1997), and (5) organisational factors. These issues are discussed in the following sections.

TELE-MEDICINE ADOPTION: A THEORETICAL FRAMEWORK

Larsen (1998) states that information systems innovations are considered key enablers for business innovativeness. On the other hand, he asserted that the increased rate of failure among IS projects within organisations calls for an increased understanding about IS innovations (Moore & Benbasat, 1991). Innovation can be defined as an idea, practice or product that is perceived as new by the potential adopters even if it had existed earlier elsewhere (Rogers, 1995). The recent success and emergence of tele-medicine using the video conferencing (VC) technology in the early 1990s is an innovative approach of its adoption for medical purposes. In search for models that would explain technologies adopted by organizations, Rogers' (Rogers, 1983, 1995) model appeared to be the most widely accepted model by researchers in identifying critical characteristics for innovations (Moore & Benbasat, 1991, 1996; Premkumar & Roberts, 1999; Thong, 1999). Rogers classical adoption model is made up of the following factors: relative advantage, complexity, compatibility, observability, and trialability (*Table 1*). The results of using tele-medicine (observability) are quite observable to the different hospitals and have been highly publicised by the literature (Al-Qirim, 2002; Grigsby & Allen, 1997). Cost has been outlined as an important determinant of adoption by Rogers (1995) and other researchers (Bacon, 1992; Elliot, 1996; Tornatzky & Klein, 1982) (*Figure 1*).

In the following, the different factors that influence tele-medicine success are reviewed in the light of the technological innovation literature. Further identification of these factors that facilitate and/or hinder adoption and diffusion of tele-medicine could help HHSs and policymakers in New Zealand and elsewhere in adopting tele-medicine and in overcoming different barriers that could hinder its adoption.

Table 1. Innovation characteristics

Innovation Characteristics
1. Relative advantage: the degree to which using technology is perceived as being better than using its precursor of practices.
2. Complexity: the degree to which technology is perceived as being easy to use.
3. Compatibility: the degree to which using technology is perceived as being consistent with the existing values, and past experiences of the potential adopter
4. Trialability: the degree to which technology may be experimented with on a limited basis before adoption
5. Observability: the degree to which the results of using technology are observable to others.
6. Cost: the degree to which technology i s perceived as cost effective.

Relative Advantage

Table 2 identifies some of the stakeholders involved in tele-medicine adoption and depicts their perception about tele-medicine advantages in comparison with their earlier practices (Al-Qirim, 2002; Perednia & Allen, 1995; Wayman, 1994).

1. issues concerning patient's privacy;
2. specialists may reject extending their knowledge to rural doctors (profession protection) (Gammon, 1994);
3. some physicians prefer ambulatory services as a way to break a way from the hospital's stressful environment; and
4. some busy doctors tend to see tele-medicine as an extra burden (Gammon, 1994).

The most extensive use of tele-medicine has been to support continuing education over VC. Many more doctors and nurses are now able to attend conferences or classes because the direct (travel) and indirect (out-of-office) costs are decreased (Wayman, 1994). This raises concerns about the main objective(s) of tele-medicine and how it is perceived in the minds of the adopters. Is it a teaching utility or a patient care utility? Although the former leads eventually to better care and stable physicians at rural areas, the latter is envisioned to be the ultimate goal.

Cost Effectiveness

There will be no advantage in adopting tele-medicine if the investment is not justifiable in terms of

Table 2. Tele-medicine advantage

Stakeholder	Practices with telemedicine	Earlier practices	Remarks
Specialists	Seeing patients one-on-one through poor clarity video screen, ISDN connection keeps disconnecting	One-on-one, in person	Disadvantage
	Studio scheduling and moving to studio	No need, regular appointments in physician's office.	Disadvantage
	Second opinion from expert	No or not easy or cheap option	Advantage
	Case discussion and management	Offline, local	Advantage
	Immediate reporting from video	Immediate and accurate from patient	Disadvantage
	Could record session (legal & judicial reviews)		Advantage (1)
	Meeting rural doctors	Difficult	Advantage (2)
	Training rural doctors	Difficult	Advantage (2)
	Time optimisation (reduced ambulatory)	Longer time	Advantage (3,4)
	Less time waiting for rural patients	Longer waiting time	Advantage
	Fewer referrals to specialists	Increased	Advantage
	Reduced turnover of medical staff at rural areas—they feel less isolated from the outside world		Advantage
	Logistics:		
	Seeing rural patients over video reducing waste (time, traveling, lodging, etc.)	Travel to patient	Advantage (3)
	Lost supplementary income	Supplementary income	Disadvantage
Management	Meeting rural managerial staff, managerial training	Difficult	Advantage
Patients	See specialist over the video with the presence of rural medical staff	Commute to central specialist or wait for specialist to come to rural	Advantage

its acceptable financial returns. On the other hand, healthcare providers in general, including New Zealand, emphasise the importance of providing quality care and preserving human's well-being. Thus, making the cost element one factor in the adoption decision of tele-medicine, but not the most important one. On the other hand, hospitals have limited resources and hence, it is feared that hospitals would assess the tele-medicine technology as a non-priority medical technology (Al-Qirim, 2002), which emphasises the need to strike a balance between its financial feasibility and its advantages. Let us not forget that tele-medicine is an ideal technology in a rural setting, which makes the cost element insignificant to a certain degree for various reasons. Rural areas typically experience a severe shortage in specialist staff. This is due to vast rural areas to service, poor payment levels for this specialty, significant difficulty in recruitment and retention, and the professional isolation specialists experience in rural areas are some of the reasons (Al-Qirim, 2002; Charles, 2000; Harris et al., 2001).

The potential importance of tele-medicine in impacting the health and the welfare of rural communities is tremendous. The estimates of the percentage of tele-medicine patient candidates who can be retained by the rural hospital vary between 50% and 80% (Wayman, 19945). This patient retention not only has a direct, positive effect on the rural hospital and rural physician, but also on the area economy. The average dollar in a rural community circulates seven times; each patient trip to receive speciality consultation encounters costs in gas, lodging, and food, not to mention lost wages for the patient and assisting family/friends (Wayman, 1994). Early intervention has often proved to be less expensive in the long run, so access to specialty care via tele-medicine can ultimately result in decreased healthcare costs to rural areas (Huston & Huston, 2000).

Despite the ongoing evaluations of tele-medicine feasibility in healthcare and the different attempts to measure the costs and benefits of using the tele-medicine technology, there are still not enough data to provide accurate estimates of tele-medicine costs (Huston & Huston, 2000). Another important point to indicate here is that sometimes and according to the internal policy of certain hospitals the financial benefits are hidden or intangibles and difficult to calculate. Direct costs such as the cost of equipment, training, maintenance and ongoing support, upgrades, and ongoing telecommunications are quite obvious and indeed resemble the major costs involved in any tele-medicine project. In a recent research study in the US it was suggested that reimbursement and the cost of telecommunications were identified as the most important barriers of tele-medicine adoption (Grigsby & Allen, 1997).

Perednia and Allen (1995) indicate that current literature tackling tele-medicine has failed in addressing its cost-effectiveness on the basis of its use: as a diagnostic tool and/or as a therapeutic tool and/or case management tool. This further complicates the cost/benefit formula. The concern would be whether tele-medicine is used in the correct place initially and whether it is being used effectively in any of the above three areas. It is essential in the process of adopting certain tele-medicine technology to choose the right one that matches the hospital needs. Using tele-medicine to transmit video when the case necessitates that (i.e., psychiatry, physical and occupational therapy, orthopedics, some neurology applications, etc.), text when appropriate (i.e., lab reports, patient histories and physicals, dietary evaluations, insurance information, medication histories, etc.) using email, still images (i.e., X-rays, pathology slides, lab specimen slides, CTs, MRIs, lung scans and ultra sounds) using scanners or still digital camera or fax machines, and audio (i.e., electronic stethoscope) using telephone or email. It is of utmost importance to remember that most diseases do not move and hence, there is no need for real time and full motion VC equipment (Perednia & Allen, 1995; Wayman, 1994).

Resources available for medical care are limited and the use of expensive tele-medicine technologies will reduce the total number of tele-medicine sites that can be installed regionally or nationally. While use of the latest and most powerful equipment may seem logical, the early adoption of two-way, full-motion video may be unrealistic for many rural and under-served areas (Perednia & Allen, 1995). This is due to logistical reasons concerning the quality of telecommunication lines provided to rural areas (Charles, 2000).

Evidence suggests that other forms of cost control initiatives in the US such as the establishment of health maintenance organisations (HMO) and managed care have a significant effect in the adoption of more technologies and systems than others (Baker & Wheeler, 1998). In the US, most cost-effective applications are those that are paid for by insurers, such as the use of tele-medicine for radiology, prisoner healthcare[3], psychiatry, and home healthcare. Other applications enhance access to care but are not cost effective because third-party payers (e.g., HMO) do not pay for related costs for professional fees or the implementation of the technology (Charles, 2000; Huston & Huston, 2000). However, this situation does not apply to New Zealand because healthcare providers are paid ultimately by the government to provide healthcare services to patients in the regions they serve.

There are different ways to reduce the huge expenses in setting and running the tele-medicine sites and recent research suggests that some hospitals tend to promote other services through their tele-medicine network (i.e., like renting the facility to private entities and offices in rural areas to connect to their central offices) or encourage other health providers within and outside the hospital to join them and share the facility (Al-Qirim, 2002; Perednia & Allen, 1995).

Compatibility

Perhaps the greatest dilemma associated with all these changes is how to ensure that innovations in the process of delivering care are not achieved at the expense of sacrificing widely accepted values of what constitutes the humanity of care (Noring, 2000).

Tornatzky and Klein (1982) in their meta-analysis found compatibility features to be an important determinant of adoption. Rogers' (1995) compatibility characteristic is highly stressed here because past research in healthcare (Austin, 1992; Austin, Trimm & Sobczak, 1995) considered the problem relating to physicians accepting IS for clinical purposes. The use of computers and cameras suggests a shift away from the one-on-one personal interaction now viewed as essential and desirable in healthcare delivery (*Table 2*). Issues such as "Surgeon syndrome" which is conservatism towards all other technologies than one's own was highlighted as an impediment to the adoption of tele-medicine (Gammon, 1994). Some view it as an alternative to lack of care or treatment altogether; others view it as a dramatic quality and efficiency improvement to current levels of care (Wayman, 1994). On the other hand, these significant changes to the physician's and patient's treatment environment (i.e., one-to-one through the VC *Vs*. one-on-one and in person) are expected to create resistance for the tele-medicine technology (Al-Qirim, 2002). For example, recent research found that in an extreme case, one of the clinical staff in the rural area almost fainted when she saw herself in the television screen of the VC equipment (Al-Qirim, 2002). It is important that the changes introduced by tele-medicine be compatible with the hospital's value, practice, and experience to ensure its successful adoption. Issues such as gradual introduction and motivation are highly envisaged here.

The concern is that physicians are reluctant to accept the technology. Gammon (1994) suggested that doctors in general and specialists, specifically, would be the single most influential group affecting the diffusion process of tele-medicine. Gammon (1994) distinguished between two groups of physicians: expertise delivering physicians and expertise receiving physicians. The first group consists primarily of specialists at central hospitals who either, have ambulated (conducted outside treatment visits or operations) visits and enjoyed supplementary income[4] or have contributed significantly to hospital income by treating guest patients from neighboring municipalities. By carrying out distant consultations, they experience a reduction in income both for themselves and for their hospital. Furthermore, some physicians have shown a negative attitude toward allowing receiving (primarily rural) hospitals to participate (via VC) in medical meetings, while they are positive towards participating in similar meetings when they themselves are recipients. Physicians working in environments characterised by overload and stress will most likely perceive implementation of tele-medicine as an additional burden. This, coupled with tele-medicine's replacement of ambulatory, as well as a possible fall in income will muster their resistance to tele-medicine, if not absolute sabotage towards the implementation of tele-medicine (Gammon, 1994). Development of reasonable incentives as well as measures for integrating tele-medicine into the working environment will be an important step.

Security and legal issues are some of the impediments to the success of tele-medicine in New Zealand (*Table 2*). The security of patient's data and VC encounters are important issues and need to be addressed. Legal issues relating to operating a tele-medicine network including corporate practice of medicine, patient confidentiality and privacy, malpractice, informed consent, licensure and credentialing, intellectual property, funder's (Medicare and Medicaid) payment, fraud and abuse, medical device regulation, and antitrust (price fixing) (Edelstein, 1999) are some of the major issues, which could bring any tele-medicine project to a complete halt. However, countries such as the US are well ahead in addressing these issues (Edelstein, 1999). Edelstein (1999) reports that in one session of the American Congress, 22 pieces of legislation relating to tele-medicine were introduced. Four tele-medicine-related bills have been introduced in the 106th Congress.

Complexity

Complexity in the case of tele-medicine could be divided into two parts: Firstly, complexity relating to technical limitations in the VC equipment and bandwidth. Buying the wrong or ill-specified technology such as not presenting clear picture and voice or the different components in the VC equipment are not fully compatible with each other may result in frustrating the users. Selecting the right communication technology and bandwidth such as ISDN, ADSL, and Bridges is essential in order to have clear images and voice, file download/upload, and a valid and reliable connection, respectively. It should be noted here that installing the VC equipment needs a special room with specialised lighting and acoustic system. Secondly, user's complexity is related to the ease-of-use and to the simplicity of the VC equipment. Providing appropriate training courses earlier on could assist in removing lots of the misperceptions about the complexity of the equipment. This part should not be confused with the compatibility characteristic above, such as convincing the specialists moving from their offices or clinicians to the VC theatre. It could be argued here that the perceived complexity of the VC equipment could lead to incompatible perceptions amongst clinicians. Recent research examining the acceptance of the tele-medicine technology amongst physicians suggests that perceived usefulness was found to be a significant determinant of attitude and intention to adopting tele-medicine. However, the perceived ease of use was not significant (Hu, Chau, Sheng & Tam, 1999).

Trialability

Another important point here is the issue of trying and experimenting with the tele-medicine system before adopting it. Tele-medicine involves a considerable investment in buying the equipment and the training to know how to use it. Most importantly, it should be integrated into the hospital environment in general and in the clinical area specifically to witness its effectiveness. According to the reported challenges above, trying the system in the intended real setting could provide initial and vital signs, which could assist decision-makers in making accurate decisions concerning adopting or rejecting the technology. This makes the limited trialing of the system not sufficient to yield useful results. The issue here is whether the different HHSs are willing to make this involving step or whether the suppliers will accept lending their equipment for a considerable time to HHS to trial their system — and hence remains unanswered.

DISCUSSION AND CONCLUSIONS

If tele-health services are properly introduced and based on evidence of effectiveness, "… *telehealth has the capacity to improve the quality of healthcare, provide equity of access to healthcare services, and reduce the cost of delivering healthcare*" (Noring, 2000).

This research introduced the importance of adopting the tele-medicine technology by healthcare providers in New Zealand specifically. Tele-medicine represents a great opportunity for healthcare providers in New Zealand to network and to provide integrated healthcare and administrative services to rural areas specifically. This could provide important surrogates to the different gaps existing in the HDIS of the different HHSs in New Zealand. The lack of coordination and cooperation between the different HHSs in New Zealand needs to be resolved in order for this integration to succeed.

This research relied on the technological innovation literature to guide the development of the different factors that could accelerate or impede tele-medicine adoption. These factors are important to the strategic adoption and use of tele-medicine by the different HHSs in New Zealand and elsewhere. Tele-medicine introduces various clinical and administrative advantages as highlighted in this research and these advantages could be focused in delivering quality care and services to rural patients and physicians. However, as a precursor to adoption, it is important to identify the particular advantages sought from tele-medicine, taking into consideration the adoption context and the actual needs of the different HHSs. In a worst-case scenario, tele-medicine enables specialists in the main hospital give second opinions or allow for efficient follow-up and case management. If the costs involved in adopting and running the tele-medicine project were not planned well, the whole project could be brought to a complete standstill. Considering issues such as running costs and hidden costs needs to be identified earlier on. Issues pertaining to the complexity of the technology and to its compatibility with the physician's working environment needs to be addressed with more emphasis put on the latter as it could prove detrimental to the whole success of the tele-medicine project. Therefore, providing a framework where physicians are encouraged to accept and use the technology in providing healthcare services to patients and to other rural physicians is highly stressed here.

New Zealand's small area and population (3.82 million) (NZStat, 2001) could lessen the impact of many of the big challenges that hinder tele-medicine adoption in countries such as the US. Issues like licensure and reimbursement are major impediments in the US but not in New Zealand. There is one legal system in New Zealand and hence, interstate legalities and boundaries are large issues in the US but not in New Zealand. New Zealand has a sophisticated telecommunication (networks, mobile) infrastructure, which could serve the large-scale diffusion of tele-medicine across the different HHSs. This research demonstrated that tele-medicine provides various advantages and its potential in reducing costs at different levels has been established. It is important to further assess the strategic importance of tele-medicine within the different HHSs and at the national level in New Zealand. This task is quite achievable and requires the involvement of the different stakeholders highlighted in this research. Creating a national strategic plan aiming at identifying opportunities with respect to speciality-care, rural coverage and medical needs, and other administrative objectives could assist in driving the health sector forward and in providing fast and quality care to rural patients in the first place and to all New Zealanders eventually. Creating this integrated tele-medicine network amongst the different HHSs could prove viable to healthcare delivery in New Zealand.

INTRODUCTION

Canada spans 9,976,140 square kilometers and has an approximate population of 32 million people (Statistics Canada, 2001). More than 90% of Canada's geography is considered rural or remote (Government of Canada, 2001). Despite the highly dispersed population, and, indeed, because of it, Canada is committed to the idea that a networked telehealth system could provide better access and equity of care to Canadians. Growing evidence of the feasibility and affordability of telehealth applications substantiates Canada's responsibility to promote and to develop telehealth.

Telehealth is the use of advanced telecommunication technologies to exchange health information and provide healthcare services across geographic, time, social, and cultural barriers (Reid, 1996). According to a systematic review of telehealth projects in different countries (Jennett et al., 2003a, 2003b), specific telehealth applications have shown significant socioeconomic benefits to patients and families, healthcare providers, and the healthcare system. Implementing telehealth can impact the delivery of health services by increasing access, improving quality of care, and enhancing social support (Bashshur, Reardon, & Shannon, 2001; Jennett et al., 2003a). It also has the potential to impact skills training of the health workforce by increasing educational opportunities (Jennett et al., 2003a; Watanabe, Jennett, &

Watson, 1999). Therefore, telehealth has a strong potential to influence improved health outcomes in the population (Jennett et al., 2003a, 2003b).

Fourteen health jurisdictions—one federal, 10 provincial, and three territorial—are responsible for the policies and infrastructure associated with healthcare delivery in Canada. This article presents a telehealth case study in one of Canada's health jurisdictions—the province of Alberta. The rollout of telehealth in Alberta serves as an example of best practice. Significant milestones and lessons learned are presented. Progress toward the integration of the telehealth network into a wider province-wide health information network also is highlighted.

BACKGROUND

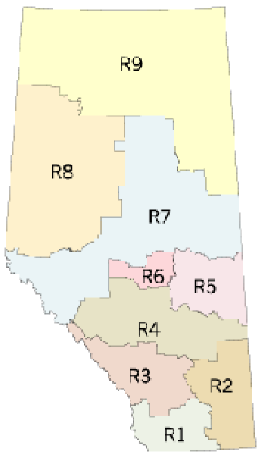
Canada's province of Alberta has a geography that is well suited to using telehealth technologies. Previous telehealth pilot projects throughout the province provided evidence of potential benefits from telehealth applications (Doze & Simpson, 1997; Jennett, Hall, Watanabe, & Morin, 1995; Watanabe, 1997). Alberta is the westernmost of Canada's prairie provinces with a total area of 661,188 km^2. Approximately 3 million people live in this western province, with two-thirds of the population living in two major cities in the lower half of the province; 19.1% of the population is distributed over the northern remote areas and southern rural communities (Figure 1) (Alberta Municipal Affairs, 2004; Statistics Canada, 2001).

In Alberta, health regions assume responsibility for acute care facilities and continuing and community-based care facilities, including public health programs and surveillance. The population sizes of health regions vary, as do their service census populations (Figure 1). The province has approximately 100 hospitals and more than 150 long-term care facilities. Health professionals are located largely in the urban centers, leaving many rural and remote areas with limited access to a variety of healthcare providers and services. In the mid-1990s, there was a physician-to-population ratio of 1:624 (Alberta Health, 1996). Most physicians are compensated on a fee-for-service basis by the provincial government (Alberta Health, 1997).

During the last decade, health reforms and restructuring have taken place in Canada, both at the federal (Kirby, 2002; National Forum on Health, 1997; Romanow, 2002) and provincial (Clair, 2000; Fyke, 2001; Mazankowski, 2001; Ontario Health Services Restructuring Commission, 2000) levels. These reforms were conducted in response to important trends challenging the Canadian Medicare system, such as escalating costs for new technologies and drugs, aging population, and increasing public expectations. Furthermore, health reforms addressed the issue of access to healthcare services for some groups, such as Aboriginal people and populations living in rural and remote parts of the country (Romanow, 2002).

Major challenges include the scarcity and isolation of healthcare professionals in many communities because of Alberta's large landmass; varied, extreme, and unpredictable climate; and population dispersion. Such realities were recognized as principal factors motivating the consideration of a provincial health information network. Alberta began to plan such a network in the mid-1990s, with the objectives of exploiting health information technologies and linking physicians, allied health professionals, hospitals, clinics, health organizations, and Alberta Health and Wellness (the provincial government's department of health) (Government of Alberta, 2003; Jennett, Kulas, Mok, & Watanabe, 1998). This network, entitled Alberta Wellnet, was a joint initiative by Alberta Health and Wellness and stakeholders in the health system. Initially, a core set of priority initiatives consisted of a pharmacy information network, telehealth, a healthcare provider office system, continuing and community care services, service

Figure 1. Health regions in Alberta (Government of Alberta, 2004)



Health Region	Region # on Map of Alberta	Population*	% of Alberta Population	# of Videoconference Sites
Chinook	R1	152,636	4.9	8
Palliser	R2	98,074	3.1	9
Calgary	R3	1,122,303	35.9	34
David Thompson	R4	286,211	9.2	27

Northern Lights	R9	69,063	2.2	16
Total		3,123,744	100	174

event extract, population health and surveillance, and diagnostic services information sharing. This article describes the development of the provincial telehealth network in Alberta.

THE PROVINCIAL DEVELOPMENT OF THE TELEHEALTH NETWORK

Just prior to the establishment of Alberta Wellnet, an anonymous philanthropic foundation expressed interest in exploring the feasibility of developing an integrated, province-wide telehealth network based on need, capability and support. One of the authors (ES) initiated discussions with the foundation through an intermediary, and a small team of content experts was assembled to begin dialogue. The foundation requested a letter of intent and a presentation of concept to substantiate the benefits of allocating funds to telehealth. Following internal review and external consultation, the foundation allocated $525,000 for the preparation of a telehealth business plan. A project planning team was formed to serve as the province-wide planning group and to oversee the preparation of the business plan. This team incorporated representatives from the RHAs, the health sector, the universities, and the community. Two province-wide focus groups were held with representatives from the stakeholder groups to discuss content and approach, and a number of meetings were held between the CEOs (chief executive officers), their RHAs, and boards. The 17 regions and the two provincial boards at that time indicated their support in principle for a provincial telehealth network. The foundation's acceptance of the Provincial Telehealth Business Plan provided a commitment of up to $14 million to fund a provincial telehealth network pursuant to the satisfaction of a number of conditions (Table 1). The milestones associated with the development of the network are outlined in Table 2.

Specifically, the provincial telehealth network began its rollout in 1999 and continues to evolve and develop. A Provincial Telehealth Committee (PTC) comprised of health region, physician, and Alberta Health and Wellness representatives was formed in 1999 to provide strategic direction to this provincial initiative. Figure 1 outlines the current status of the network. In October 2004, there were 261 active telehealth systems that were networked and centrally connected through a network consisting of a combination of ISDN, SW56, and AGNPac. Applications were clinical, educational, and administrative in nature, and sessions were charted between 2002 and 2004

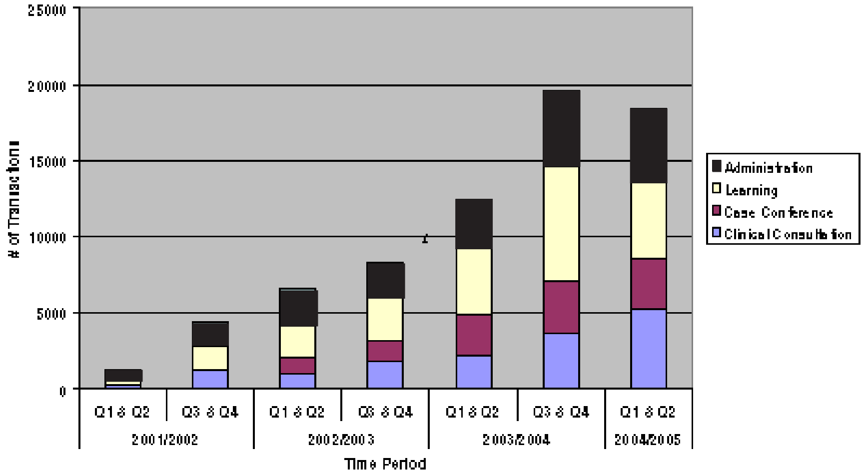
Table 1. Donor foundation conditions

- Funds to be used for capital purposes only
- 2 to 1 matching funds required ($7,000,000)
- Province-wide network (a minimum of 75% of the population, at least 12 Health Regions)
- Improve access (remove distance, especially for remote, isolated rural)
- Incorporation of all current pilot projects
- Sustainable, integrated into the health information system

Table 2. Milestones

1994	Health reform and restructuring in Alberta established 17 Regional Health Authorities (RHAs), down from >200.
1995	An anonymous philanthropic donor foundation expressed interest in exploring the feasibility of developing an integrated province-wide telehealth network based on need, feasibility, and support.
1996	Initial Business Plan supported the concept of a provincial telehealth plan. Potential allocation of $14 million, providing a number of conditions could be met.
1996	Initial plans for a provincial health information network (Alberta Wellnet) began.
1997	Telehealth Coordination (ATCC) and Implementation Planning Committees (ATIPT) formed with action plans regarding policy, infrastructure implementation, and operational solutions. Vision and overall management Report produced by the Telehealth Working Committee, with input from all stakeholders.
1997	$7 million one-time commitment, plus $1 million operating costs commitment from Alberta Health.
1997	Provincial Health Authorities' Association re-established a Charitable Foundation to receive and administer funds.
1997-8	The Alberta Medical Association's Committee on Fees and Alberta Health opened the way to potential payment for telehealth services.
1997-8	Telehealth handbook compiled to provide guidelines for Regions initiating telehealth activities. ATIPT merged with ATCC.
1998	Joint Planning Committee held with Alberta Telehealth Coordinating Committee (ATCC), the RHAs, and the Provincial Boards resulting in four priority telehealth applications: psychiatry; emergency care; radiology; and continuing education. Frameworks for three issues were discussed: 1) Needs assessment models, 2) Funding models, and 3) Provincial telehealth infrastructure and network.
1998	"Decision Document" produced for the Minister of Health, the RHAs, the anonymous philanthropic foundation, and the Alberta Medical Association. Business models for the four priority areas evolved, along with working groups assigned to each.
1999-00	Establishment of Provincial Telehealth Committee and coordinator.
1999-04	Central support services were initiated and deployed, including an interoperability standard testing framework for vendors, a scheduling system, followed by bridging and gatewaying services, and core evaluation and costing frameworks, processes, and tools.
2003	Alberta's RHAs reduced from 17 to 9 Health Regions.
2003	30 different clinical disciplines included in Telehealth.
2003-6	Provincial Telehealth Strategic Business Plan approved. Five critical success factors were articulated. A number of proposed initiatives were put in place.
2003-6	Telehealth Clinical Grant Fund established. Two calls for proposals have occurred, resulting in the funding of approximately 20 clinical projects and anticipated approval for an additional 20 projects.
2004	10,000th telehealth clinical consultation occurred.
2004	Clinical telehealth service extended to First Nations Communities.
2004	Telehealth scheduling system extended to the Territory of Nunavut.
2004	First provincial clinical telehealth forum held. Second one approved for 2005.

Figure 2. Growth of Telehealth—Increased administrative, learning, case conference, and clinical consultation transactions



(Figure 2). In 2004, the network's 10,000th clinical consultation occurred, and clinical services were extended to the First Nations' communities.

Since 2001, central supporting services have been established to support all stakeholders. For example, an Internet-based telehealth scheduling system initially was deployed in 2001 to facilitate coordination of telehealth activities throughout the province and has been used successfully to support approximately 30,000 telehealth events. The system now is being shared with several other jurisdictions (Nunavut, Saskatchewan, some mental health sites in British Columbia, Alberta First Nation's and Inuit Health Branch sites). Other core services included an interoperability standards testing site for vendors at Alberta Research Council, bridging and gatewaying services as well as costing models and core evaluation frameworks. For example, a home telehealth business case template was completed to facilitate health region analysis of this mode of service, while a newly developed site-based costing model provided support for further research and the development of a sustainable economic model for telehealth in Alberta. Further, a comprehensive provincial evaluation process is in development. To this end, an Inventory of Telehealth Evaluation Activities in Alberta was completed in order to establish a baseline and to inform refinements to the existing evaluation framework. Associated indicator standards are being aligned with the Alberta Health and Wellness Quality Framework. The Health Information Standards Committee of Alberta recently approved a new Alberta telehealth videoconferencing standard, as technological standards are continuously evolving.

A Provincial Telehealth Strategic Business Plan (2003-2006), developed by the PTC on behalf of health regions and approved by the Council of CEOs, articulates five critical success factors to realize the full potential of the Alberta Telehealth network. These five foci include (1) providing timely access to quality care, (2) collaborating effectively, (3) securing and effectively managing resources, (4) creating a culture that fosters change, and (5) formalizing the evaluation process and enhancing telehealth research.

At present, all of Alberta's Health Regions have telehealth programs in place. Due to required health system and provider buy-in rate, the clinical applications were slightly slower to evolve. As a consequence, a project that established incentives for the development of clinical telehealth applications was initiated. Alberta Health and Wellness funded a Telehealth Clinical Grant Fund (overseen by the PTC) resulting in more than 20 clinical telehealth projects, including cardiology, emergency, diabetes, urgent mental health, and pediatric services. A recent call for proposals is expected to result in funding of 20 additional projects, some of which will be extended to First Nations Communities.

SIGNIFICANT LESSONS LEARNED AND OBSERVATIONS

There were many lessons learned during the development of the Provincial Telehealth Program. They fall into two broad categories: (1) Business, Funding, and Sustainability (four items) and (2) Policy, Operational, and Infrastructure Issues (15 items) (Table 3). A number of key observations also emerged. These included the need to:

- Understand the nature and the implications of health reform and restructuring;
- Identify and clarify policy and operational issues around specific applications;
- Incorporate adequate telecommunications infrastructure;
- Respect diversity in priorities as well as preparedness and state of readiness among Health Regions;
- Ensure provision for sustainable operational support; support preparation of business models for shared telehealth needs in the Health Regions;
- Pay special ongoing attention to human factors, including the reengineering and business change management work place processes; and
- Involve end users, including physicians, nurses, and administrators, early in the planning process and conceptual design.

FUTURE TRENDS AND DIRECTIONS

Today, a major focus for the province is integrating the provincial telehealth program with other provincial health information initiatives. These include the Electronic Health Record Initiative, the Physician Office Support Program (POSP), and the Pharmacy Information Network (PIN). A second focus is on migrating from the current platforms to a high-speed, high-capacity IP broadband backbone (i.e., the SuperNet project) (Government of Alberta, 2002). In parallel, the province is continuously examining new evolving technologies and partnerships that can optimize the use of ICTs within the health sector, with a focus on quality of care, patient safety, and evidence-based decision making at the point of care.

CONCLUSION

The deployment of the provincial telehealth network continues to grow and to strengthen. Many milestones were encountered in the development of the Alberta Telehealth Network (Table 2). Several significant lessons learned also were documented (Table 3). While significant progress has been made, challenges and impediments remain for the creation of a functional, sustainable, and integrated province-wide telehealth network. Specifically, the successful integration of telehealth into a broad provincial health information and health system demands attention to human, system, and workplace factors. The significance of several critical factors cannot be ignored: different degrees of regional and sectoral readiness to adopt telehealth as well as diversity in selected telehealth priorities, potential cultural shift in the way providers work and learn, training needs,

Table 3. Lessons learned

Business, Funding, Sustainability

- The preparation of business models for shared telehealth needs in the Health Regions was helpful to ensure buy-in and progress.
- There is a great deal of work remaining after program initiation.
- Funding opportunities to cover the initial and ongoing operating costs of Telehealth require ongoing vigilance.
- Accountability for all network components required articulation.

Policy, Operational and Infrastructure Issues

- Raising awareness of telehealth and its potential continues to be challenging, as telehealth encompasses a variety of areas and technical complexity, which is difficult to reduce to simple language.
- A number of policy and operational issues around specific applications were identified and required further study and clarification.
- Cross-jurisdictional policy work is extremely time consuming. For example, the number of editions of the consent policy framework was extremely high.
- Respect for diversity of “state of readiness”, priorities, and partners/collaborators among Regions was required.
- A representative governance structure was required. All stakeholders needed to participate in the planning and decision-making during the early stages of rollout.
- A “decision document” for the Minister of Health, the Health Authority, the anonymous philanthropic foundation, and the Alberta Medical Association was a tool to enhance successful integration and buy-in.
- A clear understanding of the nature and implications of health reform and restructuring are required before telehealth can be integrated into a regional health system. Telehealth must align with and support major health reform initiatives to continue to be supported by and successful in the provincial funding structure. It must also take into consideration the convergence of technologies as it evolves.
- Alberta Health, the Ministry of Health, was a key player in initial successful implementation.
- Consideration of the province’s overall health information approach was important. Multiple reporting requirements are needed.
- In early stages, policy and integration committees were helpful to move agendas along. Commitment was central as expertise, time, as well as expenses were volunteered.
- Continual revisiting of critical issues with RHAs and Provincial Boards, along with ongoing active participation, was required. Perseverance in planning and development is rewarded.
- Adequate infrastructure (telecommunications, trained staff, etc.) for a network was critical.
- Identification of “pressure points,” along with provincial barriers and obstacles was difficult, but essential to move the agenda along.
- Implementation requires close attention to human, system, and workplace factors.
- Ongoing evaluation and monitoring is required for continuous quality improvement.

and required public/private/academic sector collaborations.

It also was observed that telehealth and e-health initiatives make substantial impacts in key areas of health reform. Integration requires close attention to the ongoing healthcare restructuring movements as well as to the convergence of technologies. There is a tendency to simply add technology to existing processes; however, some of these processes need to be reengineered in order to realize the full potential of telehealth. Further, changing funding processes to better accommodate telehealth is extremely difficult; the amount and quality of evaluation research on the impact of investments in telehealth must be increased to support the decision makers.

The provincial telehealth network initiative provides ongoing progress reports as health reform and restructuring continue and as integration with other provincial health information initiatives continues.

ACKNOWLEDGMENTS

The authors wish to acknowledge the commitment and many volunteer hours of members on the various committees, planning teams, and working groups associated with the rollout of the Alberta Telehealth Initiative. The authors acknowledge the assistance of Winston Teo, Heidi Brandstadt, and the Health Telematics Unit in the preparation of this manuscript. The authors also wish to acknowledge both the foresight and generosity of the anonymous donor foundation that served as the catalyst for this initiative.

KEY TERMS

AGNPac: AGNPac is a government of Alberta IP network.

Bandwidth: The range of frequencies transmittable through a transmission channel. If the channel is unique, the band is called baseband. If the channel is made multiple through a process of multiplexing, the band becomes wideband and can support data, voice, and video at the same time. (1) The difference between the highest and the lowest frequencies in a data communication channel. (2) The capacity of a channel. (3) A measure of the amount of information and, hence, its transfer speed, which can be carried by a signal. In the digital domain, bandwidth refers to the data rate of the system (e.g., 45 Mbit/sec) (Beolchi, 2003). Bandwidth is a practical limit to the size, cost, and capacity of a telehealth service.

Broadband: A popular way to move large amounts of voice, data, and video. Broadband technology lets different networks coexist on a single piece of heavy-duty wiring. It isolates signal as a radio does; each one vibrates at a different frequency as it moves down the line. Its opposite is baseband, which separates signals by sending them at timed intervals (Beolchi, 2003). Future networks, like those being deployed in Alberta, will carry these higher speed communications (i.e., Broadband ISDN).

E-Health: An emerging field in the intersection of medical informatics, public health, and business, which refers to health services and information delivered or enhanced through the Internet and related technologies. In a broader sense, the term characterizes not only a technical development but also a state of mind, a way of thinking, an attitude, and a commitment for networked, global thinking to improve healthcare locally, regionally, and worldwide by using information and communication technology (Eysenbach, 2001). The Commission of the European Communities (2004) declares that e-health tools or solutions include products, systems, and services that go beyond simply Internet-based applications and include tools for both health authorities and professionals as well as personalized health systems for patients and citizens.

IP: Internet Protocol is the network layer protocol for the Internet (Beolchi, 2003).

ISDN: Integrated Services Digital Network is a set of international digital telephone switching standards that can be used to transmit voice, data, and video. It offers the advantages of error-free connections, fast call setup times, predictable performance, and faster data transmission than possible when using modems over traditional analogue telephone networks. Basic ISDN services combine voice and data, while broadband services add video and higher-speed data transmission. ISDN offers end-to-end digital connectivity (Beolchi, 2003).

SW56: Switch56 is digital telecommunication that transmits narrow-bandwidth digital data, voice, and video signals.

Telehealth: Encompasses the use of advanced telecommunications technologies to exchange health information and to provide healthcare services across geographic, time, social, and cultural barriers (Reid, 1996). Telehealth refers to all healthcare or social services, preventative or curative, delivered at a distance via a telecommunication, including audiovisual exchanges for information, education and research purposes, as well as the process and exchange of clinical and administrative data (Quebec Ministry of Health and Social Services, 2001). Homemade systems or systems used outside of official health information networks are included in the latter definition.

Chapter 4.11
IS Implementation in the UK Health Sector

Stuart J. Barnes
Victoria University of Wellington, New Zealand

INTRODUCTION

Since the mid-1980s, the UK public sector has been the subject of wide-ranging reforms involving the introduction of IS and IT. Change has been sought in the ways that services are managed and delivered, the evaluation of the quality of aforesaid services, and in accountability and costing. One of the most predominant of such changes has been the introduction of competition for services, the motivation of which has been to invite efficiency, effectiveness, and related benefits ensuing from the accrual of economies.

Pivotal to such change has been an explosion in the introduction of a variety of information systems to meet such challenges. Focusing on health care, a large part of the work of the health service involves collecting and handling information, from lists of people in the population to medical records (including images such as X-ray pictures), to prescriptions, letters, staffing rosters and huge numbers of administrative forms. Yet until recently, the health service has been woefully backward in its use of the technology to handle information by the standards of private industry.

This has been quickly changing in recent years and by 2003 the National Health Service (NHS) spent £2.8 billion annually on capital in hospitals (Department of Health, 2003a), around 10% of which was for IT. In the last 20 years, IT has added 2% to overall health expenditure (Wanless, 2001). This investment is still small by the standards of the private sector, but is all the more significant when we consider that health care is an industry which has been slow to adopt IT and one which presents some of the biggest IT opportunities (Department of Health, 2002).

BACKGROUND: INFORMATION SYSTEMS IN THE NHS

The implementation of IT in the UK health sector has been fraught with difficulties. In fact, estimates suggest that problems with the first wave of projects in the public sector, from the mid-1980s to mid-1990s, cost over £5 billion (Collins, 1994).

There are a number of high-profile examples of IS failure in the NHS, including that of Wessex Regional Health Authority's Regional Information Systems Plan (£63 million), the London Ambulance Service's Computer Aided Dispatch system (£1.1 to £1.5 million), and more recently, various Resource Management Initiative (RMI) Case Mix failures (£1 to £3 million) (Barnes & Targett, 1999).

In this section we will focus on RMI and Case Mix as an illustration, since this was one of the first initiatives for wide reaching IT-induced organizational transformation and information integration in the health sector. The systems implemented have been an important support for financial developments in the management of UK hospitals. During 2003, the importance of Case Mix systems has again come to the fore as the NHS has attempted to implement prospective payment systems (PPS) (Department of Health, 2003b).

RMI was a driving force in the move towards information systems and cultural change in the NHS. First announced in 1986, RMI was going to help clinicians and other hospital managers to make better-informed judgments surrounding how the resources they control can be used most effectively (DHSS, 1986). The Initiative was not only aimed at persuading clinicians to own the management process, but to provide them with accurate, up-to-date and relevant information which could be used to cost medical activities and improve patient care. The response to this need for improved information services available to hospital units was the development and implementation of a sophisticated and extensive package of IT referred to as the "Case Mix" information system (CMIS), an idea borrowed from the U.S., with the purpose of clinical and management audit.

Prior to RMI, the introduction of IT in the NHS was patchy and limited. Where systems existed, the technology was very varied, incompatible, archaic, and dependent upon regional computer departments to deliver necessary operational systems. The development of CMIS, with its dependence on data fed from other systems such as the Patient Administration System (PAS), radiology, pathology, theatre and nursing systems, provided a catalyst for the adoption of operational systems throughout the hospital (Barnes, 2001).

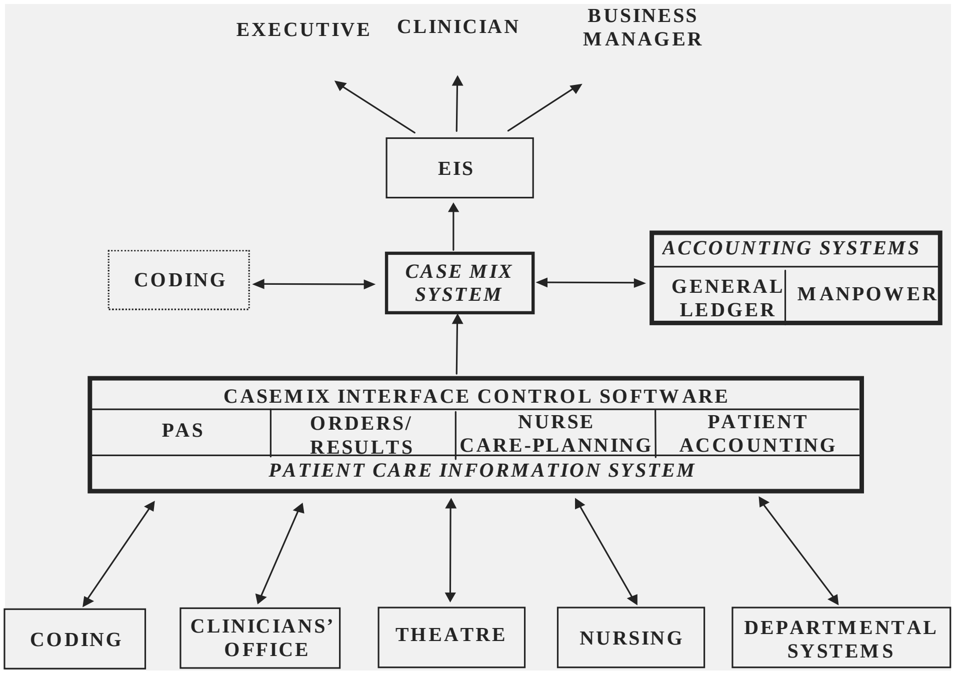
CMIS takes a central position in the hospitals' IT infrastructure, as shown in Figure 1 (an illustrative example - specifications may vary depending upon the hospital), providing a tool for collecting and analyzing data from all areas of hospital operations using an executive information system (EIS). As we can see from Figure 1, there are two main types of data feed: financial and medical. The financial feed consists of pulling data from the general ledger and humanpower systems, particularly standard costs and budgets. This contrasts with the other main feed to CMIS, that of the "patient care information system" - a label given to the array of feeder sub-systems providing information on all aspects of patient treatment and care.

Each of the feeder systems is interfaced with CMIS, so as to provide appropriate data in an acceptable format. Such data are accumulated by CMIS within the care profile sub-system: this stores the actual tests, treatments, costs, number of cases and so on to be compared with expected "ideal" profiles or projected activity levels as drawn from the financial data, enabling financial audit. Regarding clinical audit, CMIS provides the tool for assessment of the professional clinical practices of each clinician.

EXPERIENCES IN INFORMATION SYSTEMS IMPLEMENTATION

In addition to traditional problems of IS implementation, RMI also reveals a number of interesting and contrasting influences on the early implementation of strategic IS in UK hospitals:

Figure 1. The role of case mix in NHS hospitals



- *Central influence* - Regional authorities (RAs) had a substantial influence on the development of systems in a number of areas, for example investment justification, what to procure, objectives, financing, and project management milestones. Importantly, the original "standard" systems were not sensitive to the needs of individual hospitals, affecting stakeholder support and the need for project redefinition. Where relationships with RAs were tenuous, RMI was looked upon with suspicion. Initiatives imposed subsequently changed the shape and direction of the project, and created other priorities within hospitals, while recommendations about clinical coding were never clear. Central influence is, interestingly, both a reason for the existence of the project, and for many of its problems: paradoxically, it is both an enabler and an inhibitor.
- *Project purpose* **-** The problems in communicating the purpose of CMIS, and in approaching locally sensitive designs, affected the attitudes of stakeholders: the project was very much an imposed directive. Many individuals were unclear about the rationale for CMIS, and this was compounded by the traditional absence of IT within hospitals. While RM was aimed at improving resource allocation, ironically, many saw IT spending as a waste of money as opposed to direct patient care.
- *Clinicians, management and CMIS* **-** Hospitals are distributed organizations, with a variety of fragmented groups and cultures, each with their own defined roles. RMI and CMIS cut a swathe through many of these, particularly clinicians and management, and sat uncomfortably in hospitals. Where the system impinged upon the territory of individuals or groups, friction was encountered. Hospitals, for many years without IT, and with a defined structure and set of roles, found change difficult. While

politics occurred in a variety of areas, the clinician-management divide is perhaps the most interesting. Each of these groups found it difficult to adjust to a new culture and structure, and for apparently conflicting reasons: top management was often opposed to devolvement, while clinicians were wary of CMIS as a "tool of management" and a control device. Thus, paradoxically, CMIS was seen both as a tool of centralization and of devolution.

CONCLUSIONS AND FUTURE TRENDS

The complexities surrounding RMI compounded early experiences in strategic IS implementation in the NHS. Evidence suggests that success has been difficult to achieve, and that hospitals found it difficult to achieve any tangible benefits (e.g., see Barnes, 2001; Barnes & Targett, 1999; Lock, 1996). Evaluating investments is made all the more difficult by the fact that published evidence is scarce. Lock (1996) found that only 5% (by value) of all investments were the subject of published assessment, which may be an indicator of the poor value of such investments. Even published studies are far from conclusive: the "official" resource management evaluation conducted by Brunel University found "no measurable patient benefits" in its review of the six pilot sites, while costs were more than double those expected (Heath Economics Research Group, 1991).

One of the key impacts of case mix has been on the financial management of hospitals. The sustainable financial management of hospitals has recently come into question (Audit Commission, 2003). During 2003, the UK Department of Health has outlined the Government's desire to implement PPS, as outlined in its *Payment by Results* White Paper (Department of Health, 2003b). This would allow the trust financial regime (TFR) of hospitals to carry deficits and surpluses, spurring greater efficiency. This has led to some concerns that it may lead to under-investment and reduction in quality (Medicare Payment Advisory Commission, 2003; Rosenberg & Browne, 2001; Topping, 1997). On balance, the evidence from the U.S. and elsewhere seems to suggest that these systems are not detrimental to the quality of health care (Dismuke & Guimaraes, 2002; Shen, 2003).

KEY TERMS

Case Mix: On admission to a hospital, the individual patient is provided with a variety of services, each of which expends resources. Each encounter or episode has a mix of, for example, tests, treatments, accommodation, and so on. Case mix refers the combination of services and resources used for each patient episode.

Case Mix Information System (CMIS): An information system, fed with data from an array of hospital subsystems, for the principal purpose of clinical and financial audit of patient cases. Further developments to CMIS have seen other functionality added, such as contract planning, quality assurance, waiting lists, and clinical support.

Clinical Audit: The assessment of professional clinical practices. General information routinely provided includes lengths of stay, deaths and re-admissions. More specific information such as drugs administered and operative procedures performed are available via the appropriate feeder systems. The data allow aspects of case mix, clinical management, diagnostic accuracy and patient outcomes to be compared.

Clinical Coding: Categorises diagnoses and procedures for patient episodes according to a detailed clinical standard index. The most common standard is the International Classification of Diseases (ICD), particularly for financial audit, but a UK standard, Read, is very popular with medical staff. These are grouped to provide aggregate information for audit.

Executive Information System (EIS): An IS that provides high-level information tailored to the needs of decision-makers. Typically a graphics-oriented system, in the context of CMIS the EIS aggregates and uses summary data to present information to clinicians, executives and business managers in the form of graphs, histograms, pie charts, tables and so on.

Financial Audit: The budgetary assessment of the cost of hospital care. CMIS collects data on the actual tests, treatments, costs, number of cases and so on. These are then compared with expected “ideal” profiles or projected activity levels as drawn from the financial data, typically based on best practices or historical data.

Resource Management Initiative (RMI): A UK initiative providing clinicians and other hospital managers with information required to use resources to maximum effect, generally by the introduction of new IT. This was aimed at encouraging clinicians to take more interest and involvement in the management of hospital and community units, making them responsible for operational and strategic decisions.

Chapter 4.12
Applying Adaptive Structuration Theory to Health Information Systems Adoption:
A Case Study

Dana Schwieger

C. Ranganathan
University of Illinois at Chicago, USA

H. Joseph Wen
Southeast Missouri State University, USA

ABSTRACT

Adaptive Structuration Theory (AST) is rapidly becoming an important theoretical paradigm for comprehending the impact of advanced information technologies. In this paper, a modified AST model was designed to illustrate the changing inter-relationships among the variables affecting the adoption and application of a new technology into a medical organization setting. Using findings from a case study conducted over a 10-month period, the authors apply the case to the model to illustrate the complex interactions between medical billing technology and organizational processes. As the organization attempted to install and implement the new system, they found that in order to maintain daily operations, they would have to modify and adapt several aspects of the organization, technology, and operations. As the system was slowly integrated into operations and the organization's

needs evolved through the adaptation process, the study, in turn, found that different iterations of the model could emphasize different structures. The case illustrated that the capacity to manage health information systems (HIS) often requires the organization to prioritize its needs and focus its energies on a critical structure while temporarily disregarding others until the primary healthcare processes are under control.

INTRODUCTION

Driven by a need to improve utilization of information and productivity, information technology (IT) has become pervasive in the healthcare industry. Some of the areas in clinical medicine in which technology has been successfully employed include billing and scheduling, practice management, laboratory result reporting, and diagnostic systems. The use of computer technology and information technology in healthcare and its delivery is called medical informatics, which began with the computerization of hospital administration tasks in the 1960s. These systems are best thought of as cost reducing and/or quality improving technologies.

Increased demands for electronic exchange of data have been driven by both internal and external pressures. Hospitals are comprised of a multitude of specialized departments and suppliers requiring that large amounts of clinical as well as financial data be exchanged. External forces consisting of insurance company regulations and guidelines (Hagland, 1998), government mandates and restrictions as well as Medicare deadlines (Straub, 1998) have pushed organizations to adopt technologies to automate their operations. Automating these processes may reduce costs as less paper is generated, as fewer mistakes are made, and as information is transferred faster.

A Health Information System (HIS) can also increase the quality of medical care. This was the goal of many of the pioneers in medical informatics or clinical systems development. The quality improvements from hospital information systems would emerge from the improved record-keeping and decreased mistakes engendered by more administrative systems, as well as from clinical systems designed to aid in the provision of medical care.

Today, the role of HIS in medical care has expanded at an ever-increasing pace. As a result, health care professionals' familiarity with medical informatics as well as the adoption of HIS is crucial for the delivery of higher quality care. However, the challenges of applying IT to healthcare are very real. Concerns of privacy and confidentiality of data, lack of national standards for protecting medical data, the need for large scale investments, and the requirement for behavioral adaptations on the part of patients, physicians, and organizations are just a few of the impediments to the adoption and use of IT in healthcare.

Rural area medical practices are especially feeling squeezed by the demands being placed upon the use of technology in the medical field. Although their use of HIS is limited, governmental regulations and the demands of insurance clearinghouses are forcing these clinics to adopt automated billing technologies. Some clinics, unable to afford billing technology capable of electronic data exchange, have been forced to merge with other practices or close their doors. Those clinics that could afford the technology experienced the challenges associated with adopting this new billing system into their business operations.

This paper uses a version of Adaptive Structuration Theory (AST) to examine the challenges faced by a rural medical clinic as it adopts new billing technology. AST provides a conceptual change model that helps capture the longitudinal change process. This paper proposes a modified AST model, which provides a theoretical framework that explains the appropriation process of medical electronic billing systems (MEBS). In recent years, MEBS has become a critical tool for supporting healthcare services. The appropriation of MEBS in a medical center involves a great deal of change, which, if not carefully considered, could result in significant difficulties. Using a case study approach, this research identifies appropriation issues when planning and evaluating MEBS usage in medical centers.

LITERATURE REVIEW

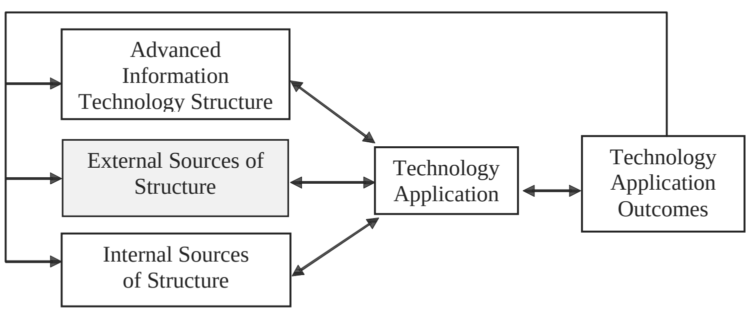
Changes in information technologies cannot be viewed as isolated events; rather, one must be mindful of the interdependent, reciprocally structuring relationships that exist between the information technology and the organization (Lucas & Baroudi, 1994; Orlikowski & Baroudi, 1996). One strand of research dealing with this type of incorporative change process is adaptive structuration theory originally posited by DeSanctis and Poole (1994) as an extension of Anthony Giddens' structuration theory (Giddens, 1979, 1994). Adaptive structuration theory focuses upon the interrelated dynamics embedded in the application/creation of the technology that is in use by the organization through the combined processes of human interaction, technology, and organizational social structures (Griffith, 1999; Lucas & Baroudi, 1994). This study attempts to extend the research in adaptive structure theory through the development of a modified version of DeSanctis and Poole's 1994 model. The model is depicted in Figure 1.

DeSanctis and Poole found that AST, over time, led to changes in the rules, processes, and procedures which were used within group decision support system social interactions. In their study, DeSanctis and Poole (1994) defined AST as "an approach for studying the role of advanced information technologies in organization change" (p. 121). Their research, however, focused upon a "snapshot" of a meeting in which group decision support systems were being used to study interaction at the micro- or individual level of the organization rather than at the institutional level. In light of their definition, AST could best be applied from a longitudinal perspective rather than just an instance in time.

This study extends the scope of research in the area of emergent organizational structure by applying a modified version of DeSanctis and Poole's model to a management information system at the macro-level of organization structure. Case study research is applied to describe and analyze the intraorganizational structural changes that develop in a multi-clinic, Midwest-based medical organization as a result of the introduction and implementation of medical billing technologies into daily operations.

Structuration theory has been approached from three different schools of thought: institutional,

Figure 1. Research model adapted from DeSanctis and Poole's 1994 model



decision-making, and socio-technical. The institutional school of thought viewed technology as an opportunity for change rather than as a causal agent of change (Barley & Tolbert, 1997; Kling, 1980). Under this perspective, technology did not determine behavior. Instead, people generated social constructions of technology (DeSanctis & Poole, 1994; Orlikowski, 1992).

The literature focusing on the decision-making school of thought emphasized the cognitive processes associated with rational decision-making and adopted a psychological approach to the study of technology and change (DeSanctis & Poole, 1994). The socio-technical school of thought combined the institutional and decision-making perspectives by incorporating the power of existing social practices with the influence of advanced technologies for shaping interaction. This, in turn, was thought to bring about organizational change (DeSanctis & Poole, 1994).

DeSanctis and Poole (1994) continued along the socio-technical line of thought with AST. This theory accounted for the structural potential of technology while maintaining focus upon the use of technology as a primary determinant of technology impacts. Their study examined the effects that occurred when advanced technologies were brought into social interaction to affect behavioral change.

Few studies have examined the affects of the diffusion process from the perspective of AST. The diffusion process was considered from beginning to end using the diffusion model posited by Kwon and Zmud (1987) and later modified by Cooper and Zmud (1990). Diffusion literature was applied in parallel to the foundational constructs of the adapted research model to define structure of advanced information technology, external sources of structure, internal sources of structure, technology application, and finally, technology application outcomes.

RESEARCH MODEL

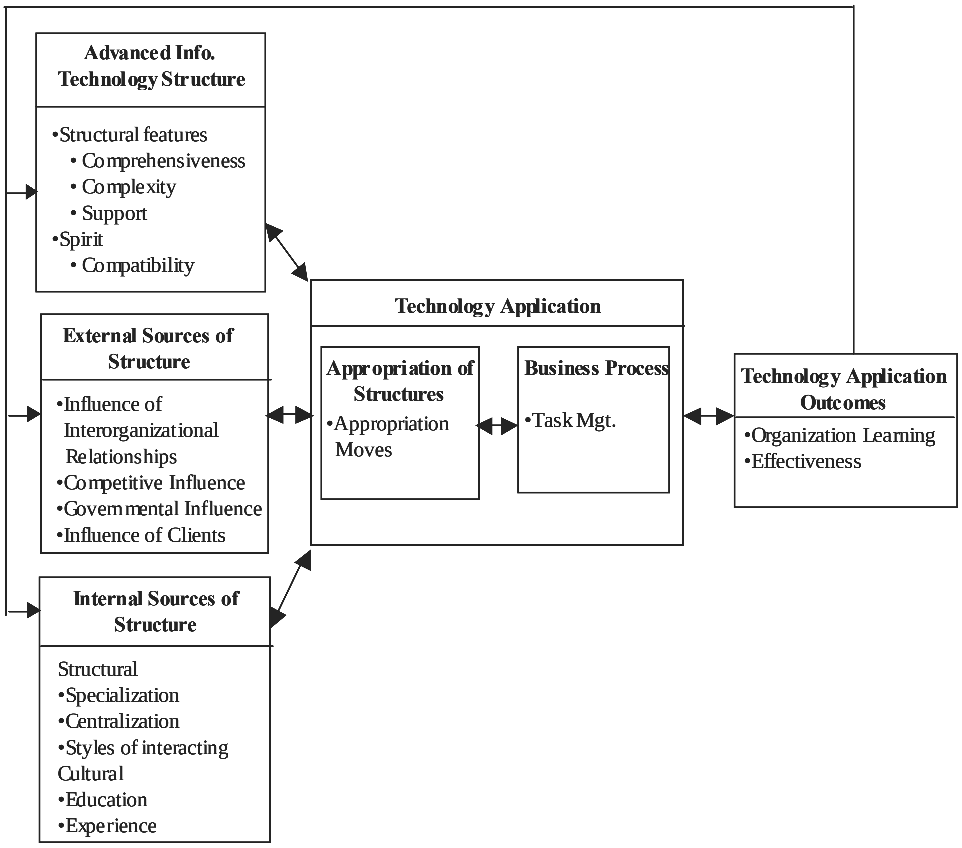
By combining AST (DeSanctis & Poole, 1994) with diffusion theory (Kwon & Zmud, 1987), a model encompassing both areas is proposed. The constructs of the model are defined, for the most part, using Kwon and Zmud's (1987) literature review on diffusion theory and a simplification of DeSanctis and Poole's original model. The research model displaying construct definitions is presented in Figure 2. Each construct of the model is defined in the following paragraphs and illustrated in the accompanying tables associated with each variable.

Advanced Information Technology Structure

Advanced information technology structure is defined as the structural features and the spirit of the technology that outline the expected use of technology within an organization. One of the two elements of structural features includes the technology's comprehensiveness in terms of the number and variety of features and capabilities that users are offered. These resources direct how information is gathered, managed, and manipulated by users (DeSanctis & Poole, 1994). The second element is the level of complexity defined as the degree of difficulty that users experience in using the new technology (Kwon & Zmud, 1987). Complexity can be affected by the ease of use of the application, ease of learning through tutorials, user-friendly screens, help screens, documentation as well as customer service and support.

Spirit of the technology is defined as the "general intent of the technology with regard to values and goals underlying the structural features" (DeSanctis & Poole, 1994, p. 126). Spirit defines the behaviors appropriate in using the technology and helping users understand and interpret its meaning to the organization (DeSanctis &

Figure 2. Research model



Poole, 1994). The spirit of advanced information technology is defined by compatibility. Compatibility is related to the "fit" of an innovation to an organization in relation to the organization's needs and its underlying goals and values (Avolio & Dodge, 2001; Kwon & Zmud, 1987). The construct ranges defining advanced information technology structure are illustrated in Table 1.

Table 1. Advanced information technology structure construct definition range

Advanced Information Technology Structure	Traditional	———	Customizable
Structural Features	Basic	———	Full-featured
Comprehensiveness	Basic	———	All-Inclusive
Complexity	Elementary	———	Advanced
Support	Poor	———	Rich
Spirit	Unfavorable	———	Favorable
Compatibility	Unsuited	———	Well-suited

Table 2. External sources of structure construct definition range

External Sources of Structure	Reactive	———	Proactive
Influence of Interorganizational Relationships	Reactive	———	Proactive
Influence of Competition	Reactive	———	Proactive
Influence of Government	Reactive	———	Proactive
Influence of Clients	Reactive	———	Proactive

External Sources of Structure

External sources of structure consist of interorganizational relationships, governmental influence, competitive influence, and client influence. Interorganizational relationships examine the influence exerted on an organization through affiliations with other organizations. Governmental influence examines the effect that government has on technology application decisions. Competitive influence explores the effect that competitive organizations have on technology application decisions. Client influence assesses the influence patients have on the organization. Thus, the external environment is related to the variability of the environment in regards to instability and turbulence provided by outside sources and the actions taken in regards to these variations (Kwon & Zmud, 1987). See Table 2.

Internal Sources of Structure

Internal sources of structure are divided into two parts: structural and cultural (Table 3). Structural sources of structure consist of specialization and centralization. Specialization is defined as a diversity of specialists within an organization in which individuals or groups of individuals have special functional skills (Kwon & Zmud, 1987). Centralization relates to the concentration of decision-making activity (Kwon & Zmud, 1987). A centralized focus increases the decision-making activity of upper management while a more decentralized organization can increase the decision-making capabilities of lower-level employees.

Cultural sources of structure consist of education, experience and styles of interacting. The organization members' style of interacting can

Table 3. Internal sources of structure construct definition range

Internal Sources of Structure	Less Developed	———	Developed
Structural	Less Developed	———	Developed
Specialization	Generalized	———	Functional
Centralization	Low	———	High
Cultural	Less knowledgeable	———	Knowledgeable
Education	High School Diploma / GED	———	Advanced Degree
Experience	Little	———	Extensive
Styles of interacting	Informal	———	Formal

be influenced by a centralized structure, the formality of management operations, and the boundaries of hierarchical or functional levels. Members of the organization are influenced by the knowledge, education, and experience with technology, both actual and perceived, that others in the organization have.

Technology Application

Technology application is defined as the means by which the technology application outcomes are formulated. This portion of the model consists of two interacting variables, appropriation of structures and business processes (Table 4). The technology application process of the model is influenced by, and likewise influences, advanced information technology structure, external sources of structure, internal sources of structure, and technology application outcomes.

Appropriation of Structures

Appropriation of structures is the degree to which the members of the decision-making body agree on what structures should be accepted through adaptive moves as well as their application. Thus, the technology is defined through the use of its features by the organization rather than just its features alone (Reinig & Shin, 2002; Salisbury, Chin, Gopal, & Newsted, 2002). This is influenced by the intended purposes and meanings associated with applying the technology. The technology structures can be used directly, related to other structures, replaced by other structures, or interpreted as they are applied. Increased agreement on appropriation of structures can lead to greater consistency in the organization's usage patterns of advanced information technology.

Business Processes

Business processes are the actual courses of action in which businesses perform in daily operations. Hunt (1996) defined business process as "a series of steps designed to produce a product or service" (p. 3). Uses of technology and management of tasks can be in-line with the appropriation of structures. As the appropriation of structures vary over time and across adopters, decision processes and technology application outcomes can likewise vary. The business processes determine how the technology can be implemented within the organization. Likewise, the management of the technology can affect implementation of the technology to accommodate business processes.

Technology Process Outcomes

Technology process outcomes are defined as effectiveness and organizational learning (Table 5). Organizational learning may be defined as gaining the necessary knowledge, skills (Attewell, 1992), and expertise (Premkumar & Ramamurthy, 1995) to effectively utilize a technology and apply it to business process. Cooper and Zmud (1990) defined effectiveness as the ability to

Table 4. Technology application construct definition range

Technology Application	Traditional	———	Innovative

Task Management	Traditional	———	Innovative

Table 5. Business process outcomes construct definition range

Decision Outcomes	Low Quality	High Quality
Organizational Learning	Less Successful	Successful
Effectiveness	Less Favorable	Favorable

take full advantage of the information system being implemented. This sub-property examines the fit of the technology as it has been applied to the needs of the organization and its related technological needs. The technology application outcomes are affected by the information gained through the technology application process as well as the implementation of the technology application outcomes. This, in turn, affects technology application processes as well as the medical electronic billing technology structure, external sources of structure, and the internal sources of structure.

RESEARCH METHOD

A case study approach was applied to a multi-physician family practice located in the Midwest and identified as "Family Medical". This organization was selected for the study based upon its current level of growth and application of technology to business operations. Family Medical had been formed six years prior to the study when two separate practices, "Practice A" and "Practice B" consolidated their operations into Practice A's larger medical facility. Upon consolidation, Practice B's medical records were manually coded into Practice A's electronic billing system. Over the 6-year time period, Family Medical had faced tremendous change and technological upheaval as they first combined the operations of two separate facilities and then realized that a new billing application would be necessary to accommodate the aging technology and continuously swelling database. The combined medical practice had grown to provide services to over 22,000 patients and as Practice B's medical records were gradually added to the database, the efficiency of the system slowly declined.

The director of MIS and operations and a billing clerk were interviewed using a focused interview technique. The flexibility of the open-ended questions was supportive of the exploratory nature of the study and allowed for both the collection of facts as well as opinions. Through the utilization of multiple interviews, a more thorough clinic perspective was provided via observation through multiple viewpoints contributed by each medical office interviewee (Straub, 1998).

Documentation and statistics published by the U.S. Department of Health and Human Services, Health Care Financing Administration, American Medical Association, and Medicare were reviewed as they related to medical clinic mandates and regulations. Through site visits, direct observations were made of the medical billing technology and billing procedures employed in the medical office. Information regarding processes, environmental conditions, office attitudes, and structure were observed.

RESULTS

The application of new technology into the business operations of Family Medical illustrated the complex interactions between advanced information technologies, internal and external sources of structure, the application of technology to business processes, and, ultimately, the outcomes of the application of the technology to business processes.

The main contact person at Family Medical was "Steve," the business manager. He was in charge of overseeing several aspects of business operations including, accounting, billing operations, and information systems. Although Steve recognized the benefits and necessity of technology in the medical office setting, he was still recovering from the stressful toll placed on his company by the latest technology overhaul and regretted losing the stability of the former system.

The previous system was a fairly fail-safe system. Employees just typed into dumb terminals on a Unix platform. It was very easy to use and there was little margin for user error. The old application caused very few organizational problems unlike the new software. Actually, our old software matched the practice more so than the new software that we purchased.

The decision to purchase the new billing technology arose after the two practices joined forces and realized that they needed to update their outdated billing technology to accommodate current medical billing trends as well as the heavier usage of the system. Newer systems were capable of providing features such as system integration, graphical user interfaces, statistics and sophisticated charting and reports. Although Steve was more familiar with the managerial side of operations rather than the technical side, the Board of Directors elected him to lead the management team in the search for a medical billing system replacement.

It took 2 years for us to choose our billing software and we still chose a bad system. There were a lot of changes in the medical billing technology industry during the time we were trying to select a new system. It was like trying to hit a moving target. There was an evolution going on in the industry. We would go to one conference and the software and company would be there, then, we would go to another conference and the company would have been bought, sold or absorbed by another company. By the time we had gotten down to the actual selection, there were really only two or three integrated software packages to choose from. This was a bad time to have to be choosing a software package. There was too much volatility.

At the urging of the Board of Directors, the management team finally settled upon an application to recommend. They gathered their research and formalized a report to present at the next board meeting.

Ultimately, management chose the billing software with approval of the Board of Directors. The software was chosen based upon the features that it provided, specifically, the electronic medical records module of the medical clinic management features. The organization did not focus upon the features of the billing technology [in the practice management portion] of the application. Ironically, we have never been able to get the medical clinic management features to work correctly and the only part of the application that we utilize is the billing portion. In retrospect, we feel that we should have paid more attention to the practice management portion of the application.

Although the selected package came with numerous bells and whistles, Family Medical failed to focus on the features that most fit the needs of the organization and its application to business processes. Family Medical also failed to involve a contract lawyer in carefully delineating the responsibilities of the vendor and the associated timeline in which all parts of the implementation process were to be fulfilled. Several implementation factors were orally discussed and supposedly settled by representatives from Family Medical and the software vendor. However, as the implementation process unfolded, Family Medical found that several services provided by the vendor such as training, conversion, installation support, and post-installation support did not quite meet their expectations.

The conversion and implementation processes were worse than they should have been. The installation team was interested in getting the application installed, but not necessarily right, and then moving on. We had so many problems that it was amazing that anything got done.
The changeover [to the new system] was to take place over a long weekend. Complications arose during the installation process and several of the modules would either not work at all or not interoperate with other modules in the system. … Half way through the patient record upload, the system froze. The technicians tried repeatedly to upload the patient records, but due to "compatibility" issues between the new server and the data upload module of the application, the records would not upload and had to be entered manually. In the process of uploading the data, they had corrupted both the patient information as well as the old system rendering both systems unusable. On top of that, no backups had been created to use to restore the old system. Once most of the modules of the system appeared to be up and running, the vendor's installation team took off.
We didn't really know what would and wouldn't work until we started trying to use the system. When we started filing claims, we found out a lot of things were not right, we were not getting acknowledgments back and claims were not getting to where they were supposed to go. By that time, it was too late. The installation team had left and when we would call the vendor's support line, they would either not answer the phone or not return our messages. … It took a whole year to track down every problem one by one and figure out why it happened.

Internal structure: The internal structure of Family Medical experienced tremendous upheaval. Before the new medical software was installed, the organization was functionally-oriented around payer source with employees specializing in specific billing areas such as Medicare, Medicaid, big insurance companies, and so forth. In order to keep operations afloat, the formalized organization structure disintegrated and job responsibilities were assigned on an as-needed basis. People were shifted from various positions to input records into the system.

At the beginning, it was a matter of trying to stay afloat. After the new technology was implemented, we frantically tried to enter all of the patients into the system and be prepared to bill patients on a daily basis. The most important thing that we had to do was to make sure that the patients that we had that day were in the system, covered and billable. The system was used for very little other than processing the day's billing. During this time period, everyone had to be able to help out in other positions. Except for the phone operators, there was no specialization. We moved toward a system where everyone had to do everything. The organization lost in terms of efficiency and speed. The levels disappeared and it was a matter of the company CEO working directly with the billing clerks in order to get the bills processed. Managers and senior account representatives who had more experience and expertise in terms of handling patients, helped in getting the charges and payments posted because we could not afford to bring in a lot of outside help to get everything entered. Patient demographic data is now being entered by reservationists rather than anyone who can be spared and we hope to go back to being more functionally oriented.

Employee morale and respect for various levels of the organization dwindled as problems continued to surface and blame was cast between departments. Areas throughout the organization were affected by the problems caused by the new system.

We went through a period of time when the clinic (medical side also) was waiting on the billing and insurance office to catch up. Everyone perceived the billing department as being very unfamiliar with medical billing technology as well as technology in general. They took some flack for not being caught up because cash flow was so affected. We did not have enough money to give raises for over a year.

At first, if you would have asked the employees if the managers knew what they were doing, they would have said, "No! They have no clue." We were seen as being pretty incompetent in this system, billing processes as well as other forms of technology. The managers were there on nights and weekends, struggling with the billing clerks to get patient records entered. The employees were influenced by seeing the managers get in there and work side-by-side with the people in the billing department. Now that things are starting to settle down in the billing department with the new technology, the attitude toward the competence of this department is no longer as harsh.

Family Medical utilized both informal and formal communication channels throughout the diffusion process. The organization took the standard training and then modified it and condensed the documentation to make it easier for the average person to read. Before the system was installed, they formally discussed with the employees the benefits of getting the new system. They also encouraged the employees to be supportive in assisting each other in trying to learn and use the new system. After the system was installed and the clinic started experiencing problems, management held formal meetings to discuss the problems with the employees as well as actions being taken to remedy the situation.

We did a lot of ground work and training to try to prepare the employees for the new system. We presented the system to them as being an opportunity to receive training that they would never get anywhere else. We tried to let them know that they were being trained so that they could become familiar with the technology and be able to use any system…. Everyone was willing to share information. What one person learned, that person was ready and willing to share to make everyone's lives easier. …Management also had to be very upfront and honest with their people and admit to the implementation problems and their level of difficulty. We had many meetings where the problems were discussed and we had to prioritize the issues.

Technology appropriation: Although the system that was purchased had numerous features for both the business and practice sides, Family Medical was unable to utilize its full capabilities. Not only did they have to deal with the installation problems, they were also faced with the fact that they had purchased the wrong application to fit their business operations. Family Medical was resigned to using the features that they could get to work with minimal to no problems and that fit their operations, ignoring the features that did not fit their organization and continuing to attempt to configure those pieces of the application that they thought would fit their organization but were not yet functional.

The application has a lot of nice features if we could ever learn to use them. It's just too complex. It is more appropriate for a hospital rather than a medical clinic setting. It even has the wrong type of accounting system for what we need in a medical clinic. We purchased the application due *to the medical record portion, but we've never been able to get it to work. We decided to leave the medical record portion of the application alone since it would not work. …We could use some of the information for medical informatics if that part of the system worked. The potential is there, but we just have too many problems to use it.*

Application to business processes: As the technology was applied to the business processes, Family Medical realized that they would have to adapt their daily business operations in order keep the business running. Their main concern was processing the patients to be seen that day so that the patient's information would be available when he/she arrived at the clinic and available for bill processing at the end of the day. They focused their energies on using the billing portion of the application and adapted their business processes to accommodate the technology that worked and the resources that were available. Ancillary operations were foregone to accommodate the more pressing business need of bill processing and payment. Without this function, Family Medical would be unable to finance continued operations.

It is difficult to separate where the problems were. There were some problems with the clearinghouse, some problems getting the information from the clearinghouse to the carrier, and some problems with the feedback process in place to make sure that all of the claims were electronically sent and received by the carrier. We have had to alter the way that we did things and our processes, to some extent, to fit the way that the software worked. The billing process changed due to the problems with the technology. We had everyone go through training for using the application for their job and then we had to move people to different positions in order to get jobs done. The management team had to decide what the priorities were and what could be done and what could be let go. There will probably still be things to catch up on a year from now. …We let a lot of things go that would normally be done on a daily basis just because they were the priorities to keep the business running and to take care of patients. We were too busy trying to deal with the day's patients...

External influences: Overcoming internal application appropriation and implementation issues does not define the limits of the issues Family Medical faced in the application of the technology to business processes. There are several external factors which affected the appropriation of the billing technology to business processes. Due to glitches in the software, some of the bills were not being electronically sent to certain insurance carriers. Family Medical did not realize this omission of data until two to three weeks after the bills had been processed. This prompted them to start developing a system of checks and balances to implement in coordination with the insurance companies to insure that bills were being correctly received.

Their business processes were also heavily influenced by their interactions with Medicare as well as customers. As their biggest external business partner, procedural changes in Medicare's electronic claims handling increased delays in claims processing and, thus, receipt of payments. Time gaps between the patients' office visits and when they would receive their bills added to the confusion of an already complicated document. In response, Family Medical prepared and trained additional staff to specifically handle customer billing inquiries.

… Some of our bills were not getting processed due to errors in the data tables. We didn't find this out until several weeks had passed. We are in the process of changing the system of checks and balances due to the problems that we have encountered with the new software. …Most of the issues that arise from external sources are generated by Medicare. They are the most well-

established of our external associates. Most of our problems with Medicare arise when they change fiscal mediaries or carriers. This affects the clearinghouse also. It really causes problems with our cash flow because we won't get paid on our processed claims for a while. When Medicare changes to a new carrier, Medicare stops processing claims for about six weeks, thus, this adds to the amount of time that it takes to get the money. Medicare also influences the software developers. They are the ones who have to look at the governmental mandates and write patches to keep their users in compliance.
The customer responses also drive our decisions. The customers are still not happy with the statements that they are getting. This will influence our purchase decision when we replace the current application. There are too many business problems that arise from people not understanding their bills.

Outcomes: Family Medical learned that they had to adapt their use of technology, business processes, and organizational structure in order to maintain a minimal level of business operation effectiveness. They continue to wade through the numerous problems created by the implementation of their new medical technology and long for the proficiency of their original system. Although the new system has not been completely installed and configured, they have already begun discussing the possibility of purchasing a replacement system.

The employees liked the previous billing system and its ease of use and navigation. Even though the new system has a graphical interface, after all of the problems we have been through, they still prefer the previous system and would like to go back to it. … We hope to be using another application in five years.

DISCUSSION

There are several lessons that can be learned from the technology adaptation process experienced by Family Medical regarding choosing a technology, the purchase process, and working with vendors and employees.

Solicit the input of effected employees in the purchase decision and process. Family Medical's employees resented having a new technology pushed upon them and especially the fact that they found out about the new technology shortly before the changeover occurred.

Match technology features to business needs. Family Medical chose technology based upon extra features that impressed them rather than the features that would fit the needs of the organization. Once the technology was installed, they found that the features that they needed were not what they had wanted but acceptable and the features that had enticed them to purchase the package were not even functional.

Establish priorities and be willing to adapt as needed. Family Medical was forced to prioritize needs and make immediate and sometimes substantive adaptations in order to keep operations running. Job functions changed across several levels of the organization as the CEO moved from plotting long-term strategies to assisting with data entry. The technology implementation goals of the organization changed from implementing an organization-wide comprehensive health information system to getting a few of the integral billing modules operational so the billing office could perform daily functions.

Obtain the services of a contract lawyer. Several of the promises that the vendor had made to Family Medical were not in writing and were forgotten after the software was purchased. Training, documentation, installation, data integration, maintenance, support, and updates are some of the factors that need to be determined before a purchase contract is signed.

CONCLUSION

Examination of the model through case study analysis illustrated the interconnected relationships between advanced information technology, external sources of structure, and internal sources of structure on the technology application process. The research found that organizations might adapt any or all of those structures to accommodate the business processes or the appropriation of technology to the business processes. Business processes could also be adapted to accommodate the appropriation of the technology and vice versa.

As illustrated by Family Medical's discontinued use of the medical record module and its continued work with the configuration of the non-working modules, part of the technology appropriation process could be learning what features of the application do not work as well as what to do to accommodate and overcome technical difficulties. The capacity to manage business process tasks might require the organization to focus its energies and resources on one structure or certain aspects of structures and temporarily disregard others. To overcome their numerous technological problems, Family Medical found that it had to prioritize its business operations and focus its energies and resources on those processes that were integral to maintaining daily operations. Auxiliary processes were disregarded until the primary business processes were under control.

The adaptive structuration process is a cyclical process in which the organization continues to adjust to its structures as well as to structural changes. The study found that different iterations of the model could emphasize different characteristics of the variables. When the new technology was first introduced, for the most part, the organization utilized a functionally-oriented internal structure with employees assigned to completing the business processes for a particular payer. Due to the onslaught of problems associated with the introduction of the new system, the internal structure essentially disintegrated as available employees were assigned to work on the highest priority task at hand. As the problems became better controlled, the managers started to return the organizational structure to the functional focus.

One concern regarding previous AST research was the lack of focus on one level of the organization. While analyzing the case study data and applying the data to the model, it was difficult to focus on only one level of the organization. Elements from the individual, departmental, and organizational levels all seemed to provide influence in this analysis of AST especially as the levels consolidated.

From observations of Family Medical, the researchers found that it is oftentimes best for an organization to delay the purchase of a technology if they are unable to find an appropriate system that provides a good fit with the organization and matches their most significant needs. However, this alternative is only a viable option if the current system is functional and supplementary resources can be used to maintain or achieve the required level of operations. Problems that arise in a system that is poorly matched to the organization will magnify the employees' level of dissatisfaction.

Communication to employees, both implicit and explicit, plays a significant role in the diffusion process. In addition to normal information sharing methods, when problems arise during the implementation process, it may be necessary for upper-level management to conduct frequent formal meetings to keep employees up-to-date on the status of the situation. As illustrated in the Family Medical case, the employees were greatly affected by the dedication and support management communicated as they worked side-by-side with the billing clerks.

By making adjustments to their internal and external structures, business processes, technology, and application of technology, Family Medical was able to persevere through the technology diffusion process. Although several of the results of the diffusion process were rather negative, application of the case to the model verifies the reciprocal relationships between the constructs.

Chapter 4.13
Adoption of Mobile E-Health Service:
A Professional Medical SMS News Service in Finland

ABSTRACT

This study investigates physicians' willingness to adopt a professional medical SMS news service in the Finnish healthcare sector. A concise survey using SMS mobile technology was conducted on March 5, 2003. Two hundred and fifty-nine out of 685 responded within 24 hours, and 90% of these answers were received within 6 hours after the survey was sent out. The response rate was 38%. Findings from this simple SMS survey showed that physicians had positive perceptions of the SMS news service. Nearly 60% of the respondents have used it. Some of the answers included spontaneous feedback about the SMS news service, which revealed valuable comments and suggestions regarding further improvements to it. The SMS survey as a new data collection technique needs academic attention. Implications and future research are briefly discussed.

INTRODUCTION

Mobile commerce (m-commerce) has been an important focus of research in recent years. Generally, m-commerce is defined as the extension of electronic commerce (e-commerce) from wired to wireless computers and telecommunications, and from fixed locations to any time, anywhere, and anyone (Keen & Mackintosh, 2001), that is, the use of mobile technologies and devices to provide, sell, and buy convenient, personalized, and location-based services. Many healthcare organizations are turning to m-commerce or wireless solutions in order to achieve better, more effective, and efficient practice management (Wickramasinghe & Misra, 2004). A number of companies are extending their Internet services for physicians for use with personal digital assistants (PDAs) or other mobile devices. For example, the use of PDAs among doctors is rising, and had reached 27% by 2001 in the United States (Harris Interactive, 2001). In Europe the leaders, in terms of the percentage of general practitioners who used PDAs in their practices, were The Netherlands (31%), the United Kingdom (18%), Spain (17%), France (11%), and Germany (10%) (Harris Interactive, 2002). Mobile e-health services might offer an answer to healthcare challenges in the 21st century (Goldberg & Wickramasinghe, 2003).

Text-based technology or short messaging service (SMS) is one of the underlying technology platforms for m-commerce. Compared with wireless Web-based technologies, that is WAP, another m-commerce platform, SMS has a simple user interface and is supported by most mobile phones. Recent years have seen the adoption of SMS worldwide in many sectors of commerce, for example, news, weather forecasting, retail, entertainment, and so forth.

The rapid diffusion of SMS has also inspired some applications in the healthcare industry, for example, a professional medical SMS news service. Medical knowledge is changing constantly. It is not easy for physicians to keep their knowledge and information up to date to help in their patient care and patient management efficiently on the one hand, and to maintain the level of their professional competence on the other (Jousimaa, 2001). A professional medical SMS news service might help physicians keep their knowledge up to date and provide information about recent medical development trends and new discoveries. The aim of this chapter is to investigate how ready physicians are to adopt an available professional medical SMS news service that is currently implemented in the Finnish healthcare sector. First, we present the theoretical background underlying the study. In the following, we present the study context and the survey administration. The method we used for data collection is described in Section 4. In section 5, the results are reported. Discussions and conclusions are at the end.

PHYSICIANS' ADOPTION OF TECHNOLOGY

Users' perceptions of and intentions to adopt an information system (IS) and the rate of diffusion and penetration of technology within and across organizations are two important foci in IS research (e.g., Straub, Limayem, & Karahanna-Evaristo, 1995). They are understood to constitute an essential aspect, property or, value of information technology (Orlikowski & Iacono, 2001). It is generally accepted that the usage of information systems at work could increase employees' productivity in their work, and improve individual and organization performance. System usage is an important dimension for measuring IS success (DeLone & McLean, 1992, 2003). In particular, physicians' adoption of IS in healthcare is aimed to improve the health quality of human beings. In the past few decades, the conclusions of many studies based on different theoretical approaches and research methods have proved and confirmed that usefulness of a supportive medical IS is very important in influencing a physician's decision to use it. For example, Chau and Hu (2002a, 2002b) based their study on classical IS adoption models (e.g., Davis, Bagozzi, & Warshaw, 1989; Moore & Benbasat, 1991) and collected data by means of a questionnaire to investigate physicians' behavior towards adopting new technology. They found that usefulness was one factor determined a physician's adoption of telemedicine technology. Jayasuriya (1998) conducted his research in a similar style. His study indicated that health professionals were willing to use technology in their jobs when they perceived it to be useful for their performance. Many studies have also been conducted using qualitative methodologies. For example, Mayer and Piterman (1999) studied the attitudes of Australian general practitioners towards evidence-based medicine by using a focus group method. They concluded that physicians' readiness to accept technology was influenced by its relevance (usefulness) to general practice, as well as the local contextual and patient factors. Using a prototype simulation study for 1 week in a hospital in Germany, Ammenwerth et al. (2000) successfully found that in order to meet the diverse requirements of different professional groups, the developer was needed to design "multi-device mobile computer architecture". Then, the usefulness of the mobile information and communication system in clinical routines was more likely to be improved.

Obviously, results from different studies by different research methods seem to confirm that usefulness is a fundamental determinant of physicians' readiness to adopt different technologies. The selection of different research methods varies according to the individual IS researcher and largely depends on the problem he/she aims to solve. As suggested by Moody and Buist (1999), the real question is not whether the research method is appropriate per se, but whether it is appropriate in order to answer the question being asked.

STUDY CONTEXT AND THE SURVEY ADMINISTRATION

The Finnish Medical Society Duodecim is a leading provider of medical knowledge and information in Finland. It has put much effort into improving the quality of medical knowledge. It has also adapted new technologies to distribute knowledge to physicians, for instance, CD-ROM, intranet, the Internet, and wireless technology (e.g., Han, Harkke, Mustonen, Seppänen, & Kallio, 2004a, 2004b, 2004c; Jousimaa, 2001).

Duodecim Publishers Ltd., owned by the Finnish Medical Society Duodecim, has developed and provided the SMS professional medical news service (SMS news service for short) for physicians currently employed in the Finnish healthcare sector, including hospitals, healthcare centers, private doctors, and so forth. The news team at Duodecim Publishers Ltd. maintains the service. The physicians subscribe to a specific number of services. After the service has been set up, the physicians receive one item of news a day. Currently, they do not need to pay for the service because of support from Pfizer Finland Ltd. Limitations of SMS technology mean that the service does not include any pictures. With the rapid diffusion of multimedia message (MMS) technology, pictures will be included as well. The SMS news service began in 2002.

After the SMS news service had been implemented for about 1 year, the developer, Duodecim Publisher Ltd. and its supporter Pfizer Finland Ltd., conducted a survey to investigate the physicians' acceptance of the SMS news service and their feedback. Time is of the essence for the service providers in order for them to respond to physicians' changing needs effectively and efficiently. Traditional methods of conducting surveys, for example, mailed paper questionnaires, usually take weeks or months to complete. Therefore, the use of a new medium to distribute the survey was needed. The practitioners com-mended SMS technology. The SMS survey, thus, was conducted on March 5, 2003. It was sent to the target group (685 physicians; among those, 259 subscribers to the SMS news service) as an SMS message, and the answers were gathered via the same medium.

Concerning the limitations of SMS technology, the survey had only one question, that is, “How do you perceive the SMS medical news service by Duodecim?” with three predefined answer alternatives, which were:

a. “The service is really good and useful.”
b. “It is OK, but needs to be improved.”
c. “I haven’t subscribed to the service.”

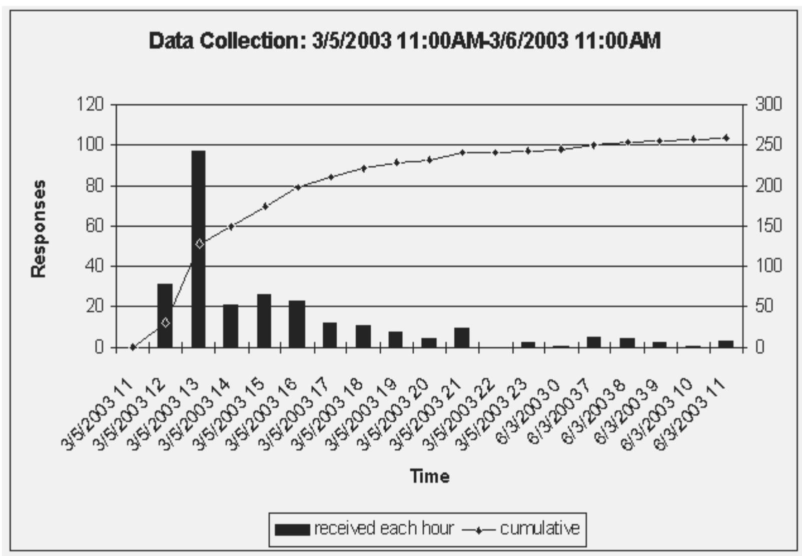
The survey was administered by a company that has experience of mobile marketing and is located in Helsinki. The question was sent out on March 5, 2003, at 12:52 p.m. The whole time span for data collection was 24 hours. On March 6, 2003, 12:00 p.m. sharp, the procedure was finished.

DATA COLLECTION

In Figure 1, we present the time span and numbers of answers collected between March 5, 2003, 11:00 a.m. and March 6, 2003, 11:00 a.m. The x-axis indicates the time series, categorized by hour. The left y-axis shows the numbers of responses received each hour and the y-axis on the right illustrates the cumulative sums of all received answers. Altogether 259 answers (out of 685) were received and the response rate was 38%. Two responses contained empty replies. Among the 259 who subscribed to the service, the response rate was extremely good, over 50%. Some of the answers included spontaneous feedback about the service, which was very valuable.

The majority of answers (>85%, n = 221) were gathered within 6 hours (before March 5, 2003, 19:00) of sending out the question, over 50% (n = 149) within 2 hours (before March 5, 2003, 14:00). Before midnight March 5, we received 243 answers, nearly 95% of the responses; only 16 were sent back on March 6. We soon noticed

Figure 1. Data collection procedure



that the answers received each hour reached a peak between 1 and 2 p.m. on March 5, 2003. The number of responses during this time span was close to 38% (n = 97) of the total.

RESULTS

A basic summary report of our quantitative data is shown in Figure 2. Of 257 usable answers, 31% (n = 79) perceived that the SMS news service was really good and useful. Seventy-three (28%) thought some improvement was necessary. Thirty-two percent of the physicians had not yet subscribed to it. We received 22 answers that did not select any of the predefined alternatives, and we therefore assigned them to D.

We analyzed the content of the feedback provided spontaneously with the three alternatives and other comments categorized as D.

- **Arguments with A**
  Physicians who replied with the A option really liked the service and thought it was very useful for their work. They also showed a positive future intention towards the service. As one physician wrote:

  "[The service] is very useful and I would like to receive the messages in the future.…"

  Although acknowledging the usefulness of the SMS news service, physicians still expected information from traditional channels. A physician replied:

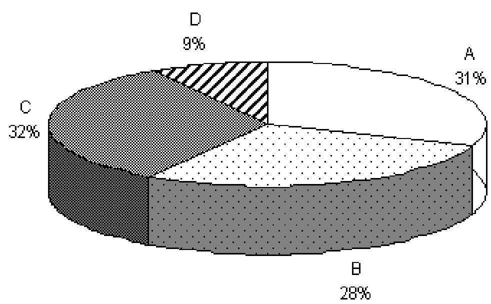
  "The messages are excellent for me and I would be happy to receive other newsletters as well."

- **Arguments with B**
  Most of those who selected B did not specify very much about how to develop the system. Several physicians did give suggestions, however. One physician mentioned that

  "Occasionally one gets news from a short message. [It is] a different picture of the matter compared with the original text [e.g., in newspapers]."

  This message indicated that, as an emerging information distribution channel, mobile SMS was expected to be compatible with other traditional media, such as the texts

Figure 2. Survey results



published in newspapers or on the Internet. On the other hand, physicians also welcomed the SMS news:

"I have during weekdays several times had the time to read the same news on the Internet, but it's good to have repetitions."

Three physicians suggested that the SMS news might include more extensive sources or specialized fields.

"… [the news might come] along with Internet references or more extensive sources."

"… Develop the messages for specialized fields, i.e., information to the correct address...."

"… More accurate sources of references could make it easier to find the article (e.g., about the disadvantage of epilepsy medication)."

Those suggestions shed light on how to improve the content of the SMS news service. Reference sources that help physicians go further to check the latest medical information are quite demanding. Physicians also need information from their specialized fields that are better suited to meet their personal requirements as to the specific knowledge they want to acquire.
Some physicians pointed out that the SMS medical news should be longer; the shortness of SMS was considered a drawback. Comments were received such as:

"The messages could be even longer."

"Apparently the shortness of SMS causes limitations."

- **Arguments with C**
  The feedback came with option C provided several reasons why physicians did not subscribe to the services. The first and obvious reason was they did not need the SMS news service, for example:

"Not used and not needed."

"Not used and I don't want it."

The second reason was some physicians still stick to other distribution channels, such as newspapers or the Internet.

"I haven't followed the text message news. I read newspapers."

"It is easier to read from the Internet."

The third reason was that technical problems with the SMS news service and physicians' lack of relevant technical knowledge hindered their usage of the SMS news service. Complaints included:

"I have not received any news even though I have subscribed."

"I have tried to get the service without success.…"

"Not used since I don't know how.…"

The fourth reason was the small screen of the mobile device: *"I would prefer to read them as e-mails due to the small screen of my mobile phone … probably better with the communicator."* The size of the screen is not comparable with PC-based media apparently.
Some physicians also lacked the time to subscribe to the service: *"I'm in principle interested, but haven't had time to pick up the instructions."* Physicians are usually

very busy. Lack of time is frequently cited as a reason for not adopting new information systems (Berg, 1999).
Besides those negative comments, we also found positive intentions from some non-adopters:

"I will activate."

"I would like to have in use…"

"Reading news as SMS can in principle be feasible."

- **Arguments collected from D**
A content analysis of the feedback we classified as D was conducted as well. We found that there were three main suggestions from the physicians:

1. The service still had some bugs; problems with receiving and opening the service were common complaints. For example:

"None of the text messages that I ordered have been activated, so I have not received any news at present."

"I have not received any news even though I got confirmation of my order."

"For some reason, I have not received news for a long time."

"I acted according to instruction but didn't receive any messages."

"How is it activated?"

These messages indicated that the developer and the service content provider have to pay more attention to the technical problems associated with the SMS news service. The growing number of complaints of the difficulties in activating and receiving it might be a severe barrier for physicians to continue using it.

2. The current length of the message (160–200 characters) was considered both a limitation and an advantage. We got freely formulated feedback of the kind:

"160 characters is quite a limited amount. But on the other hand, one doesn't bother to read too long stories."

"During office hours a short and concise [message] is better...."

Obviously the limited length means that the news has to be concise. This means that they can then save time when reading the news during a busy working day.

3. The news service is quite general; more categories of specialties and more in-depth news are required. For example:

"Seems like a good idea. Personally, I would like to choose those fields that interest me."

"I would wish for more information about urology.…"

These messages revealed that physicians demand more services that meet their "personal" needs. The current service is targeted at all physicians as one uniform group. The developer has to take "personalization" into consideration as a further improvement to the SMS news service.

DISCUSSIONS

On the Survey Question

The findings from this simple SMS survey showed that physicians had positive perceptions of the service. Those responses for options A and B indicated that, generally, the ones (31%) who were happy with the service really liked it, and an almost equal number (28%) thought the service should be improved. The total answers in categories A and B reached 59%.

Arguments came with the predefined alternatives and those categorized as D overlapped in some cases. In brief, they highlighted several important issues concerning how to improve the service in the future. First, technical problems have to be solved immediately. It constitutes a barrier to physicians' usage of the service continuously, or hinders their subscriptions. Possible guidance on how to open and use the service should be improved as well. Ease of use is always considered a crucial driver for the success of an information system. Mobile technology is no exception (Han, Mustonen, Seppänen, & Kallio, 2004d). Second, the length limitation of SMS technology means not only that the news has to be concise, which was considered a time-saving way to read it, but also made it impossible to include more information in one message. With the development and diffusion of MMS, technically the news items could easily be made longer. Third, the physicians demand "personalization." The fact that the current service included only general topics did not exploit to the full advantages of mobile technology, that is, personalized services to mobile users. Therefore, it might undermine the value added by the SMS medical news service. A personalized service for physicians' news needs would enhance their knowledge, which would be highly relevant to their specialties, and provide the information that they desire most. Fourth, as an emerging technology, SMS competes with traditional channels of distributing medical news. The traditional channels, for example, newspapers and the Internet, have dominated information delivery for a long time. Currently, SMS is a complementary channel, but far from the dominating one. A good thing is that it is warmly welcomed by most of the physicians. It has strong growth potential for the future. It adds comparatively more value to physicians' work in terms of flexibility and personalization or localization.

Nearly one third of the respondents had not yet subscribed to the SMS professional medical news service. Attention has to be paid to the reasons why they did not subscribe to the services in order to increase the speed of its diffusion. Compared with the important issues for improving the service referred to above, we find that strong efforts to improve the service might remove the negative "reasons" that impede some physicians from subscribing to it.

On the Data Collection Method

The survey was supported by SMS mobile technology, namely, an SMS survey. We received a 38% response rate within 24 hours, and 90% of responses came within 6 hours after the survey was sent out. We acknowledge the pros and cons of the SMS survey.

Pros

- It is a time-efficient method. The response time is very short compared to other media. Most of the respondents answered within 6 hours after the question was sent out. Within 24 hours, or 1 day, the procedure was completed.
- It is a method that attracts more responses. Compared to traditional survey methods, which usually receive response rates lower than 20%, the survey received a 38% response rate, which was very encouraging. It is also worth highlighting that we received such a high response in 1 day. This is not possible via other media.
- It is a cost-effective method. By using SMS technology, the practitioners have saved a lot of money compared with surveys conducted by other media, for example, paper mail. In Finland, an SMS message costs less than 0.16 Euro.
- It is a method that makes a survey focus on the most important questions. So far, the

limitation of the SMS technology, only allowing 160–200 characters, does not permit inclusion of many questions.

- It is a method supported by new mobile technology. With the development of new technologies, IS researchers try to adapt them to conducting specific studies. For example, tape recording, video recording, Internet, and so forth. The adoption of SMS mobile technology is a trend.
- It is a method containing both quantitative and qualitative data. In the survey, we obtained answers to our predefined alternatives as well as freely formulated feedback. This feedback provided us with fruitful and interesting suggestions, for example, how to improve the SMS medical news service, or why someone did not subscribe to the service.

Cons

- It is a method restricted by technological limitations. The length limitation, 160–200 characters, made it impossible to include more questions that might cover more aspects of a research focus.

Beside those pros and cons of the SMS survey, conducting the survey itself to investigate physicians' acceptance of the SMS medical news service was a very successful experience. Time is crucial for the practitioners to adjust their business models according to the changing demand of customers. Apparently, adoption of mobile technology to support this research is more efficient than other media.

CONCLUSIONS

Users are a key driver for the success of mobile commerce as well as mobile e-health services. It has become increasingly important for IS researchers and practitioners alike to investigate the important factors triggering users' adoption behavior in the new technological context. This chapter is intended to investigate physicians' acceptance and opinions regarding the SMS professional medial news service, a simple mobile e-health service. Physicians' opinions were evaluated using data collected from 257 respondents practicing in the Finnish healthcare sector. Some implications can be drawn from the findings of the study.

An important further development of the mobile e-health service would be to enhance "usefulness" by "personalizing" it. User adoption theories assert that usefulness is the main driver for an individual to adopt a specific information technology. The perceptions of usefulness of the SMS medical news by physicians demonstrate strong possibilities for continuing usage in the future. Providing personalized service is a better way to enhance the "usefulness" of the service. A successful mobile service should be flexible, add value, and take full advantage of mobile technology (e.g., Carlsson & Walden 2001, 2002a, 2002b). It is quite demanding to personalize the SMS professional medical news service according to physicians' different information needs. System developers and contents providers alike should move beyond the limits of current possibilities and devise a service that physicians must have in their working and daily lives. Physicians' work is characterized as busy, pragmatic, and lacking in time (Berg, 1999). A personalized SMS medical news service, on the other hand, fits their work practice. Concise and desirable personalized SMS medical news will both save their time in a busy working day and provide them with new medical knowledge at any time and in any place.

From a managerial standpoint, the findings of this study reveal that, in order to facilitate physicians' motivations to use a technology, it is important to have proper training programs or information sessions to help overcome potential technical difficulties, and also to focus on how the medical news service can help keep their professional knowledge updated. It is better to encourage and cultivate positive intentions towards using the SMS medical service in the work practice. We have to be aware that it is the users and their use, not advanced mobile technology that will drive m-commerce growth to a new level (Jarvenpaa, Lang, Takeda, & Tuunainen, 2003). Obviously, it is equally important for any mobile e-health service as well.

Using SMS to do market research, so-called mobile marketing (Haig, 2002), is not new. The survey reported in this chapter has revealed the benefits of such research. It is a new data collection technique that is time efficient and cost effective. It provided answers in a very short time. The medical news service developer and content providers received "instant" results that help them investigate the problems and find solutions almost at the same time. The SMS survey is not like traditional surveys that usually take months or years; it is a new attempt to do the survey in hours or days with the aid of new mobile technology. It also reduces the cost of the survey. Mail surveys are usually very expensive, as are Internet surveys, which charge a monthly fee. The main weakness of the SMS survey is obviously its length limitation; it excludes the possibility of many questions in the survey. However, it means concentrating on the most important message that practitioners want to know immediately. Such instant feedback might represent high business value for practitioners.

From the management perspective, the SMS-based data collection technique is a very important form of two-way communication and an interaction mechanism for contacting the users—physicians—in the study directly. It is a much more powerful way to speak with physicians and learn their experiences in a relatively short time. It would be very beneficial for service providers to improve the SMS medical news service according to physicians' real needs. The responses from nonadopters revealed that service providers also could adapt the SMS text-messaging survey to inspire awareness of this new mobile medical service, which might lead to mass adoption quickly (Rogers, 1995).

Future research efforts are needed to address these questions rigorously. We might define a complete set of alternative answers for the question (from positive to neutral to negative). We also could ask permission from more physicians to participate in such surveys in order to receive more information both for service development and management purposes. The technical limitations of SMS made it impossible to investigate more relevant questions. Therefore, possible integration with other data collection methods might be necessary.

The research reported here could be seen as a preliminary study reflecting physicians' reactions to a mobile e-health service, especially an SMS professional medical news service. Since the vast majority of the respondents had probably used the SMS professional medical news service in their daily work, their appreciation of the service may be considered as a solid basis for future improvement of the mobile service in healthcare. As far as the external validity of our results is concerned, we have to be cautious since the findings describe the situation in Finland, a country characterized by a very high penetration of mobile phones, and a strong national "mobile fever." Physicians in the Finnish healthcare sector seem to be no exception to this general rule.

ACKNOWLEDGMENT

Our warmest thanks go to Pfizer Finland Ltd. for its support for the survey. The first author would also like to thank Ms. Stina Störling-Sarkkila for her support in translating the Finnish data into English.

Chapter 4.14
Computer-Based Health Information Systems:
Projects for Computerization or Health Management?
Empirical Experiences from India

Ranjini C. R.
Lancaster University, UK

Sundeep Sahay
University of Oslo, Norway

ABSTRACT

Large investments are being made to reform the health sector in developing countries as the potential of ICTs in achieving health goals is being increasingly recognized. However, there have been various reports that indicate this potential of ICT is not being fully realized on the ground in particular settings. In this chapter, an empirical investigation of the introduction of health information systems in the primary health-care sector in India is reported. Three cases—the India Health Care Project, Family Health Information Management System, and Integrated Health Information Management Systems—are presented. The authors argue against adopting a technocentric approach during the development of the HIS and suggest that these efforts should be sensitive to the sociotechnical context. Furthermore, a variety of constraints are identified. The chapter concludes with a discussion on the potentials of integration to address some of the identified constraints.

INTRODUCTION: THE CHALLENGES OF HIS IN DEVELOPING COUNTRIES

The plural of datum is not information.

~ Anonymous

Information and communication technologies in primary health-care settings offer a number of opportunities to enhance the efficiency of administration and improve the delivery of health-care services. Health information systems (HISs), geographic information systems (GISs), telemedicine, Web-based initiatives, and the development of health-care databases (see Bodavala, 2002) are examples of a few ICT-based initiatives currently ongoing in the primary health sector in India, and also in other developing countries. Despite the undoubted potential that ICTs provide, obtaining their practical benefits on the ground is a very complex undertaking, and there are various reports of total, partial, sustainability, and replication failures (Heeks, Mundy, & Salazar, 2000). Contributing to this unrealized potential are a number of complex interrelated issues such as inadequacies in both the computer-based infrastructure (for example, Nhampossa, 2004) and physical infrastructure of roads and transportation, which are required for the transmission of reports (Mosse & Nielsen, 2004); that is, there is a lack of proper network infrastructure, the persistent presence of legacy systems embroiled with different institutional interests (Nhampossa), weak human-resource capacities both in numbers and skills (Chilundo, 2004), heavy workload of health staff who need to give priority to providing care over administrative tasks like reporting (Mosse & Sahay, 2003), and a culture of information use that sees periodic reports as primarily fulfilling the needs of the bureaucracy rather than using the information to support action (Quraishy & Gregory, 2005). All these contextual influences make the challenge of introducing ICTs in the health-care sector a very difficult one in practice (Sahay, 2001).

The critical role that HISs can play in public health has been emphasized since the early 1980s in attempts to integrate data collection, processing, reporting, and use to strengthen management at all levels of health services (Lippeveld, Sauerborn, & Bodart, 2000). HISs in most developing countries have been described by researchers and also policy documents emerging from international agencies as being grossly inadequate (for example, Lippeveld, Foltz, and Mahouri, 1992; World Health Organisation [WHO], 1987). Sauerborn and Lippeveld (2000) argue that this ineffectiveness stems from various reasons including the irrelevance and poor quality of data being gathered, duplication and waste among parallel HISs, lack of timely reporting and feedback, and poor use of information. As a result, what we typically find is HISs that are data led rather than action led (Sandiford, Annett, & Cibulski, 1992); in this sense data is an end in itself rather than a basis for planning, decision making, and evaluating interventions. Institutionally, HISs in developing countries are situated in rather centralized structures (Braa, Heywood, & Shung King, 1997; Braa & Nermukh, 2000; Braa et al., 2001) in which local use of information is not encouraged (Opit, 1987). This has led Sandiford et al. to comment that what is needed is not necessarily more information but more use of information.

While as a part of various health reform efforts, including HIS, ICTs are being actively introduced by international agencies and national and local governments, what is often found is that the focus of such efforts are primarily on the means, computerization, rather than the ends of what needs to be achieved: strengthening information support for health management. Introducing ICTs in the development of HIS is not necessarily the silver bullet that solves the efficiency problem of the health services (Sandiford et al., 1992), and over the years research has emphasized that critical issues to be addressed in the implementation of IS are social and organisational, not solely technical (Anderson & Aydin, 1997; Walsham, 1993). As Helfenbein et al. (1987) have argued, changing the way information is gathered, processed, and used for decision making implies making changes in the way an organisation operates. They also suggest that producing and utilizing information more effectively will affect the behaviour and motivation of all personnel.

Policy makers (for example, under the sector-wide approach policy) and also researchers (for example, Piotti, Chilundo, & Sahay, 2005) propose that the integration of an HIS provides mechanisms to address some of the existing inefficiencies of HIS and to develop new forms of health data analysis. For example, the management of HIV programmes requires data from various sources such as the mother, child, and HIV-specific programmes. Rather than developing new HISs, it is argued that the existing systems should be effectively integrated. However, integration of HIS is a complex task. In a study on a national STI (sexually transmitted infections)/HIV/AIDS programme in Mozambique, Piotti et al. (2005) analysed the multiple reporting systems that were in place. Systems for the prevention of mother-to-child transmission, volunteers, counseling and testing, blood-transfusion services, AIDS patients under follow-up for the treatment of infections and/or antiretroviral therapy, rural-district AIDS inpatients, and AIDS patients under follow-up for home-based care were among the many reporting systems that they identified. Despite formal instruments to support the reform efforts to integrate the HIV/AIDS HIS, the multiplicity of reporting systems continued to exist, each with its own practices and processes. The integration of the HIS is not merely a technical or social task, but it is sociotechnical in nature.

We argue that taking a technological determinist perspective on HIS development implies a lack of sensitivity to the sociopolitical and institutional context, and contributes significantly to the unrealized potential of the computerization of HIS in developing countries. There is an urgent need to shift this focus from computerization itself to the question—What is it that we want to achieve through computerization?—in order to strengthen these HIS-focused reform efforts. Analysis of this question helps to develop an argument against the adoption of a technocentric approach to the development of HIS and to instead approach this effort with a focus on integration and sensitivity to the sociotechnical context. Introducing computers does not in itself lead to better handling and use of information, and the challenge is to initiate a parallel informational reform process where information is seen as a resource for action rather than for fulfilling the needs of the bureaucracy.

The present chapter analyzes empirically some of these challenges, drawing upon a study of three specific HIS initiatives introduced in primary health-care settings in Andhra Pradesh (AP; a state in southern India): The India Health Care (IHC) project, the Family Health Information Management System (FHIMS), and Integrated Health Information Management Systems (IHIMS). In the following section, we provide a brief summary of the broad context of the health sector and HIS in India. We next describe the research setting followed by a narrative of the HIS projects. Later, we present our analysis and discuss the challenges and opportunities inherent in shifting the focus of HIS efforts from computerization itself to how it can support health management. Finally, some brief conclusions are presented.

THE INDIAN HEALTH SECTOR CONTEXT

The goal of health policy in India has been stated as supporting universal and free primary health care for all (Gupta & Chen, 1996). A primary health centre was conceived in India as an institutional structure to provide integrated preventive, promotional, curative, and rehabilitative services for the entire rural population. The primary health sector includes primary health centres (PHCs), subcentres (SCs), community health centres, and upgraded PHCs in some areas. Each PHC is expected to provide health care for a population of about 30,000, whereas in practical terms, this ranges from 20,000 to 70,000. More details on the health sector in Andhra Pradesh are provided later.

The health staff in the PHCs and SCs generate considerable amounts of data about the services that they render, collate them on a weekly or monthly basis, and report them in prescribed formats, sometimes duplicating the same report format to different departments or programme managers. These informational activities take up a considerable amount of the health staff's time. Moreover, frontline health assistants are mere producers of data rather than its users. While the focus on reporting serves to fulfill the needs of the bureaucracy and their dependencies on international aid agencies, and the potential need for epidemiological analysis, information is rarely ever used to guide local action at the level at which the data are collected (Sahay, 2001). There are also quality-related issues that inhibit the active use of data. For example, data collected at every level are aggregated, and by the time these data reach the higher levels of the health system, the specific situations in the peripheral areas are completely masked (Quraishy & Gregory, 2005). The flow of data is largely unidirectional from the lower levels to the higher ones (see Figure 1), with very little constructive feedback being given to the local levels to strengthen their work processes. Instead, often the only feedback is in the form of a reprimand, where health staff are pulled up for not meeting their (rather unrealistic) targets. Mechanisms to facilitate mutual exchange of information are also minimal.

Acknowledging these limitations of the existing HIS during the launch of a new programme named the National Rural Health Mission, the prime minister of India, Dr. Manmohan Singh, called for reorienting the HIS to support local action (April 12, 2005):

The monitoring systems have to become oriented outward towards the community and not upward towards the bureaucracy. For example, so far the health information we have in our country through the National Family Health Services Reports are seen at State and Central levels and hardly ever at district and below district levels. If information is to lead to action, it should be available and used at the local level. We must reorient the information system to support an accountability-structure by developing district health reports, state health reports and so on.

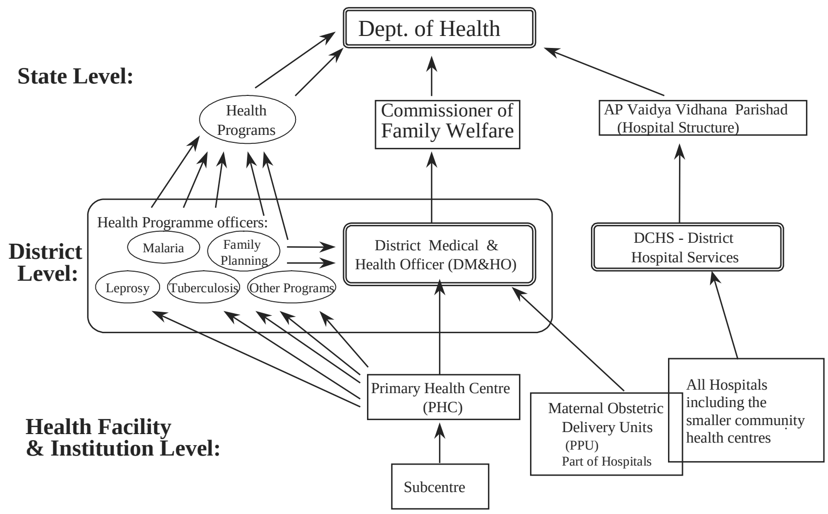
While the challenges to HIS reform are now being recognized at the policy level, the harder task is to address them on the ground. With this as the backdrop, we now shift to describing the specific research setting and the particular HIS implementation efforts.

The empirical material reported here is derived from a situational analysis of the implementation of three HIS projects in AP, a state with a population of 75.7 million (http://www.censusindia.net). Figure 1 provides a broad structure of the health-sector network and an overview of health information flows in Andhra Pradesh.

Subcentres have been established under the PHCs at a rate of one for every 5,000 people in rural areas, and one for every 3,000 people in tribal areas. One or two health assistants (auxilliary nurses and midwives) work at the SCs and are responsible for outreach programmes. They travel from one village to another to provide services such as immunisation, antenatal care, family planning, information and education activities, and school health programmes to the rural population. PHCs serve as the hub for implementing national programmes such as population control, and disease-control programmes like malaria, tuberculosis, leprosy, and gastroenteritis among others. Mainly, however, the PHCs are the cornerstone of the maternity and child health programme, now integrated into the reproductive and child health programme.

For example, one district, Chittoor, has a population of about 3.75 million served by 84 PHCs,

Figure 1. Health Information Flow (Source: Sahay & Walsham, 2005, p. 44).



each theoretically catering to a population of about 30,000. Each PHC has under it about four to seven SCs, each of which in turn is supposed to cater to a population of about 5,000. In practice, the PHC population varies from 25,000 to 40,000, and the SCs from 4,000 to 8,000. The state has about 1,386 PHCs, of which 470 PHCs are expected to provide round-the-clock services for safe deliveries. There will also be 268 hospitals, dispensaries, community health centres, and mobile units, and 10,568 SCs spread across 23 administrative districts, covering an area of about 246,793 sq km. In Andhra Pradesh, there are about 2,848 medical officers, 506 community health officers, 1,686 multipurpose health extension officers, 1,621 female multipurpose health supervisors, 614 public health nurses, about 11,000 multipurpose health assistants (also called auxiliary nurses and midwives), and 500 other administrative staff at the primary health centre level (family welfare [FW] departmental manual).

RESEARCH SETTINGS: ONGOING HIS INITIATIVES IN ANDHRA PRADESH

Over the last few years, HIS projects have been initiated in the Family Welfare Department (FWD) in AP to help provide electronic support tools to the health staff at different levels of the organisation. These HIS efforts of the state government were initiated with the backdrop of larger good-governance reform policies initiated by the former chief minister Chandrababu Naidu within the framework of SMART governance (Simple, Moral, Accountable, Reliable, and Trustworthy). As a component of this ambitious good-governance policy, the chief minister drew up vision statements for every government department. The government's IT vision states, "Andhra Pradesh will leverage Information Technology to attain a position of leadership and excellence in the information age and to transform itself into a knowledge society." The vision document also established ambitious and demanding goals for the health department to be achieved by the year 2020. These goals were, among others, to achieve infant and child mortality rates of 10 per 1,000 (live births) and 20 per 1,000, respectively, a total fertility rate of 1.5 (average number of children per woman), and population growth of 0.8% a year. Good governance and the use of ICTs in public administration were emphasized to help achieve these goals.

In January 2002, the government of Andhra Pradesh brought out a strategy paper on governance and public management that forms the basis for governance reform activities in the state. In the book *Good Governance Initiatives in Andhra Pradesh* (Mohanty, Jones, & Rao, 2004), 28 projects have been documented to disseminate examples of good practices in the field of governance and public-sector reforms. The introductory chapter notes that:

governance involves mechanisms, processes and institutions, through which people articulate their characteristics of good governance to include: rule of law, participation, transparency, responsiveness, consensus, equity and inclusiveness, economy, efficiency and effectiveness, and accountability…The government of Andhra Pradesh has adopted an approach of combining knowledge, technology and citizen-centricity as the key strategy to improve governance in the state. (p. iii)

This focus on good governance to reform public services is indeed welcome. However, there is a need to shift the focus from merely elaborating on the content of reforms to the feasibility of implementing them on the ground. Implementation of these modern and managerial models to support good governance and best practices is complex and problematic (Madon, Sahay, & Sahay, 2004). Given the excessive focus on the provision of infrastructure rather than on implementation and use, asymmetries exist between macro-level governance policies and the micro-level implementation of particular ICT projects (Madon, Sahay, & Sudan, 2005).

Toward a Computerised Health Database: Vision and Reality

In Andhra Pradesh, toward achieving Vision 2020 and the SMART objectives, the government undertook a number of IT initiatives, some of which have had direct implications for the health initiatives under study. One such initiative was the Multipurpose Household Survey (MPHS).

The MPHS was an ambitious project of the government of Andhra Pradesh to build a massive name-based database of 75.7 million citizens and 76.5 million land records to help provide a social-security identification number for every citizen of the state. The survey was originally compiled in 1995. It was later computerised and the data was hosted on a central server for public access. The citizen's database with about 130 data elements has been installed in 1,125 mandal[1] revenue offices. Although this database was created by the state revenue department for its own purposes, the government passed a directive that MPHS should be used as a standard database by all government departments and other agencies in an attempt to prevent multiplicity of databases. In order to comply with this directive, other departments started to add data from their own databases to the MPHS.

Creating a name-based database with various socioeconomic indicators for a population of 75.7 million is a challenging task. A consultant in the revenue department explained that this database was compiled in 1995 by conducting a household survey, and subsequently between 1998 and 2003 two private companies were given contracts to update these data and also to include other data such as deaths, births, migration, and so forth. Additional data (such as the number of school-going children and the number of working children in the age group 6 to 14) from another survey called the Human Development Survey (HDS), which was conducted by the planning department, was integrated with the MPHS data in January 2000. Integrating the data from the HDS into the MPHS database had inherent problems because the basic unit for the MPHS was the village and that for the HDS was the habitation.[2] In the HDS, data were collected on total numbers and not on the details of all individuals in a family. For example, details about a family included the total number of children in the age group of 0 to 5, the number of illiterates above 15 years, and the number of family members above 65 years, while in the MPHS, data were collected about every individual member. There were commissions and omissions because of the migration of people, and also because some people were reluctant to give their details for the survey. There were also quality issues raised about the HDS data as they had been collected by school children. As a result, the database was not accurate, and the quality of data was very poor.

In addition, with regard to our main concern here, the HIS, the PHC as the fundamental unit for the state health department did not match with the fundamental unit of the revenue department (the owners of the MPHS), the village. As a result, many of the health parameters necessary for health services were not included in the MPHS database, and it had to be updated with these data subsequently.

Around the time that the MPHS was being upgraded, in June 2000, Infodev (the Information for Development Programme), an agency of the World Bank, granted $250,000 in funding for the first of the projects under study here: the IHC project. The key objectives of the IHC were to reduce or eliminate the redundant entry of data prevalent in paper registers, to generate monthly reports automatically for health assistants, and to make data electronically available for further analysis and compilation at higher levels of the health-care system. The project was eventually implemented in 200 subcentres (spread across 32 PHCs). The larger objective of the initiative was to reduce infant mortality and maternal mortality by improving the quality of antenatal care and child health through improved information management.

The second project under study here, the FHIMS, was an offshoot of the IHC project. One district, Nalgonda, out of the 23 districts in the state was selected to pilot this project. It took off simultaneously in all 67 PHCs in the district in 2002. The information needs at different levels forced the family welfare department to embark on a more elaborate project to have information systems not just at the PHCs, but also in the district offices and the state office. The overall aim of the project was to "computerize the activities of the PHCs as a whole to take care of (a) Family Welfare needs (b) control of communicable diseases and (c) PHC management" (CFW, Office of the Commissioner of Family Welfare, 2003).

As already mentioned, during the initial days of the IHC project, it was decided that MPHS should form the basis for a name-based health registry, and that instead of conducting a new survey, the health staff should update the MPHS. The survey data were crucial for both the projects because they were to be the foundation of the name-based IS. This name-based system (with details such as, for example, who has malaria) was to replace the earlier one in which data were collected based on numbers (for example, how many cases of malaria in a region). In the FWD, the family or household was the basic unit of analysis, and it was expected that the database would maintain this unit of analysis, along data on births, marriages, family planning methods, antenatal and postnatal cases, immunisation of children, deaths, and diseases. It was argued by the proponents of the name-based system that it was necessary to provide targeted health care, especially in following up with antenatal cases, immunising children over a period of time, and in tracking patients. While the officially stated aim of the FHIMS was to improve patient-specific care, in practice, as one doctor said, the rationale underlying FHIMS was to try and "prevent the manipulation of figures by the health staff, since with names it is easier to track whether or not the right numbers have been filled."

Apart from these data-related issues, there were also software challenges. A consultant in the revenue department explained:

Quality problems with the software are because each department hires an agency on its own to get the necessary fields from the MPHS. That company may not know the design of the MPHS data completely. They are given a very short time, say a month or so, to deliver the product. Understanding a huge database and to know how to do it takes time. Quality suffered because of this.

Another software programme was developed to download the MPHS and print the MPHS data on habitation in the form of a household register. A software engineer of the IT company that had been involved in the development of the software for the FWD said, "Nobody knows about the accuracy of the data. The survey was initially done for the revenue department. We did not know the software codes because it was done many years back. We cannot assure the accuracy of the data."

The development of the FHIMS software was contracted to an IT company located in the state capital at a cost of about $68,500, and the requirements included 17 modules (such as family welfare activities, tuberculosis control, leprosy eradication, budget monitoring, personnel information, etc.). The software was developed on an Oracle back end using Visual Basic. Although the project itself was delayed (because the household survey, which was expected to be completed by December 2003, was still ongoing in March 2004 in many PHCs), the software was expected to be deployed toward the end of 2003. The health department mobilised about $7.3 million for the project through a consortium of funding agencies including the World Bank to buy about 1,500 computers and install it in every PHC and district office, and in the state office, and load the computers with Oracle software (with a license fee of about $200 per computer) and Microsoft software.

The idea of computerization was that the MPHS data would be loaded in the FHIMS software, and using this health survey, data could be entered (based on names). It was soon realized, however, that the MPHS data was unsuitable because of quality issues and the fact that the data did not match the needs of the health department. As already mentioned, this was because the MPHS was conducted by the revenue department and hence did not have all the data that were necessary for the health department.

This process of collecting data for such a massive population, as can be imagined, was a complicated task and involved multiple challenges. When the health staff took the MPHS survey books to their respective habitations, they found them afflicted with many errors. Many health assistants complained that names were missing or inaccurate, ages of family members were wrong, or sometimes data on entire habitations were missing. Sometimes there would be a Muslim name for the head of the household, and the family members would have Hindu names (a quite unlikely possibility!). In another instance, the same name (of a head of the family) was in all the families in a particular habitation. Also, since house numbers were not arranged in an order in many villages, the health assistants had to rely on the names of people to locate their families.

Health assistants were expected to do the survey in addition to their regular work. Some of the health assistants said they were ordered to conduct this survey at their own cost and time. However, higher officials disagreed and said doing such surveys is part of their job. The health assistants would go in the evenings after work to conduct the survey, and had to be accompanied by their husbands because they had to travel after dark. Also, as the list of names in the forms (printed from the FHIMS database) given to them did not match the people who were physically located in the habitations, they found it easier to buy new books and write the names by pen themselves. However, in the absence of any financial support, the health staff had to buy these books at their own cost. Because of time constraints, and the fact that they had to enter whether a person had (or had not) a list of about nine diseases and particulars of physical disability (six types) in code numbers, the assistants would typically simply enter "no" for all. A project coordinator of the FHIMS explained some of these difficulties experienced by the health assistants while conducting the survey during the pilot phase of the project as follows:

The other big difficulty that our staff faced is that they were given registers…per habitation, per village like that. Each book runs, depending on the size of the habitation, anywhere between 500 and 600 pages. Some habitations are really big and have 10,000 people. Our health assistants have to go to the field with these registers, not knowing on which page the family they have to survey is on because the books do not have any index. Addresses are not printed in a serial order as to how they are located nor are the names listed in an alphabetical order. So the health assistant practically had to turn all the 600 pages or 10,000 pages every time to locate a family. And she couldn't just tear all the pages and arrange it one after the other…She knows perfectly well which house comes next to which…That was also not possible because in one sheet we had two to three families. Later, in replication phase we have made sure we get only one family per page and we now have an index for every bound book…in an alphabetical order.

After the house-to-house survey, the next stage of the project was to enter the data into the computerised database, which was a time-consuming and arduous task given the already heavy workload and time constraints of the health assistants. The data entry into the household database, which would then be imported to FHIMS, was outsourced to a private party. This private agency further recruited data-processing operators (data operators; at a salary of about less than $100 per month) to do the data entry.

During the pilot phase of the FHIMS project involving data entry, there were many omissions because the work of the data operators was not well monitored. While the health assistants were instructed to be present with their registers when data were being entered by the data operators to oversee the process, the health assistants would simply leave their registers with the data operators and go away to fulfill other duties. The data operators, for their part, found it difficult to make out the handwriting of the health assistants and the variety of informal symbols they had made in the registers. A retired district officer, who was appointed as a consultant for the project, explained why this lack of oversight of the data-entry process occurred as follows:

On many occasions health assistants were not present when the data entry was done. If the health assistant sat with the data operator with her register, that would slow down the data operator because his work would be constantly double-checked. On the other hand, work would proceed faster when the health assistant was not present because the data operator would worry less about whether he was entering the records correctly or not. Remember his payment was based on the number of records he entered per day. So naturally, his interest was not whether data he entered was right or wrong, his interest was to enter as many records as possible in a day and collect his money. The health assistants were not able to sit with the data operators, oversee and clarify, because she had so many other priorities. Moreover, that sort of accountability and sense *of responsibility was not there among most of the field staff. So, in effect, the data entry was not done in a systematic manner.*

As the project expanded, data entry was moved to the respective PHCs. Now, a new set of problems caused delays in the process. Multiple software bugs, especially due to software incompatibility between the household survey module and the FHIMS database, were some of the problems encountered. The result was that certain data, for instance, data on antenatal women who did not reside in habitation or data on pregnancies leading to abortion or medical termination, could not be entered into the database. In some PHCs, the household survey module could not be linked to FHIMS database, leading to discrepancies between the population figures that were entered and what was actually displayed in FHIMS. In fact, although it was claimed that all the data had been entered, close examination revealed later that data entry was done only for the FWD module and even then for only a portion of it.

The India Health Care Project

The IHC project was started as a pilot in three health centres in the Nalgonda district where health assistants were given personal digital assistants (PDAs) and another health centre was selected to pilot the same application on a desktop computer. Subsequently, PDAs, which are mobile computing devices, were given to about 200 women health assistants. Typically, health assistants spend a considerable amount of time collecting, collating, and reporting health data to different officials. This paperwork is time consuming and cumbersome, and historic data are difficult to manage, retrieve, and use. The health assistants submit several reports of the services they have offered to the supervisors and medical officers at the weekly and monthly meetings, generally organised at the PHCs. At times, they also submit reports on different health programmes to different functionaries and agencies. The stated objectives of the project were to reduce manual paperwork and eliminate redundant data entry, and thereby free up assistants' time for health-care delivery. The application was also expected to facilitate the generation of schedules with information pertaining to immunization and antenatal services for the health assistants, which would help them to geographically identify antenatal cases to be visited and children to be immunized. The system was also supposed to help the health assistant in tracking the history of the patients and enable her to take preventive measures such as treating high-risk pregnant women or giving timely vaccinations to children. The schedules also highlighted pending cases and those who had been missed by her in previous visits. This was supposed to help the health assistant to prioritise her work so that she could attend to cases that needed immediate attention. The PDAs were expected to eventually replace paper registers. Thus, the use of these mobile computing devices was projected as providing ample opportunities for assisting health staff in their routine work. At the PHC level, it was expected that the data from PDAs would regularly be transferred and uploaded onto desktop computers located at the PHCs and support the routine HIS.

However, the use of the PDAs was largely unsuccessful for a variety of reasons. For one, the memory supplied was insufficient (16MB). There were problems with charging the batteries in the rural areas. Many health assistants said the device was slow, and since using the device while on the job was time consuming, a few health assistants would do the data entry later in the bus on their way back from work or at home. One health assistant said she would ask her children to do the data entry at home. Those health assistants with eye-sight problems complained that they found it difficult to read small letters on the black and white screen, and said that a colour screen would have been better. Also, while standing with the PDAs in the sun made it difficult for the health assistants to see the screen clearly. Since they had to deal with long lines of people waiting to get their attention, they found it troublesome to spend time trying to enter data into the PDAs. Added to the poor quality of the MPHS and the database, there were technical problems during the uploading of data into the database. The PDAs were perceived to be costly, and the health assistants were scared that they might lose them and they would have to pay for it from their pockets. Due to these and other problems, PDA use has now stopped. A health worker shared her experience:

The PDAs which were supplied were low in memory. When we started using PDAs it was taking a lot of time to search the name, or open the screen or save the entry. When we had a long queue of patients, mothers holding their small children waiting for us to give the children immunization shots, if we were operating a PDA which was slow, the patients would be frustrated. If I don't attend to them, they will go away. So, very soon I realised this PDA was not much of use when I was on the job. So I resorted back to writing in my old book. What I did was I would go home and then again enter all the day's entry into the PDA. To tell you frankly, though it has helped me in getting schedules, it has also increased my work load.

A doctor working at a health centre also shared a similar opinion on the reasons for nonuse of the devices:

The health assistants are reluctant to use PDAs because the operating system is such that if the power is discharged or if a health assistant forgets to recharge it, all the data will vanish. She has to come to the PHC and upload the data from the desktop to the PDA. In this division, the reason for reluctance of health assistants to use computers is that we got the PDAs first and desktops later. So whenever data vanished, the software engineers would take the PDAs to Hyderabad (the state capital) and would feed the data there into the PDA. The second problem was memory. Third problem is when we said the memory is not sufficient, they changed the software so only the target population is there in the PDA. There are many software problems because of this. The health assistants who are really interested even today are not able to use them because some records are not captured properly.

Another doctor who was involved in training and supervising the project said both technical and nontechnical factors contributed to the failure of the PDA project:

The processing capacity of the PDA was slow. The intention of giving PDAs was that the health worker would give immunisation and immediately enter that data in the field. But that did not happen in practice. People won't wait. So they wrote manually in their registers. Once the immunisation session was completed, the health workers would have to again enter the data, come to the health centre and then upload the data (into the desktop). Only after that could they get the schedule. In that schedule few names would be missed because some records would be rejected. So due to all these issues health assistants were not able to use the PDAs comfortably. If these technical problems could have been solved, the percentage (of health assistants using the PDAs) would have been about 70-75%, but not 100%, because you cannot make everyone use that device. Also, battery has to be replaced after every two years or so. All these issues were not taken into consideration.

The reason to do a pilot is to try out a technology on a small scale in order to identify problems and resolve them before making a large investment. However, about 200 PDAs were brought by the IT company all at once. The consultant of the IHC project said:

The irony of it is we started the project in three PHCs initially as a pilot. So they could have procured the PDAs only for those 3 PHCs. When we raised this problem of memory they could have procured higher memory PDAs later. After having gained experience during this pilot phase they could have bought the rest of the PDAs. Anybody would do that. But the software company said they have bought all the PDAs at once. For half of the district, it was 200+ PDAs.

The poor quality of the survey database, recurring software problems, insufficient memory capacity, and the absence of timely and ongoing technical support and maintenance gradually led to nonuse of these devices on the job. The health assistants who were trained and were enthusiastic initially gradually lost interest and reverted back to their earlier manual system of recording health data. The project was neither sustainable nor was it scalable because of the costs involved. Out of 200, only about 9 health assistants were using PDAs in March 2004 during a field visit by one of the authors. During the visit, the health staff took out the PDAs from locked cupboards and showed the researcher blank PDAs that had not been used for months. In some other PHCs, we saw the children of the health assistants playing with these devices.

The aim of the project was to provide support tools that would allow health assistants to reduce the time spent doing paperwork. However, in practice, it actually increased their work. The second aim was to increase the accuracy of the data flowing up from the health assistants; however, this could not be achieved because the quality of the multipurpose survey data itself was poor. The third aim was to provide a means for getting health-care data at the village level into electronic form and generate reports. This was too ambitious to achieve because shifting from a manual to an electronic form was difficult for the reasons cited above. Finally, the project aimed to provide health assistants with information that allowed them to provide more targeted and effective services to the people. Health assistants need more than just support tools, however, but also support to use those tools. In the absence of this, they were not able to use these devices effectively. As the consultant said, "it works only if the supporting staff trouble-shoot problems promptly and in a reasonable period. But this did not happen, so gradually the health assistants lost interest and developed a negative attitude towards computers." So when plans to expand the computerisation project to the whole state were being drawn, it was decided not to opt for PDAs because of these problems, and also because it was considered too expensive.

Family Health Information Management System

The FHIMS project was conceived based on the experience of the IHC project. While the IHC project covered only one aspect of the work of the health assistants (family welfare services), it was decided by the FWD that a comprehensive HIS was necessary, and that it should include the different activities of PHCs including family welfare services, various health services (disease control, for example), and administrative aspects (such as budgets and logistics support). The department in its official circular (CFW, 2003) outlined the key objectives of this project as follows:

- To provide a name-based follow-up of family welfare services including antenatal services and immunization, and the early identification and timely referral of high-risk antenatal cases
- To improve the full immunization rates and thereby contribute to the reduction of infant mortality rates and maternal mortality rates
- To facilitate the health assistants to easily get schedules of services to be rendered in each habitation during a month; that is, to

provide schedules on pregnant women and children to be visited by the health assistants in their respective subcentres
- To reduce the burden of manual record keeping by the field staff and all the higher levels
- To contain the spread of communicable diseases and blindness by tracking incidences of diseases
- To improve the functioning of PHCs by facilitating effective service delivery
- To streamline inventory and infrastructure management at the health centres
- To manage career and training issues of field personnel

The project was conceived over the following phases: the pilot at the Nalgonda district (December 2001-November 2002), and the state-wide replication (June 2003-ongoing). We discuss these two phases followed by a summary of the identified implementation challenges.

The Pilot Phase of FHIMS at the Nalgonda District

The pilot phase of the FHIMS project was started in 67 PHCs in December 2001 about a year after the IHC project in the same district. A software engineer who had been involved throughout the design and development of IHC and also FHIMS explained that elaborate consultations were held with health officials at different levels, including health assistants, during the design of the software. However, when we spoke to many doctors, they typically said that the process had been largely top down with limited involvement of PHC-level doctors.

After the software was installed in all the PHCs, the department appointed data-processing operators (data operators) on a temporary basis for a period of 9 months to do the data entry and to train the staff during this transition period. Although data operators initiated the data-entry process, they did not seem to have the capacity to take on the role of change agents and to motivate the health staff. Although the district administration had instructed every PHC to identify a competent person as a system administrator who could act as a leader and be trained by the data operators from the beginning, this did not happen. Also, the role of systems administrators was not clearly defined, and adequate guidelines were not given to them on how to manage their regular work (for example, as lab assistants) with these additional responsibilities. Additionally, no incentives were provided to concurrently carry on both this task and that of a system administrator. The system administrators also complained that the training that was provided was inadequate and focused primarily on computer awareness with hardly anything on the FHIMS and nothing on health management itself. A coordinator for FHIMS who was involved in conducting training sessions confirmed this exclusion:

Initially, all the cadres were trained in all the modules. That was not really useful. For example, a health assistant need not know about the budget module, or vehicle or personnel module. If she knows about the family welfare module and one or two national health programmes, that should be enough. Similarly, a pharmacist need not know about budget or family welfare modules. If he knows about his stores, inside out, it is more than enough. It won't take more than 2 days. He will be more than happy if he is thoroughly trained for 2 days on his module. But they were called for 5 days and were taught all the modules. By the time they came to their module, they had probably lost interest.

The doctors said they were not fully involved in the project from the beginning and were unaware about the aims of the project. A FHIMS coordinator, who is also a doctor said:

From the beginning, the doctors did not have ownership of the data… since the time the survey started. Training on updating the registers was given only to the health assistants, and the doctors did not know what the training was about. Had the doctors at the PHCs been told about the registers, all about the project, and given guidelines as to how a health assistant has to go about her work, this is where you as a doctor have to guide them…then things would have been different. However, the doctor was bypassed. The data entry was done at a central point (not at PHCs). The doctor lost track there again. That's how they drifted slowly. They could have probably fallen back on track when the software was installed, but that didn't happen due to many reasons. Hence the doctors did not own the project.

Online data transfer took place initially for sometime, but then stopped. The coordinator of FHIMS explained why:

Online data transfer was going on in 50% of the PHCs for sometime. But the thing is, the district administration is still taking only the manual reports. It is not taking the reports generated from FHIMS because all the data are not being entered into FHIMS. So, whatever report you get from that (software), it is not complete. We can generate only one report, Form B from FHIMS. But that had a few errors. And even if you could correct one or two errors with a pen, you need the other data. And where will the other data come from?

In March 2003, the authors visited 12 PHCs, one community health centre, and the district office. The health staff complained that many software- and system-related problems were identified but not addressed. In many PHCs, the health staff did not know the passwords, and did not know how to burn CDs and save the data. At the time of our visits, a majority of the health staff were not using the computerised system, were not entering and updating the health data regularly, and hence were not generating computerised schedules or reports. The projects in most PHCs had stopped when the data operators left after their temporary tenure.

STATE-WIDE EXPANSION OF FHIMS

State-wide replication of the project involved the extension of the Nalgonda project to all the other 22 districts and 1,319 PHCs. The expansion phase of the project, which started in 2003, involved the computerisation of all the PHCs, district medical and health offices (DM&HOs), and the offices of the Director of Health and the Commissioner of Family Welfare at the state level (Circular I, CFW, 2003, p. 1). The replication involved the conduct of a household survey (to replace the MPHS data as was done in Nalgonda), the installation of computers and the FHIMS, the entering of survey data, training for the health staff, and the initiating of the other activities (such as identifying private agencies for printing MPHS books or team building) necessary for starting the project.

Based on the experience of the pilot, many changes were made during the replication phase. Survey registers were printed with an index and in alphabetical order. A team of 16 people were trained in each district, who in turn trained the health staff at the district level on how to conduct the household survey. Doctors were involved and system administrators were identified. Videoconferencing facilities were used regularly by the commissioner to coordinate and give instructions to health officials in the district, and to obtain status reports on the data-entry process. A number of circulars were sent to every PHC regularly, giving detailed instructions at different stages of implementation.

The computers were introduced in September 2003 in the PHCs, and the initial plan was to start the project by December 2003. In July 2005, one of the authors and his team conducted a situational analysis of the status of the implementa-

Table 1. Summary of the implementation challenges

*	Improving data-collection approaches
*	Developing a culture of using information to support local action
*	Providing adequate training not just in using computers to generate regular reports, but also in interpreting data
*	Providing on-site training (at PHCs) for the health staff on a regular basis
*	Adopting an iterative process to improve technical features of the software
*	Managing the workload of the staff
*	Getting health staff to start doing data entry rather than data-processing operators
*	Initiating collective participation to facilitate ownership of the systems
*	Motivating health staff to change existing work practices
*	Encouraging system administrators and doctors to take on the role of change agents
*	Building the capacity of health managers for evidence-based decision making
*	Providing timely hardware and software support
*	Addressing infrastructural issues
*	Switching over to online reporting
*	Sustaining the project over time by involving officials at the state, district, and local levels
*	Managing interdependencies (for example, the building of the health database was dependent on MPHS, which was developed by another department)

tion of FHIMS in 84 PHCs in another district (called Chittoor). This evaluation report, which was provided to the collector of the district, the DM&HOs, and the state-level authorities, identified a number of ongoing problems in the implementation of FHIMS contributing to it being far behind schedule. The evaluation identified that all the PHCs had reported software bugs of varying levels of complexity. Although household data had been entered, service data remained grossly incomplete. None of the PHCs were generating any of the reports that were needed to be sent to the district. This was because, except for one report, other reports could not be generated through the FHIMS. Although in a few cases schedules for health assistants were being printed, the demand for these schedules did not come from the health assistants themselves, but the schedules had been printed by the data operators (before they had left) and given to the health assistants. The study also revealed that on average only three or four people per PHC had received training in computer awareness through the 5-day training programme. No formal training was given to the PHC staff on FHIMS. In some cases, the data operators had provided some basic training to the system administrators. In more than 50% of the PHCs, none of the staff knew the username and password to enter the FHIMS modules after the departure of the data operators.

In summary, various factors have been identified that have impeded the implementation of the HIS initiatives discussed. These complexities are sociotechnical in nature. While some of these problems are expected given the extreme complexity of the projects, some, we believe, can be addressed by providing increased care and attention to the sociotechnical issues. In Table 1, we summarize some of these key challenges, and in the following section, we discuss how they were addressed.

DISCUSSION

One of the key recommendations of WHO (2005) in *Health and the Millennium Development Goals* is to improve the information basis on which health management decisions are made. The report notes, "making available information concerning the location, functioning, and performance of health services should also improve transparency and accountability in the management of the health sector" (p. 79). Accurate information can support better management and enhance the efficiency of health-care delivery. HIS can contribute to human development by supporting health management. Jacucci, Shaw, and Braa (2005) argue that the overall sustainability of a standards-based HIS is dependent on the quality of data and the skillful use of data at the level of collection. Local sustainability of the HIS requires the information to be of relevance not just for the managers, but also at the local level. This requires training health staff not just on the mechanics of using software, but also on public health-related topics of information use, data quality, significance of health indicators, validation, analysis, and interpretation of data, and linking these with interventions on the ground.

The implementation of HIS is not just a matter of introducing technology, but is also dependent on the social, organisational, and political issues that need to be addressed on an ongoing basis. Several authors have emphasized the need to understand and analyse information systems from a sociotechnical perspective (Coakes, Willis, & Lloyd-Jones, 2000; Kling & Lamb, 2000; Walsham, 1993). For example, Kling (1987) and Kling and Scacchi (1982) utilize Web models to take into account the social relations between the set of participants, the infrastructure available for its support, and the previous history of commitments in the organisation around computer-based technologies. Walsham (1993) provides an analytical framework for understanding the mutually shaping linkages that exist between content, social context, and social processes of IS. Over the years, several authors have both applied Walsham's structural framework and also expanded it by including various facets of the economic, cultural, and political context (e.g., Avgerou & Walsham, 2000; Jarvenpaa & Leidner, 1998; Madon, 1993; Sahay, 2000; Walsham, 2001). Avgerou and Madon (2004) argue "for broadening of the perspective of situated research to make explicit the contextual origins of the meanings, emotional dispositions, and competencies actors bring to bear on the interactions that constitute these processes" (p. 176).

Even though a participatory approach was stated to have been adopted to a certain extent during the design and implementation of the FHIMS, in practice, this did not evolve into effective and sustainable partnerships resulting in end users owning the new system. As an example, the HISP team conducted a situation analysis in the 84 PHCs of the Chittoor district in August 2005 after the contracts of the data-processing operators responsible for the FHIMS implementation were discontinued. The analysis revealed that in about 50 of the 84 PHCs, the FHIMS system had not been used since the departure of the operators because the PHC staff did not even know the password to log into the system, indicative of the absence of a partnership between the implementing team and the end users, and the lack of local ownership of the system. This raises the need to adopt complementary or alternative approaches that can facilitate the creation of local capacity and ownership. This requires the trainers to play multiple roles from building technical capacity to motivating the staff, and facilitating the change processes at multiple levels (Tomasi, Facchini, & Maia, 2004). Building these capacities is a slow and gradual process, but they are crucial and fundamental for the collective ownership of the project. This requires the need to shift the focus from being primarily on technology to the various surrounding processes required to strengthen the informational basis of health management. Some ways in which these challenges are being addressed in the FHIMS case is now discussed.

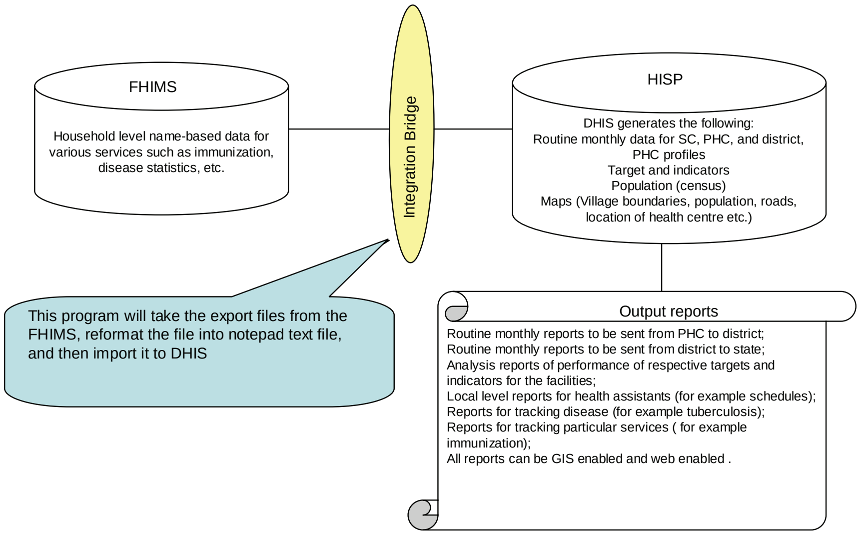
Shifting Focus from Technology to Information: Empirical Experiences from IHIMS

In order to address the various implementation challenges, the State Health Department endorsed in July 2005 a project called Integrated Health Information Management System (IHIMS) through a Memorandum of Understanding (MoU) with HISP India[3] (a not-for-profit society set up by the University of Oslo). HISP is an ongoing, large-scale action research initiative that operates as a global network across a number of developing countries. HISP was started in India in December 2000, and was operating in some limited areas parallel to the FHIMS project, which had a state mandate. Since FHIMS was the official state project, and HISP was seen primarily as a university research and development project, HISP was always vulnerable to being terminated by the state in favour of FHIMS. As a strategy to protect itself against such an event, the HISP management proposed to the state the IHIMS project, which would integrate the individual capabilities of the FHIMS and HISP projects and develop synergies to contribute to the overall health information management in the state. The integration logic argued by HISP was informational rather than technological. While FHIMS was a name-based software, the District Health Information Software (DHIS), a not-for-profit customised open-source software developed by HISP, was a facility-based system. By linking the two technological systems, it was argued that an integrated informational analysis could be carried out both at the level of individuals and health facilities. Also, since the DHIS was linked to the Web and GISs, the integrated system could provide visual representations of the information on the Web and maps, something not currently possible with FHIMS.

Technically, the integration was developed in the following way. With its focus on name-based data, FHIMS was capable of generating subcentre-based reports and schedules to help the health staff identify which households to visit and when. The name-based household data was entered into the FHIMS, through which the subcentre-based reports were generated. The data were then aggregated and imported into the DHIS by facilities (subcentres) and processed, which resulted in the generation of various analysis reports, including on the GIS and Web. The integration was thus proposed to convert some of the raw (household based) data into useful information through the use of analytical tools, and to improve the representation of the data using GIS-generated maps. In arguing for the integration, the HISP team emphasized that map-based reports would be useful for district- and state-level officials, for example, in resource-allocation decisions (such as opening a new facility or buying an ambulance). The conceptual schema of the integration proposed, and subsequently accepted, through the MoU under the IHIMS project is depicted in Figure 2.

The IHIMS implementation commenced in August 2005, and the first phase of the project was a situation analysis to try to understand the status of the earlier FHIMS implementation and the underlying challenges. A key problem identified was that the operators who had been working previously in the PHCs under the FHIMS project had operated as independent islands and had not involved the health assistants in the PHCs. As a result, there was little development of local expertise and ownership of the system. As mentioned earlier, in nearly 50 of the 84 PHCs, even

Figure 2. The FHIMS-HISP integration



the passwords to log on to the system were not known to the staff in clinics there. In contrast to the approach of the operators whose focus was on data entry, the HISP's emphasis was on system facilitation whereby the data entry and report generation was not done by the trainers, but by the health staff themselves, supported and facilitated by the trainers. Also, there was a difference in the focus of the training content, which was not limited to the mechanics of the software, but also to issues of how information can be made useful to support local action.

After the situation analysis in August, the HISP trainers were assigned to a cluster of four to five PHCs and were responsible for providing ongoing support to the staff on site in each of the PHCs. This on-site training approach was radically different from the earlier FHIMS training strategy of one large district-level 3- to 5-day training programme followed by literally no support to the staff in the course of their everyday work. From August to November, a key focus of the IHIMS project was on completing the huge amounts of backlog in data entry in the FHIMS database, and trying to change the mindsets of the health staff from FHIMS to IHIMS, which included both DHIS and FHIMS. At the end of November 2005, an evaluation of the IHIMS indicated that 68 of the 84 PHCs had completed the backlog of data entry, and they had generated the Form B, mother and child report, and also the Forms A and C, for communicable diseases and other health services. The way IHIMS worked was that data for the Form B was entered into the FHIMS, and the report accordingly generated. However, the data required to generate Forms A and C were directly entered into the DHIS database, and the reports were generated through the DHIS. The FHIMS technically was not capable of developing the Forms A and C, but through the integration of the two systems, the whole suite of reports could be generated. Another evaluation at the end of December indicated that the number of PHCs that had generated the Forms A, B, and

C was now 75, and the remaining 9 had serious structural problems (lack of staff or very large PHCs). Also, some of the PHCs, in addition to the routine reports of Forms A, B, and C, had also started to generate some analysis reports such as those for conducting inter-subcentre comparison. The HISP's training focus in the future was to be increasingly on the analysis reports and the use of information for action.

The relative success of the IHIMS programme can be attributed to three key reasons. First, by linking up the FHIMS and DHIS, the state government gave opportunities for the different people involved to pool their strengths and capacities rather than fight with each other. Second, the individual capabilities of the two systems could be innovatively combined so that the FHIMS software was used for generating subcentre-based reports while the DHIS provided the facility-specific reports and also incorporated different forms of representation including the Web and GIS. Third, alternative training approaches could be included through the integration. Unlike the FHIMS project, in which training focused primarily on the use of computers, HISP emphasized the use of information, including the generation of reports, the analysis of data, and the use of GIS to make visible spatial correlations in health data. Also, HISP tried to develop the capacity of the health assistants and other staff at the PHC in the local use of information. This effort is part of a larger and long-term process of developing an information culture where data is not just seen as a mindless effort to fulfill the needs of an uncaring bureaucracy, but a resource that can strengthen the everyday local work. This approach is compatible with Sandiford et al.'s (1992) argument:

the ability to analyse and interpret data is indispensable but insufficient to overcome the inertia of the status quo to ensure that the information is translated into decisions and action….The need to tailor the presentation of information to the intended audience must be recognised. (p. 1085)

The analysis capabilities of the DHIS could be emphasized through various preprogrammed tools that provided the user with the ability to make comparisons and present data in the form of graphs, charts, and maps. Similarly, GIS provided particular analytical tools that enabled the mapping of health status and diseases, programme planning, displaying health-care coverage, planning health infrastructure and maintenance, and comparing performance indicators across PHCs (Sauerborn & Karam, 2000).

Prior research in the domains of IS and HIS, both in developed and developing countries, has emphasized that integrating systems is no easy task as it involves aligning social, technical, and political linkages, and fostering coalitions and building synergies (Chilundo, 2004; Hanseth, Ciborra, & Braa, 2001). We agree with Chilundo, who has argued that the integration of ISs is not only a technical exercise, but involves the creation of a heterogeneous network comprised of various groups of people, technological artefacts, medical practices, and different information systems. While, at one level, integration can be seen as an attempt to reduce some of the heterogeneity in the system arising from a multiplicity of information systems, by adopting a modular approach to integration, heterogeneity can be encouraged rather than neutralized. While both the DHIS and FHIMS were capable of operating independently, in combination they were able to produce the whole set of reports required by the health department. Integration of not only the technical systems also implied bringing together different training approaches and also the pooling of financial and human resources. For example, the system administrators, a post created to support the FHIMS implementation, now were made the focal persons under the IHIMS and became responsible for the generation of the reports from both the DHIS and FHIMS systems.

In summary, we argue that the integration of systems can provide potential opportunities to address some of the implementation challenges discussed earlier. However, the philosophy underlying the integration attempts should not be to neutralize or eliminate one system, but to see how synergies can be created through drawing upon the positive aspects of both the systems and associated resources. For example, through IHIMS, the positive aspects of FHIMS, which were the name-based service schedule and summary reports, and DHIS, which was the facility-based reports, could be meaningfully incorporated toward the broader goals of health management.

CONCLUSION

The case studies presented earlier provide evidence of the importance of adopting a sociotechnical and integrated approach to the development of HIS. Too often, the introduction of ICTs is equated with development as an end in itself rather than as a means for supporting health management, which can in practice support development. These projects end up as largely computerisation projects and unsuccessful ones at that, rather than effective health-management initiatives. The introduction of computers, and the development and implementation of HIS in itself are not sufficient. Rather, the focus should be on how to develop and improve the informational base whereby information comes to be seen as a resource at all levels—at the local, district, state, and national levels—rather than just for bureaucracy.

There is typically an overemphasis on technical aspects during the implementation of HIS, and a relative neglect in addressing problems of information support that is necessary for better health management. The challenge is to move away from this pattern and to adopt a more integrated, holistic, and comprehensive approach to reforming informational and organisational practices. Introducing a HIS, particularly a name-based system, without addressing issues related to information generation, management, and use (analysis, interpretation, and evidence-based decision making) does not solve existing problems of poor quality of data, or the manipulation of figures, because health staff working in the field may have their own logic, stakes, and priorities that might not align with the goals of the promoters. That is, introducing information technology and systems does not in itself necessarily lead to better information practices or better health management. The challenge is not just to have adequate information, but to make better use of it and have a greater ability to act on it.

A grand vision to have a unified system (one-for-all purposes), as in the case of MPHS and FHIMS, may be attractive, but it brings with it numerous problems and is difficult to put effectively in practice. Instead, a more realistic approach should attempt to recognise what exists, what works well, and at what costs new systems are being built. While the name-based approach of the FHIMS is useful at the community level to track patients and provide targeted health care, HISP emphasizes the use of analytical tools for better health management and for capacity building of health staff. Initiating synergies between the FHIMS and DHIS through an integrated approach, as is being empirically attempted, provides opportunities to develop more sustainable health information systems that either of the systems by themselves cannot provide. These opportunities come through increased technical functionalities to serve different needs, a pooling of financial and human resources, and the incorporation of different and complementary training approaches.

ACKNOWLEDGMENTS

The authors would like to thank Professor Lucy Suchman for her helpful comments on previous drafts of this chapter. We would also like to thank the officials at the office of the Commissioner of Family Welfare, Andhra Pradesh, all the health staff and members of HISP India, and the FHIMS team for their support.

ABSTRACT

Evaluating clinician satisfaction with an electronic medical record (EMR) system is an important dimension to overall acceptance and use, yet project managers often lack the time and resources to formally assess user satisfaction and solicit feedback. This article describes the methods used to assess clinician satisfaction with an EMR and identify opportunities for improving its use at a 300-physician academic practice setting. We administered an online survey to physicians and *nurses; 244 (44%) responded. We compared physician and nurse mean ratings across 5 domains, and found physicians' satisfactions scores were statistically lower than nurses in several areas (p<.001). Participants identify EMR benefits and limitations, and offered specific recommendations for improving EMR use at this facility. Methods used in this study may be particularly useful to other organizations seeking a practical approach to evaluating EMR satisfaction and use.*

INTRODUCTION

The degree of interest and momentum in furthering the widespread adoption and use of electronic medical record (EMR) (or electronic health record systems) is at an all time high in the United States. Healthcare providers, purchasers, payers and suppliers are all looking to the EMR as a tool to help promote quality, enhance patient safety, and reduce costs. Despite this energy, recent estimates indicate EMR adoption rates in ambulatory care remain in the 15-20% range (Hillestad et al., 2005). Cost, lack of uniform interoperability standards, limited evidence showing use improves patient outcomes and clinician acceptance are among the barriers to widespread EMR adoption (Bates, 2005). Those who have overcome these initial hurdles and made the transition from a paper-based medical record system to an EMR often lack the time, resources and expertise to evaluate the system's impact on the organization, including clinician use and satisfaction with the system (Anderson & Aydin, 2005; Wager, Lee, & Glaser, 2005).

Use and satisfaction are two key measures of the success of any information system (DeLone & McLean, 2003), including EMR system success (Anderson & Aydin, 2005). Various researchers have assessed physician use and satisfaction with the EMR (Sittig, Kuperman, & Fiskio, 1999; Gadd & Penrod, 2001; Penrod & Gadd, 2001; Likourezos et al., 2004; Joos, Chen, Jirjis, & Johnson, 2006) and some have found that user group perspectives can differ even within the same institution (Wager, Lee, White, Ward, & Ornstein, 2000; O'Connell, Cho, Shah, Brown, & Shiffman, 2004b; Hier, Rothschild, LeMaistre, & Keeler, 2005). Assessing user reaction to the human-computer interface is also an important dimension (Sittig, Kuperman, & Fiskio, 1999; Despont-Gros, Mueller, & Lovis, 2005) in evaluating EMR satisfaction. Likewise, the timing of the evaluation study is important. Conducting formative evaluation studies during enterprise EMR implementation can be particularly useful in identifying perceived problems and making adjustments to the implementation plan or reallocating resources as needed (Friedman & Wyatt, 1997; Burkle, Ammenwerth, Prokosch, & Dudeck, 2001; Anderson & Aydin, 2005; Brender, 2006).

Our study was designed to assess physician and nurse use and satisfaction with an enterprise-wide ambulatory care EMR. We incorporated into the evaluation a means of assessing physician and nurses' reactions to the human-computer interface and also solicited their input and suggestions on how to improve the system's usefulness to our organization. This article summarizes the methods used, findings, and relevance to other organizations in the throes of implementing and evaluating EMR acceptance.

BACKGROUND

The Medical University of South Carolina (MUSC) in Charleston, South Carolina has implemented an electronic medical record (EMR) system, known as Practice Partner Patient Record® in the majority of its ambulatory clinics over the past few years. Although EMR use is not new to MUSC (family medicine has used the system since the early 1990s and internal medicine since the mid-1990s), it was not until February 2004 that we secured funding to deploy the EMR throughout the ambulatory care enterprise. When the system is fully implemented, paper medical records will have been replaced, and both primary care and specialty providers will share a *single* electronic medical record for their patients. This message was conveyed from the top down, starting with senior leadership and the dean of our medical school.

The EMR product itself has many of the attributes of a typical EMR system, including electronic health data capture, results management, decision-support, and electronic communications. However, MUSC has not yet installed enterprise-wide direct order entry nor activated the preventive care reminder functions. Disease-specific progress note templates are available for facilitating program note entry; however, direct data entry is not a requirement for using the system, and transcribed notes can also be incorporated. The system also includes a prescription writer, which allows prescriptions to be entered and tracked in the patient record while automatically checking for interactions with other medications and documented allergies. Patients receive printed prescriptions at the time of the visit; the prescriptions are not yet sent electronically to the pharmacy.

We provided formal training sessions to physicians, nurses and administrative support; however, nurses and administrative staff received at least four hours of initial training, while most physicians only had 30-45 minutes of training. Nurses and administrative staff were trained in small groups in a classroom setting with computer workstations for each individual. Physicians were offered several options for training, including small group sessions, but the far majority opted for one-on-one training with a clinical analyst. Knowing that physicians' schedules were harried, we decided to provide more intensive training to nurses and administrative staff. We felt if nurses and administrative staff were comfortable with the system, they could assist physicians in their respective departments as needed.

The purpose of the study was to gain insight into user satisfaction and determine if there were differences in user group satisfaction, and solicit formal feedback on how to improve the system's use at our organization. We defined 'user' as any MUSC employee or student who had been issued an EMR login and password. This article describes the methods used to conduct the survey and the results from our attending physician and nurse user community.

METHODS

Survey Instrument

We conducted preliminary interviews with physicians and nurses regarding their views and experiences with the EMR, but were interested in soliciting input from all EMR users at MUSC. Given the size of the user group, we decided to adopt a survey approach. We adapted the *Questionnaire for User Interaction Satisfaction (QUIS)*, developed by researchers at the University of Maryland, for use in this study after reviewing the literature, consulting with medical informatics professionals and soliciting input from EMR physician leaders at MUSC. The QUIS has been tested as a valid and reliable instrument in settings similar to MUSC (Chin, Diehl, & Norman, 1988) and was used recently by researchers affiliated with Brigham and Women's Hospital to assess physician satisfaction with its internally developed outpatient EMR (Sittig, Kuperman, & Fiskio, 1999). The QUIS has also validated for online administration (Slaughter, Harper, and Norman, 1994). The instrument assesses user satisfaction in five major domains, with four to six questions in each: (1) overall user reactions, (2) screen design and layout, (3) terminology and system messages, (4) learning, and (5) system capabilities. Recognizing that participants might respond differently depending upon whether they were assessing how long it takes to open the application or navigate within it, we separated the item "system speed" survey component into two statements—system launch speed and navigation speed. We asked participants to rate each question on a scale from 0 (the lowest) to 9 (the highest) level of satisfaction.

We included several additional items in the survey: (a) demographic data (e.g., position, age, gender), (b) use of the EMR (whether provider dictated notes or directly entered them into EMR), and (c) three open-ended questions, in which participants were asked to identify the three greatest benefits or advantages and three greatest limitations or disadvantages to using the EMR and any recommendations they have for improving the use and effectiveness of the EMR within their clinic or at MUSC. The items and scale from the QUIS were kept intact. A draft survey was sent to a pilot group of physicians, nurses and administrative staff. Suggested changes were incorporated into the final version of the survey. Institutional Review Board approval was obtained prior to conducting the study.

User Population and Survey Administration

We sent an e-mail message from one of the authors (who happened to serve as chair of the Physician Information Council) to all attending physicians and nurses listed in the EMR user database. Our sampling frame included all individuals who had been issued an EMR username and password—for a total population of attending physicians (245) and nurse EMR users (304) of 549. In the e-mail message, participants were asked to click on an embedded hyperlink to complete the online questionnaire. We gave participants the option of printing and faxing the completed survey to us (48 surveys were returned by fax). Two reminder notices were sent—one week and two weeks following the initial mailing. All participants were assured confidentiality of their responses.

Data Analysis

Survey responses were downloaded from the survey provider to an electronic database and then imported into SPSS for analysis (Windows, 2005).

Responses to open-ended questions were grouped and assigned to categories by the primary author, experienced in qualitative research. These were then tabulated within each of the categories and discussed among the participating authors.

RESULTS

Demographics of Participants and Their Use of EMR system

We received 244 completed surveys from attending physicians and nurses for an overall response rate of 44%. Forty-seven (47%) of physicians and 38% of nurses responded. 32% of participating physicians and 98% nurses are women; 85% are between the ages of 30-60, equally distributed within each decade of life. Nearly 37% of physicians and 19% of nurses reported having prior experience with other EMR systems, and 62% have used the EMR at MUSC for at least one year.

When physician participants were asked how often they dictate patient information that is eventually transcribed into the EMR, 39% reported frequently (defined as more than 50% of the time), 4% sometimes (25-50% of the time) and 58% reported rarely or never (defined as less than 25% of the time) (n=109). Almost 40% of participants reported having paper medical records pulled daily for patient visits, 14% sometimes, and 44% rarely or never (n=108). 70% reported that they access the EMR remotely on at least a weekly or daily basis.

Satisfaction with EMR

We assessed the internal consistency reliability of the five domains of the QUIS part of the survey (Table 1) and examined mean satisfaction scores for attending physicians and nurses for each item within the five domains. Overall Crohbach's alpha was 0.961.

Attending physician and nurse mean scores are shown in Table 2. Items were rated on a scale of 0 to 9, with 0 being the most negative, 9 the most positive. Both groups gave low ratings to system launch speed and clarity of error messages. Items rated most positive by both groups included system noise, ease in reading characters, consistency of terms, and the clarity of messages appearing on-screen. We calculated overall satisfaction scores for physicians and nurses using the average of the six items in the overall user reaction domain as a proxy. Overall satisfactions scores were 4.67 and 5.50 (t-test, $p < .001$) for attending physicians and nurses, respectively. We compared attending physician ratings of the other 22 individual items with those of nurses and found that the physicians' mean ratings of the EMR were statistically significantly lower in nine of the 22 items ($p<.05$). Using one-way ANOVA, we found no difference in overall satisfaction between experience groups, less than 6 months, 6-12 months, 1-2 years, and more than 2 years.

Table 1. Reliability of domains (Crohbach's Alpha)

Domain	Alpha
Overall user satisfaction	.911
Screen design and layout	.859
Terms and system information	.891
Learning	.876
System capabilities	.835
Overall	.961

We also ran a standard multivariate regression with overall satisfaction score as the dependent variable and the 22 remaining items as independent variables and found two items were significant predictors of overall satisfaction—(1) task can be performed in a straightforward manner ($p<.001$) and (2) clarity of help messages on screen ($p<.01$).

Perceived EMR Benefits, Limitations and Recommendations for Improved Use

Participants were asked three open-ended questions:

- What have you found to be the three greatest benefits or advantages to using the EMR?
- What have you found to be the three greatest limitations or disadvantages to using the EMR?
- What recommendations do you have for improving the use and effectiveness of the EMR within their clinic/area at MUSC?

Benefits/Advantages to the EMR System

Nearly 82% of physicians and 56% of nurses identified availability and accessibility of the patient's record as a major benefit or advantage to using the EMR. See Table 3. Included in this category were comments related to having access to other clinic notes and records and having remote access to the EMR. One physician commented, "*Everyone has access to the entirety of the record across all disciplines.*" Another noted, "*The EMR greatly facilitates communication among primary care providers and specialists by having all patient information in one place.*" Other frequently cited benefits included (a) quality of record/documentation (legibility, data consistency and accuracy, organization of record, coding/compliance); (b) comprehensiveness and completeness of patient

Table 2. Physician and nurse mean satisfaction scores by domain/item

Domain	Item (0-9 scale)	Physician	Nurse
Overall satisfaction	Terrible……………………………………Wonderful	5.07	5.92*
	Difficult……………………………………Easy	5.17	6.21*
	Frustrating……………………………………Satisfying	4.33	5.09*
	Inadequate Power……………………………………Adequate Power	4.45	5.02
	Dull……………………………………Stimulating	4.65	5.39*
	Rigid……………………………………Flexible	4.42	5.41*
	Overall satisfaction composite score	**4.67**	**5.50***
Screen Design and Layout	Characters on the screen: Hard to read……………………Easy to read	6.67	7.16
	Highlighting on the screen simplifies task: Not at all……………Very much	5.49	6.54*
	Organization of information on screen: Confusing……………Very clear	5.45	6.17*
	Sequence of screens: Confusing……………………Very clear	5.56	5.81
Terms and System Information	Use of terms throughout system: Inconsistent……………………Consistent	6.09	6.58
	Computer terminology is related to the task you are doing: Never…………Always	5.89	6.31
	Position of messages on screen: Inconsistent……………………Consistent	6.05	6.48
	Messages on screen which prompt user for input: Confusing…………Very clear	5.42	6.14*
	Computer keeps you informed about what it is doing: Never…………Always	4.90	5.42
	Error messages: Unhelpful……………………Helpful	3.22	4.19
Learning	Learning to operate the system: Difficult……………………Easy	5.23	5.98*
	Exploring new features by trial and error: Difficult……………………Easy	4.73	5.76*
	Remembering names and use of commands: Difficult……………………Easy	4.93	5.51
	Tasks can be performed in a straight forward manner: Never…………Always	5.06	5.74*
	Help messages on the screen: Confusing……………………Clear	4.14	5.12*
	Supplemental reference materials: Confusing……………………Clear	4.10	5.45*
System Capabilities	System speed (to open or launch program): Too Slow…………Fast Enough	2.65	2.85
	System speed (to navigate within EMR, e.g. open a note): Too slow…………Fast enough	4.41	4.13
	System reliability: Unreliable……………………Reliable	4.72	5.01
	System tends to be: Noisy……………………Quiet	7.23	7.87*
	Correcting your mistakes: Difficult……………………Easy	5.12	4.96
	Experienced and inexperienced users' needs are taken into consideration: Never……………………Always	4.68	5.31

**significant at the p>.05 level*

Table 3.Most frequently cited benefits/advantages to using MUSC's EMR system

EMR Benefit	**Physicians** n=114	**Nurses** n=130
Availability and access to patient record	81.6%	56.2%
Quality of record/documentation	36.0%	14.6%
Comprehensiveness and completeness of record	33.3%	25.4%
Positive impact on efficiency	13.2%	10.0%
Continuity of care and standards of care	13.2%	10.8%
Ease of use	12.3%	15.4%
Avoidance of perils of paper	9.6%	20.0%

record (e.g., medications, results from diagnostic tests); (c) impact on efficiency (e.g., speed, timeliness in completing notes);(d) continuity of care and standards of care (e.g., templates, continuous outpatient record); and (e) avoidance of perils inherent with paper records (e.g., no lost charts, no moving charts).

Limitations/Disadvantages to the EMR System

Limitations or disadvantages identified by at least ten participants are listed in Table 4. The two most-cited limitations or disadvantages of the EMR were speed and cumbersome user

Table 4. Most frequently cited limitations/disadvantages to using MUSC's EMR system

EMR Limitation	**Physicians** n=114	**Nurses** n=130
Cumbersome user interface	38.6%	24.6%
Speed/too slow	37.3%	32.3%
Having to access multiple clinical systems or poor integration with other systems	17.5%	4.6%
Problems with templates	11.4%	4.6%
Insufficient training and support staff	11.4%	3.8%
Downtime (including system crashes or system locking/ freezing up)	14.0%	21.5%
Time-consuming to use	13.2%	14.6%

interface. Both physicians and nurses described the system as being too slow. Approximately 20 participants mentioned that the start time to open the application was particularly problematic. System downtime, including the moments when the "system crashes", "locks up or freezes" and requires user to "reboot" were described as frustrating by 14% of physicians and 22% of nurses. One physician commented that system crashes are frustrating: "*The program froze three times today while I was editing the same note, losing the edits each time. I spent 30 minutes trying to edit a single note without success*." A nurse noted, "*When the system is down, you are put completely on hold*." Several participants also expressed frustration with the amount of typing required and the time-consuming nature of entering data into the system. Understanding error messages and correcting mistakes also emerged as points of frustration. Comments reflecting concerns including statements such as: "*too much trial and error*", "*if you don't already know how to do something, you'll never figure it out", and "some error messages don't tell you how to solve the problem*."

Suggestions for Improving EMR Use at MUSC

Participants gave numerous written suggestions for improving EMR use at MUSC—73% of the physicians and 49% of nurses wrote comments. Suggestions ran the gamut from *"provide more training", "fix bugs in system", "address speed and reliability of system*", *to "make it more user friendly*."

Several common themes emerged from the written suggestions. Some of these relate to how the EMR is structured and used at MUSC and others relate more directly to the Practice Partner application itself. General suggestions included (1) address the speed/performance issues, (2) expand training and support personnel/resources, (3) improve the user interface/templates and simplify data entry, and (4) integrate more fully with other MUSC applications (e.g., scheduling, lab, radiology).

DISCUSSION

Nearly 250 physician and nurse EMR users at MUSC participated in this study. Nurses are more satisfied overall with the EMR system than are attending physicians. The greater system acceptance by nurses may be due to the approach MUSC took in implementing the EMR enterprise-wide. Initial efforts were focused on nurses and administrative staff, because these individuals were expected to lead in the effort. We felt if nurses were comfortable with the system, they could assist physicians. The downside of this approach is it has been time-consuming and resource-intensive to roll out the EMR throughout all the ambulatory care areas. Consequently, some physician users have not been fully trained on all of the system capabilities—yet, they have been using the application for two or more years.

Additionally, 58% of participating physicians report that they rarely, if ever dictate. Earlier studies have shown that data entry can negatively impact physicians' perceptions of their time, particularly if physicians are not proficient typists or comfortable entering information in the examination room with the patient (Gadd & Penrod, 2001; Penrod & Gadd, 2001; O'Connell, Cho, Shah, Brown, & Shiffman, 2004a; Hier, Rothschild, LeMaistre, & Keeler, 2005; Scott, Rundall, Vogt, & Hsu, 2005; Linder et al., 2006).

Researchers at Partners HealthCare System conducted a time-motion study and found no differences in primary care physician time utilization before and after EMR implementation, yet the majority of their physicians still perceived that the EMR required more time than paper records to document patient information (Pizziferri et al., 2005). Nurses in an earlier study reported that the EMR enabled them to finish their work much faster than before implementation (Likourezos et al., 2004); although we did not ask this specific question, it may help explain why MUSC nurses generally viewed the system more positively than physicians.

Nurses also tended to value the "avoidance of the perils of paper" more often than the physicians did, yet they did not mention availability as a major benefit as often as physicians did. We categorize these measures of availability/accessibility and avoidance of periods with paper separately, yet they are related. Nurses are responsible for ensuring that the patient's record is available at the time of the visit, thus, they experience the "grief" when the record is not available. Physicians are not the ones searching for the paper record, so they may not describe the benefit in quite the same manner. On the other hand, physicians were more likely to mention the benefits associated with having access to clinic notes from other physicians and more likely to comment on the overall quality of the documentation. Having a more "complete" picture of the patient's care (e.g., other visit notes, ancillary test results) stood out as particularly important to physicians. The EMR benefits identified by MUSC physicians and nurses are consistent with earlier studies (Sittig, Kuperman, & Fiskio, 1999; Gadd & Penrod, 2001; Penrod & Gadd, 2001; Likourezos et al., 2004; Joos, Chen, Jirjis, & Johnson, 2006).

Physicians and nurses had similar concerns when asked about limitations of the system or opportunities for improving its use at MUSC. In fact, speed and performance-related concerns seemed to cast a cloud over the benefits. Physicians and nurses identified speed and the slowness of the system as a *major* concern—launching the system was particularly problematic. Yet, in our multivariate regression analysis, system speed did not show up as a significant predictor of overall satisfaction. Although this finding surprised us, an earlier study at Brigham and Women's also found that system "response time" was not correlated with overall user satisfaction (Sittig, Kuperman, & Fiskio, 1999). Factors associated with physicians' ability to effectively use the system were more likely to be predictors of EMR satisfaction than speed alone.

In addition to their concerns with speed and performance, nearly 40% of the physicians felt the user interface was cumbersome, took too many clicks, and made it difficult to make corrections or changes. A common complaint was the "*system requires too many steps or clicks to perform a simple task*." Other institutions using different EMR applications have found their clinicians share these same concerns (Sittig, Kuperman, & Fiskio, 1999; Wager, Lee, White, Ward, & Ornstein, 2000; Gadd & Penrod, 2001; Penrod & Gadd, 2001; Miller & Sim, 2004; Scott, Rundall, Vogt, & Hsu, 2005). Some of the difficulty or frustration at MUSC may stem from a lack of sufficient training. For example, we observed from the open-ended comments that participants are frustrated with aspects of the system they may not fully understand how to use (e.g., writing prescriptions, modifying templates). Other frustrations may stem from using an EMR whereby primary care providers and specialists share and record their notes in a *single* patient record. Historically, each set of providers had specialty-specific records that only those in the specific group could view and modify.
