Contents
by Volume

Volume I

Section 1. Fundamental Concepts and Theories

This section serves as the foundation for this exhaustive reference tool by addressing crucial theories essential to the understanding of medical informatics. Chapters found within these pages provide an excellent framework in which to position medical informatics within the field of information science and technology. Individual contributions provide overviews of knowledge management in healthcare, health portals, and health information systems, while also exploring critical stumbling blocks of this field. Within this introductory section, the reader can learn and choose from a compendium of expert research on the elemental theories underscoring the research and application of medical informatics.

Section 2. Development and Design Methodologies

This section provides in-depth coverage of conceptual architectures, frameworks and methodologies related to the design and implementation of medical information systems and technologies. Throughout these contributions, research fundamentals in the discipline are presented and discussed. From broad examinations to specific discussions on particular frameworks and infrastructures, the research found within this section spans the discipline while also offering detailed, specific discussions. Basic designs, as well as abstract developments, are explained within these chapters, and frameworks for designing successful e-health applications, mobile healthcare systems, and clinical decision support systems are discussed.

Volume II

Section 3. Tools and Technologies

This section presents extensive coverage of the interaction between healthcare and the various technologies that both derive from and support the research of practitioners, students, and patients alike. These chapters provide an in-depth analysis of mobile technologies and their use in healthcare, while also providing insight into new and upcoming technologies, theories, and instruments that will soon be commonplace. Within these rigorously researched chapters, readers are presented with countless examples of the tools that facilitate and support medical innovations. In addition, the successful implementation and resulting impact of these various tools and technologies are discussed within this collection of chapters.

This section introduces and discusses the ways in which information technology has been used to shape the medical and biomedical sectors and proposes new ways in which IT-related innovations can be implemented within organizations and in society as a whole. These particular selections highlight, among other topics, the implementation of telehealth and the evolution of new, computerized systems in hospitals. Contributions included in this section provide excellent coverage of today's medical environment and insight into how medical informatics impacts the fabric of our present-day global village.

Volume III

Section 5. Organizational and Social Implications

This section includes a wide range of research pertaining to the social and organizational impact of medical informatics around the world. Chapters introducing this section analyze organizational factors in health informatics and patient centric health information systems, while later contributions offer an extensive analysis of the Internet's role in revolutionizing accessibility to medical-related information. The inquiries and methods presented in this section offer insight into the implications of medical informatics at both a personal and organizational level, while also emphasizing potential areas of study within the discipline.

Section 6. Managerial Impact

This section presents contemporary coverage of the managerial implications of medical informatics, more specifically related to successful IT governance in the healthcare sector. Particular contributions address the implementation of large IT projects in healthcare institutions and the effective measurement of cost efficiency in healthcare. The managerial research provided in this section allows executives, practitioners, and researchers to gain a better sense of the role of IT in both healthcare and medical research.

Volume IV

Section 7. Critical Issues

This section addresses conceptual and theoretical issues related to the field of medical informatics, which include maintaining high ethical standards and ensuring that sensitive medical information remains private. Within these chapters, the reader is presented with analysis of the most current and relevant conceptual inquires within this growing field of study. Particular chapters also address mining biomedical literature, standardization of health and medical informatics, and fuzzy logic in medicine. Overall, contributions within this section ask unique, often theoretical questions related to the study of medical informatics and, more often than not, conclude that solutions are both numerous and contradictory.

Section 8. Emerging Trends

This section highlights research potential within the field of medical informatics while exploring uncharted areas of study for the advancement of the discipline. Chapters within this section highlight evolutions in evidence-based medicine, the future of e-health, and web portals for medical data. These contributions, which conclude this exhaustive, multi-volume set, provide emerging trends and suggestions for future research within this rapidly expanding discipline.

Preface

The need to efficiently deliver and process information in the healthcare and biomedical sectors is a primary concern among practitioners, researchers, and patients alike. Medical informatics—a field that has emerged at the intersection of information technology and medicine—has transformed modern healthcare and created new, more pervasive methods for access to information, records, and even medical advice. As medical informatics continues to evolve and researchers continue to create and implement technologies for use in the study and practice of medicine, we must continue to understand, develop, and utilize the latest in medical research and exploration.

In recent years, the applications and technologies generated through the study of medical informatics have grown in both number and popularity. As a result, researchers, clinicians, practitioners, and educators have devised a variety of techniques and methodologies to develop, deliver, and, at the same time, evaluate the effectiveness of their use. The explosion of methodologies in the field has created an abundance of new, state-of-the-art literature related to all aspects of this expanding discipline. This body of work allows researchers to learn about the fundamental theories, latest discoveries, and forthcoming trends in the field of medical informatics.

Constant technological and theoretical innovation challenges researchers to remain informed of and continue to develop and deliver methodologies and techniques utilizing the discipline's latest advancements. In order to provide the most comprehensive, in-depth, and current coverage of all related topics and their applications, as well as to offer a single reference source on all conceptual, methodological, technical, and managerial issues in medical informatics, Information Science Reference is pleased to offer a four-volume reference collection on this rapidly growing discipline. This collection aims to empower researchers, practitioners, and students by facilitating their comprehensive understanding of the most critical areas within this field of study.

This collection, entitled **Medical Informatics: Concepts, Methodologies, Tools, and Applications**, is organized into eight distinct sections which are as follows: 1) Fundamental Concepts and Theories, 2) Development and Design Methodologies, 3) Tools and Technologies, 4) Utilization and Application, 5) Organizational and Social Implications, 6) Managerial Impact, 7) Critical Issues, and 8) Emerging Trends. The following paragraphs provide a summary of what is covered in each section of this multi-volume reference collection.

Section I, **Fundamental Concepts and Theories**, serves as a foundation for this exhaustive reference tool by addressing crucial theories essential to understanding medical informatics. Opening this elemental section is "Evaluation of Health Information Systems: Challenges and Approaches" by Elske Ammenwerth, Stefan Gräber, Thomas Bürkle, and Carola Iller. This selection addresses some of the primary issues and challenges in evaluating the use of IT in healthcare and suggests methods for improvement. Specific issues in medical informatics, such as the emergence of the Internet as a healthcare tool and knowledge management as it pertains to the healthcare industry, are discussed in selections such as “The Telehealth Divide” by Mary Schmeida and Ramona McNeal and “Knowledge Management in Healthcare” by Sushil K. Sharma, Nilmini Wickramasinghe, and Jatinder N.D. Gupta. Within the contribution “Information Technology (IT) and the Healthcare Industry: A SWOT Analysis,” authors Marilyn M. Helms, Rita Moore, and Mohammad Ahmadi utilize the SWOT analysis (strengths, weaknesses, opportunities and threats) to conceptualize and further evaluate the many issues facing IT implementation in healthcare, which include improved patient safety, cost, and user resistance. The selections within this comprehensive, foundational section allow readers to learn from expert research on the elemental theories underscoring medical informatics.

Section II, **Development and Design Methodologies**, contains in-depth coverage of conceptual architectures and frameworks, providing the reader with a comprehensive understanding of emerging theoretical and conceptual developments within the development and utilization of medical technologies. “The Development of a Health Data Quality Programme” by Karolyn Kerr and Tony Norris presents the case of the New Zealand Ministry of Health’s construction of a new data quality strategy aligned with the current health information program. Other selections, such as “Building Better E-Health Through a Personal Health Informatics Pedagogy” by E. Vance Wilson and “The PsyGrid Experience: Using Web Services in the Study of Schizophrenia” by John Ainsworth and Robert Harper, offer insight into the design and use of Web services to guide and inform medical decisions. The design and implementation of mobile-based health services is explored at length in selections such as “Enabling Conceptual Framework for Mobile-Based Application in Healthcare” by Matthew W. Guah; “Design of an Enhanced 3G-Based Mobile Healthcare System” by José Ruiz Mas, Eduardo Antonio Viruete Navarro, Carolina Hernández Ramos, Álvaro Alesanco Iglesias, Julián Fernández Navajas, Antonio Valdovinos Bardají, Robert S. H. Istepanian, and José García Moros; and “The M-Health Reference Model: An Organizing Framework for Conceptualizing Mobile Health Systems” by Phillip Olla and Joseph Tan. From basic designs to abstract development, chapters such as “A Cross-Cultural Framework for Evolution” by Pekka Turunenand and “A Distributed Patient Identification Protocol Based on Control Numbers with Semantic Annotation” by Marco Eichelberg, Thomas Aden, and Wilfried Thoben serve to expand the reaches of development and design methodologies within the field of medical informatics.

Section III, **Tools and Technologies**, presents extensive coverage of various tools and technologies and their use in creating and expanding the reaches of health and biomedicine. The emergence of wireless and mobile devices and the opportunities these devices present for revolutionizing traditional patient care is the subject of articles such as “PDA Usability for Telemedicine Support” by Shirley Ann Becker; “A Preliminary Study toward Wireless Integration of Patient Information System” by Abdul-Rahman Al-Ali, Tarik Ozkul, and Taha Landolsi; and “Choosing Technologies for Handheld and Ubiquitous Decision Support” by Darren Woollatt, Paul Koop, Sara Jones, and Jim Warren. Advancements in imaging for medical and biomedical applications are analyzed and assessed in several selections, which include “Imaging the Human Brain with Magnetoencephalography” by Dimitrios Pantazis and Richard M. Leahy and “Imaging Technologies and their Applications in Biomedicine and Bioengineering” by Nikolaos Giannakakis and Efstratios Poravas. The latter of these two chapters discusses biomedical imaging technologies such as MRI and x-ray, offering insight into the research opportunities these technologies have provided as well as the limitations associated with their use. The rigorously researched chapters contained within this section offer readers countless examples of modern tools and technologies that emerge from or can be applied to the medical and healthcare sectors.

Section IV, **Utilization and Application**, investigates the use and implementation of medical technologies and informatics in a variety of contexts. This collection of innovative research begins with “Successful Health Information System Implementation” by Kristiina Häyrinen and Kaija Saranto in which primary success factors for employing health systems, such as system qualities, information quality, usage, user satisfaction, and individual impact, are analyzed. The delivery of health information via telecommunications networks (also known as telehealth) is studied in selections such as "Telehealth Organizational Implementation Guideline Issues: A Canadian Perspective" by researchers Maryann Yeo and Penny A. Jennett and "Tele-Medicine: Building Knowledge-Base Tele-Health Capability in New Zealand" by Nabeel A. Y. Al-Qirim. Further contributions explore other key strategies and factors that relate to the successful use of electronic health records, mobile e-health, ICT, and knowledge management in a medical environment. From established applications to forthcoming innovations, contributions in this section provide excellent coverage of today's global community and demonstrate how medical informatics impacts the social, economic, and political fabric of our present-day global village.

Section V, **Organizational and Social Implications**, includes a wide range of research pertaining to the organizational and cultural implications of medical informatics. "Using Hospital Web Sites to Enhance Communication" by Sherrie D. Cannoy and Lakshmi Iyer investigates patient communication-enhancing features of hospital Web sites, ultimately contending that a hospital's Web presence must both address and cater to users' communication needs in order to be effective. Web portals and their use in fostering social interaction and knowledge enhancement are explored at length in chapters such as "Intelligent Portals for Supporting Medical Information Needs" by Jane Moon and Frada Burstein, "Health Portals and Menu-Driven Identities" by Lynette Kvasny and Jennifer Warren, and "Empowerment and Health Portals" by Mats Edenius. Other issues that are surveyed within this section include the implications of the digital divide in healthcare within Michele Masucci's "Digital Divide and E-Health Implications for E-Collaboration Research" and community-centered IT outreaches within Rosanna Tarsiero's "Community-Based Information Technology Interventions for Persons with Mental Illness." Overall, the discussions presented in this section offer insight into the integration of medical informatics in society and the benefit these innovations have provided.

SectionVI, **Managerial Impact**, presents contemporary coverage of the managerial applications and implications of medical informatics. Core concepts such as information security management, outsourcing, and healthcare technology management are discussed in this collection. "Information Assurance in E-Healthcare" by Sherrie D. Cannoy and A. F. Salam addresses the healthcare industry's limited adoption of IT advancements, which is now being remedied by new advancements in information assurance that guarantee the safety of patients' medical records. Similarly, within their article "Modelling Context-Aware Security for Electronic Health Records," Pravin Shetty and Seng Loke suggest context-based security policies for health organizations, which are able to adapt to new, incoming threats. Later contributions, such as "E-Health Dot-Coms' Critical Success Factors," further investigate the Internet's role in reshaping healthcare. Within this selection, authors Abrams A. O'Buyonge and Leida Chen evaluate the business models utilized by heath-information Web sites (such as WebMD) and present the lessons learned from a managerial perspective. The comprehensive research in this section offers an overview of the major issues that healthcare practitioners, governments, and even consumers must address in order to remain informed about the latest managerial changes in the field of medical informatics.

Section VII, **Critical Issues**, presents readers with an in-depth analysis of the more theoretical and conceptual issues within this growing field of study by addressing topics such as the quality and security of medical information. Specifically, these topics are discussed in selections such as "Medical Ethical and Policy Issues Arising from RIA" by Jimmie L. Joseph and David P. Cook and "E-Health Security and Privacy" by Yingge Wang, Qiang Cheng, and Jie Cheng. The latter of these two selections investigates relevant concepts, technologies, limitations, challenges, and trends in e-health security and privacy, along with standards such as the Health Insurance Portability and Accountability Act (HIPAA). Similarly, in contributions such as "Reliability and Evaluation of Health Information Online" by Elmer V. Bernstam and Funda Meric-Bernstam, the issue of how to effectively evaluate online health information is debated and a how-to guide for obtaining medical information online is suggested. Later selections, which include "Ontology-Based Spelling Correction for Searching Medical Information," review more novel issues, such as the difficulty in retrieving medical information online due to errors in spelling medical terms. In this chapter, researchers Jane Moon and Frada Burstein from Monash University propose an ontology-based architecture that would assist users with medical information retrieval. In all, the theoretical and abstract issues presented and analyzed within this collection form the backbone of revolutionary research in and evaluation of medical informatics.

The concluding section of this authoritative reference tool, **Emerging Trends**, highlights research potential within the field of medical informatics while exploring uncharted areas of study for the advancement of the discipline. The development and deployment of new forms of health information technologies (HITs) are proposed in Avnish Rastogi, Tugrul Daim, and Joseph Tan's "Charting Health Information Technology Futures for Healthcare Services Organizations," while the latest innovations in e-heath systems are analyzed in Pirkko Nykänen's "E-Health Systems: Their Use and Visions for the Future." In the contribution "Outsourcing of Medical Surgery and the Evolution of Medical Telesurgery," Shawna Sando asserts that, due to the rising cost of healthcare in the United States, the best alternative for some low- and middle-class citizens is to seek medical care overseas—to engage in "medical tourism." Other new trends, such as the emergence of evidence-based medicine, the creation of biotechnology portals in medicine, and revolutions in emergency medical services, are discussed in this collection. This final section demonstrates that medical informatics, with its propensity for constant change and evolution, will continue to both shape and define the modern face of healthcare and the ways in which we interact with health-related information.

Although the contents of this multi-volume book are organized within the preceding eight sections which offer a progression of coverage of important concepts, methodologies, technologies, applications, social issues, and emerging trends, the reader can also identify specific contents by utilizing the extensive indexing system listed at the end of each volume. Furthermore, to ensure that the scholar, researcher, and educator have access to the entire contents of this multi-volume set, as well as additional coverage that could not be included in the print version of this publication, the publisher will provide unlimited, multi-user electronic access to the online aggregated database of this collection for the life of the edition free of charge when a library purchases a print copy. In addition to providing content not included within the print version, this aggregated database is also continually updated to ensure that the most current research is available to those interested in medical informatics.

As medical technologies and the methods for evaluating medical data continue to evolve and new ways to store, process and access information are discovered, medical informatics will become an increasingly critical field of study. The nature of personal heath records, diagnosis, and even treatment have changed drastically due to the efforts of researchers, practitioners, and patients to make medical information more easily available, more secure, and of a higher quality than ever before. Innovations in the effective storage, retrieval, and understanding of medical information capitalize on the constant technological changes that seek to streamline and improve modern society.

The diverse and comprehensive coverage of medical informatics in this four-volume, authoritative publication will contribute to a better understanding of all topics, research, and discoveries in this developing, significant field of study. Furthermore, the contributions included in this multi-volume collection series will be instrumental in the expansion of the body of knowledge in this enormous field, resulting in a greater understanding of the fundamentals while also fueling the research initiatives in emerging fields. We at Information Science Reference, along with the editor of this collection, hope that this multi-volume collection will become instrumental in the expansion of the discipline and will promote the continued growth of medical informatics.

Medical Informatics (MI): Major Concepts, Methodologies, Tools & Applications

Joseph Tan
Wayne State University, USA

INTRODUCTION

Medical informatics (MI) is an inherently complex subject. The widening scope of its knowledge may be traced to the cross-disciplinary interactions of specialized knowledge domains – in particular, those of information sciences, computer sciences, and clinical sciences.

Over the last several decades, the field and sub-fields of MI – with its focus on clinical-based data and processes, and that of the even broader health informatics (HI) area (which embraces both clinical-based and health services administrative domain datasets and processes) – have now matured with the aim of achieving notable goals by transforming both complex organizational knowledge-based services as well as data-intensive, information-laden processes. These goals include improving physician-patient communications and relationships, promoting a higher quality of life, and achieving a more efficient and effective healthcare services delivery system.

With the first record of medical information came the germination of the MI concept. Its rapid diffusion is evidenced by the support it receives from an eclectic well of traditionally established medical practices, an increasing range of applied health data methodologies, and more efficient and effective clinical research tools and applications. Dissatisfied with the insufficient ways in which early forms of medical data were largely acquired and interpreted, academics and learned practitioners from diverse clinical and informatics disciplines have spurred the development of MI through their contributions.

Today, characteristic of its expanding scope, MI has branched into administrative health informatics, bioinformatics, clinical informatics, consumer health informatics, dental informatics, health management and services informatics, health sciences informatics, telematics, nursing informatics, pharmacy informatics, public health informatics, and veterinary informatics. A variety of names for MI have also arisen, including, but not limited to, computer-based medical information systems (MIS), methods of information in medicine, medical computer science, medical information processing, medical decisional models, medical computer technology, among other, closely related medical information systems/information technology (IS/IT) terminologies.

MI Definitions & Evolving Perspectives

Every MI student should be cognizant of MI's roots and the many attempts, over the years, to differentiate among the diverse perspectives of its developing sub-fields. Accordingly, a survey on early efforts to define the MI field and sub-fields can be extracted from the extant literature including archived, existing, and more recent MI-related journals such as *Angewandte Informatik*, *BMC Medical Informatics & Decision Making*, *Computer Programs in Biomedicine*, *Computers and Biomedical Research, International Journal of Bio-Medical Computing, International Journal of Electronic Healthcare, International Journal of Healthcare Information Systems & Informatics, International Journal of Medical Informatics*, *Canadian Medical Informatics, Journal of the American Medical Informatics Association, Journal of the American Society for Information Science, Journal of Clinical Computing, Journal of Healthcare Information Management, Journal of Medical Systems, Medical & Biological Engineering & Computing, Medical Decision Making, and Methods of Information in Medicine*. Owing to space limitation, the readers are asked to seek out further readings, as provided in the citations and other parts of this 4-volume work.

Primarily among countries influenced by Western Culture and Civilization, the conceptualization of MI began with a series of academic debates and educational efforts. These debates and efforts sought to provide substantive arguments for the preference of one school of thought over another, so that clinical students might be better educated, and to allow for the many aspects and identities of this germinating field to be differentiated. Indeed, the key definitions of MI found over the decades have provided us with a rich understanding of its different roots and perspectives. Among the earliest definitions, for instance, Collen (1977) conceived MI broadly as the computerization of medicine, including medical services, education, and research. Years later, van Bemmel (1984) defined MI on the basis of the knowledge and experience gained from processing and communicating medical and health care information via a paired theoretical-practical lens on the medical process. The Blois-Shortliffe (1990) description of MI largely evolved the *central hypothesis*, which is presented separately in this overview. Their biomedical perspective rendered MI operational by relating it to the storage, retrieval, and optimal use of clinical data, information, and knowledge for diagnostic, therapeutic, and prognostic problem solving. Stead, in 1998, referred to MI as a "science" on the nature, structure, collection, and use of health information. Most recently, Hersh (2002) defined the MI field as an integrative discipline that interweaves the applications of computational, cognitive, informational, organizational, and other sciences on the processes and use of clinical and biomedical information.

Put together, a cohesive definition of MI for the purpose of this work may be conceived as a *complex science that integrates relevant theories, design methodologies, and knowledge of best practices drawn from various cognitive, computational, informational, organizational, and other expert knowledge domains when applied synergistically to collecting, storing, organizing, manipulating, using, and disseminating clinical-based and health-related information.* Over the last two decades, we have seen the evolution of MI to a broadening diversification of sub-fields and major themes. Some of these sub-disciplines include, for example, health management information systems (HMIS) and/or health information management (HIM), health care information systems (HCIS) and/or health care information technology (HCIT), health decision support systems (HDSS) and/or clinical decision support systems (CDSS), telehealth and/or telemedicine, consumer health informatics, e-health, patient-centered e-health (PCEH), and m-health.

For the convenience of the readers, Table 1 provides a list of the acronyms mentioned in this review with its associated terminology listed for easy reference.

Table 1. Acronyms for MI Readers (©J. Tan, 2008. Used with permission)

Acronym	Associated Term
AHIMA	The American Health Information Management Association
AI	Artificial Intelligence
ATA	American Telemedicine Association
CCHIT	Certification Commission for Healthcare Information Technology
CDSS	Clinical Decision Support Systems
Cio/cto	Chief Information Officer/Chief Technology Officer
COSTAR	Computer Stored Ambulatory Record System
CPR	Computerized Patient Records
CSFs	Critical Success Factors
CTA	Cognitive Task Analysis
DEA	Data Envelopment Analysis
EBM	Evidence-Based Medicine
E-DSS	Expert Diagnostic Support System
EHRs	Electronic Health Records
EKG or ECG	Electrocardiography
ES	Expert Systems
GIS	Geographical Information Systems
GST	General Systems Theory
HCIS/HCIT	Health Care Information Systems/Health Care Information Technology
HCTM	Health Care Technology Management
HDSS	Health Decision Support Systems
HELP	Health Evaluation (through) Logical Processing
HHS	Health and Human Services
HI	Health Informatics
HIM	Health Information Management
HIMSS	Health Information Management & Systems Society
HIPAA	Health Insurance Portability and Accountability Act
HIS	Hospital Information Systems
HMIS	Health Management Information Systems
HMOs	Health Maintenance Organizations
ICT	Information & Communications Technology
IS/IT	Information Systems/Information Technology
JCAHO	Joint Commission on Accreditation of Healthcare Organizations
M-Health	Mobile Health
MI	Medical Informatics
MIS	Medical Information Systems
MS	Multiple Sclerosis
MUMPS	Massachusetts General Hospital Utility Multi-Programming System
NNs	Neural Networks

Table 1. continued

Acronym	Associated Term
ONCHIT	The Office of the National Coordinator for Health Information Technology
OOAD	Object-Oriented Analysis and Design
OSS	Open Source Software
PCEH	Patient-Centered E-Health
POMR/PROMIS	Problem-Oriented Medical Record/ Problem-Oriented Medical Information Systems
RMRS	Regenstrief Medical Record System
SA/SD	Systems Analysis/Systems Design
SDLC	Systems Development Life Cycle
SNOMED	Systematized Nomenclature of Medicine
SSM	Soft System Methodology
TMR	The Medical Record
TPR	True-Positive Rate
TNR	True-Negative Rate
u-health	Ubiquitous Healthcare
v-health	Virtual Healthcare
VR	Virtual Reality
VPR	Virtual Patient Records

MI History

Notwithstanding, "informatics" as a revolution in scientific methodologies may be traced to the 1946 invention of ENIAC, the first truly "electronic" computer used for high-speed mathematical tabulations during WWII. What followed evolved into the era of mainframes, where only the very large and well-funded hospitals of developed countries such as the United Kingdom, France, Sweden, Italy, Japan, Germany, Canada, and the US could afford to house/use these first-generation, large-scale computers that tended to fill entire floors. Processing computerized health data on a massive scale dictated that the dawn of MI thinking be characterized by the use of apparently sophisticated mechanisms, which could only be manned by highly-paid scientists and skilled professionals. During those early years, a key challenge was that of developing reliable and dependable health information and recording systems for hospitals supporting patient care and laboratory services. Eventually, specialized computer languages such as Medlars, Medline, SNOMED (Systematized Nomenclature of Medicine), and MUMPS (Massachusetts General Hospital Utility Multi-Programming System) were developed. These eventually led to the successful design and implementation of major computerized health record systems and databases, such as COSTAR (Computer Stored Ambulatory Record System), RMRS (the Regenstrief Medical Record System), TMR (The Medical Record), HELP (Health Evaluation through Logical Processing) system, and POMR/PROMIS (the Problem-Oriented Medical Record/Information Systems). Historical developments of these various systems play a paramount role in both the broader MI and the more specific hospital information systems (HIS) movements.

Indeed, functional hospital information systems soon became a reality when a growing group of hospitals across the US (including Akron Children's, Baptist, Charlotte Memorial, Desconess, El Camino, Henry Ford, Latter Day Saints, Mary's Help, Monmouth Medical Center, St. Francis, Washington Veteran's Administration, and others) as well as Europe (including Sweden's Danderyd Hospital and Karolinska Hospital, England's London Hospital and Kings Hospital, and Germany's Hanover Hospital) collaborated to advance the development of a prototype for efficient and effective management of health records. Despite the risk of major failures, these "pioneering" hospitals invested large sums of money, time, and effort to accomplish the mission of hospital computerization. With the surging interest expressed by these hospitals, and the potential market opportunities that arose from this movement, large computer vendors such as Burroughs, Control Data, Honeywell, IBM, and NCR began providing generous support for this development. Lockheed Information Systems Division, McDonnell-Douglas, General Electric, Technicon Corporation, and several other companies experienced in applying computers to the management of complex systems also joined in the effort. Ultimately, the Technicon system, which was initiated by Lockheed for the El Camino Hospital in Mountain View, California, and later bought over and improved by the Technicon Corporation under the leadership of Edwin Whitehead, became the "successful" prototype that laid the foundation for the majority of functional hospital information systems we know today – systems that gradually diffused throughout North America and Europe. The major lesson in the El Camino project was the significance of paying attention to users' information needs and of effecting a change in users' attitudes, especially if there is major resistance from key stakeholder user groups, such as physicians and nurses.

As evidence of continuing gains in productivity and efficiency were traced back to computerization, the early and mid-70's saw a growing diffusion of large-scale data-processing applications in medicine and health record systems among major teaching hospitals. As noted, COSTAR, RMRS, TMR, and POMR were among these early and successful prototypes. COSTAR, a patient record system developed at the Massachusetts General Hospital by Octo Barnett, was later extended to record patient data on different types of ailments, such as multiple sclerosis (MS-COSTAR). RMRS is a summary-type patient record system implemented in 1972, and TMR is an evolving medical record system developed in the mid 1970s at the Duke University Medical Center. POMR, developed by Lawrence Weed in the 1970s, is an important health record methodology offering a logical and group-based approach to medical problem solving. All participating members of the patient's healthcare team can easily follow through on the prescribed treatment protocol by linking the problem list (serving as the record's table of contents) in POMR to its database (comprising the history, physical examination, and initial laboratory findings), the initial plan (including tests, procedures, and other treatments), and the documented progress notes.

When minicomputers and microcomputers were introduced into medicine during the late 1970s and early 1980s, physicians and clinical practitioners quickly realized the speed and astounding harnessing power with which computers could process large and massive volumes of medical and other health-related data. This would improve not only clinical decisional efficiencies, but also its effectiveness. During this time, increasing interest in the application of artificial intelligence (AI) to medicine and health decision support systems (HDSS) soon created an explosive growth in the MI field. At the same time, major progress in MI was achieved by various attempts among clinicians to use medical computation for dentistry, radiology, pharmacy, nursing, as well as the incorporation of rule-based and frame-based algorithms into expert systems for the purpose of training resident physicians or less-than-expert clinicians. Notably, MYCIN and INTERNIST-1 are among the most popularly cited and well-documented clinical expert systems (Shortliffe et al. 2001). Altogether, the MI movement contributed heavily to the use of these automated record systems, as well as their applications of expert systems for training physician specialists and guiding decisions of less-than-experts. Eventually, it was only a matter of time before a considerable need for the diffusion of MI concepts into all the different sub-specialty medical areas would arise.

In summary, the MI discipline has continued to expand, with immense diversification and integration of concepts found in the medical sub-fields linking healthcare information management, medicine, computer technology, and information science. In the early years, established areas of MI concerned general medical informatics, clinical medicine decision making, biomedical computing, computing in biomedical engineering, nursing informatics, pharmacy informatics, dentistry informatics, hospital information systems, and education. Today, the extension of the MI concept is recognized by every discipline under the umbrella of health sciences that relates to linking rapidly advancing technologies to health and patient care services delivery.

At this point, it is important for the readers to glance briefly through the remaining sections of this overview chapter. Section II focuses on basic MI concepts, theories, and its central hypothesis. Section III highlights MI development and design methodologies. Section IV concentrates on MI tools and applications. Section V surveys MI major themes, utilization and applications, while Section VI shifts focus to MI organizational and social impacts. Section VII reviews key implementation issues and managerial impact of MI. Section VIII discusses critical issues, and Section IX highlights MI emerging trends. Section X concludes the entire exposition with a concentration on how the different underlying issues, themes, and emerging trends may be joined together to achieve effective medical informatics services, education, and research in the coming years.

BASIC CONCEPTS, THEORIES & CENTRAL HYPOTHESIS

Informatics basically refers to advances in the information sciences, a discipline which has accumulated an impressive array of methods for data, information, and knowledge processing. Informatics, when applied to medicine, combines human and computer elements to generate timely and relevant patient data, organized medical information, and accumulated knowledge, which, together, aids clinicians in retrieving, storing, analyzing, disseminating, and sharing diagnostic, therapeutic and prognostic decisions, treatment planning, and evaluation processes. Other commonly encountered MI terms include health informatics, clinical informatics, health information systems, health information technology, health information management, medical information science, as well as medical (health) informatics and telematics.

Health Data, Clinical Information & Medical Knowledge

In MI conceptualization, health data are subtly differentiated from clinical information and medical knowledge. Whereas the former emphasizes some form of source-gathered raw fact, such as recording a patient's medical history before generating any meaningful information processing, the latter terms entail converting data into organized clinical information-knowledge. Hence, the significance lies in the application of readily available methods or tools to produce accessible, appropriate, accurate, and aggregated information-knowledge from sourced data. At the level of converting information into knowledge, the same rules apply. With more complex methods or cognitive-based techniques, "wisdom," "rules of thumb," "probabilities," and other "likely associations" – all of which aid pattern recognition and future health-related decision situations, under increasingly complex or uncertain situations – are produced from seemingly unrelated information. Medical knowledge, in this sense, refers to the cumulative experience of applying useful clinical information management techniques to yield timely and significant decisions.

In essence, health data are specific facts and parameters. A good piece of datum is characterized by its accuracy, completeness, relevance, reliability, security, and timeliness. Accuracy is achieved when health data recorded are true, precise, and valid about the status of a patient's condition; for example, a temperature of 102°F recorded as 101°F is approximate but, nevertheless, inaccurate. Completeness dictates that all required health data should (and must) be recorded; for example, a unique identifier must exist in the patient master index (PMI) for each patient recorded in a database in order to differentiate among individual patients. Relevance ensures that appropriate and necessary data is made available to authorized clinical staff whenever and wherever necessary; for example, cardiologists should be able to view their patients' electrocardiography (EKG or ECG) reports in order to monitor the progress of their patients' heart conditions. Reliability requires that health data recorded are trustworthy and consistent; for example, if the allergy list of a patient exists in a hospital food services system, the same list should also be accessible from, and appear in, its pharmacy system. To ensure that patient data confidentiality is not compromised, and to safeguard against potential data misuse, security and privacy regulations stipulate that only designated persons with valid access rights can view or make authorized changes to recorded data. Last, but not least, timeliness ensures that the available health data are current and accessible for the decisions and tasks at hand, especially when they are of a crucial nature, such as in life and death situations.

Clinical data are unique and somewhat different from the financial and accounting data that are captured in routine business transactions. Clinical data are typically obtained in many different forms, so that the episodes and/or trajectory of care a patient encounters may be generated on a longitudinal basis. Even so, data about a patient may be entered by different clinicians, in different departments, and at different times to show the progress of the patient's wellness recovery: for example, a nurse may jot down the demographics, weight, temperature, and blood pressure measurements of a patient arriving at the clinic; then, through lengthy progress notes, the physician and/or other specialists would record their observations about and diagnosis of the patient's symptoms and complaints. While some of these data are textual in nature, quantitative analysis, in many instances, can also be made by comparing certain measurements taken of the patient to those from a relevant cohort of patients. Moreover, the physician and/or specialists may send the patient for further laboratory tests and other diagnostic scans, which will offer additional measures or markers. Subsequently, these data can be fitted with various biostatistical and/or complex computational models, tabulated and/or presented graphically to check for familiar patterns, and further digitized for convenient sharing among other clinical experts for the purpose of second opinions or referral interpretations. Indeed, it is the accumulated knowledge, embedded in the different biostatistical and mathematical models, that these expert medical consultants rely upon for accurate pattern matching when performing further diagnostic, therapeutic, and prognostic decisions about the patient. Thus, all the while, from admitting to discharging a patient, this cycle of data-information-knowledge processing is repeated continuously to enhance the art and science of MI.

In practice, every clinician is also a health informatician. MI starts with the collection of meaningful, accurate, relevant, complete, and usable datasets. While health databases must be properly organized and rendered accessible and available to health informaticians in a timely fashion, it is also critical to consider and understand, prior to the data gathering process, the requirements that these databases pose. Otherwise, managing and maintaining inappropriate or unnecessary data, especially in large medical databases, may wastefully drain away valuable and critical organizational resources.

Users of medical and health-related data range from patients to care providers, government agencies, health care planners, judicial agents, educators, researchers, and third-party payers. Different types of users may also require different scopes, formats, and presentations of data. To achieve best practices in MI, a full comprehension of the central hypothesis underlying the MI philosophy is critical. However, before discussing this core informatics ideology, we will first survey some of the key MI theories.

For years, MI researchers and academics from across the globe have attempted to etch an identity for the MI field. Yet, the evolution of its many definitions and perspectives, the explosive growth of the field and the continuing diversification of its sub-fields made it a very difficult task to cumulate a tradition for MI theories, methods and practices. Nonetheless, it may still be argued that MI conceptual foundations are rooted in several generally cited theories: the general systems theory, decision analytic theory, various human information processing, problem-solving and cognitive theories, as well as relevant social and organizational theories such as the theory of innovation diffusion, theory on management change, theory of interpersonal behavior and technology acceptance model. Due to space limitation, we will only cover a few of the more popularly cited theories.

GST

General Systems Theory (GST), or "Cybernetics," is a cornerstone of MI development. GST has played a key role in many other contemporary sciences during the emerging information era (Bertalanffy, 1968). The theory begins with the empirical observation that every "system," regardless of its disciplinary domain, shares some common characteristics in its underlying structure such as system synergy and system triad, and exhibits some similar behavioral patterns such as statistical constancy, growth, decay and/or other known (unknown) patterns.

All systems have objects and attributes. Objects constitute the components of a system, whereas attributes are the properties associated with these objects; essentially, an attribute is an abstract descriptor that characterizes and defines the component parts of the system. A person is an object and the attributes may be the person's demographics. A system combines all the objects and their attributes and defines the relationships among these objects, thereby enabling the different parts to add up to some greater whole than all of its individual parts. For example, the emergent property of a university system is more than just its faculty, students, classes and degree programs because of the many interfaces it coordinates among the objects related to the university, the community it serves, and the various donors and funding agencies that support the university's existence.

More generally, a system is a set of interrelated elements. An open system is one that interacts with its environment whereas a closed system does not. The structure of a system may involve a hierarchy of embedded subsystems, each having its own unified purpose that contributes jointly to the functioning of the larger system. The functioning of these subsystems can also vary in complexity. The simplest process involves a triad: an input, a process and an output. More complicated functioning may involve a series of conversion processes, positive and negative feedback mechanisms, and the channels through which the environment can exert its influence. Viewing the health service delivery industry from an open systems perspective will therefore provide valuable insights into the functioning and structure of the contextual system for MI technologies and applications. As such, understanding the application of GST on health services delivery systems can better define the role and function of the MI applications.

In designing an expert system for diagnosing problems of lower back pain (see Lin Lin et al. in Tan, 2005), for example, objects of the system may include the patients, the therapists attending to the patients, and the expert diagnostic system itself. The attributes describing the object "patient" may include the patient's demographics, a brief description of the pain patterns experienced by the patient, the cause of the injuries leading to the pain, the level of pain and an estimated length of time the pain has persisted. Moreover, the treatment plan for the pain to be administered daily may vary depending if the patient is highly motivated to get well, the potential for the patient to move and be tolerant of the pain, the patient-therapist relationship, whether or not there is a job action among the therapists at the time of the treatment administration, or if there has been a sudden snow-storm, making it difficult to transport the patient to the treatment facility. In general, it is expected that those therapists using the expert diagnostic support system will have gained a better judgment over time to guide the patient treatment protocol to reach some level of statistical stability or equilibrium than those not aided by the system, if the expert system is to be considered functioning efficiently and effectively.

A major body of MI knowledge and research is therefore the application of GST in the context of patient treatment planning and the development and use of computerized decision aids to obtain valuable insights into the behavior of complex, real-world systems. As computerized decision models are attempts to imitate systems from a particular viewpoint, and clinicians (or groups of clinicians) who run mostly through rational decision-making mechanisms are sub-systems in the larger context of MI user-computer systems, the close relationship between computerized models and clinicians cannot be overly emphasized. Such computerized aids are primarily supported by the application of decision analytic theory, which is discussed next.

Decision Analytic Theory

Decision analytic theory has also been widely applied in MI to provide logical rationalization on relatively complex judgmental tasks, for example, the application of well-tested decision rules such as Bayesian technique to ease computation and reduce uncertainties about clinical guidance on whether to proceed or not proceed with a certain form of therapy or surgical intervention for a certain patient. Its appeal in MI is, therefore, its ability to provide the clinical decision makers with a model, such as a decision analytic or computerized model, that would yield a more accurate and rational representation of the clinical case reality. In the MI context, the application of decision analytic theory on clinical decision problems has been largely defined by the use of programmable models to reduce complexities, and achieving a decision outcome that lessen its influence from that of mere human emotion and biases.

When incorporating programmable and semi-programmable models for MI applications, a taxonomy of models along a decision complexity continuum, including, but not limited to, decision analysis techniques, mathematical programming, computer simulation models, heuristic programming, and non-quantitative (qualitative data) modeling should be considered. Incidentally, these models are not intended to replace the decision makers, but to serve as aids to the clinicians in rationalizing their decision-making process and justifying their final choices. For example, if a clinician is armed with a set of data that contains information about the probability of the onset of multiple sclerosis (MS) for a particular patient, it may be important for the clinician to consult with a decision aid to guide the prognosis before jumping into conclusion based simply on short-sighted self-evaluation of the complex dataset. Hence, the term “decision support tools” is often used.

Decision analysis is popularly used to aid clinical decisions under uncertainty and risk. Two simple examples are the use of decision tables and decision trees. The computation essentially generates the expected outcome of each alternative among a given set of alternatives on the basis of available (unavailable) information about the environment and converts the information on uncertainty into risk estimates by means of Bayesian technique, Markov chains or other more esoteric mathematical or probabilistic models.

In situations where there can be many more alternatives and it is not possible to generate a manageable set of alternatives, mathematical programming takes the approach that reality can be simplified and represented as a set of mathematical equations or relationships. These relationships represent the constraints and limitations on the number of inputs as well as the relationships between inputs and the outcome variables. The commonly employed linear programming technique used in providing optimal solutions to many well-structured, mostly single goal (criteria) problems is a simple illustration of mathematical programming. Other more sophisticated mathematical programming techniques used to solve complex, semi-structured, multi-criteria problems include non-linear programming, dynamic programming, 0-1 programming, and data envelopment analysis (DEA).

If the complexity of the problem situation increases to the extent that the relationships among the variables cannot be conveniently simplified into a series of mathematical relationships, then computer simulations, certainty factors and stochastic modeling may be used. In "survival analysis" where prognostication is to be predicted by a clinician, for instance, methods such as life tables, Kaplan-Meier analysis, and Cox regression may be used. In a computer simulation, either the real distribution of variables can be used, or a probabilistic distribution may be applied to model the variable distribution to be simulated. In this respect, using simulation to model reality can allow the relationships between variables to be kept either very simple or closer to reality. Moreover, data that have been collected in the past may be used to test and validate the simulation model. When the validity of the simulated model can be demonstrated, further experiments can be constructed to compare various alternatives. These experiments have the advantage that time can be compressed significantly, allowing several months or years to be modeled quickly within a single simulation run that may last only a few minutes. In contrast to mathematical programming, however, only good enough ("satisficing") solutions rather than optimizing solutions can be expected from the use of computer simulation models.

In highly complex situations where the problems are considered somewhat ill-structured and even simulation cannot be applied, heuristics or rules-of-thumbs such as rule-based systems, frame-based systems as well as neural networks (NNs) methodology are often employed by decision makers to aid problem solving. These heuristics may be incorporated into a computer model of the situation; thus, the term, heuristic programming. An example of heuristic programming is the use of expert methods such as neural computing (networks). NNs are experimental computer designs that purport to build intelligent algorithms. NNs operate in a manner modeled after our human brains, in particular our cognitive ability to recognize patterns. Another class of heuristic models is that of genetic algorithms. Genetic algorithms randomly generate initial solutions to specific procedures, which can then be further recombined and mutated at random just as in an evolutionary process to produce offspring solutions that may yield better offspring and parent solutions or new algorithms. For example, a set of generic operators can be used to generate specific procedures for developing routing and scheduling heuristics for solving an ambulance dispatching problem. These generic operators can then be stored for generating new algorithms. In this way, new customers can be added, routes can be merged, and the sequence of customers can be modified using different sets of generic operators. A form of visual interactive modeling can then be used to allow the user to see the results and intervene to change the procedure if the results are not as experienced. Other examples of heuristic programming include the use of fuzzy logic, case-based reasoning and rough-set methods since these techniques often incorporate experts' heuristics in generating problem solutions.

At the farthest end of the decision complexity spectrum lie the non-quantitative (qualitative analysis) models. The field of non-quantitative analysis is very young and there is a need for considerable research to examine the applications of different approaches and use of computerized models for such analysis. The rationale for clinicians to employ MI thinking such as using an ES, AI or even human-controlled robots instead of relying on knowledge and/or experience gained through the traditional case-by-case bedside training is to achieve a high level, combined human-automated intelligent symbiosis in the art of using and interpreting medical evidence.

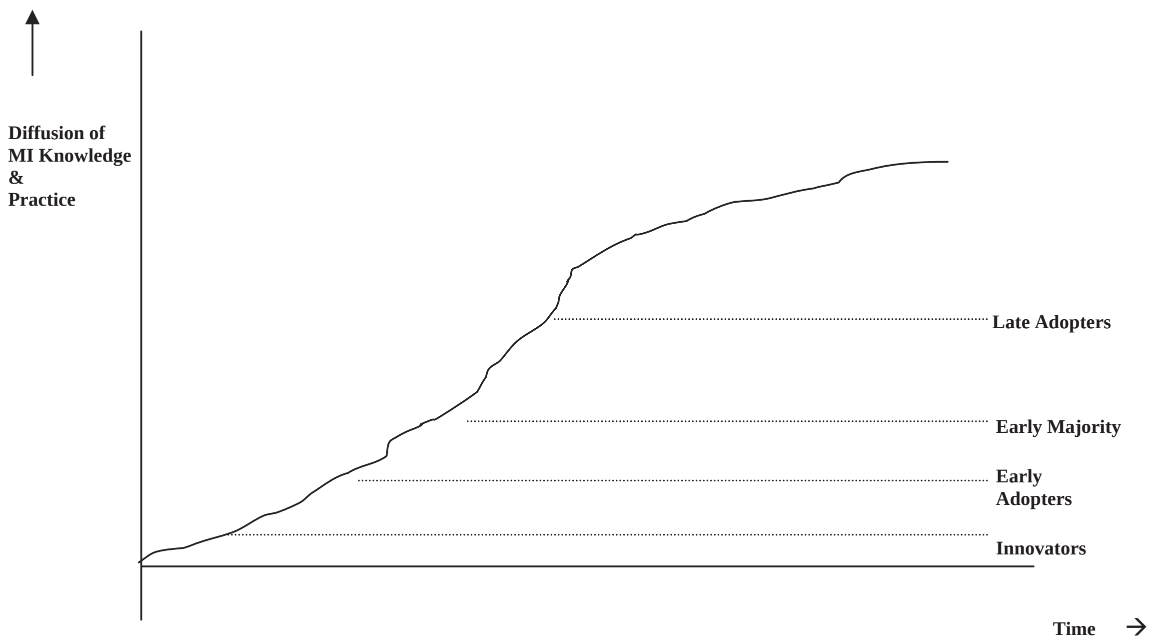
Social & Organizational Theories

As with any emergent discipline, the need for innovation, continuing growth and development encourages MI researchers and practitioners to draw selectively from theories proposed and tested in many related but previously established disciplines. Specific to MI diffusion strategies, the social and organizational theories have provided insightful guidance for MI research and practice.

In the context of the innovation diffusion theory, for example, the rate and patterns of MI growth as a discipline, in and of itself, are expected to follow the well-known S curve of innovation diffusion (Rogers, 1983). The innovation diffusion growth pattern typifies the stages of adoption of knowledge and practice in a new field. For instance, the researchers who adopt a new form of analytic method on the basis of their own recognition and awareness of the desirability of this method as applied to similar problems identified in another more establish field will adopt it before others in the MI research and practice community. The first adopters of the new model are known as the innovators. Others who follow will then become early adopters. They will not have access to all of the information that the innovators have about the new model so that they often tend to regard the innovators as experts and will readily adopt the practices advocated by these experts. An additional link to this chain is classified as the early majority, who are then followed by late adopters.

Figure 1 shows the diffusion pattern of MI knowledge and practice over the last few decades. As shown, we are entering an era between the so-called early majority and the late adopters for the diffusion of MI knowledge and practice. This implies that the continuing growth and diffusion of MI knowledge and practice in the coming years is expected to still be relatively high as more and more scholars from various clinical sub-specialties enter the MI discipline. In other words, it appears timely for us to begin consolidating our past knowledge and experience in the MI field and to identify key gaps for future MI research and practice. The release of this particular work is a testament to the rapid growth and expansion of MI field in recent years.

Figure 1. The diffusion of medical informatics (MI) knowledge and practice (© 2008 J. Tan. Used with permission.)



l

As well, the diffusion theory further implies that successful MI implementation can be achieved through critical support provided by a champion who could act as the innovator or expert, followed by grass-root user groups such as nurses and physician residents (who are willing to become early adopters) to break down the resistance that may be inherent to medical technological innovation and the additional need for attitudinal and behavioral change towards such an innovation. As a critical mass of user support gathers strength, success is eventually achieved due to the proliferation of early majority and late adopters.

More specifically, there have been recurring themes and increasing interests among both the academic and practitioner communities on the potential impact of effective technology management strategies among healthcare organizations and modeling the technology acceptance process. In their contribution on Health Care Technology Management (HCTM), Eisler, Tan and Sheps (in Tan, 2008) took the perspective of technology as the *extension of human and organizational ability*. Based on the results of their study, they found that the major critical dimensions for successful HCTM include the following: (a) Strategic Management factors; (b) Management of Change and Innovation factors; and (c) Organizational Management factors. Among these factors, the functions of a chief technology officer (CTO) were found to be have the largest differences in reported perception based on implementation ratings and gap scores between high performing and low performing teaching hospitals. This result strongly confirmed the message from the literature about the necessity of executive attention and leadership for HCTM. Besides leadership, coordination, and facilitation, the responsibilities of the CTO include such activities as gatekeeping, advocacy, funding, sponsorship, policy and procedure development, promotion, capacity building, and overseeing the technology management system.

Another set of organizational factors that were shown to be critical for successful HCTM include identifying customer needs and priorities; the organizations having effective strategies to respond flexibly and readily to technological change; and the routine evaluation and benchmarking of organization's performance as a function of technology management activities. In summary, organizational theories indicate that there are key differences in HCTM sophistication among healthcare institutions. Major differences occur in areas of strategic technology management, followed by change management, and to a lesser extent, organizational management.

At this point, we would like to steer the readers to a key conceptualization on MI that brought about the informatics revolution in medicine. We called this, the MI "central hypothesis."

The Central Hypothesis

The informatics revolution in medicine during the 1960s and the 70s brought about a surging interest in MI, especially among biostatisticians, public health advocates and epidemiologists, occupational health and environmental scientists, radiologists, general physicians, dentists, pharmacists, nurses and other health professionals. Essentially, many of these clinicians were questioning the use of medical information/knowledge derived merely from the traditional bedside training paradigm. This eventually led to a movement in support of more intelligent applications of effective computerized decision aids that incorporated complex statistical techniques and probabilistic models for improved medical information analysis. In the 1980s, evidence-based medicine emerged to further guide medical decisions and substantially changed the traditional approach to medical reasoning.

Moreover, one should familiarize oneself with a number of commonly used terms in generating diagnostic, therapeutic and prognostic decisions in MI. For instance, public health informaticians describe the impact of diseases on a specific population using terms such as incidence and prevalence rates. "Incidence rates" refers to new occurrences in terms of the number of people newly infected with the disease, usually over a year whereas "prevalence rates" refers to the proportion of people having already been infected with the disease at a particular point in time relative to the size of the population who have already been exposed to the disease.

When testing a particular patient for a specific disease, the sensitivity-specificity dimension of the test is another pair of closely related terms used in MI. A test is said to be as sensitive as it is able to identify those people who truly have the disease (*true positive rate*) among those who have tested positively while a test is said to be as specific as it is able to rule out those people who truly do not have the disease (*true negative rate*) among those who have tested negatively.

Related key concepts used in determining the health status of a patient in diagnosing for the presence of a disease is the positive vs. negative predictive values as derived from the sensitivity-specificity dimension of the test. On the one hand, positive predictive value uses the underlying concepts of incidence-prevalence rates and sensitivity of the test to help a clinician predicts with some assurance the likelihood of the patient having been infected by a disease. On the other hand, negative predictive value uses the same concepts of incidence-prevalence rates and specificity of the test to help a clinician estimates more confidently the increased likelihood of the patient not having been infected by the disease being tested.

When determining the health status of a person with respect to a certain disease, clinicians must therefore recognize that each medical diagnosis is, after all, only an estimation process. What is important is to determine if more tests are truly needed to increase the likelihood estimates and if particular treatments are to be planned and evaluated. In most instances, the patient is subjected to a range of medical tests with the intent that the clinician will arrive at an increasingly comfortable measure of likelihood that the patient will indeed have (or not have) the disease. This, in turn, ensures that the appropriate planning is adopted based on the best treatment protocols available and that the patient will actually benefit from the treatment regiment, considering the fact that the patient indeed do have the disease. In medicine, both false negatives and false positives are costly, not only to the clinicians but even more so to the patients. This is where MI plays a key role and can have a significant impact.

The central hypothesis of the MI philosophy, thus, is that the entire cycle of medical information gathering, storage, analysis, comparison and estimation from one medical test to another can be better managed through the intelligent application of an "informatics" ideology. If this goal is achieved on an ongoing basis, both the clinician and the patient can ultimately contribute to a higher quality of life and an improved wellness to the society. A deep appreciation of this central hypothesis is critical for those yearning to be next generation medical/health informaticians.

MI DEVELOPMENT & DESIGN METHODOLOGIES

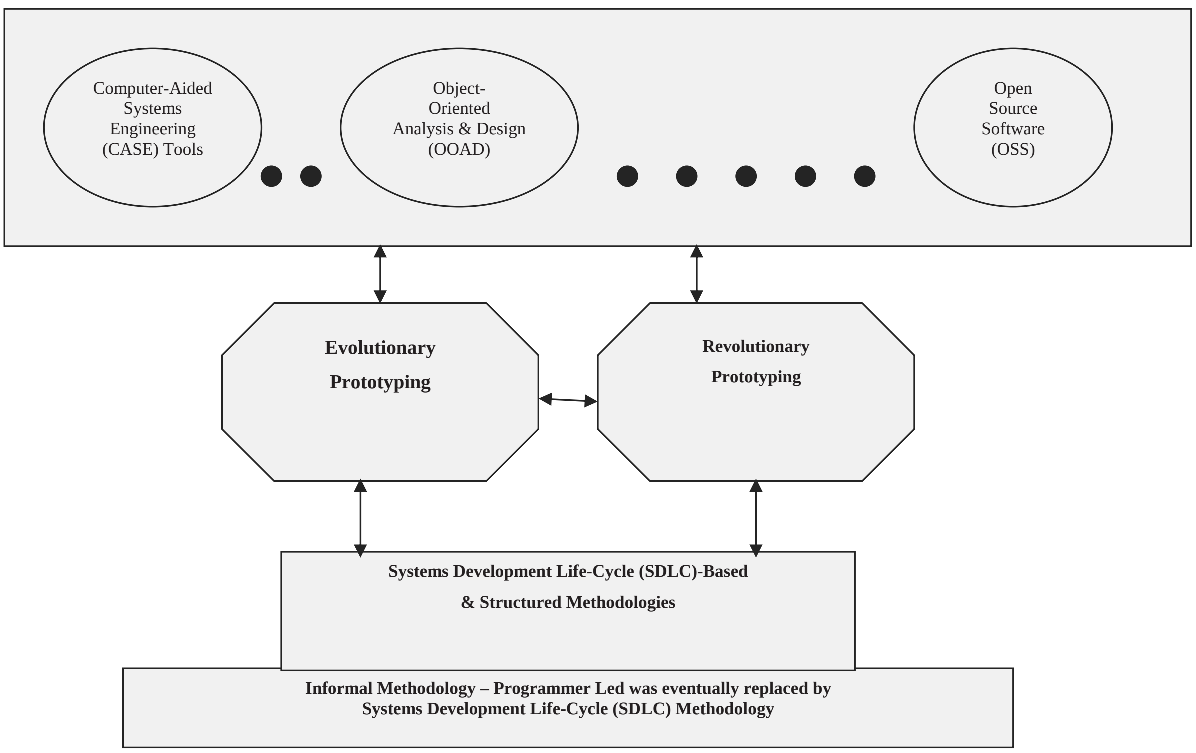
As we have noted previously, a high failure rate of MI deployment has been attributed largely to the lack of attention on the applications of social and organizational theories, in particular, as these theories relate to MI development and design context. It has been estimated that medical systems have an almost fifty percent higher chance of failure than most other information systems deployment due to the specific nature of resistance faced in health care – for example, both physicians and nurses have their own professional cultures and belief systems that may not be aligned with those of managers, systems analysts and informaticians. Hence, new methods for system design and evaluation in this area are badly needed.

Essentially, MI development and design methodologies should bring together the different pieces of the MI puzzle – data, people, hardware and software, network and other resources – towards achieving a vision of an effectively deployed MI systems. Indeed, the challenges of working with physicians who not only have their own professional culture, but may also be considered as much customers as employees of the health care institution in which they practiced is a critical issue for MI technology diffusion. To realize the vision of an accepted MI system throughout the health care institution, the informatics analyst must therefore be able to create a shared vision among key stakeholders with unwavering support from top management. Acceptance of the MI system from key users through active participation in the MI design and development process will be paramount, especially for physician and nurse users.

Once the specification of the system has been fully vetted by the relevant stakeholders, the next step will then be executing a set of related but critical activities including systems analysis, design and evaluation. Systems analysis relates to activities involving the review of current information architecture and the organization needs from the users' perspectives. In contrast, systems design relates to activities involving the specification of new information architecture and systems requirements. Finally, systems evaluation relates to activities involving the continuing testing and endorsing the designed MI system – that the designed MI system is exactly what is needed and will be used once implemented.

The early period of MI development and design has been characterized by the absence of any formalized system development methods. Typically, it was the programmer who bore the major responsibility. Over the years, as user needs became more complex, the need for a formal development process became evident; subsequently, various design methodologies were championed to help minimize the problems of uncoordinated MI development. Each methodology has been based on a philosophical view, which can range from an exclusive focus on the technical aspects to a focus on the user side. Most prominent among the MI development methodologies include the traditional systems development life cycle (SDLC) approach, the structured techniques, prototyping and more contemporary models as shown in Figure 2.

Figure 2. The evolution of medical informatics (MI) design & development methodologies (© 2008 J. Tan. Used with permission)



The SDLC approach involves following a rigid set of procedures beginning with feasibility study. This is followed by systems investigation, analysis, design, and evaluation. The final step entails systems maintenance and review and the entire life cycle is then repeated. While this approach was a significant improvement over the informal leaving-it-to-the-programmer attitude, it nevertheless failed to marshal strong support and acceptance of MI systems among key stakeholders often because of the lack of active user involvement throughout the analysis, design and evaluation phases of the process.

Structured techniques provided an entirely new perspective to systems development with a greater concentration on systems analysis (SA) and systems design (SD) phases – phases where input from end-users are most critical to the eventual success of the implemented system. Use of diagramming techniques, for example, data flow diagrams to depict the data flows between one process and another helps to bring in the views of the users. Other methodology, for example, Structured Systems Analysis and Design Methodology, extends the soft system methodology (SSM) and emphasizes the analysis and design stages of the SDLC model to better capture the views of the end-users.

Nonetheless, both SDLC-based and structured techniques required that users are able to specify in advance the information requirements in the MI system. However, users are often unable to verbalize what they want, and even if they do, their wants may not exactly reflect their real needs. This is evidenced by the many revisions most newly developed MI systems must undergo before these are finally accepted. One philosophical approach that addresses this problem creatively is rapid vs. evolutionary prototyping.

In evolutionary prototyping, the proven "SDLC" and structured methodologies are essentially incorporated into prototyping merely to fine-tune the MI development process, to engage greater user participation, and to enhance user acceptance of the final product. In rapid (revolutionary) prototyping, the designer often uses a creative trial-and-error process to generate an initial prototype quickly. In this instance, fourth generation languages are often applied to produce these rapid initial prototypes. The users as well as programmers are then encouraged to test out, validate and fine-tune these prototypes. Such iterations are then repeated until a final acceptable MI product is achieved.

Today, the evolution of MI design methodologies has moved from the rigid procedural SDLC-based and structured approaches to rapid prototyping to more contemporary models. Prime examples include Computer-Aided Systems (Software) Engineering (CASE) tools, Object-Oriented Analysis and Design (OOAD) and Open Source Software (OSS). CASE tools automate different parts of software or systems development and can assist with any or all aspects of the SA and SD processes. OOAD focuses on the objects that are acted upon in the development process. The methodology is based on the premise that software should be developed out of standard, reusable components wherever possible. Finally, OSS supports the ideology of making certain licensing of the source code for particular working prototypes freely accessible and generally available for other intending users' adoption and modification within the programming community.

As the number of OSS products in the MI field such as VistA system (a computerized patient records system developed in MUMPS by the US Department of Veteran's Affairs), OpenEMed (another patient record system), and OSCAR (a family practice office management and medical record system) becomes popularized over time, the OSS model of software development have continued to spread in the MI community. Indeed, recent studies (e.g, Erickson et al. 2005; DeLano, 2005; Scarsbrook, 2007) have shown that the OSS development model can be beneficial in reducing software development costs effectively and allowing for very rapid scientific advancement due to the open sharing of information and software as a way to overcome certain barriers of standardization. A case where OSS adoption is largely responsible for a number of low-cost products implemented successfully throughout the hospital is the Beaumont Hospital in Ireland (Fitzgerald & Kenny, 2004). OSS adoption has also been noted to reduce the need for frequent vendor turnover, lower development costs, and lessen the impact due to the lack of standards affecting electronic patient records in the primary care area (Kantor et al. 2003).

Altogether, the application of social and organizational theories and the adoption of a practical approach to MI design and development that integrates the different user characteristics, technological and organizational components within the larger context of technology change management, evolving user demands and new organizational arrangements will ensure the successful implementation of future increasingly complex MI systems.

MI TOOLS & APPLICATIONS

In this section, our focus on MI tools and applications will encompass the emergence of the evidence-based medicine (EBM) movement in the 1980s, which has significantly changed the way in which medical information is now used in routine healthcare decisions as discussed in Tan (2005), a taxonomy of the decision-aiding strategies or techniques as advocated by Zachary (1986), and the expert knowledge elicitation methods as discussed in Tan with Sheps (1998). Throughout these discussions, the concepts of the electronic medical records (EMR) and the electronic health records (EHR) will be used to illustrate the applicability of these tools.

Evidence-Based Medicine

Evidence-based medicine practice requires the clinician to articulate a clear statement of a patient's medical problem, to screen actively through the extent literature relating to the patient's problem, to evaluate the evidence critically, and from the resulting knowledge, to make the best treatment decisions with regard to the patient's problem.

Markovitz in Tan (2005) described EBM as a five-step process: (1) identify the "clinical question" relevant to the patient by means of asking the following question: "In a given patient population, does a particular intervention, compared to controls or standard therapy, result in an improved outcome?"; (2) use bibliographic databases such as MEDLINE which can be accessed through convenient interfaces like OVID (http://www.ovid.com) and other EBM resources on the Internet to search for problem-related evidence; (3) critically appraise the findings, validity, and applicability of the evidence; (4) incorporate the appraised evidence into the values, preferences and beliefs uphold by the patient; and (5) self-evaluate the process on a continuing basis to further enhance its efficiency and effectiveness. With a wave of advances in biostatistical and clinical research methods, EBM can be achieved typically from sourcing multiple information such as relevant clinical practice guidelines, clinical trials, systematic reviews, and meta-analysis of past studies found in high quality, peer-reviewed journals that focus on the patient's problem.

To illustrate, a trained clinician who is asked to check on the EHR or EMR of a patient (with all the annotated progress notes) should also be expected to be familiar with the terminologies of clinical epidemiology, biostatistics, clinical trial methodology and clinical research designs in order to confidently perform a critical appraisal and rating of the published literature as pertaining to the health status of the examined patient. In many instances, in order to develop acceptable and trusted treatment guidelines for best practices in MI for the patient, the trained physician may consult with a committee of scientists and expert clinicians who may have collectively rated the strength of recommendations for a particular treatment based on the evidence for efficacy or for adverse outcome supporting a recommendation vis-à-vis the quality of evidence supporting the recommendation. The National Guideline Clearinghouse (NGC: http://www.guideline.gov/), sponsored by the US Agency for Healthcare Research and Quality, offers a trusted/authoritative source for such guidelines. In addition, the trained physician may also consult with an increasing number of full-text or summary form guidelines drawn from various professional societies and/or organizations that have used a documented EBM approach have been included and made available through this unique site.

In the realms of medical research, the following is a sampling of key terms that should be clearly understood as these form the building blocks of many research designs and are the basis for a proper evaluation of the MI research literature: informed consent, the internal review board (IRB), debriefing, bench vs. clinical research, prospective vs. retrospective research, control group vs. treatment group, focus groups, blinding vs. double-blinding, randomized control trials, cohort or longitudinal studies vs. case-control studies, attrition, sampling frame, sampling size, power, effect size, statistical vs. clinical significance, qualitative vs. quantitative research, and many other terms (e.g., relative risk, relative risk reduction vs. absolute risk reduction), all of which can be easily found in a standard text on health informatics (see Jordan, 2002) or research methodology (see Kerlinger, 1973;1986). Table 2 provides a glossary of key terms in MI research.

A more detailed explanation of these terms is outside the scope of this review. At this point, we turn to the Zachary (1986) taxonomy of cognitively based decision-aiding strategies.

A Taxonomy of Decision-Aiding Techniques

Several decision-aiding tools and techniques in MI and other healthcare informatics domains have become popular among MI analysts and researchers. A taxonomy of these ranges from information control techniques to process models and/or choice models to representational aids to analysis and reasoning methods to judgment refinement and amplification. Outside of the scope of this discussion would be more complex MI tools and new methodologies such as rough-set analysis, neural networks, and fuzzy-set theory, all of which have been presented in great detail in Tan with Sheps (1998).

Information control techniques involve the storage, retrieval, and organization of data, information and knowledge. Common examples include clinical databases such as an EMR or an EHR or even a comprehensive pharmaceutical database that will permit a physician to look up on comparable prescriptions for use in treating a diagnosed illness. A model-based management system which incorporates the application of a data envelopment analysis (DEA) methodology, for example, to profile the relative efficiency and effectiveness of best practices among a group of selected physicians awaiting the renewal of certain hospital privileges or a knowledge base management system such as an expert system programmed to provide online medical consultation to a physician resident on a specific clinical intervention procedures when faced with a complex MI decision may well be added as enhancement to the basic functioning EMR, EHR or other health database management system.

Process and choice models are computational models that may be applied respectively to help predict the behavior of real-world processes such as through the use of “what-if” capabilities or to solve multi-criteria problems with such techniques as those involving the integration of individual criteria across different aspects and/or alternative choices, for example, the application of multiattribute and multialternative utility models. In other words, these models could be programmed as simply as a single Excel function with “what-if” analysis or could be enriched with a series of increasingly complex computational models. Use of these models can be enriching for physicians who need to make complex decisions beyond just abstracting information from an EMR or EHR.

Representational aids refer to expressions of manipulation of specific representations of decision problems. For example, a visual representational aid could be graphics-based where the clinician reading a set of EMR and EHR progress notes is supplemented with supporting evidence from digital radiological images and reports to help interpret the captured information on the patient wellness recovery. At the

Table 2. Glossary of Key Terms for MI Research Literature (©J. Tan, 2008. Used with permission)

Term	Definition
Attrition	The number of participating subjects dropping out of a study
Bench Research	Laboratory research performed on chemical or biological elements such as cells, genes, and other cultures rather than living human subjects
Blinding	Participants are ignorant of their group treatment assignments during a study
Case-control Studies	The use of naturally occurring vs. control groups to classify study participants
Clinical Research	Research conducted with living human participants
Clinical Significance	The applicability and importance of a study's findings in real-world situations
Cohort Studies	Group (cohort) assignments are not randomized but based on known exposure
Control Group	A group that does not receive the test stimulus but is observed for comparison
Debriefing	A process to correct subjects' wrong/unethical perceptions at end of a study
Double Blinding	Both participants and investigators are ignorant of study group assignments
Effect Size	The degree for which a study variable impacts on the study outcome(s)
Focus Groups	Recruited subjects to draw opinions/observations on various research artifacts
Informed consent	Let subjects know of the study's purpose, risks and credentials of researchers
Internal Review Board (IRB)	An institutional ethics committee to evaluate the potential benefits vis-à-vis the risks of a proposed research
Power Analysis	Method to guide study design/sampling so as to achieve a desired effect size
Prospective Research	A study where subjects' data are followed through "looking forward" in time
Qualitative Research	Research methodology that reflects an objective and positivist legacy
Quantitative Research	Research methodology that reflects a subjective, interpretative approach
Randomized Control Trials (RCT)	Relatively short (prospective) clinical experiments that use randomization as a means of group assignments and controls, requiring lengthy IRB approvals
Retrospective Research	A study where data on subjects are examined by "looking backward" in time
Sampling Frame	The population or list of objects (sampling units such as persons) in a sample
Sampling Size	The number of subjects needed in a study to attain valid scientific evidence
Statistical Significance	Level to which study sample results mimics results expected in a population
Treatment Group	Participants assigned into a group who will be given the intervention studied

community level, a geographical information system (GIS) to depict specific population health hazard distribution or an epidemic among neighboring communities of a county would be a spatial representation of the captured environmental and population health data. Other representational tools could include matrix data and model representational methods.

Analysis and reasoning methods are means of performing problem-specific reasoning on the basis of a representation of a decision problem. For instance, in abstracting information from an EMR or EHR on a patient diagnosed with multiple sclerosis, the clinician may use the symbolic reasoning embedded in an expert system to aid him or her to make a prognosis for this patient. Another example would be the application of mathematical programming techniques for clustering various cases from different cohorts of patients exhibiting similar symptoms and requiring comparable treatments.

Finally, judgment refinement and amplification techniques are formalization and quantification of heuristic judgment processes, for example, bootstrapping and Bayesian theorem application. As discussed throughout Tan with Sheps (1988), medical informaticians have typically employed these analytic tools and techniques as well as automated intelligence applications to enhance decisions rather than simply make a judgment based on EMR or EHR data. Furthermore, these applications can be useful for various clinical areas such as cancer, emergency medicine, utilization review, population health monitoring, and nursing. This brings us to knowledge elicitation methods, a key MI tool and application in building and designing expert systems.

Knowledge Elicitation Methods

Expertise in MI and other healthcare informatics domains (e.g., health information management, nursing informatics, and pharmacy informatics) can generally be grouped along a continuum ranging from laypersons to experts. On the one hand, a layperson may be considered simply as someone who has only common sense or everyday knowledge of the domain. An expert, on the other hand, is someone who has gained specialized knowledge of the domain after many years of training. In between these extremes are beginners (novices), intermediates, and sub-experts. Beginners/novices are those with pre-requisite knowledge assumed by the domain; intermediates are, by default, those whose domain knowledge are just above the beginner level but just below that of the sub-expert level while sub-experts are those with generic but not substantive, in-depth knowledge of the domain. In this section, we discuss approaches to the knowledge extraction problem encountered in designing and developing ES, intelligent DSS and other equally intelligent forms of integrated and emerging MI technologies and applications.

A wide range of techniques has evolved from studies in diverse fields and disciplines (e.g., medical cognition, cognitive psychology, artificial intelligence, organizational science, computer science and linguistic) in terms of eliciting knowledge from humans for the purpose of incorporating such expertise into specialized computer software. Among the more established techniques discussed in the literature are interviews, computer-based interactive techniques, methods involving rating and sorting tasks, protocol analysis, and cognitive task analysis (CTA). Owing to limited space, we will only highlight briefly each of these techniques and their implications for MI development and applications.

Apparently, interviews are direct means of acquiring knowledge from experts; they can be structured or unstructured. In structured interviews, the expert or non-expert may be probed, based on a structured protocol, to describe in sequence how specific cases are normally dealt with when they are performing a certain task, particularly under uncertain or complex situations. In unstructured interviews, the same expert (non-expert) may be asked similar type and related questions in no particular order, depending on answers previously provided. It is also possible for the interviewer to probe for further clarification or to lead the study subject to talk on particular aspects of the problems if the interviewer feels that previous answers provided are inadequate. The disadvantage of using interviews is that it is difficult to expect anyone to be able to articulate precisely the hidden knowledge that is to be extracted because most people will tell us what they think they would be expected to do in performing a certain task then to state what they actually do.

Reading the data abstracted from an EMR or EHR, an expert will anchor on certain important information that a novice may well miss out. Novices also tend to have difficulty differentiating what may be considered the most important pieces of information recorded and this is where eliciting knowledge from a novice vs. an expert in real-world case management helps to generate a high quality consultative expert system such as MYCIN.

Computer-based interactive approaches to knowledge extraction involve having the study subjects use interactive tools or computer programs known as knowledge-based editors to assist them in directly generating computer-assisted knowledge acquisition. OPAL is an example of a graphical knowledge acquisition system for a cancer therapy management program whereas INTERMED is a collaborative project which uses experimental tools for extracting knowledge of medical practice guidelines based on experts' interpretations of written guidelines. Another application of computer-based interactive approach is the use of software designed to analyze case data, thereby automatically inducing the inference rules. In this case, the interactive approach used is essentially an indirect means of knowledge acquisition, that is, a method for which inferences are made about the nature of the expert knowledge from computer analysis of case data. These case data may be abstracted from an EMR or EHR.

Psychological research in judgment and personality studies has contributed to the elicitation of knowledge via use of rating and sorting tasks. Here, the attempt is to create a classification scheme, thereby identifying the domain elements along certain meaningful taxonomies. For instance, experts can be asked to sort concepts printed on cards into meaningful clusters. Similarly, these experts may be asked to rate concepts along a certain continuum or among different categories. As an illustration, experts may be asked to rate different whiplash cases involving rear-ended motor vehicle accidents into "mild", "intermediate" and "severe" categories based on varying reports and injuries. In this way, the hidden knowledge based on the experts' general opinions as well as interpretations of these cases can be elicited. A standardization of these terms to describe the different clusters for which the cases may be discriminated can then be captured into the EMR or EHR for the respective patient.

Protocol analysis or thinking aloud may be considered a critical direct approach for knowledge elicitation. This technique has received considerable attention in cognitive psychology. The question has been whether experts are better able to articulate the knowledge they possess in thinking aloud when asked to solve a problem than less-than-experts and what are the notable differences between the thinking strategies of experts versus less-than-experts with regards to solving the same problem in specialized domains. One application of this method in the field of medical cognition is to record down the interactions of experienced physicians (or residents) with patients in terms of diagnosing the patients' problem. The analysis of these differing interactions would provide researchers with insights into the different thinking strategies of residents versus expert physicians when faced with similar diagnostic problem cases. The intent is to use the extracted knowledge for programming intelligent computer software that can serve as useful decision support tools for training residents in real-world settings. Just as interviews, a major problem with protocol analysis is the ability of the experts (or non-experts) to accurately verbalize what may be hidden in their respective thinking/reasoning processes. In many cases, protocol analysis need not be taken under real-life physician-patient interactions, these could also be generated from expert or less-than-expert abstraction of EMR or EHR data on particular patients.

Finally, CTA extends most, if not all, of the above traditional task analysis approaches to include ways of capturing higher-level cognitive processes in task performance as well as physical behaviors (see Kushniruk and Patel in Tan with Sheps, 1998). CTA refers to a set of methodologies, including the use of structured interviews, video analysis of work situations, and protocol analysis or other approaches, that can be applied separately or jointly to capture the knowledge, skills, and processing strategies of experts versus less-than-experts when given complex tasks to solve. CTA generally involves six steps: (1) identify decision problems to be studied in the analysis; (2) generate decision tasks or cases; (3) obtain a record of expert problem solving for the task(s); (4) obtain a record of the problem solving of novices and intermediates for the same task(s) that was (were) presented to the experts in step 3; (5) analyze the performance of experts versus less-than-experts; and (6) recommend the systems requirements, design specifications, and knowledge base contents for the MI development. After repeated and careful investigations as well as rigorous analyses of the data derived from the application of these several steps can we only expect to gain proper and valuable insights towards achieving the right mix of information-knowledge elements by the less-than-experts needed to support their decision making and complex problem solving. In fact, even experts will find an intelligent ES developed from CTA approach useful as the system can serve as a sounding board to situations involving critical life-death decisions. Again, these complex problem situations can be abstracted as typical EMR or EHR cases.

Our review of MI tools and applications has focused on how experts vs. less-than-experts can be aided in making complex medical decision. With patient data captured in EMR and EHR, it is possible to generate powerful tools by capturing and creating expert systems to aid these decisions in complex situations. This, in turn, leads us to the need for recognizing major themes, utilization and applications of the rapidly expanding MI field, which we will now explore.

MI MAJOR THEMES, UTILIZATION & APPLICATIONS

The increasing complexities of the MI "identity" as a result of its explosive growth in inter-disciplinary and multi-disciplinary directions call for an analysis of its major themes, utilization and applications. Over the years, a number of sub-fields, major themes, utilization and applications within the broader MI movement have emerged.

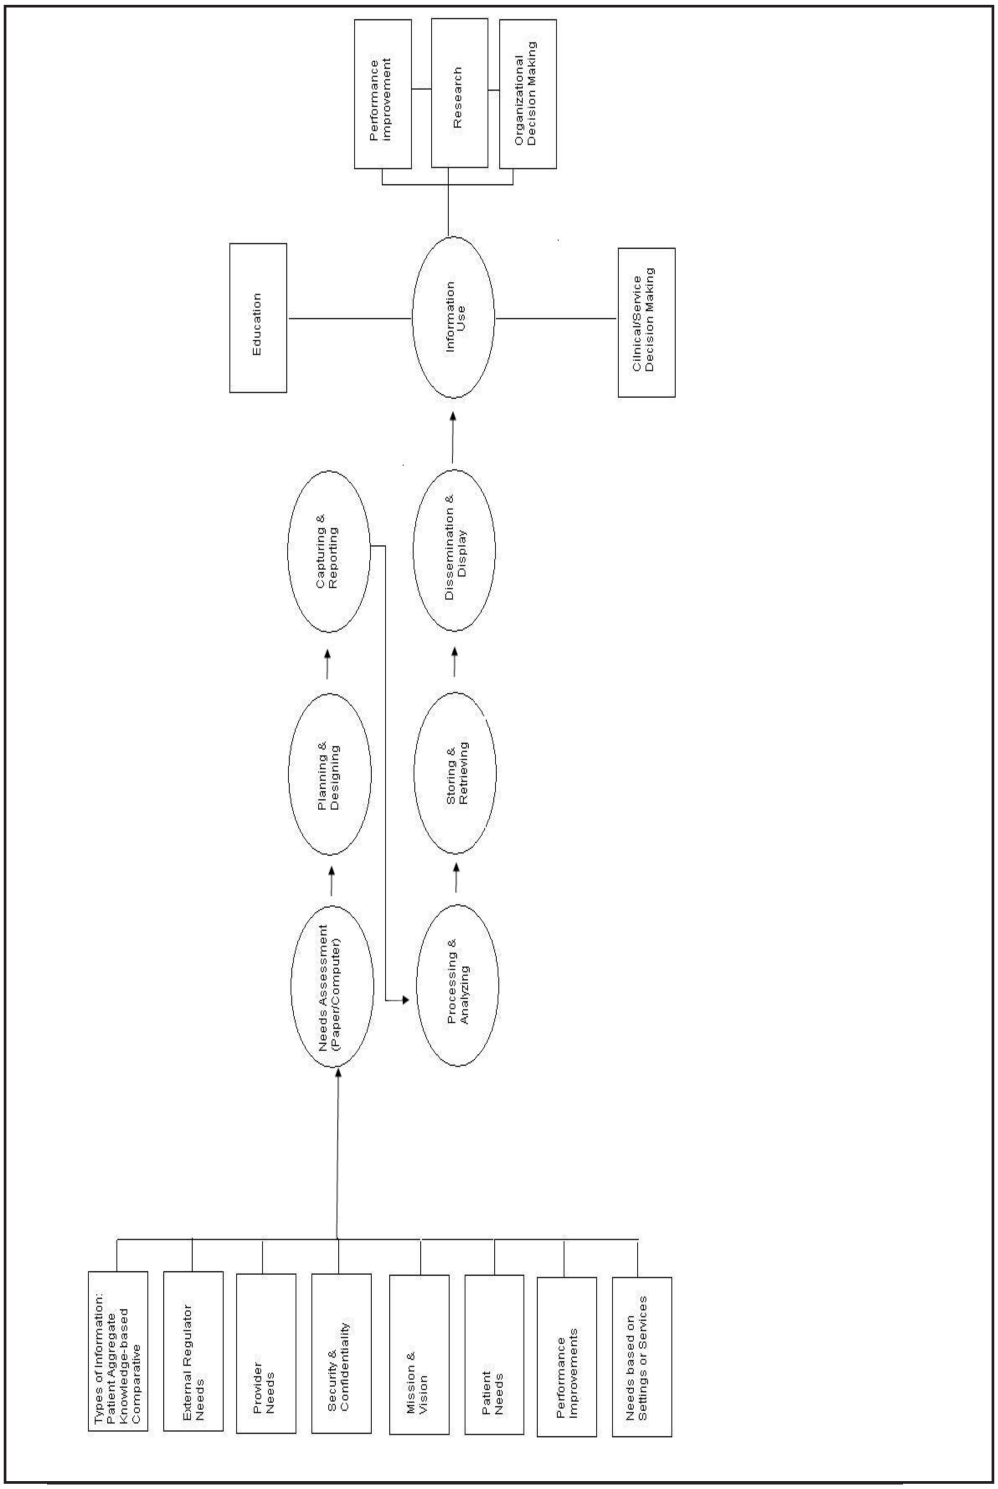
With the limitation on space for this overview, we will briefly cover three key themes encompassing various current utilization and applications that cut popularly across many of the MI sub-fields:

1. Healthcare Information Management (HIM)
2. Health Decision Support Systems (HDSS)
3. Telemedicine

Healthcare Information Management (HIM)

Encompassing a major branch of applied healthcare informatics, HIM professionals are trained to safeguard the accessibility, timeliness, integrity and security of high quality patient records for use by various health professionals. As such, these professionals are expected to be competent in many aspects of applied healthcare informatics, including best practices in health data recording, clinical coding standards and methodologies, Health Insurance Portability and Accountability Act (HIPAA) rules, health laws and regulations pertaining to the preservation of high quality healthcare datasets, healthcare data computing and analytic methods, critical issues on health information systems design and development, and the need to maintain an organizational view of HIM in an evolving and modernized healthcare environment. The American Health Information Management Association (AHIMA) and Health Information Management and Systems Society (HMISS) are the key professional organizations offering certification to HIM professionals and most textbooks written for these certification examinations rely heavily on the 2005 JCAHO (Joint Commission on Accreditation of Healthcare Organizations) model for managing information, as shown in Figure 3.

Figure 3. JCAHO Management of Information Model, 2005 adapted from http://www.jointcommission.org/NR/rdonlyres/656F7F4B-2ECA-4847-8811-B7B54DDA1584/0/LAB2008IMChapter.pdf p.3 of 18



Parallel to the HIS curriculum advocated in Tan (1995; 2001), the JCAHO model depicts a data-information-knowledge processing strategy with collected patient-specific data being aggregated to produce useful and comparable information to accumulate knowledge for supporting the HIM professional activities.

One cornerstone HIM technology that is now being seriously touted to improve patient care delivery is Electronic Health Records (EHRs). Like most HIM applications, EHRs contain both hardware and software components interacting with the human component as a catalyst to bring about customized, efficient and effective sought-after solutions to problem tasks (i.e., generate information-knowledge for patient care decisions) in the different areas of health services delivery. In the US, initial efforts to standardize health information infrastructure were made by ONCHIT, the Office of the National Co-ordinator for Health Information Technology formed under the US Department of Health and Human Services (HHS) in 2004. Headed by Dr. David Brailer, ONCHIT's mission was to achieve a US-wide adoption and diffusion of interoperable EHRs by 2014. When Dr. Brailer subsequently resigned, the HHS separately funded a nonprofit, private group, the Certification Commission for Healthcare Information Technology (CCHIT), to complete the work on setting standards for EHRs and supporting networks. Vendors meeting these standards were to be certified by CCHIT. By 2006, for example, CCHIT had certified a list of 22 ambulatory EHR products.

Beyond HIM, strong interests in MI among health researchers, educators and practitioners during the late 1980s and early 1990s quickly diversified into areas of expert method applications, clinical decision support systems, nursing decision support systems and other forms of health decision support systems.

Health Decision Support Systems (HDSS)

Researchers have always wanted to add intelligence to computer systems, and its extension to medical IS/IT quickly became noted as a most valuable and noteworthy MI application domain. Intelligent medical IS, it is thought, should be able to mimic the thinking processes of expert clinicians. How such thinking processes may be engineered and expert knowledge programmed into automated systems are issues related to ES development process, an issue we have discussed earlier in the review.

Cognitive scientists believe that the human brain may often be conceived as a "living super-computer." Experiments conducted on the human stimuli-response system inform us of the familiar stories of how human perception, pattern recognition, biases and judgments are formed when exposed to various forms of external stimuli (information) in structured vs. less-than-structured task situations. Findings from many of these studies have stimulated the design of various forms of DSS. Tan (1998) differentiated among data-based DSS, model-based DSS, knowledge-based DSS and graphics-based DSS. The application of a database management approach in which access to various organizational data sources can be achieved via a single, multidimensional data depository is basic to all forms of DSS. A model-based DSS, then, provides the decision maker with the added capability of drawing from a variety of models to fit the problem task situation via the use of a model-base management component. In contrast, the knowledge-based DSS, or more simply, an ES, makes use of embedded rule-based algorithms, frames, neural networks and fuzzy logic to augment human decisions. Finally, the graphics-based DSS, such as a geographical information system (GIS), capitalizes on the power of human visualization through the use of a flexible, graphics-driven interface component. A GIS application in healthcare services may be the digital mapping of a certain epidemic such as the HIV infection among a subpopulation group across various Sub-Sahara African countries to study the spread of the prevailing ailment. This knowledge can then be used to target regional interventions effectively for specific population groups rather than focusing treatments on isolated individuals.

A group HDSS combines analytic modeling, network communications, and decision technology to support group thinking, problem formulation, and goal seeking solutions. It aims essentially at easing the group decision-making processes, and among other things, its use will not only reduce the cognitive burden, but also the mental effort associated with groups of decision makers. A major benefit of group HDSS is its potential for increasing efficiency, effectiveness and productivity of group interactions through the application of asynchronous board meetings, online forums or special group chat facilities. Put together, in conceptualizing and designing any health group/organizational DSS, an important strategy is to achieve a good mix and match of the many different forms of DSS that will best support the combined decision needs of the group or organization.

At this point, we turn to another major theme of MI, telemedicine.

Telemedicine

Telemedicine, telematics or telehealth, according to the American Telemedicine Association (ATA), has a history of moving from the linking of two geographically separate points to achieve a medical service with the potential to administer invasive telesurgical procedures at a distance (first wave), to the use of digital networks to perform virtual consultations, including diagnoses of disease and disorders (second wave), to the empowerment of patients with medical expertise to achieve a higher level of wellness (third wave). In other words, telehealth has continued its mission to expand the boundaries and capabilities of medical services delivery to the underserved populations regardless of their geographical locations as it has the advantage of quickly transferring the medical expertise and capability concentrated in an area to another with low accessibility. The focus of telemedicine has been on medical services, not the changing technologies although changing technologies have accelerated the telehealth movement.

As the cost of such expertise transfer continue to reduce substantially with advancing low-cost telecommunications technology and increased competition, the demands for all forms of telemedical services are growing rapidly and efforts have been underway to seek Federal and third party approval for reimbursing telemedical services. Teleradiology and telephathology are among the first successful applications of telemedicine services as far as gaining third party approval for payment reimbursements. In teleradiology, x-rays or scanned images of patients are digitized and stored electronically for sharing among multiple health providers at geographically distant sites without the need for physician-patient or physician-physician interactions. Like teleradiology, no patient interaction is also needed in telephathology as the phathologists are able to provide diagnosis and consultation remotely via exchange of digitized microscopic or routine surgical images. So far, studies have documented the relative accuracy of telephathological diagnosis, which has spurred its approval for Medicare and Medicaid reimbursements, besides teleradiological services. We expect that with greater interactions among subspecialty consultants and the referring pathologist, telepathology readings would continue to improve.

Teledermatology, teleneurology and telepsychiatry are other examples of telemedicine applications where teleconsultation plays a key and active role. Beyond teleconsultations, more dynamic interactions may also be achieved in telemedicine, for example, telecare as in telehomecare and telenursing healthcare, telelearning as in videoconferencing and online medical education, and telesurgery. Telesurgery is apparently much more interactive in nature. Telegastroscopy, for instance, involves both remote consultations and surgical procedures. Indeed, the rapid development of robotics, sensor networks and sensor-based remote-activated and monitoring devices to support telesurgical and virtual reality (VR) interventions all promise a brighter future for telemedicine.

Next, we shift focus to social and organizational implications on MI diffusion.

MI ORGANIZATIONAL & SOCIAL IMPLICATIONS

A major aspect to successful MI diffusion and implementation has to do with overcoming the barriers that are related to social and organizational factors. In terms of organizational and social implications for MI diffusion, not only is it critical to underscore its impacts on individual users, groups and organizations, but also it is important to relay how the MI technology may ultimately affect the larger context of our health services delivery system and on society.

As we enter the next era of the MI field, knowledge of MI impacts will pave new directions for MI technology development and innovation. Still, impediments on the future growth and development in MI will surface such as the growing complexity of legal and security issues in MI.

Impacts on Individuals, Groups and Organizations

MI impacts significantly on the individual user, especially the clinician with respect to work habits, information processing efficiency and decision-making capability, as well as reliance on automated intelligence; on a group level, it impacts on the quality of teleconsultations among clinical experts, volume of information exchanges and effectiveness of group decisions; and on the organization level, it impacts on the quality of organizational patient care delivery and global competitiveness.

More specifically, at the individual level, it is critical to know if use of MI applications will result in speed, accuracy, greater clinical significance and decision-making effectiveness for the clinical user. For example, it may be argued that physicians who are equipped with a Blackberry or an iPhone that will serve both as a cellular phone with an automated reference drug directory, and a Net appliance with the capability to access a built-in e-prescription system will be able to better perform an intelligent online prescription request order for their patients anytime, anywhere than physicians who do not adopt such a technological innovation. At the group level, MI will impact on the ability of expert consultants to share and exchange data, to coordinate teamwork and progress group diagnostic and therapeutic activities. A virtual patient record (VPR) system for use by multiple care providers, for example, is one that will integrate all of the information provided by the different clinicians regarding the patient at anyone time.

At the organizational level, MI diffusion will impact on changes such as organizational reporting structure, work habits and culture. Not only will MI be expected to improve clinical productivity and enhance intra-organizational communications, but also it will redefine clinician-patient relationship, improve organizational image, alter organizational culture, increase market competitiveness and open up new avenues for new collaborations, organizational arrangements and partnership services. Health organizations will adopt a more sensitive attitude and mindset towards information sharing and an evolving culture with the experience of having gone through a major MI diffusion; for example, an organization may completely change the way it performs patient care because of automated intelligence, online training, telework habits and virtual network capabilities. When MI implementation fails, the resulting consequences can also be devastating for an organization not only in terms of costs but also personnel turnover, changes in technical leadership and reporting structure and the potential for future MI resistance from users.

Impacts on Health Services Delivery System and Society

The same impacts discussed previously may now be extended to the entire health services delivery system as well as society. For example, the use of the Internet to transfer massive amount of media-rich patient data and the availability of knowledge systems such as robots and automated intelligent systems may induce many legal and ethical questions about privacy, security, as well as individual and institutional intellectual property rights issues. One contention, for example, is: Who owns all the different pieces of the stored medical information about a particular patient? Another question may be: What information should (should not) be kept online about an individual and who has the right to alter the information stored on a MI database? In the past, many of these and other similar questions have prevented desired progress in the MI field. With the enactment of HIPAA rules, answers to many of these questions are becoming clearer but not definite until test cases move forward and authoritative court decisions have been pronounced.

Critical societal impacts of MI advances include changes in how work may be performed (e.g., telecommuting, virtual patient visits, self-diagnosis), changes in the availability, accessibility and affordability of medical expertise to the underserved patient population, new opportunities for cyber-crime and new ways of purchasing telehealth services for consumers, new gadgets and automated devices for helping seniors and the disabled, the construction of healthy "smart" houses and new methods in self-care, wellness promotion and lifestyle changes, and in redefining the quality of one's life. Imagine how MI applications can not only improve the efficient and effective functioning of a group of doctors and nurses, but patients who have access to specialized MI equipment and devices may also be aided to perform self-care and reduce the burden on hospital emergency services.

One sensitive question, for example, has to do with the determination of technological resource allocation to decide who among the "surviving" patients should be saved in the aftermath of an epidemic or major health hazards? Take the September 11 scenario and the fact that there just are not enough first responders and facilities around to save all of the victims who were immediately affected. How does society go about deciding where to allocate the limited MI and other resources to achieve the most justifiable results? These and other aspects of social impacts such as digital divide, cost effectiveness and the productivity paradox relating to ethical, security, legal and political concerns still need to be worked out and answers to these questions are never easy. They will be further explored in the section on critical issues.

MI MANAGERIAL IMPACT & KEY IMPLEMENTATION ISSUES

Any innovation, including MI, will become obsolete if not diffused. In practice, MI diffusion issues relate to MI strategy and vision as well as many other critical issues, which have been discussed partly in the theoretical section of this review such as MI technology management, leadership and acceptance-resistance experiences in MI implementation and will be further explored in the next section.

Here, our focus is on activities dealing with the need for management to create an MI strategy and vision for diffusing competitive, cost-effective MI applications in key areas throughout a healthcare organization. These issues summarize the MI managerial impact.

MI Strategy

While there may be good reasons to support MI innovation such as enhanced patient care, more intelligent clinician decision outcomes, and greater efficiencies in the clinical evaluation process, new efforts may fail for lack of a successful MI strategy.

In essence, MI strategy entails aligning the business or organizational mission (the goals) with the information needs of the users (particularly those of the clinicians and nurses for health care organizations) in the delivery of patient care (the tasks). In other words, three key questions should be asked when structuring an MI innovation diffusion strategy: First, “Is the MI strategy targeted to fulfill the core mission of the organization?” For example, in the case of a center for cancer treatment and research, plan should be in place to position this particular center to become one of the best places in the world to seek cancer treatment owing to its MI innovation diffusion strategy. Second, “What is the clinical significance of the MI innovation?” Here, the center clinicians should actually be benefiting significantly in their practices due to employing MI innovation – the effects should be evidenced in more medical breakthroughs and error prevention due to improved treatment decision outcomes. Finally, “Is the MI innovation serving its ultimate purpose of augmenting patient care delivery?” Herein lies the significance of the MI diffusion equation – are these systems functioning appropriately to save lives, improve the treatment center’s image, and strengthen the provider-patient relationships so cherished by the organization.

A major trend in MI strategic planning is the shifting of responsibilities and power from traditional IS/IT professionals to end users, and more appropriately, to top management. This trend is justified because of the growing acceptance of the notion that IT is a corporate and strategic resource and should be properly managed just like any other organizational assets including land, labor and capital. More recent approaches call for a shortening of the time span among MI strategic planning sessions and more attention paid to the changing marketplace. Regardless of the time span in-between strategic planning sessions, there is always the need to conduct environmental assessment before moving onto the formulation of a MI strategy.

One approach to MI strategic planning is scenario planning. Here, competing multiple futures may be first envisioned and strategies are then developed and tested against these possible futures. The MI vision is then set within these possible futures and further reconciled with current reality. For example, if the MI vision is one in which intelligent, sensor-based medical devices are to be used to monitor cancer patient round-the-clock while the current reality involves only regular treatment visits and emergency monitoring, then the transition to the new MI-intensive environment will not only call for changes in work practices and habits, but new ways of connecting patients to the cancer center electronically. Indeed, no single approach to MI strategy formulation is considered superior; instead, a blending of approaches is often recommended as the various approaches deal with different aspects of creating a feasible MI strategy.

MI Implementation

The challenges of MI implementation are often interwoven with many other social and organizational challenges, including the integration of quality planning, quality control and quality improvement processes to evolve a secure, well-managed, and quality-focused MI environment, the integration of information management technology, organization management technology, and user-interface technology for building an efficient, organization-wide infrastructure to support MI innovation and expansion, and the integration of data, model, and knowledge elements for designing effective MI applications.

Any MI implementation will bring about some form of organizational change, for example, changes in the organizational reporting structure, changes in the level of computing competence required of current and future clinical users, and changes in the information flow processes and decision-making functions of the organization. To ensure that clinicians will have the appropriate knowledge, skills and attitudes that are critical for addressing concerns arising from these MI related changes, it is important that health organizations also address staffing and training issues such as having an aggressive recruitment program for attracting valuable MI professionals from among competitors, creating opportunities for training and development, and employing winning strategies for the retention of knowledgeable and well-trained MI experts.

At the core of MI implementation is overcoming user resistance and cultivating user acceptance through a continuous process of buy-in, quality improvement, participatory decision making such as efforts to involve the users in identifying their information needs, involving them in systems specification, system analysis, systems design, vendor selection, system testing and providing them with flexible and extensive user training opportunities. Remember that physicians and most other clinicians have complex schedule and will not work around their schedule just to attend a training meeting. Moreover, opportunities for input from all end-users of the MI systems will only ensure that the designed system meet the expectation and needs of the users. Most importantly, the users will only be willing to most likely use the system on an increasing basis if they find that there are ways to tell them that the systems benefited them in lightening their workload and in improving their productivity, giving them more time to do patient care. As well, availability, accessibility, efficiency, effectiveness and ease of use of the systems all play a part towards getting the users hooked on the systems.

Together, these key challenges typically point towards the need for an integration of environmental, technological, and organizational components for driving and directing the implementation of various MI technologies and applications successfully within the larger intra-organizational or inter-organizational systems context. Other MI administrative issues may include policies dealing with privacy, security and confidentiality of patient records, legal and ethical considerations in clinical data collection, analysis, and distribution, and organizational policies regarding authorized use of MI.

CRITICAL ISSUES

As noted, the primary objectives of most, if not all, MI implementation are reduced operational costs, greater patient satisfaction, and better quality clinical decisions. As MI systems promise to make information and decision handling more efficient and effective in reducing costly errors and unnecessary delays, as well as projecting an improved professional image, it is important to implement MI applications that are accepted by its users (clinicians).

Critical Success Factors

What factors determine the success of an MI innovation diffusion effort? Critical Success Factors (CSFs) for MI diffusion are those factors that will drive the success of MI diffusion. Based on past studies, commonly held managerial factors for success include effective technology management (TM) and executive leadership, as well as infrastructural factors whereas organizational and social factors include implementation factors and culture-specific factors. The focus of this section will be on the managerial factors as the organizational and social factors are elaborated in Section VII on organizational and social impacts.

Briefly, technology leadership and the management of the MI capacity within the health organization are key success factors for MI innovation and implementation. Top management must work to ensure that appropriate infrastructural support is in place to develop the MI expertise needed to support current and future managerial and organizational functions and activities. In many cases, executive leadership is expected, including directives and policy setting by the chief information officer (CIO) in order to guide necessary organizational restructuring for efficient information processing and effective decision making, the revamping of decision processes, the bridging of MI innovation with changing environment, and the rapid adaptation of new MI capabilities to support increasingly sophisticated clinical information services in this age of information and knowledge explosion.

As we have noted, it is important for an effective MI strategy to impact on the business of the organization. The resistance to MI implementation experienced within an organization is largely due to poor alignment between MI strategy and organizational strategic plan, inadequate communications, lack of user training, and support from top management. A champion for MI to forming a task force that would marshal the needed support and user-analyst relationship and/or user participation throughout the development of MI strategy is an important ingredient to achieve MI diffusion, utilization and acceptance. Without a champion at the senior management level, it is likely that MI resources will not be well allocated and its needs for efficient and effective transformation of the organizational work habits will not be supported. This is especially true for health care organizations, with its established tradition of intensive paper-based information processing, professionally oriented physicians and nurses, and traditional management habits.

Other Issues

Other issues concern computer literacy among clinicians and all health organizational workers catering to patient care functions, the digital divide, the productivity paradox, ethical, legal and security issues. Again, an in-depth treatment of any of these issues is more properly the devotion of another chapter. Here, we will only brief touch on some of them.

Computer literacy, which can often translate into resistance, can be a threat even for highly trained professionals, as they do not want to be embarrassed for showing ignorance about their lag in technological expertise in front of their colleagues. Thus, it may be wise to conduct separate training sessions for executives, physicians, nurses, middle managers and staff.

A broader impact of computer literacy is the digital divide, where it is apparent that we need to pay special attention to the underserved population who may find accessibility to information technology and use of Internet a real challenge. Especially vulnerable are some special groups such as seniors who are also classified as minority and those living in impoverished parts of many of the inner cities. In this instance, the emerging field of e-health is making an impact. Tan and colleagues, for example, are working on educating a group of these seniors in selected urban Detroit areas on healthy aging and lifestyle changes through the use of Internet-based educational software known as the eHealthSmart program. A major aim of this program is to provide Internet-based tutorials on smoking cessation and weight management to the elderly and seniors who are eager to use computers to help themselves in changing their unhealthy lifestyle behaviors.

Another critical issue is the productivity paradox, which refers to the phenomenon that, to date, we have yet to witness the same level of productivity improvements achieved with the automation of processes in the service industry since the advent of computers in the way we have witnessed the effects of automation on productivity experienced in the manufacturing industry. In other words, information technologies, with its increasing applications across all service sector industries, have not been widely productive as anticipated. Apparently, it is argued that, on the one hand, we are not out of the woods yet in terms of maturing from old aged manufacturing productivity and efficiency while, on the other hand, we have yet to reach the stage of being fully immersed in the digital economy to leverage on technological productivity and efficiencies on a massive scale. Time can only tell when this generation will reach the threshold of a critical mass of technology usage to achieve the productivity and efficiency that we have already experienced in manufacturing, albeit the gradual slowdown. What this implies literary is the need for greater and higher MI diffusion in the current century, especially with health care taking a lead role. After all, which industry would thrive with automation in this economy when we are faced with an aging population, an accelerating health care expenditure of approximately 16% to17% of our

GNP? Hopefully, many of us will live to see the promise land of technological productivity that MI diffusion and automation will usher us in.

In terms of security and privacy issues, the health care organization is held responsible as the gatekeeper for securing private and critical information on hundreds and thousands of individual patients. Imagine someone finding a jump drive or disks containing private hospitalization records of certain patients who may also be important political figures, legendary athletes, famous entertainers or key legislative and policy makers. Imagine also that intruders are able to hack into the various MI systems and access key information on patient and hospital personnel identification, laboratory test results and digitized radiological images of different patients, or information on storage facilities for key pharmaceutical products and controlled substances. The ramification for losing any such information can be devastating for both the individuals whose information has been stolen as well as for the institution serving as the gatekeeper of our most private and confidential information.

EMERGING TRENDS

Moving on to emerging trends of MI thinking and sub-specialties that have surfaced in recent years, we observe that there are basically two streams of innovation. One group of paradigm shift includes consumer health informatics, electronic healthcare (e-health) and all its sub-fields such as electronic medicine (e-medicine), e-homecare, and patient-centered e-health (PCEH). Another group of paradigm shift concerns mobile healthcare (m-health) technologies, ubiquitous healthcare (u-health), and virtual healthcare (v-health). Here, it is possible only to provide readers with brief glimpses of these sometimes overlapping but emerging MI trends. Readers who are interested in pursuing further details can refer to the readings provided in the bibliography and the rest of this 4-volume work.

Consumer health informatics is bringing about a consumer-driven health care model in that consumers will play a more active and decisive role regarding managing their own health and well being. For the educated consumer, greater access to quality health information is, in and of itself, a form of therapy. E-health is a paradigm shift to re-channel clinical expertise into the hands of the less-than-experts through the applications of e-technology. E-technologies encompass complex MI network design and consumer-oriented informatics, the Internet, wireless communications and emerging technological applications such as web services and remote clinical monitoring devices and management systems. E-medicine, another MI sub-fields, refers to affordable and acceptable use of MI to support health-related services, surveillance, information, education, knowledge, and research dissemination. It is the use of advanced information and communications technology (ICT) to bridge geographic gaps and improve care delivery and education. Patient-centered e-health (PCEH), in a nutshell, represents one of the paradigm shifts that is part of the larger e-health movement where not only is the role of healthcare providers being redefined, but where the expectation bar for consumers to participate actively in decisions leading to their own health as well as the overall quality and acceptability of e-healthcare informatics and services are being raised. Moreover, we see that the various disciplines of e-clinical care, e-public health care, e-nursing and e-homecare overlap to a considerable extent. Apparently, it has not become easier, but more fuzzy, to distinctively separate the different knowledge domains of “e-health,” which is the umbrella concept to encompass most, if not all, of these emerging MI sub-disciplines and sub-fields.

M-health, an extension of the e-health concept, refers to mobile-health or use of remote, satellite-based networks, cellular-based networks, and other wireless networks (e.g., sensor-based networks) to effect health data exchange services as well as clinical information and decision support services. Ubiquitous healthcare (u-health), and virtual healthcare (v-health) are the next evolution of MI where concepts such as virtual community networks, ES/HDSS embedded in walls, table-tops, refrigerators, and other objects in the surrounding environment, as well as VR such as use of head mounted displays, smart houses and wearable computing are becoming commonplace. Examples include a doctor checking the status of a patient's wellness in real time by connecting to a nano-sensor device installed in a patient's home or attached physically in some shape, form or manner to the patient or a monitoring system, which automatically contacts the designated health agency to initiate treatment procedure while alerting on an impending heart attack for a patient. Such an evolution can be expected to provide an ubiquitous MI resource for delivering patient care services.

The trending of the MI movement towards achieving u-health and v-health may soon become a reality when personalized information exchanges, integrative knowledge sharing, and decisional support and communications can happen in real time between an institutional care provider and the patient. Electronic health records will be available, accessible, affordable and adaptable to our needs. Nano-science and gene-based therapies will be possible because of intelligent mining of these personal records not only to serve us in terms of our wellness recovery whenever we are injured, but also brings about a sense of equity among the community, serving even those who are unable to insure themselves. Notwithstanding these changes, we have seen how a young discipline such as the MI field can grow and expand quickly to affect every aspects of our daily living, in particular, our health care system, our community and our health.

CONCLUSION

In bringing this discussion to a close, we will use the example of designing a expert diagnostic support system (E-DSS) useful for both physicians and patients to show how the different major facets of MI themes, its theories, central hypothesis, tools/methods, diffusion and impacts can all be combined to achieve effective health care. First, this E-DSS may have to be divided into two components, one to support experts (i.e., physicians, nurses and clinical therapists) and the other for layperson (i.e., consumer, patient) support. This MI tool will, say, be focused on wellness promotion areas such as smoking cessation, weight management, and nutrition advice. On the one hand, the expert component of this E-DSS will mimic the hypothetico-deductive approach used by most clinicians in deriving diagnostic decisions, which is, essentially, an iterative process of data collection, interpretation and hypothesis generation and refinement until a satisfied level of certainty is reached. On the other hand, the layperson component of the E-DSS will mimic an online tutorial for layperson to be educated with the expertise programmed into the different health promoting educational modules. Thus, this E-DSS concept illustrates the central hypothesis of MI philosophy, which is simply to enhance decision making, based on the GST that underlies also many of the evolving MI themes that we have reviewed so far, where synergy effects can be achieved with the combination of individual components in the design of MI applications.

Second, for most of the clinical decisions associated with the E-DSS such as knowing if a female patient is at risk for diabetes due to unhealthy lifestyles, the sensitivity-specificity methodology forms the basis for hypothesis generation. For the E-DSS to "think" like an expert clinician, the system must therefore be taught the different likelihood of specific symptoms to a health challenge, such as the likelihood of having diabetes as a result of being obese, unchanged smoking habits or poor lifestyle behaviors. Such likelihood, better expressed in terms of probability, is a measurement derived from health statistics. The cutoff point in which a patient is diagnosed with a particular challenge is the result of continuous data collection and analysis, for example, a female patient 50 years old is diagnosed with diabetes when her blood glucose reading reaches 5.5. If this cutoff point is reduced, then the sensitivity of the blood glucose test increases while the specificity decreases. Thus, if the cutoff point for diagnosing diabetes for the above clinical group is reduced to 5.4, then more patients will be diagnosed with diabetes. The cutoff point is then a guideline to diagnosing diabetes. However, a patient with a blood glucose reading of 5.6 does not necessarily have diabetes. This is because every clinical test has false positives as every clinical test result is made up true positives, true negatives, false positives, and false negatives. As we noted previously, the true-positive rate (TPR) is the sensitivity probability of a test result and measures the likelihood that the patient being suspected of having the disease does have a positive test result. Conversely, the true-negative rate (TNR) is the specificity probability of a test result and measures the likelihood of a non-diseased patient having a negative test result.

The initial hypothesis of a patient having a certain disease or condition is the pretest probability (i.e., prevalence). This judgment may be based on prior experience or on knowledge of the medical literature. When tests and examinations are conducted, the initial hypothesis is verified, thereby yielding the predictive value, or resulting in the posttest probability. Predictive value is the probability that a disease is present based on a test result. The posttest probability then becomes the pretest probability of the next hypothesis. This leads to the Bayes' theorem to calculate the posttest probability using the pretest probability and the sensitivity and specificity of the test. Herein lies the foundation of MI theory and methodology on which our clinical reasoning model is built upon and programmed into the expert component of the E-DSS to support clinical and diagnostic decisions. It is possible, of course, to apply other methodologies such as neural networks, heuristic programming and case-based reasoning, but our intent here is merely to illustrate a common and specific MI methodology based on a well-known decision theory, the Bayes' theorem. On the layperson component, the E-DSS may be supported with a knowledge base where expert knowledge on weight management, smoking cessation or healthy nutrition can be made available for online consultation.

In terms of MI diffusion and impacts, the E-DSS as we have illustrated must be supported by healthcare organizations that would promote wellness such as third-party payers and accepted by the intending clinical and layperson users in order to be effective and have a positive impact on the individual, group, organization and society. Specifically, the clinician will have a better control of predicting the risk for particular patient to have, say, obese-related diseases, the patient will have a better management of their own lifestyles with access to expert knowledge, the health maintenance organizations (HMOs) or the government will be able to reduce payments on treatment costs due to healthier subscribers, our society will have less burden to bear as people age more gracefully and the list goes on. Further, most HMOs and governmental agencies have numerous other patient record systems with varying computer platforms and data storage structures. How this E-DSS can be integrated or embedded into the larger organizational computing infrastructure is a key challenge. In other words, rather than having patient data stored redundantly in the E-DSS as well as other separate systems such as computerized patient records (CPR), it may be possible to network these different systems so that the same data are stored only once and can be shared virtually among the different sub-systems such as in the HMO's EHRs that was discussed previously. Other related challenges include the need to align the goals of the organization (the business) with the goals of the different sub-systems, for example, the clinician's aim to treat his or her patients speedily, and the aims of the IS/IT support departmental staff to coordinate data collection and standardization, to improve computer-user interfaces, to train users and to encourage their active participation in managing and harnessing the technology. Until a seamless alignment is achieved, the diffusion of MI such as the E-DSS technology will be limited due to lack of acceptance among its supporters.

Finally, the greatest impact of a system like the E-DSS we discussed here will be felt when it can be made available to any clinician as well as any layperson worldwide and not just those living in a certain area or country. In this sense, the development of sensor networks and ubiquitous computing is an ideal platform for MI development. When software applications are run through these wireless networks, the limitations on geographical location and time disappeared. In other words, the necessary health expertise can be made accessible, available and affordable 24/7 anywhere in the world to less-than-expert physicians and underserved patients. When the access interface becomes ubiquitous, the dynamic interactions between the clinician and the patient may not only be limited to diagnostic decision making and treatment planning, but it will be 24/7 monitoring even for disease prevention, lifestyle changes and wellness promotion. As people live longer, such new demands on the next generation MI innovation will certainly be on the rise. Nonetheless, security is always the major issue when MI applications are to be accessed ubiquitously. The integrity, privacy and confidentiality of clinical data must not be compromised when MI development moves in this direction.

About the Editor

Joseph Tan, Dip, BA, MS, PhD, holds a professional diploma in civil engineering from Singapore Polytechnic, an undergraduate degree in mathematics and computer science from Wartburg College, IA, a master's degree in industrial & management engineering from the University of Iowa, and a PhD in management information systems from the University of British Columbia (UBC). He has been a tenured associate professor, teaching in the Department of Healthcare & Epidemiology at UBC for many years prior to serving as professor and head of the Information System and Manufacturing (ISM) Department, School of Business, Wayne State University.

Professor Tan publishes widely in numerous computing, ergonomics, information systems, health informatics, health education, e-health and e-business journals and has served as guest editor and member of various journal editorial boards. He sits on key organizing committees for local, national, and international meetings and conferences. Professor Tan's research, which has enjoyed significant support in the last several years from local, national and international funding agencies and other sources, has also been widely cited and applied across a number of major disciplines, including healthcare informatics and clinical decision support, health technology management research, human processing of graphical representations, ergonomics, health administration education, telehealth, mobile health, and e-health promotion programming.

Section I
Fundamental Concepts and Theories

This section serves as the foundation for this exhaustive reference tool by addressing crucial theories essential to the understanding of medical informatics. Chapters found within these pages provide an excellent framework in which to position medical informatics within the field of information science and technology. Individual contributions provide overviews of knowledge management in healthcare, health portals, and health information systems, while also exploring critical stumbling blocks of this field. Within this introductory section, the reader can learn and choose from a compendium of expert research on the elemental theories underscoring the research and application of medical informatics.

Chapter 1.1
Evaluation of Health Information Systems:
Challenges and Approaches

ABSTRACT

This chapter summarizes the problems and challenges that occur when health information systems are evaluated. The main problem areas presented are the complexity of the evaluation object, the complexity of an evaluation project, and the motivation for evaluation. Based on the analysis of those problem areas, the chapter then presents recommendations of how to address them. In particular, it discusses in more detail what benefits can be obtained from applying triangulation in evaluation studies. Based on the example of the evaluation of a nursing documentation system, it shows how both the validation of results and the completeness of results can be supported by triangulation. The authors hope to contribute to a better understanding of the peculiarities of evaluation in healthcare, and to provide information how to overcome them.

INTRODUCTION

It is hard to imagine healthcare without modern information and communication technology (ICT). It is evident that the use of modern information technology (IT) offers tremendous opportunities to reduce clinical errors, to support healthcare professionals, and to increase the efficiency of care, and even to improve the quality of patient care (Institute of Medicine, 2001).

However, there are also hazards associated with ICT in healthcare: Modern information systems (ISs) are costly, their failures may cause negative effects on patients and staff, and possibly, when inappropriately designed, they may result in healthcare professional's spending more time with the computer than with the patient. This all could have a negative impact on the efficiency of patient care. Therefore, a rigorous evaluation of IT in healthcare is recommended (Rigby, 2001) and is of great importance for decision makers and users (Kaplan & Shaw, 2002). Evaluation can be defined as the decisive assessment of defined objects, based on a set of criteria, to solve a given problem (Ammenwerth et al., 2004).

The term ICT refers to technologies as such. Whether the use of these technologies is successful depends not only on the quality of the technological artifacts but also on the actors (i.e., the people involved in information processing and the organizational environment in which they are employed). ICT embedded in the environment, including the actors, is often referred to as an IS in a sociotechnical sense (Berg, Aarts, & van der Lei, 2003; Winter et al., 2001).

Many different questions can lead the evaluation of IT. Within evaluation research, two main (and often rather distinct) traditions can be found: The objectivist (positivistic) and the subjectivistic tradition (Friedman & Wyatt, 1997), which are related to the dominant use of either quantitative or qualitative methods (for details, see Chapter XII).

Despite a large amount of published evaluation studies (e.g., van der Loo, 1995) found over 1,500 citations on evaluation of healthcare IT between 1967 and 1995, and Ammenwerth and de Keizer (2004) found 1,035 studies between 1982 and 2002; many authors report problems during evaluation. One of the main problems frequently discussed is the adequate choice of evaluation methods. While objectivistic researchers tend to concentrate on quantitative methods, subjectivistic researchers mainly rely on qualitative methods. Sometimes, a mixture of methods is applied. For example, qualitative methods are used to prepare quantitative studies, or quantitative measurements are used to support qualitative argumentation. However, there is still usually one tradition which dominates typical evaluation studies, leading to a focus either on quantitative or qualitative methods.

Many researchers point to the fact that this domination of one method or tradition may not be useful, but that a real integration of various methods from both traditions can be much more helpful to get comprehensive answers to given research questions. The integration of the complementary methods (and even beyond this, of data sources, theories and investigators), is discussed under the term triangulation.

In this chapter, we first want to review some of the underlying reasons that make evaluation of healthcare IT so difficult. We will structure the problems into three main problem areas: the complexity of the object of evaluation, the complexity of the evaluation project, and the motivation to perform evaluation. We will discuss means how to overcome the discussed problems.

As one more detailed example, we then discuss what benefits can be obtained from applying triangulation in an evaluation study. Based on the example of the evaluation of a nursing documentation system, we show how both the validation of results and the completeness of results can be supported by triangulation.

TYPICAL PROBLEMS IN EVALUATION OF IT IN HEALTHCARE

First Problem Area: Complexity of the Evaluation Object

When understanding IT as part of the IS of an organization, it is clear that evaluation requires not only an understanding of computer technology, but also of the social and behavioral processes that affect and are affected by the technology. This complexity of the evaluation objects has some important consequences. First, the introduction of IT takes time. It is not enough to implement the technology and then to immediately measure the effects. Users and workflow need a lot of time to get used to new tools and to completely exploit the new possibilities (Palvia, Sharma, & Conrath, 2001). Thus, evaluation results can develop and change during this first period of use. Then, even after an introduction period, the evaluation object may steadily change (Moehr, 2002; moving evaluation target). For example, the use of IT may be affected by changes in work organization, or in staff. It is nearly impossible to reach a stable situation in a flexible healthcare environment which makes evaluation results dependant of the point in time where the evaluation took place. In addition, each IS in our definition is quite unique. While the IT may be similar in various departments, workflow, users and used functionality may be different. In addition, the organization of its introduction as well as the overall user motivation may differ. Thus, even when the same IT is introduced, its effects may be varying (Kaplan & Shaw, 2002). The influence of such factors on the results of an evaluation study is often hard to disentangle (Wyatt, 1994), posing the problem of external validity (Moehr, 2002): Many evaluation studies may be valid only for the particular institutions with their specific IS.

The complexity of the evaluation object is an inherent attribute in healthcare IT evaluation and cannot be reduced. However, there are some ways to handle this problem in evaluation studies. To address the problem of external validity, the IT and its environment that is going to be evaluated should be defined in detail before the beginning of the study. Not only the software and hardware used should be described, but also the number of users and their experience and motivation, the way IT is introduced and used, the general technical infrastructure (e.g., networks) and any further aspects that may influence the usage of IT and its effects. The functionality and the way it is really used should also be of importance. Only this information may allow interpretation of the study results and comparison of different locations. Then, to address the problem of the moving evaluation target, all changes in the IT and its interaction with the users should be carefully documented during the study. For example, changes in workflow, in staffing, or in hardware or software should be documented with reference to the ongoing evaluation. This permits the explanation of changes and differences in effects measured during the study period. Another approach to address the problem of the moving evaluation target may be to define smaller evaluation modules. This would allow the evaluation design or evaluation questions to be adapted to changes in the environment. Each module answered a question related to a defined phase of the introduction of the IT. In addition, an evaluation must be planned in a long-term perspective in order to allow the users and the environment to integrate the new IT. Hence enough resources for long-term evaluation (e.g., over several months or even years) should be available.

Second Problem Area: Complexity of the Evaluation Project

Evaluation of IT is performed in the real and complex healthcare environment, with its different professional groups, and its high dependency on external influences such as legislation, economic constraints, or patient clientele. This poses problems to the evaluation projects, meaning the planning, executing and analyzing of an IT evaluation study. For example, the different stakeholders often have different conceptions and views of successful IT (Palvia et al., 2001). The different stakeholder requirements can serve as a frame of reference for evaluation during the early phases of the IT life cycle, but also guide evaluations during later phases. In each case, multiple-stakeholder views may lead to a multitude of (possibly conflicting) evaluation questions (Heathfield et al., 1999).

Depending on the point of view adopted, the evaluation will require different study designs and evaluation methods. The evaluation researcher must decide, for example, on the evaluation approach, on the adequate evaluation methods (e.g., quantitative vs. qualitative), and on the study design (e.g., RCT vs. observational study). Each has its own advantages and drawbacks (Frechtling, 1997; Moehr, 2002), making their selection a rather challenging endeavor. This multitude of possible evaluation questions and available evaluation methods makes the planning of an evaluation study quite complex.

The complexity of the evaluation project has several consequences. First, the overall success of IT is elusive to define (Palvia et al., 2001), and it is therefore often difficult to establish clear-cut evaluation criteria to be addressed in a study (Wyatt, 1994). Each stakeholder group may have individual questions, and a universal evaluation in terms of absolute or relative benefits is usually not feasible (or, from a more subjectivistic point of view, not even possible). It is also unrealistic to expect that the IT itself will have a direct and easy to measure effect on the outcome quality of patient care, like in a drug trial (Wyatt, 1994). Thus, indirect measures are often used such as user satisfaction or changes of clinical processes, which, however, do not give a really complete picture of the benefits of IT. Often, changes in the evaluation questions may occur during the study (e.g., based on intermediate evaluation results, new insights, changes in stakeholders' opinions, or changes of the IT [scope creep]; Dewan & Lorenzi, 2000). Changes in study questions, however, may be difficult to balance with study resources. Finally, the selection of adequate evaluation designs and evaluation methods is often regarded as a problem during evaluation studies. Evaluators may not be sufficiently aware of the broadness of available approaches, or be too deeply embedded in either the qualitative or the quantitative paradigm, neglecting the possible contributions of the complementary approach. Thus, inadequate methods or study designs may be chosen which may not be able to answer the original study questions.

The following suggestions may be useful in order to deal with the complexity of the evaluation project. First, it is recommended that the general intention of the evaluation and the starting point should be agreed early on. In principle, evaluation should start before the new IT is implemented, in order to allow for early gathering of comparative data, and then continue during all phases of its life cycle (VATAM, 2000). Then, the areas of evaluation should be restricted to aspects which are of most importance to the involved stakeholders, and which can be measured with the available resources. A complete evaluation of all aspects of a system (such as economics, effectiveness, and acceptance) is usually not feasible. A balance between the resources of a study and the inclusion of the most relevant aspects has to be found. In addition, sufficient time should be invested into the definition of relevant study questions. All involved stakeholder groups should discuss and agree on the goals of evaluation (VATAM, 2000). The selected study questions should be relevant for decision-making with regard to introduction, operation or justification of IT (Ammenwerth et al., 2004). Conflicting goals should be discussed and solved, as they are not only problematic for an evaluation, but for the overall management of new IT. Fourth, when new evaluation questions emerge during the study, they should only be included in the study design when it is possible without creating problems. Otherwise, they should be tackled in consecutive studies. Each shift in evaluation questions must thoroughly be documented. For each study question, adequate methods must be chosen. A triangulation of methods may be useful to best answer the study questions (Heathfield, Pitty, & Hanka, 1998). For example, to address the effects of a nursing documentation system, both quantitative methods (time measurement, user acceptance scales, documentation quality measurement) as well as qualitative methods (focus group interviews) were used. We will discuss this example later on in more detail.

Third Problem Area: Motivation for Evaluation

An evaluation study can normally only be conducted when there is sufficient funding, and a sufficient number of participants (e.g., staff members, wards). Both these variables depend on the motivation of stakeholders (e.g., hospital management) to perform an evaluation. Sometimes, this motivation is not very high, because, for example, of fear for negative outcome, or of fear for revealing deficiencies of already implemented technology (Rigby, Forsström, Roberts, & Wyatt, 2001). In addition, the introduction of IT in an organization is a deep intervention that may have large consequences. It is thus often very difficult to organize IT evaluation in the form of an experiment, and to easily remove the system again at the end of the study in case the evaluation was too negative.

Even with a motivated management, it may be difficult to find suitable participants. Participating in a study usually requires some effort from the involved staff. In addition, while the users have to make large efforts to learn and use a new, innovative system, the benefit of joining a pilot study is usually not obvious (the study is conducted in order to investigate possible effects), but participation may even include some risks for the involved staff such as disturbances in workflow. In summary, due to the given reasons, the hospital management as well as involved staff members is often reluctant to participate in IT evaluation studies.

The described problem has consequences for the study. Without the support and motivation of the stakeholders to conduct an evaluation study, it will be difficult to get sufficient resources for an evaluation and sufficient participants willing to participate. Second, due to the given problems, the study organizer tends to recruit any participant who volunteers to participate. However, those participants may be more motivated to participate than the "normal" user. This leads to the well-known volunteer effect, where results are better when participants are motivated. In addition, evaluation results are not only important for the involved units, but also for the overall organization or for similar units in other organizations. To allow transfer of results, the pilot wards or pilot users must be sufficiently representative for other wards or users. But, as each IT within its environment is quite unique (see Problem Area 1); it is difficult to find comparable or representative participants.

To increase the number of participants, two approaches should be combined. First, the responsible management should be informed and motivated to support the study. The result of an evaluation study may be important to decide on new IT, and to support its continuous improvement. Then, the possible participants could be directly addressed. It should be made clear that the study provides the opportunity to influence not only the future development of IT in healthcare but also the own working environment. User feedback of study results may act as an important driving force for users to participate in the study. Offering financial compensation or additional staff for the study period may help to gain support from participants and from management. As in clinical trials, multicentric studies should be considered (Wyatt & Spiegelhalter, 1992). This would largely increase the number of available participants. This means however, that study management requires much more effort. A multicentric study design is difficult when the environment is completely different. In addition, the variation between study participants will be bigger in multicentric trials than in single-center ones. This may render interpretation and comparison of results even more difficult (cp. discussion in Problem Area 1).

Summary of General Recommendations

The above discussed problems and approaches will now be summarized in a list of 12 general recommendations for IT evaluation in healthcare:

1. Evaluation takes time; thus, take your time for thorough planning and execution.
2. Document all of your decisions and steps in a detailed study protocol. Adhere to this protocol; it is your main tool for a systematic evaluation.
3. Strive for management support, and try to organize long-term financial support.
4. Clarify the goals of the evaluation. Take into account the different stakeholder groups. Dissolve conflicting goals.
5. Reduce your evaluation questions to an appropriate number of the most important questions that you can handle within the available time and budget. If new questions emerge during the study, which cannot easily be integrated, postpone them for a new evaluation study.
6. Clarify and thoroughly describe the IT object of your evaluation and the environment. Take note of any changes of the IT and its environment during the study that may affect results.
7. Select an adequate study design. Think of a stepwise study design.
8. Select adequate methods to answer your study questions. Neither objectivist nor subjectivist approaches can answer all questions. Take into account the available methods. Consider being multimethodic and multidisciplinary, and consider triangulation of methods, data sources, investigators, and theories. Strive for methodical (e.g., biometrics) advice.
9. Motivate a sufficient number of users to participate. Consider multicentric trials and financial or other compensation.
10. Use validated evaluation instruments wherever possible.
11. Be open to unwanted and unexpected effects.
12. Publish your results and what you learned to allow others to learn from your work.

One of the most discussed aspects is the selection of adequate methods and tools (Point 6) and, here especially, the adequate application of multimethodic and multidisciplinary approaches (Ammenwerth et al., 2004). The interdisciplinary nature of evaluation research in medical informatics includes that a broad choice of evaluation methods is available for various purposes. In Sections II and III of this book, several distinct quantitative and qualitative evaluation methods have been presented and discussed in detail. All of them have their particular application area. However, in many situations, the evaluator may want to combine the methods to best answer the evaluation questions at hand. Especially in more formative (constructive) studies, a combination of methods may seem necessary to get a more complete picture of a situation. To support this, the method of triangulation has been developed and will now be presented in more detail.

THE THEORY OF TRIANGULATION

The term triangulation comes from navigation and means a technique to find the exact location of a ship base on the use of various reference points. Based on this idea, triangulation in evaluation means the multiple employments of data sources, observers, methods, or theories, in investigations of the same phenomenon (Greene & McClintock, 1985). This approach has two main objectives: First, to support a finding with the help of the others (validation); second, to complement the data with new results, to find new information, to get additional pieces to the overall puzzle (completeness; Knafl & Breitmayer, 1991).

Triangulation is, based on work by Denzin (1970), usually divided into the following four types, which can be applied at the same time:

- **Data triangulation:** Various data sources are used with regard to time, space, or persons. For example, nurses from different sites are interviewed, or questionnaires are applied at different times.
- **Investigator triangulation:** Various observers or interviewers with their own specific professional methodological background take part in the study, gathering and analyzing the data together. For example, a computer scientist and a social scientist analyze and interpret results from focus group interviews together.
- **Theory triangulation:** Data is analyzed based on various perspectives, hypotheses or theories. For example, organizational changes are analyzed using two different change theories.
- **Methods triangulation:** Various methods for data collection and analysis are applied. Here, two types are distinguished: within-method triangulation (combining approaches from the same research tradition), and between-method triangulation (combining approaches from both quantitative and qualitative research traditions, also called across-method triangulation). For example, two different quantitative questionnaires may be applied to access user attitudes, or group interviews as well as questionnaires may be applied in parallel.

It should be noticed that the term triangulation is only used when one phenomenon is investigated with regard to one research question.

The term triangulation is often seen strongly related to the term multimethod evaluation; because methods triangulation is seen as the most often used triangulation approach. However, as we want to stress, it is not limited on the combination of methods, but also describes combination of data sources, investigators, or theories.

Example: Triangulation during the Evaluation of a Nursing Documentation System

Background of the Study

Nursing documentation is an important part of clinical documentation. There have been some attempts and discussions on how to support the nursing documentation using computer-based documentation systems.

In 1997, Heidelberg University Medical Center started to introduce a computer-based nursing documentation system in order to systematically evaluate preconditions and consequences. Four different (psychiatric and somatic) wards were chosen for this study.

In the following paragraphs, we will concentrate on those parts of the study that are relevant for the triangulation aspects of the study. Please refer to other publications for more details on methods and results, such as (Ammenwerth, Mansmann, Iller, & Eichstädter, 2003; Ammenwerth et al., 2001).

Three of the four study wards had been selected by the nursing management for the study. On all three wards, the majority of nurses agreed to participate. Ward B volunteered to participate. The four study wards belonged to different departments. Wards A and B were psychiatric wards, with 21 resp. 28 beds; Ward C was a pediatric ward for children under two years of age, with

15 beds; Ward D was a dermatological ward, with 20 beds.

Our study wards were quite different with regard to nursing documentation. In Wards A and B, a complete nursing documentation based on the principles of the nursing process–for details on nursing process, see, for example, Lindsey and Hartrick (1996)–had been established for several years. In contrast, in Wards C and D, only a reduced care plan was documented; documentation was mostly conducted in the ward office. Only in Ward C, major parts of documentation were also conducted in the patients' rooms. The youngest staff member could be found in Ward D; the staff least experienced in computer use was in Ward C.

Study Design

The software PIK (Pflegeinformations-und Kommunikationssystem, a German acronym for "nursing information and communication system") was introduced on those four wards. The functionality covered the six phases of the nursing care process. The study period was between August 1998 and October 2001. Wards A and B started in 1998 with the introduction of the documentation system; Wards C and D joined in 2000.

The study consisted of two main parts: The objective of the more quantitative study was to analyze the changes in the nurses' attitudes with regard to nursing process, computers in nursing, and nursing documentation system, after the introduction of the computer-based system. Standardized, validated questionnaires were applied based on Bowman, Thompson, and Sutton (1983), for nurses' attitudes on the nursing process; on Nickell and Pinto (1986), for computer attitudes; on Lowry (1994), for nurses' attitudes on computers in nursing; and on Chin (1988) and Ohmann, Boy, and Yang (1997), for nurses' satisfaction with the computer-based nursing documentation system. We carefully translated those questionnaires into German and checked the understandability in a prestudy. We used a prospective intervention study with three time measurements: approximately three months before introduction ("before"); approximately three months after introduction ("during"); and approximately nine months after introduction ("after").

The second part of the study was a more qualitative study. Here, the objective was to further analyze the reasons for the different attitudes on the wards. The quantitative study exactly described these attitudes, and the qualitative study was now intended to further explain those quantitative results. The qualitative study was conducted in February 2002, after the analysis of the quantitative study was finished. In this qualitative study, open-ended focus group interviews were conducted with up to four staff members from each ward (most of them already have taken part in the quantitative study), with the three project managers from each department, and with the four ward managers from the wards. Open-ended means that the interviews were not guided by predefined questions. We used two general questions that started the interviews (e.g., "How are you doing with PIK?" "How was the introduction period")? The rest of the interview was mostly guided by the participants themselves, with relatively little control exerted by the interviewers.

All interviews were conducted by a team of two researchers. They took about one hour each. The interviews were audio taped and analyzed using inductive, iterative content analysis based on Mayring (1993). This means that the transcripts were carefully and stepwise analyzed, using the software WinMaxProf98.

In the following paragraphs, only those results of the quantitative and qualitative study relevant for the triangulation aspects of the study will be presented. Please refer to the already mentioned study publications for more details.

Results of Quantitative Analysis of User Attitudes

All in all, 119 questionnaires were returned: 23 nurses answered all three questionnaires, 17 nurses answered two, and 16 nurses answered one questionnaire. The return rates were 82% for the first questionnaire, 86.5% for the second questionnaire, and 90.2% for the third questionnaire. A quantitative analysis of the individual items of the questionnaires revealed unfavorable attitudes, especially in Ward C. In both Wards C and D, the nurses stated that the documentation system does not “save time” and does not “lead to a better overview on the course of patient care.” In addition, in Ward C, the nurses stated that they “felt burdened in their work” by the computer-based system and that the documentation system does not “make documentation easier.” In Wards A and B, the opinions with regard to those items were more positive.

The self reported daily usage of the computer-based documentation system was quite similar among all wards: about 1 to 2 hours a day during the second and third questionnaires, with highest values in Ward B and lowest values in Ward A. The self-confidence with the system, as stated by the nurses, was rather high on all wards during both the second and third questionnaire. The mean values were between 3 and 3.7 during the second questionnaire and between 3.4 and 3.8 during the third questionnaire (1=minimum, 4=maximum).

Statistical analysis revealed that the overall attitude on the documentation system during the third questionnaire was positively correlated to the initial attitude on the nursing process, to the attitude on computers in general and to the attitude on computers in nursing. Both computer attitude scores were in turn positively correlated to the years of computer experience. For details, see (Ammenwerth, Mansmann, et al., 2003).

Overall, the results of quantitative analysis pointed to a positive attitude on the computer-based nursing documentation already shortly after its introduction, which significant increase on three of the four wards later on. However, on ward C, the quantitative results revealed negative reactions, showing a heavy decline in the attitude scores during the second questionnaire. On ward C, the overall attitude of the computer-based system remained rather negative, even during the third questionnaire. What could be the reasons? In order to answer this question, a subsequent qualitative study was conducted.

Results of Qualitative Analysis of User Attitudes

This part of the study was conducted as planned. Overall, about 100 pages of interview transcript were analyzed. Details of the interviews are published elsewhere (Ammenwerth, Iller, et al., 2003); we will summarize only the main points.

In Ward C, some distinct features came up in the interviews that seem to have lead to low attitude scores at the beginning. For example, the nursing process had not been completely implemented before, thus the documentation efforts now were much higher. Documentation of nursing tasks covered a 24 hour day, due to the very young patients and their high need for care. Thus, the overall amount of documentation on Ward C was higher. Patient fluctuation was also highest in ward C. Nurses found it time-consuming to create a complete nursing anamnesis and nursing-care plan for each patient. The previous computer experience and number and availability of motivated key users was seen as rather low in Ward C. Then, during the introduction of the nursing documentation system, the workload was rather high in Ward C due to staff shortage, which increased pressure on the nurses. Finally, and most important, nursing documentation had previously at least partly been carried out in the patients’ rooms. However, during our study, computers were installed only in the ward office. No mobile computers were available, which, according to the nurses, lead to time-consuming and inefficient double documentation.

Interesting differences were found between the nurses and the project management. For example, the nurses stated in the interviews that they were not sufficiently informed on the new documentation system, while the project management stated to have offered information that had not been used. Another example is that the nurses felt that training was insufficient. In the opinion of the project management, sufficient opportunities had been offered. We will later see how this divergent information helps to complete the overall picture.

In Ward D, the attitude on the documentation system was high in the interviews. The nurses saw benefits, especially in a more professional documentation, which would lead to a greater acknowledgment of nursing. Standardized care planning was seen to make care planning much easier, without reducing the individuality of the patient. Overall, the ward felt at ease while working with the new documentation system.

In Wards A and B, the attitudes were also positive. The nurses stressed the better legibility of nursing documentation in the interviews. They said that time effort for nursing care planning was lower, but overall, time effort for nursing documentation was much higher than before. The interviews showed that the introduction period had been filled with anxiety and fear about new requirements for the nurses. Now, after some time, the nurses felt self-confident with computers. An interesting discussion arose on the topic of standardization. Most nurses felt that standardized care plans reduced the individuality of the care plans, and that they did not really reflect what is going on with the patient. Finally, those wards, too, mentioned insufficient teaching and support in the first weeks.

These rather short summaries, from the interviews, should highlight some distinct features of the wards, showing similarities (e.g., on insufficient teaching and fears at the beginning), but also differences (e.g., on the question on standardized care plans or time effort).

APPLICATION OF TRIANGULATION IN THIS STUDY

After analysis of the quantitative study and the qualitative study, we now want to see how the different results can be put together to get a broader picture of the effects and preconditions of a nursing documentation system. We thus applied all four types of triangulation as described by Denzin (1970):

- **Data triangulation:** Various data sources were used: Within the quantitative study, data triangulation with regard to time was used as the questionnaires were submitted three times to the same users (data triangulation with regard to time). In addition, in the interviews, not only nurses but also project management and ward management were interviewed (data triangulation with regard to persons).
- **Investigator triangulation:** Within the qualitative study, the two interviewers had different backgrounds (one more quantitative coming from medical informatics, the other, more qualitative, coming from social science). Both acted together as interviewers, analyzed the transcript together, and discussed and agreed on results and conclusions.
- **Theory triangulation:** We learned from various complementing theories to better understand the results of our studies. For example, to explain the implementation phases, we took ideas both from the book of Lorenzi and Riley (1995; first-, middle-, and second-order change) as well as from the change theory of (Lewin, 1947; unfreezing, moving, refreezing phase). With regard to user evaluation, we used the technology

acceptance model (TAM) of Davis (1993), and the task-technology-fit model (TTF) of Goodhue (1995).

- **Methods triangulation:** We applied between-methods triangulation by applying both quantitative questionnaires and qualitative focus-group interviews to investigate user's attitudes.

As stated in the introduction, triangulation has two main objectives: To confirm results with data from other sources (validation of results) and to find new data to get a more complete picture (completeness of results). We will now briefly discuss whether triangulation helped to achieve those goals.

Validation of Results

Validation of results is obtained when results from one part of the study are confirmed by congruent (not necessarily equal) results from other parts of the study. In our example, some parts of the study showed congruent results:

First, both the questionnaire and the interviews focused on attitudes issues. In this area, both approaches lead to congruent results, showing, for example, favorable attitudes in three wards. In addition, both the questionnaires and the interviews showed problems with regard to the user satisfaction with the nursing documentation system in Ward C. However, as the interviews were conducted later, they could better show the long-term development in the wards. Hence, both data sources thus showed congruent results.

Second, we found congruent results of the two scales attitudes on nursing process and attitude on the computer-based nursing documentation system within the standardized questionnaires. Both focus on different attitude items, both showed comparable low results in Ward C and higher results on the other wards, pointing to congruent measurements.

Those two selected examples show how results of some parts of the study could be validated by congruent results from other parts of the studies.

Completeness of Results

Besides validation, triangulation can increase completeness when one part of the study presents results which have not been found in other parts of the study. By this new information, the completeness of results is increased. The new information may be complementary to other results, or it may present divergent information.

In our study, both questionnaires and interviews presented partly complementary results, which led to new insights. For example, impact of the computer-based documentation system on documentation processes and communication processes had not been detected by the questionnaire (this aspect had not been included in the questions). However, the documentation system seems to have influenced the way different healthcare professionals exchanged patient-related information. This led to some discussion on this topic on all wards in the interviews and seems to have had an impact on the overall attitude. Those effects only emerged in the group interviews (and not in the questionnaires); enlarging the picture of the effects of the nursing documentation system and helping to better understand the reactions of the different wards.

Another example is the complementarity of the results in the interviews and questionnaires in Ward C. The interviews were done some time after the questionnaires. Thus, during this time, changes may have occurred. The change theory of Lewin (1947) stated that organizational changes occur in three phases: unfreezing (old patterns must be released, combined with insecurity and problems), moving (new patterns are tested), and refreezing (new patterns are internalized and seen as normal). The low attitude scores in Ward C, even at the last measurement point, indicate that the ward was in the moving phase during this time. During the interviews, the stress articulated by the nurses seems to be less severe. This can be interpreted as Ward C's slowly changing from the moving into the refreezing phase.

Triangulation can thus help to get a more complete picture of the object under investigation. Often, especially when applying various methods during the investigation, the results will not be congruent, but they may be divergent (e.g., contradictory). This is an important aspect of triangulation, as divergent results can especially highlight some points, present new information, and lead to further investigation.

In our study, we found some divergent results. For example, during the group interviews, nurses from one ward stressed that they do not see a reduction in effort needed for documentation by the computer-based system. However, in the questionnaires, this ward indicated strong time reductions. This differences can lead to the questions of whether time efforts are judged with regard to the situation without the nursing documentation system (where the amount of documentation was much lower, and so was the time effort), or with regard to the tasks that have to be performed (the same amount of documentation can be done much quicker with the computer-based system). This discussion can help one better understand the answers. Interesting differences of point of view could also be found between the staff and the project management of one ward in the group interviews. While the nurses of this ward claimed in the interviews that training was suboptimal, the project management stated that sufficient offers had been made. Those apparent contradictions may point to different perceptions of the need for training by the different stakeholders. Those insights may help to better organize the teaching on other wards.

As those (selected) examples show, triangulation helped us to obtain a better picture of the reaction of the four wards. The evaluation results also led to some decision on how to improve the technical infrastructure as well as how to better organize the teaching and support in some wards. All wards are still working with the computer-based nursing documentation system.

DISCUSSION

Medical informatics is an academic discipline and, thus, evaluation is an important part of any system development and implementation activity (Shahar, 2002; Talmon & Hasmann, 2002). However, many problems with regard to healthcare IT evaluation have been reported. Wyatt and Spiegelhalter (1992) as well as Grémy and Degoulet (1993) already discussed the complexity of the field, the motivation issue, and methodological barriers to evaluation. Examples of meta-analysis of IT evaluation studies confirm those barriers (e.g. Brender, 2002; Johnston, Langton, Haynes, & Mathieu, 1994; Kaplan, 2001).

In this chapter, we elaborated on a number of important problems and categorized them into three areas: the complexity of the evaluation object, the complexity of the evaluation project with its multitude of stakeholders, and the motivation for evaluation.

A kind of framework to support evaluation studies of ISs may be useful to address the problem areas discussed in this chapter. In fact, many authors have formulated the necessity for such a framework (e.g., Grant, Plante, & Leblanc, 2002; Shaw, 2002). Chapter XIV will present a framework for evaluation in more detail. One important part of such a framework is the call for a multimethod evaluation. While triangulation has long been discussed and applied in research (one of the first being Campbell & Fiske, 1959), the idea of the possible advantages of multimethod approaches or triangulation in more general terms is not really reflected in medical informatics literature.

The background of multimethod approaches has been more deeply discussed in Chapter XII.

In general, both quantitative and qualitative methods have their areas and research questions where they can be successfully applied. By triangulating both approaches, their advantages can be combined. We found that both complementary and divergent results from the different sources gave important new information and stimulation of further discussion.

In the past, there has been a more basic discussion about whether intermethods triangulation is possible at all. It is discussed that the epistemological underpinnings between quantitative and qualitative research paradigms may be so different that a real combination may not be possible (Greene & McClintock, 1985; Sim & Sharp, 1998). However, this argumentation is not taking into account that a tradition of research has formed beyond subjectivistic and objectivistic paradigms. Evaluation methods are chosen accordingly to research questions and the research topic. Thus, the question of which methods to apply and how to combine them only can be answered with respect to the research topic and the research question and not on a general basis. Thus, as important as this discussion might be in the light of progress in research methods, evaluation researchers in medical informatics may be advised to start to select and combine methods based on their distinctive research question. This gives evaluation researchers a broad range of possibilities to increase both completeness and validity of results, independent of his or her research tradition.

CONCLUSIONS

Evaluation studies in healthcare IT take a lot of time, resources, and know-how. Clearly defined methodological guidelines that take the difficulties of IS evaluation in healthcare into account may help to conduct better evaluation studies. This chapter has classified some of the problems encountered in healthcare IT evaluation under the three main problem areas of a) complexity of the evaluation object, b) complexity of the evaluation project, and c) limited motivation for evaluation. We suggested a list of 12 essential recommendations to support the evaluation of ISs. A broadly accepted framework for IT evaluation in healthcare that is more detailed seems desirable, supporting the evaluator during planning and executing of an evaluation study.

Focusing on methodological aspects, we have presented some basics on triangulation and illustrated them in a case study. The correct application of triangulation requires–as other evaluation methods–training and methodological experience. Medical informatics evaluation research may profit from this well-established theory.

Chapter 1.2
Assessing E-Health

The Cleveland Clinic, USA

ABSTRACT

While healthcare is the biggest service industry on the globe, it has yet to realize the full potential of the e-business revolution in the form of e-health. This is due to many reasons, including the fact that the healthcare industry is faced with many complex challenges in trying to deliver cost-effective, high-value, accessible healthcare and has traditionally been slow to embrace new business techniques and technologies. Given that e-health to a great extent is a macro-level concern that has far reaching micro-level implications, this chapter first develops a framework to assess a country's preparedness with respect to embracing e-health (i.e., the application of e-commerce to healthcare) and from this, an e-health preparedness grid to facilitate the assessment of any e-health initiative. Taken together, the integrative framework and preparedness grid provide useful and necessary tools to enable successful e-health initiatives to ensue by helping country and/or organization within a country to identify and thus address areas that require further attention in order for it to undertake a successful e-health initiative.

INTRODUCTION

Technology has the potential to help solve many of the problems faced by developed and developing countries alike; from improving healthcare delivery to opening up commerce opportunities. The number of nations offering e-commerce solutions is increasing every year, and consequently the number of workplaces that have Internet connection for business activities has been rapidly growing worldwide. Table 1 provides three estimates of e-commerce forecasts. These projections clearly highlight the important role of e-commerce on the global economy. However, as the Secretary General of the United Nations notes in his forward to the e-commerce and development report (UNCTAD, 2002), "knowing that an instrument is powerful is not enough to ensure that it will be put to the best use. We need to understand how it works, and how and when it should be used … and maximize its power."

Within the umbrella of e-commerce, one area, e-health, has yet to reach its full potential in many developed countries, let alone developing countries. Each country is positioned differently and has varying potential and preparedness regarding embracing e-commerce technologies generally and e-health in particular. Given the macro-level nature of many issues pertaining to the development of e-health (Alvarez, 2002), in order to be more effective in their e-health initiatives, it is important for countries to assess their potential, identify their relative strengths and weaknesses, and thereby develop strategies and policies to address these issues to effectively formulate and implement appropriate e-health initiatives. To do this effectively, it is valuable to have an integrative framework that enables the assessment of a country's e-health preparedness. This chapter proposes to develop such a framework that can be applied to various countries throughout the globe and from this to generate an e-health preparedness grid. In so doing, we hope to facilitate better understanding of e-health initiatives and thus maximize their power.

E-HEALTH

Reducing healthcare expenditure as well as offering quality healthcare treatment is becoming a priority globally. Technology and automation have the potential to reduce these costs (Institute of Medicine, 2001; Wickramasinghe, 2000), thus, e-health, which essentially involves the adoption and adaptation of e-commerce technologies throughout the healthcare industry (Eysenbach, 2001), appears to be a powerful force of change for the healthcare industry worldwide.

Healthcare has been shaped by each nation's own set of cultures, traditions, payment mechanisms, and patient expectations. Therefore, when looking at health systems throughout the world, it is useful to position them on a continuum ranging from high government involvement (i.e., a public healthcare system) at one extreme, to little government involvement (i.e., private healthcare system) at the other extreme, with many variations of a mix of private–public in between. However, given the common problem of exponentially increasing costs facing healthcare globally, irrespective of the particular health system one examines, the future of the healthcare industry will be partially shaped by commonalties such as the universal issue of escalating costs and the common forces of change including a) empowered consumers, b) e-health adoption and adaptability, and c) shift to focus on the practice of preventative versus cure driven medicine, as well as four key implications,

namely a) health insurance changes, b) workforce changes and changes in the roles of stakeholders within the health system, c) organizational changes and standardization, and d) the need for healthcare providers and administrators to make difficult, yet necessary choices regarding practice management.

E-health is a very broad term that encompasses various activities related to the use of many e-commerce technologies and infrastructures, most notably the Internet, for facilitating healthcare practice. The World Health Organization (WHO, 2003), a major world health body, defines e-health as "being the leveraging of the information and communication technology (ICT) to connect provider and patients and governments; to educate and inform health care professionals, managers and consumers; to stimulate innovation in care delivery and health system management; and, to improve our healthcare system". In contrast, a technologically oriented definition of e-health is offered by Intel, which refers to e-health as "a concerted effort undertaken by leaders in healthcare and hi-tech industries to fully harness the benefits available through convergence of the Internet and healthcare".

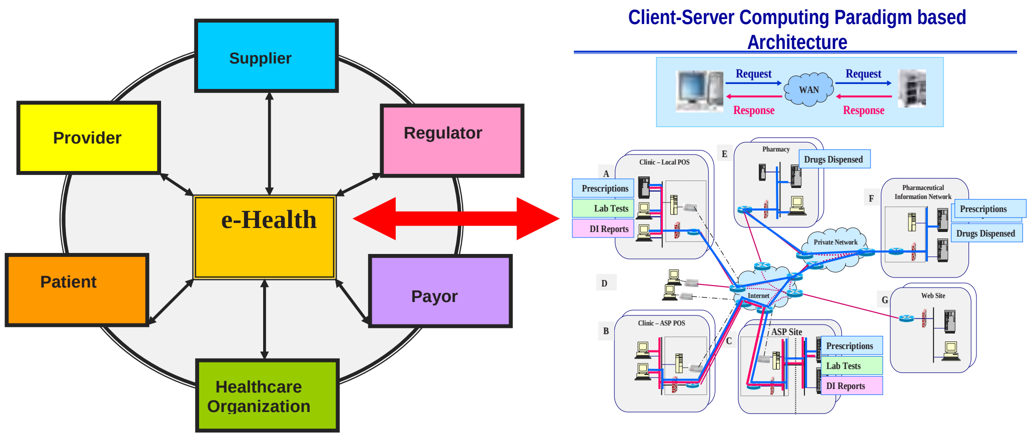
Health professionals are increasingly being drawn into evaluating the Internet as a source of consumer information for health and medicine. Practitioners report that a growing number of patients arrive at their offices either with questions related to appropriate Web sites to visit or a large variety of health-related content gathered from the Internet. Some of this content may prove extremely helpful to the health and/or recovery of a patient. Because the Internet has created new opportunities and challenges to the traditional healthcare information technology industry, the advent of e-health seems fitting to address both these opportunities and challenges. The new possibilities for facilitating effective healthcare delivery fall primarily into the following main categories: a) the capability of healthcare consumers to interact with their providers online (B2C = "business to consumer"), b) the possibility to improve healthcare institution-to-institution transmissions of data (B2B = "business to business"), and c) The new possibilities for peer-to-peer communication of healthcare consumers (C2C = "consumer to consumer").

A more comprehensive definition of e-health would need to incorporate the healthcare, business, and technological perspectives; hence we define e-health as an emerging field at the intersection of medical informatics, technology, public health, and business. Thereby, e-health entails the delivery of health services and health information through the Internet and other related e-commerce technologies. In a broader sense, the term characterizes not only a technical development, but also a state-of-mind, a paradigm shift, and a commitment for networked global thinking to improve healthcare locally, regionally, and globally by using information and communication technologies (Geisler,1999).

WEB OF PLAYERS IN HEALTHCARE

Figure 1 depicts the Web of healthcare players and the key elements of the e-health architecture that serves to support the interactions between and within this Web of players. What is of particular importance when trying to assess e-health initiatives is a) it is imperative to understand the implications of any e-health initiative on all the players who make up this Web, and b) to realize the full potential of the Internet or Web-based technologies that make up the IT architecture so that the most effective and efficient e-health initiative is, in fact, designed and implemented. To get a better appreciation for this we must first understand the traditional competitive forces affecting any organization and then the role of the Internet in impacting these forces (Geisler, 2001).

Figure 1. Web of e-health players (Source: Wickramasinghe et al., 2004)



TRADITIONAL COMPETITIVE FORCES

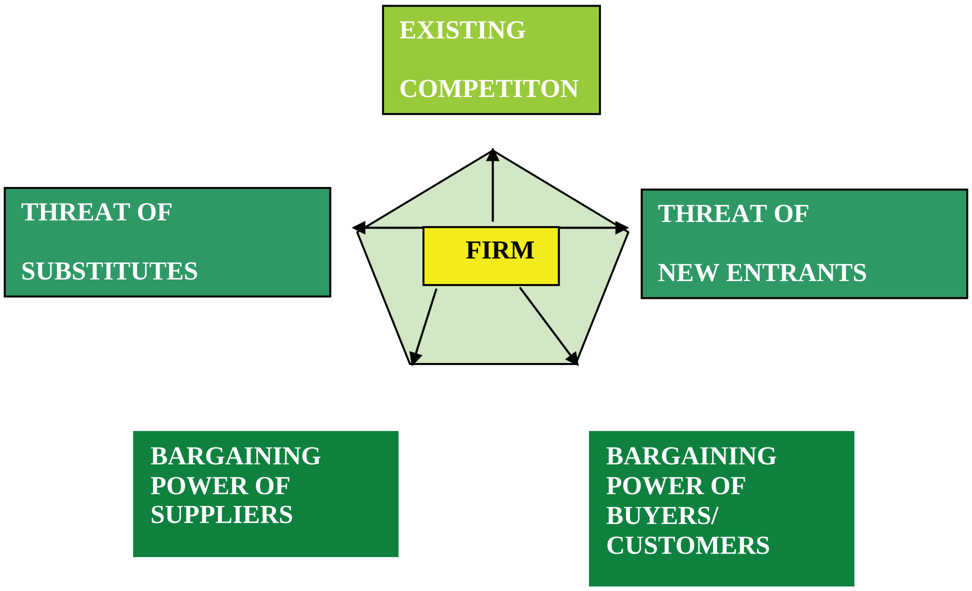
The strategy of an organization has two major components (Henderson & Venkatraman, 1993). These are a) formulation-making decisions regarding the mission, goals and objectives of the organization, and b) implementation-making decisions regarding how the organization can structure itself to realize its goal and carryout specific activities. For today's healthcare organizations, the goals, mission and objectives all focus around access, quality and value and realizing this value proposition for healthcare then becomes the key (Wickramasinghe et al., 2004). Essentially, the goal of strategic management is to find a "fit" between the organization and its environment that maximizes its performance (Hofer, 1975). This then describes the market-based view of the firm, developed by Michael Porter (1980). The first of Porter's frameworks is the generic strategies.

The use of technology must always enable or enhance the businesses objectives and strategies of the organization. This is particularly true for 21st century organizations, where many of their key operations and functions are so heavily reliant on technology and the demand for information and knowledge is so critical. A firms' relative competitive position (i.e., its ability to perform above or below the industry average) is determined by its competitive advantage. Porter (1980) identified three generic strategies that impact a firm's competitive advantage. These include cost, focus, and differentiation. Furthermore, Porter (1980) noted that two, and only two, basic forms of competitive advantage typically exist: cost leadership and differentiation.

Firms can use these two forms of competitive advantage to either compete across a broad scope of an industry or to focus on competing in specific niches, thereby leading to three generic strategies. Porter (1980) noted that firms should be cautious about pursuing more than one generic strategy, namely cost, differentiation, and focus. For example, if a cost leadership strategy is adopted, it is unlikely that a firm can also maintain and sustain differentiation, because it would not be possible to simultaneously pursue the costly capital investment or maintain high operating costs required for differentiation and, thus, in the long run, the firm has a confused strategy which leads to failure.

In order to design and develop one's strategy, an organization should first perform an industry analysis. Porters five forces (or competitive forces) model is most useful (Porter, 1980, 1985). Figure 2 depicts this model. Essentially, Porter has taken concepts from microeconomics and modeled them

Figure 2. Porter's competitive (five) forces model



in terms of five key forces that together outline the rules of competition and attractiveness of the industry.

The forces are as follows:

1. **Threat of new entrant:** a company new to the industry that could take away market share from the incumbent firms
2. **Threat of substitute:** an alternative means that could take market share from product/ service offered by the firms in the industry
3. **Bargaining power of buyers:** the strength of buyers or groups of buyers within the industry relative to the firms
4. **Bargaining power of suppliers:** the strength of suppliers relative to the firms in the industry
5. **Rivalry of existing competition:** relative position and market share of major competitors

The collective strength of these five forces determines the attractiveness of the industry and thus the potential for superior financial performance by influencing prices, costs, and the level of capital investment required (Porter, 1985). Once a thorough industry analysis has occurred, it is generally easier for a firm to determine which generic strategy makes most sense for it to pursue and enables the firm to exploit most of its core competencies in its existing environment.

In this chapter we propose the application of Porter's (1985) five forces model to the Web of e-health players shown in Figure 1. Healthcare delivery organizations and the industry that supports them are competing and cooperating for patients and resources. They compete as suppliers of services, technology, and other industrial resources. This competition is among the entities in the healthcare sector as well as with organizations in other industries. The Web of e-health serves as an instrument that mediates the relations among the five forces (Geisler, 1999). This in turn creates several opportunities for the organizations involved to improve and enhance their abilities to navigate the competitive environment of their industry.

Table 2. The three e-opportunity domains and their components

Domain	Components
e-operations	• Automation of administrative processes • Supply-chain reconfiguration • Reengineering of primary infrastructure • Intensive competitive procurement • Increased parenting value
e-marketing	• Enhanced selling process • Enhance customer usage experience • Enhanced customer buying experience
e-services	• Understanding of customer needs • Provision of customer service • Knowledge of all relevant providers • Negotiation of customer requirements • Construction of customer options

ROLE OF THE INTERNET OF THE COMPETITIVE FORCES

Feeny (2001) presented a framework that highlights the strategic opportunities afforded to organizations by using the Internet. In particular, he highlights three e-opportunity domains. Table 2 details these domains and their respective components.

E-OPPORTUNITIES IN HEALTHCARE

Given the three areas of e-opportunities discussed previously, Glaser (2002) identified several key e-opportunities for healthcare, detailed in Table 3.

The Goals of E-Health

The preceding definition of e-health is broad enough to capture the dynamic environment of the Internet and at the same time acknowledge that e-health encompasses more than just "Internet and Medicine." Thus, e-health strives to achieve many goals beyond the use of the Internet. These goals, taken together perhaps best characterize what e-health is all about (or what it should be about; JMIR, 2003). Some of these goals of e-health include the following:

- **Efficiency:** One of the promises of e-health is to increase efficiency in heathcare, thereby decreasing costs. One possible way of decreasing costs would be by avoiding duplicative or unnecessary diagnostic or therapeutic interventions, through enhanced communication possibilities between healthcare establishments and through patient involvement (Health Technology Center, 2000). The Internet will naturally serve as an enabler for achieving this goal in e-health.
- **Quality of care:** Increasing efficiency involves not only reducing costs, and thus is not an end in and of itself but rather should be considered in conjunction with improving quality one of the ultimate goals of e-health.

Table 3. The e-opportunities for healthcare organizations

Domain	Components
e-operations	• Internet-based supply purchasing • Prescription writing, formulary checking, and interaction checking using hand-held devices
e-marketing	• Delivery of consumer health content and wellness management tools over the Internet • Use of consumer health profiles to suggest disease management and wellness programs
e-services	• Patient-provider communication and transaction applications • Web-based applications to support the clinical conversation between referring and consulting physicians
Crossing multiple domains	• Increasing the level of information content in the product • Increasing the information intensity along the supply chain • Increase in the dispersion of information

A more educated consumer (as a result of the informational aspects of e-health) would then communicate more effectively with their primary care provider which will, in turn, lead to better understanding and improved quality of care.

- **Evidence-based:** E-health interventions should be evidence-based in the sense that their effectiveness and efficiency should not be assumed but proven by rigorous scientific evaluation and support from case histories. Web-accessible case repositories facilitate the timely accessibility of such evidence and thus help in achieving the necessary support of a diagnosis or treatment decision. The evidence-based medicine goal of e-health is currently one of the most active e-health research domains, yet much work still needs to be done in this area.
- **Empowerment of consumers and patients:** By making the knowledge bases of medicine and personal electronic records accessible to consumers over the Internet, e-health opens new avenues for patient-centered medicine, enables patient education and thus increases the likelihood of informed and more satisfactory patient choice (Umhoff & Winn, 1999).
- **Education:** The education of physicians through online sources (continuing medical education) and consumers (health education, tailored preventive information for consumers) makes it easier for physicians as well as consumers to keep up to date with the latest developments in the medical areas of their respective interests. This, in turn, is likely to have a positive impact on the quality of care vis-à-vis the use of the latest medical treatments and preventive protocols.
- **Extending:** Extending the scope of healthcare beyond its conventional boundaries, in both a geographical sense as well as in

a conceptual sense, leads to enabling such techniques as telemedicine and virtual operating rooms, both of which are invaluable in providing healthcare services to places where it may otherwise be difficult or impossible to do.

- **Ethics:** E-health involves new forms of patient-physician interaction and poses new challenges and threats to ethical issues such as online professional practice, informed consent, privacy and security issues (Healthcare Advisory Board, 2002). However, this is not an intrinsic feature of e-health but rather a feature of the Internet technology which is the foundation for all e-business initiatives, therefore, e-health along with e-government, e-insurance, e-banking, e-finance, and e-retailing must all contend with these ethical issues. Given the nature of healthcare, these issues could be more magnified.
- **Equity:** To make healthcare more equitable is one of the aims of quality generally identified by the American Institute of Medicine (Institute of Medicine, 2001) and is one of the goals of e-health. However, at the same time there is a considerable threat that e-health, if improperly implemented and used, may deepen the gap between the haves and the have nots, hence the need for a robust framework to ensure the proper implementation of e-health initiatives. In particular, some of the key issues for equity revolve around broad access and familiarity with the technology.

Today, a large number of patients and consumers already use the Internet to retrieve health-related information, to interact with health providers, and even to order pharmaceutical products (for example drugstore.com). For example, it has been noted that "the number of Medline searches performed by directly accessing the database at the National Library of Medicine increased from 7 million in 1996 to 120 million in 1997, when free public access was opened; the new searches are attributed primarily to non-physicians" (JMIR, 1999). Thus, the Internet will act as a catalyst for evidence based medicine in particular and e-health generally in two ways: First, it enables health professionals to access timely evidence. Second, it enables consumers to draw from the very same knowledge base, leading to increased pressure on health professionals to actually use the evidence (PWC, 2003).

Key Challenges of E-Health

By 2005, 88.5 million adults will use the Internet to find health information, shop for health products, and communicate with affiliated payers and providers through online channels, according to Cyber Dialogue (PWC, 2003). Today, the e-health consumer demand includes the need for specific health services, such as obtaining information when faced with a newly established diagnosis.

Many key challenges must be addressed to develop optimal partnerships between consumers and other groups of healthcare stakeholders. Some of these include the need for:

- Meaningful collaboration with healthcare recipients,
- Efficient strategies and techniques to monitor patterns of Internet use among consumers,
- Preparation for upcoming technological developments,
- Balancing between connectivity and privacy,
- Better understanding of the balance between face-to-face and virtual interactions, and
- Equitable access to technology and information across the globe.

When we consider the domain of e-health at the macro level, three important issues must be carefully considered (Cyber Dialogue, 2001);

namely, Procurement, Connectivity, and Benefits. We briefly discuss each in turn.

E-Procurement

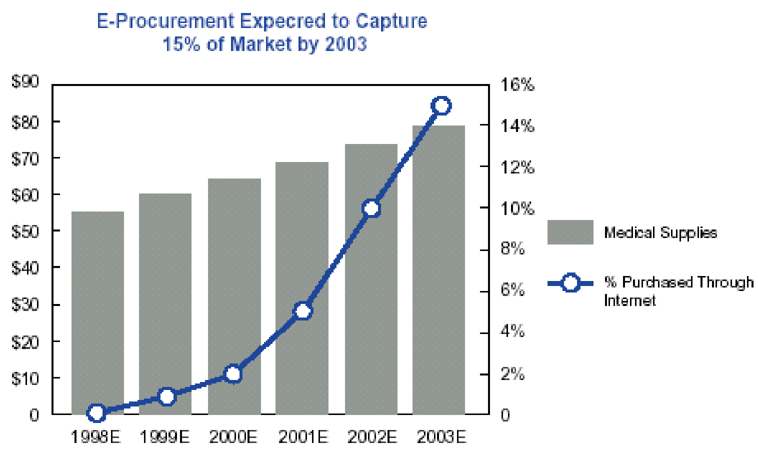
Health systems must begin to contemplate how their organizations will adapt and leverage Internet-based tools to manage their medical supply chains. Procurement in healthcare supplies must move toward an e-business platform for data interchange because of the ubiquity and cost effectiveness of the Internet, the primary e-business platform. The Internet decreases many of the restrictions placed by geographic and time barriers and also facilitates the use of incorporating artificial intelligence solutions, such as intelligent agents that can be deployed to hunt for best buys. Buyers and suppliers also must work together toward standardization, including the development of a universal product numbering system to facilitate e-procurement. As shown in Figure 3, e-procurement of medical supplies is estimated to grow to 15% of medical supply spending in the U.S. by 2003, according to a Deutsche Bankreport (PWC, 2003)

E-Connectivity

Healthcare has traditionally been locally delivered because a patient's usual first port of call is their local primary care physician. To reorient such a tradition, connectivity companies, which on the other hand have a global rather than local focus, must be pragmatic and move in incremental steps when connecting healthcare organizations. Technology is the integral tool, but it will not achieve its full potential or live up to its promise unless healthcare organizations successfully deploy it and then keep track of their clinicians' and administrative workers' effective use of it. To do so, managers must design processes and metrics for productivity; otherwise, it is like expecting someone to drive a car when his or her experience is limited to a 10 speed bicycle. However, healthcare organizations will find that achieving Web-enabled connectivity offers the most opportunity initially, and that other functions such as disease management, outcomes management, and demand management can be Web-enabled later.

Health plans and hospitals are beginning to migrate to the Internet for claims-related transactions as the first step of a broader Internet strategy. This

Figure 3. Estimated U. S. medical e-procurement market sales (Source: Dialog Cybercitizen Health Trend Report [Re. No. 49], by Odyssey Research, 2003. Available online from www.odysseyresearch.org)



is illustrated in Figure 4. Because many organizations continue to use EDI for claims submissions, transactions surrounding claims (e.g., eligibility, referrals) will thus logically be the first to be targeted for e-health connectivity. Those health plans that are adopting Internet connectivity for these functions view them as the foundation on which to build other Internet-enabled partnerships with patients and providers.

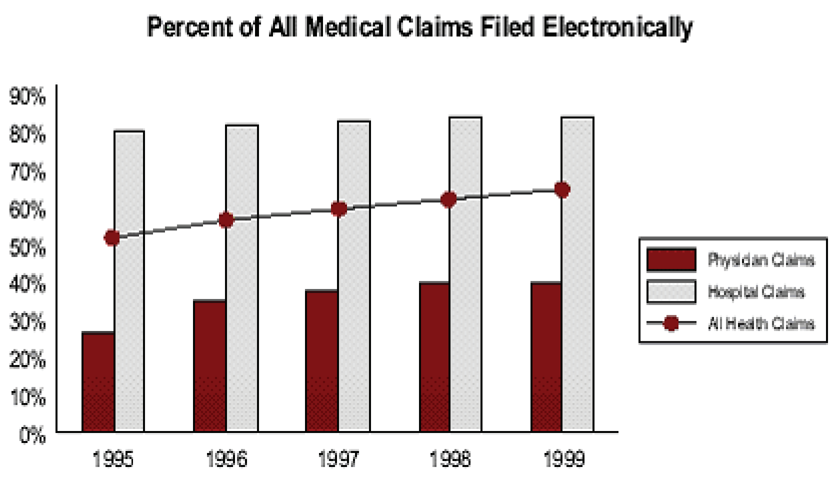
The number of healthcare transactions is outpacing the growth of health spending, creating a critical need to automate the handling of such transactions through the adoption of e-health. The number of claims submitted increased by about 7% during the past five years, according to the Health Data Directory. In contrast, healthcare spending has increased at between 5% and 6% during the same period (ibid). Many of the functions associated with claims submissions and payment are repetitive tasks that are more efficiently done by computers. The most expensive processes are not the claims submissions themselves, but the tasks surrounding the claims processing, such as eligibility checks and referrals. Coupled with increasing labor shortages, there is an urgent need for healthcare organizations to reengineer their processes.

Health plans must understand physicians' needs when designing Internet-based solutions and that first-mover advantage is not as important as a system that works. Many non-healthcare organizations have benefited from first-mover advantage in adopting e-commerce initiatives, which means they had access to the most capital, the best partners and could establish solid brand recognition. However, this is not necessarily an appropriate strategy for healthcare as healthcare is more pragmatic and a "show-me" industry where successful models replicate specialty by specialty.

E–Benefits

American industry has discovered the benefits of e-business. Like the conundrum of the chicken and the egg, many employers and health plans are awaiting the development and implementation of e-benefits and e-insurance products. Health plans do not want to deliver Web-based products if employers are not ready to use them. Employers

Figure 4. Increase in the percentage of electronically filed claims (Source: Dialog Cybercitizen Health Trend Report [Re. No.. 49], by Odyssey Research, 2003. Available online from www.odysseyresearch.org)



cannot deliver e-benefits products until health plans develop them. However, starting with online benefits enrollment, this aspect of e-health is evolving in stages. A by-product of this evolution is the fusion of employee responsibility and empowerment; hence, employers will gradually cede more control for health benefits to employees themselves. One of the primary drivers of e-benefits is delivery of self-service capabilities in which employees can customize their own insurance plans and have ready access to them, just as they do with their brokerage accounts. By putting this information at their fingertips, employees may become more fiscally responsible about those benefits. Ultimately, they may want complete control over more and more aspects of their benefits. To empower employees toward that end, some employers will have to embrace a defined contribution model, also called self-directed or consumer-directed health plans. This builds on the findings of the report "Defined Contribution Healthcare," which specifically discusses the various models of defined contribution health plans (ibid).

The national research conducted by PricewaterhouseCoopers (PWC, 2003) indicated that few employers are willing to adopt self-directed, otherwise known as defined contribution, health plans today, but will more likely move incrementally toward Web-enabling benefits processing and hence shifting more responsibility to employees. As employers adopt more e-health initiatives and Web-enabled functions, they will move more responsibility for choices to employees. As that balance of responsibility tips towards the employees, employers will need to assess how ready their workforce is to accept increasing levels of responsibility (Geisler, 2000).

If a significant portion of the healthcare insurance market moves to self-directed and Internet health benefit accounts, physicians may be most directly and adversely affected. Some contribution health plans have medical savings accounts as a centerpiece. In these accounts, employees pay out of a medical savings account for routine expenses up to $1,500 or $2,000. Physicians will need to contend with patients who are paying cash for their visits and who may shop around for the best value. Figure 5 shows the statistics of the probability of customers using the Internet when they have accessibility to PCs.

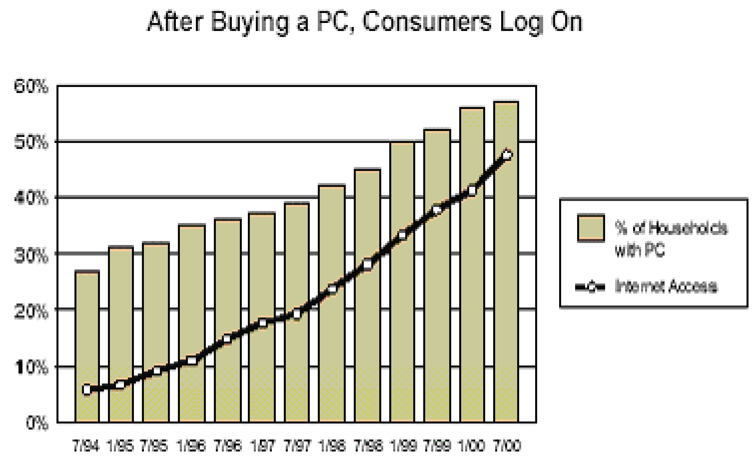
As the utility function of benefits moves toward the Internet, insurers must then develop products that serve new and existing customers, such as e-quote products that assist brokers and other intermediaries. Further, they also must follow the changing needs of consumers whose response to defined contribution health products is to date largely untested.

In summary then, the effective addressing of the key e-health issues of procurement, connectivity, and benefits requires standardization, a pivotal prerequisite for the implementation of successful e-health initiatives. Without such standardization the exchange of documents and other procurement information, connectivity, and e-commerce enabled benefits clearly become more problematic. Unfortunately, standardization is woefully lacking in too many areas of healthcare, let alone e-health. Given the opportunities for e-health to benefit various aspects of healthcare and the far reaching impact of any such e-health initiative, it becomes imperative then to have frameworks and models that not only bring to the forefront the key e-health issues but also provide guidelines for how to effectively bring to bear successful e-health initiatives for all healthcare organizations.

A FRAMEWORK FOR ASSESSING E-HEALTH POTENTIAL

We propose the framework shown in Figure 6 to assess the e-health potential and preparedness of countries. Healthcare polices are generally developed to a large extent at a macro, country level and thus we believe it is also necessary when

Figure 5. Internet usage among customers (Source: Dialog Cybercitizen Health Trend Report (Re. No.. 49), by Odyssey Research, 2003. Available online from www.odysseyresearch.org)



looking at e-health to first take a macro perspective and analyze the level of the country in terms of embracing e-health. The framework highlights the key elements that are required for successful e-health initiatives and therefore provides a tool that allows analysis beyond the quantifiable data into a systematic synthesis of the major impacts and prerequisites. The framework contains four main prerequisites, four main impacts, and the implications of these prerequisites and impacts to the goals of e-health. By examining both the prerequisites and the impacts, we can assess the potential of a country and its preparedness for e-health as well as its ability to maximize the goals of e-health. We discuss the prerequisites next.

PREREQUISITES FOR E-HEALTH

As can be seen in Figure 6, the four critical prerequisites for any successful e-health initiative include information communication technology (ICT) architecture/infrastructure, standardized policies, protocols and procedures, user access and accessibility policies and infrastructure, and, finally, government regulation and control. These will now be briefly discussed in turn.

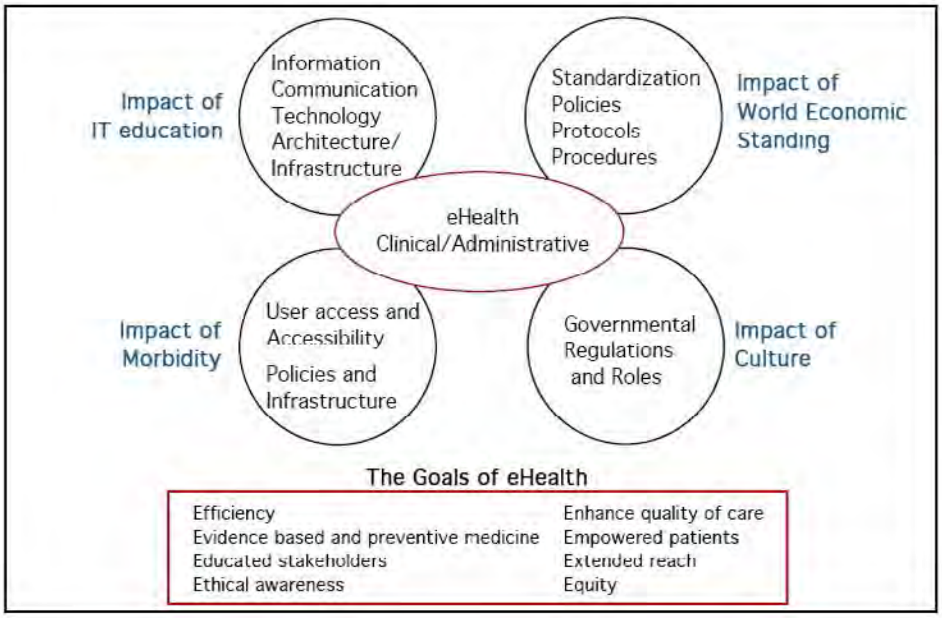
ICT Architecture/Infrastructure

The generic architecture for most e-health initiatives was depicted in Figure 1. To support such a client-server architecture special attention must be paid to the ICT infrastructure.

The ICT infrastructure includes phone lines, fiber trunks, and submarine cables, T1, T3 and OC, ISDN, DSL and other high-speed services used by businesses as well as satellites, earth stations, and teleports. A sound technical infrastructure is an essential ingredient to the undertaking of e-health initiatives by any nation. Such infrastructures should also include telecommunications, electricity, access to computers, number of Internet hosts, number of Internet Service Providers (ISPs), and available bandwidth and broadband access. To offer a good multimedia content and thus provide a rich e-health experience, one would require a high bandwidth. ICT considerations are undoubtedly one of the most fundamental infrastructure requirements.

Networks are now a critical component of the business strategies for organizations to compete globally. Having a fast microprocessor-based computer at home has no meaning unless you have high bandwidth-based communication in-

Figure 6. A framework for assessing a country's/region's e-health potential



frastructure available to connect computers with the ISP. With the explosion of the Internet and the advent of e-commerce, global networks need to be accessible, reliable, and fast to participate effectively in the global business environment. Telecommunications is a vital infrastructure for Internet access and hence for e-commerce. One of the pioneering countries in establishing a complete and robust e-health infrastructure is Singapore which is in the process of wiring every home, office and factory up to a broadband cable network which will cover 98% of Singaporean homes and offices (ibid).

Standardization Policies, Protocols and Procedures

E-health by definition spans many parties and geographic dimensions. To enable such a far-reaching coverage, significant amounts of document exchange and information flows must be accommodated. Standardization is the key for this. Once a country decides to undertake e-health initiatives, standardization polices, protocols and procedures must be developed at the outset to ensure the full realization of the goals of e-health. Fortunately, the main infrastructure of e-health is the Internet that imposes the most widely and universally accepted standard protocols such as TCP/IP and hypertext transfer protocol. It is the existence of these standard protocols that has led to the widespread adoption of the Internet for e-commerce applications.

The transformation to e-health by any country cannot be successfully attained without the deliberate establishment of standardization policies, protocols, and procedures that play a significant role in the adoption of e-health and the reduction of many structural impediments (Samiee, 1998).

User Access and Accessibility Policies and Infrastructure

Access to e-commerce is defined by the World Trade Organization (WTO) as consisting of two critical components: a) access to Internet services and b) access to e-services (Panagariya, 2000); the former deals with the user infrastructure, while the latter pertains to specific commitments to electronically accessible services. The user infrastructure includes number of Internet hosts and number of Web sites, Web users as a percent of the population as well as ISP availability and costs for consumers, PC penetration level, and so forth. Integral to user infrastructure is the diffusion rate of PCs and Internet usage. The United States and the United Kingdom have experienced the greatest penetration of home computers (Samiee, 1998). For developing countries such as India and China there is, however, a very low PC penetration and teledensity. In such a setting it is a considerable challenge then to offer e-health, since a large part of the population is not able to afford to join the e-commerce bandwagon. Countries thus have to balance local call charges, rentals, subscription charges, and so forth, otherwise the majority of citizens will find these costs a disincentive. This is particularly significant for developing and emerging nations where access prices tend to be out of reach for most of the population. Upcoming new technologies hold the promise to increase the connectivity as well as affordability level, and developing countries will need to seriously consider these technologies. In addition to access to PCs and the Internet, computer literacy is important and users must be familiar not only with the use of computers and pertinent software products but also the benefits and potential uses of the Internet and World Wide Web (ibid).

Governmental Regulation and Control

The key challenges regarding e-health use include a) cost effectiveness (i.e., less costly than traditional healthcare delivery), b) functionality and ease of use (i.e., they should enable and facilitate many uses for physicians and other healthcare users by combining various types and forms of data as well as be easy to use), and c) they must be secure. One of the most significant legislative regulations in the United States is the Health Insurance Portability and Accountability Act (HIPAA; Protegrity, 2001).

Given the nature of healthcare and the sensitivity of healthcare data and information, it is incumbent on governments not only to mandate regulations that will facilitate the exchange of healthcare documents between the various healthcare stakeholders but also to provide protection of privacy and the rights of patients. Some countries, such as China and Singapore, even control access to certain sites for moral, social, and political reasons while elsewhere transnational data flows are hindered by a plethora of regulations aimed at protecting domestic technology and related human resource markets (Goff, 1992; Gupta, 1992; Samiee, 1998). Irrespective of the type of healthcare system (i.e., whether 100% government driven, 100% private, or a combination thereof), it is clear that some governmental role is required to facilitate successful e-health initiatives.

The significance of the preceding four prerequisites on e-health initiatives will be modified by the impacts of IT education, morbidity, cultural-social dimensions, and world economic standing, as elaborated upon in the following sections.

Key Impact of E-Health

Figure six highlights four key impacts of e-health, which we now discuss in turn.

Impact of IT Education

A sophisticated, well-educated population boosts competition and hastens innovation. According to Michael Porter, one of the key factors to a country's strength in an industry is strong customer support (Porter, 1990). Thus, a strong domestic market leads to the growth of competition, which leads to innovation and the adoption of technology-enabled solutions to provide more effective and efficient services, such as e-health and telemedicine. As identified previously, the health consumer is the key driving force in pushing e-health initiatives. We conjecture that a more IT-educated healthcare consumer would then provide stronger impetus for e-health adoption.

Impact of Morbidity Rate

There is a direct relationship between health education and awareness and the overall health standing of a country. Therefore, a more health conscious society, which tends to coincide with a society that has a lower morbidity rate, is more likely to embrace e-health initiatives. Furthermore, higher morbidity rates tend to indicate the existence of more basic health needs (WHO, 2003) and hence treatment is more urgent than the practice of preventative medicine and thus e-health could be considered an unrealistic luxury and in some instances such as when a significant percentage of a population is suffering from malnutrition related diseases is even likely to be irrelevant at least in the short term. Thus, we conjecture that the modifying impact of morbidity rate is to prioritize the level of spending on e-health versus other basic healthcare needs.

Impact of Cultural-Social Dimensions

Healthcare has been shaped by each nation's own set of cultures, traditions, payment mechanisms, and patient expectations. While the adoption of e-health, to a great extent, dilutes this cultural impact, social and cultural dimensions will still be a moderating influence on any country's e-health initiatives. Another aspect of the cultural-social dimension relates to the presentation language of the content of the e-health repositories. The entire world does not speak English, so the e-health solutions have to be offered in many other languages. The e-health supporting content in Web servers and Web sites must be offered in local languages, supported by pictures and universal icons. This becomes a particularly important consideration when we look at the adoption and diffusion of evidence-based medicine, as it will mean that much of the available evidence and case study data will not be easily accessible globally due to language barriers.

Therefore, for successful e-health initiatives it is important to consider cultural dimensions. For instance, an international e-commerce study by International Data Corporation (Wilson, 1999) indicated that Web surfing and buying habits differ substantially from country to country and this would then have a direct impact on their comfort to use e-commerce generally and e-health in particular, specially as e-health addresses a more fundamental need. Hence, the adoption of e-health is directly related to ones' comfort with using the technology, and this in turn is greatly influenced by cultural dimensions. Also connected with cultural aspects is the relative entrepreneurial spirit of a country. For example, a study by Hofstede (1980) indicated that in a cultural context, Indians score high on "uncertainty avoidance" criteria when compared to their Western counterparts. As a result, Indians do not accept change very easily and are hostile towards innovation. This, then, would potentially pose a challenge to the starting up of e-health initiatives whose success depends on widespread adoption for their technological innovations. Thus, we conjecture that fear of risk and absence of an entrepreneurial mindset, as well as other cultural-social dimensions, can also impact the success of e-health initiatives in a given country.

Impact of World Economic Standing

Economies of the future will be built around the Internet. All governments are very aware of the importance and critical role that the Internet will play in a country's economy. This makes it critical that appropriate funding levels and budgetary allocations become a key component of governmental fiscal policies so that such initiatives will form the bridge between a traditional healthcare present and a promising e-health future. Thus, this would determine the success of effective e-health implementations and, consequently, have the potential to enhance a country's economy and future growth.

The World Economic Forum's global competitiveness ranking measures the relative global competitiveness of a country. This ranking takes into account factors such as physical infrastructure, bureaucracy, and corruption. Thus we conjecture that weak physical infrastructure combined with high levels of bureaucracy and corruption will lead to significant impediments to the establishment of successful e-health initiatives.

In developing its e-health initiative, a good first step for any country is to assess its standing with respect to the four prerequisites and four impacts discussed previously in this chapter. In this way it will be possible for a country to evaluate its preparedness with respect to these parameters and consequently devise appropriate policies and strategies for an effective and successful e-health initiative. In the following section, we will attempt to provide a guideline that will facilitate such an evaluation.

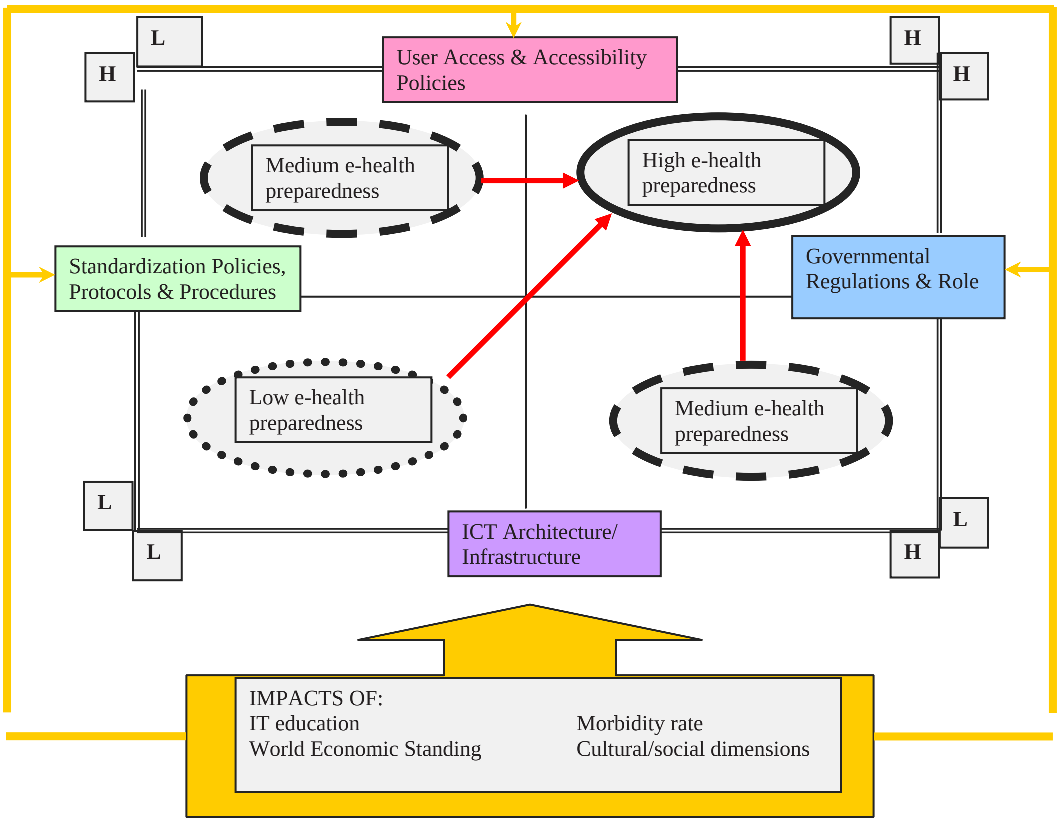
E-HEALTH PREPAREDNESS GRID

By taking the four main prerequisites as well as the four major impacts, identified in our framework in Figure 6 (i.e., information communication technology infrastructure; standardization policies, protocols and procedures; user access and accessibility policies; and infrastructures, governmental regulations and role) as well as the impact of IT education, the impact of morbidity rate, the impact of world economic standing, and the impact of cultural-social dimensions, we developed a grid for assessing e-health preparedness (see Figure 7) in which we can plot various countries with respect to these key parameters. The grid consists of four quadrants that represent the possible states of preparedness with respect to the key parameters for e-health success. The low preparedness quadrant identifies situations that are low with respect to all four prerequisites for e-health potential. The medium preparedness quadrant identifies two symmetric situations; namely, a combination of high and low positioning with respect to the four prerequisites for e-health potential. Finally, the high preparedness quadrant identifies situations that are high with respect to all four prerequisites for e-health potential. This grid not only shows the possible positioning of a given country with respect to its e-health preparedness (i.e., low, medium, or high) but also the path it must take and, more specifically, the prerequisite factors it must focus on to migrate to the ideal state of preparedness; namely, being high with respect to all four prerequisites. The grid also underscores the moderating role of the four impacts irrespective of the relative positioning on the state of preparedness of a given country.

DISCUSSION

From the e-health preparedness grid in Figure 7 we can see several implications. For countries that are low with respect to all four of the e-health prerequisites, much preparatory work is required to be e-health ready and thereby fully realize the goals of e-health (i.e., efficiency, evidence-based and preventive medicine, educated stakeholders, ethical awareness, enhanced quality care, empowered patients, extended reach and equity). For countries that map to the medium preparedness quadrant, more emphasis is needed on upgrading the deficiencies that cause them to score low on some prerequisites while they continue to maintain a high status on other prerequisites so that the full benefits of their e-health initiatives can be realized. Countries that are noted for being pioneers and leaders in the area of e-commerce in general as well as e-health in particular would be expected to map on the high quadrant. The challenge for these countries would be to maintain their high status with respect to all the

Figure 7. E-health preparedness grid



prerequisites. Furthermore, organizations within these countries can also begin to structure their respective e-health initiatives (i.e., micro-level issues) based on the key macro-level issues that both the integrative framework and e-health preparedness grid identify.

It is important to note that irrespective of their positioning on the preparedness grid (i.e., low, medium, or high), all countries must take into account the moderating effect of the four impacts on their e-health initiatives. If countries ignore the moderating effect of these four impacts, it will not be possible to fully realize a successful e-health initiative (and thus would not be able to fully realize the benefits of e-health), even if a country maps into the high-preparedness quadrant. Finally, we conjecture that the type of health system vis-à-vis the public–private continuum would not significantly impact the positioning of a country into a given quadrant. The successful experience of Singapore, albeit an isolated case, somewhat lends credence to our grid, as it would mostly fit the profile of a country in the high-preparedness quadrant and thus would be expected to successfully undertake an e-health initiative (PWC, 2003). Clearly, additional empirical validation of our e-health preparedness framework is required which we leave to future studies.

CONCLUSIONS

E-commerce, as noted by the U.N. Secretary General's address, is an important aspect of business in today's 21st century. No longer is it a luxury for nations; rather it is a strategic necessity in order for countries to achieve economic and business prosperity as well as social viability.

One of the major areas within e-commerce that has yet to reach its full potential is e-health. This is because healthcare generally has been slow in adopting information technologies. Furthermore, there is a shortage of robust frameworks that may be used as guidelines for assessing countries' e-health preparedness and identifying the key areas and deficiencies that need to be addressed in order for successful e-heath initiatives to ensue. In addition, e-health is more than a technological initiative; it also requires a major paradigm shift in healthcare delivery, practice, and thinking. We have attempted to address this gap by developing a framework that identifies the major factors involved in assessing the e-health preparedness of countries and thereby, facilitating countries to focus their efforts on the relevant issues that must be addressed in order that successful e-health initiatives follow (i.e., the goals of e-health are realized). An outcome from our analysis indicates that the relative healthcare system (i.e., whether government driven, public, or two tier) would appear to have less significance in establishing successful e-health initiatives. The first step in the development of any viable e-health strategy is to make an assessment of the current state of e-health preparedness and then how to either move to a state of higher preparedness (i.e., the high quadrant) or focus on maintaining a current high quadrant status–both of these are identified through the use of our framework and thus its value. Finally, we note that with respect to our framework other parameters also exist and could also be considered important, perhaps even as important as the ones we used. However, we believe that the framework will still function the same way (i.e., provide a useful tool for any country trying to determine and develop a successful e-health initiative), irrespective of the number of parameters; in this regard the preference should be simplicity over complexity.

ABSTRACT

Superior access, quality, and value of healthcare services has become a national priority for healthcare to combat the exponentially increasing costs of healthcare expenditure. E-Health in its many forms and possibilities appears to offer a panacea for facilitating the necessary transformation for healthcare. While a plethora of e-health initiatives keep mushrooming both nationally and globally, there exists to date no unified system to evaluate these respective initiatives and assess their relative strengths and deficiencies in realizing superior access, quality and value of healthcare services. Our research serves to address this void. This is done by focusing on the following three key components: 1) understanding the Web of players (regulators, payers, providers, healthcare organizations, suppliers, and last but not least patients) and how e-health can modify the interactions between these players as well as create added value healthcare services, 2) understand the competitive forces facing e-health organizations and the role of the Internet in modifying these forces, and 3) from analyzing the Web of players combined with the competitive forces for e-health organizations we develop a framework that serves to identify the key forces facing an e-health and suggestions of how such an organization can structure itself to be e-health prepared.

INTRODUCTION

E-health is a broad term that encompasses many different activities related to the use of the Internet for the delivery of healthcare service. Healthcare professionals are extending the use of the Internet to include a source of evidence-based consumer information as well as to facilitate the research of protocols for healthcare delivery, accessing laboratory and medical records, and performing second opinion consults (Sharma & Wickramasinghe, 2005; Sharma, Wickramasingeh, Xu, & Ahmed, 2006). Moreover, the Internet is being used by patients to become more knowledgeable about health practices as seen from their questions to their physicians (Gargeya & Sorrell, 2005).

Although, a relatively new term and unheard of prior to 1999, e-health has now become the latest "e-buzzword" used to characterize not only "Internet medicine," but also virtually everything related to computers and medicine (Sharma et al., 2006; Von Lubitz & Wickramasinghe, 2006). The scope and boundary of e-health, as well as e-heath organizations, is still evolving. However one can only imagine it will grow rapidly especially given that governments in both U.S. and Europe, and organizations such as WHO (World Healthcare Organization) are advocating that e-health be on the top of all healthcare agendas and an integral component of any healthcare delivery initiative (Von Lubitz et al., 2006).

Given the growth and variety of e-health initiatives, it becomes important to examine the forces affecting these initiatives and factors leading to the success of e-health. To date, little research examines metrics of measurement pertaining to e-health initiatives or their economic value. What are the forces of competition affecting e-heath? Are the competitive forces constrained by external considerations? Is the issue of competition an appropriate concern for e-health? If so, what are the strong and weak competitive forces? We argue that analysis of these forces would lead us to understand the long-term sustainability of any e-health initiative.

TRADITIONAL COMPETITIVE FORCES

The starting point for understanding the competitive forces facing any e-health initiative lies in understanding the fundamentals of traditional competitive forces that impact all industries and then how the Internet as a disruptive technology has impacted these forces.

The strategy of an organization has two major components (Hendersen & Venkatraman, 1993). These are 1) formulation--making decisions regarding the mission, goals, and objectives of the organization and 2) implementation--making decisions regarding how the organization can structure itself to realize its goal and carryout specific activites. For today's healthcare organizations the goals, mission, and objectives all focus around access, quality, and value and realizing this value proposition for healthcare then becomes the key (Wickramasinghe, Fadlalla, Geisler, & Schaffer, 2005). Essentially, the goal of strategic management is to find a "fit" between the organization and its environment that maximizes its performance (Hofer, 1975). This then describes the market-based view of the firm and has been predominantly developed and pushed by the frameworks of Michael Porter. The first of Porter's famous frameworks is the generic strategies (Porter, 1980).

The use of technology must always enable or enhance the businesses objectives and strategies of the organization. This is particularly true for 21st Century organizations where many of their key operations and functions are so heavily reliant on technology and the demand for information and knowledge is so critical. A firms' relative competitive position (i.e., its ability to perform above or below the industry average is determined by its competitive advantage). Porter (1980) identified three generic strategies that impact a firm's competitive advantage. These include cost, focus, and differentiation. Furthermore, Porter himself notes that two and only two basic forms of competitive advantage typically exist:

1. Cost leadership.
2. Differentiation.

Firms can use these two forms of competitive advantage to either compete across a broad scope of an industry or to focus on competing in specific niches; thereby, leading to three generic strategies. Porter (ibid) notes that firms should be cautious about pursuing more than one generic strategy; namely cost, differentiation, and focus. For example, if a cost leadership strategy is adopted it is unlikely that a firm can also maintain and sustain differentiation since it would not be possible to simultaneously pursue the costly capital investment or maintain high operating costs required for differentiation and thus in the long run the firm has a confused strategy which leads to failure.

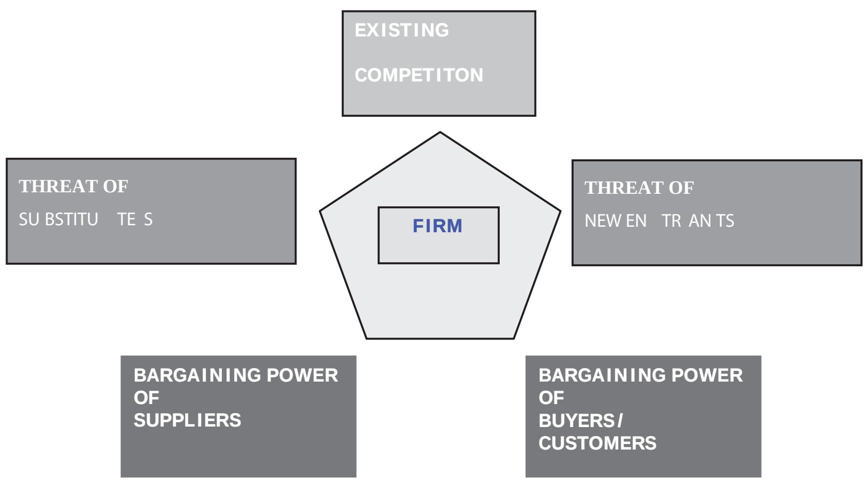
In order to design and develop ones strategy, an organization should first perform an industry analysis. Porters Five Forces or Competitive Forces model is most useful (Porter, 1980, 1985). Figure 1 depicts this model. Essentially, Porter has taken concepts from micro-economics and modeled them in terms of five key forces that together outline the rules of competition and attractiveness of the industry.

The forces are as follows:

1. **Threat of new entrant:** A company new to the industry that could take away market share from the incumbent firms.
2. **Threat of substitute:** An alternative means that could take market share from product/service offered by the firms in the industry.
3. **Bargaining power of buyers:** The strength of buyers or groups of buyers within the industry relative to the firms.
4. **Bargaining power of suppliers:** The strength of suppliers relative to the firms in the industry.
5. **Rivalry of existing competition:** Relative position and market share of major competitors.

The collective strength of these five forces determines the attractiveness of the industry and thus the potential for superior financial performance by influencing prices, costs, and the level of capital investment required (Porter, 1985). Once a thorough industry analysis has occurred, it is generally easier for a firm to determine which generic strategy makes most sense for it to pursue

Figure 1. Porter's Competitive (Five) Forces Model



and enables the firm to exploit most of its core competencies in its existing environment.

Role of the Internet of the Competitive Forces

Feeny (2001) presents a framework that highlights the strategic opportunities afforded to organizations by using the Internet. In particular, he highlights three e-opportunity domains. Table 1 details these domain and their respective components.

E-Opportunities in Healthcare

Given the three areas of e-opportunities previously discussed, Glaser (2002) identifies several key e-opportunities for healthcare. Table 2 details these.

WEB OF PLAYERS IN HEALTHCARE

Figure 2 depicts the Web of healthcare players and the key elements of the any e-health architecture that serves to support the interactions between and within this Web of players. In order to fully capture the flows of information it is necessary to first identify the primary producers and consumers of data and information within the healthcare system. At the center of the information flows is the HCIS (healthcare information system, i.e., the e-health network) because not only does it connect the key players within the healthcare system in an efficient and effective manner, but also it forms the central repository for key information such as patient medical records, billing, and treatment details. Hence, the HCIS provides the foundation for supporting the information flows and decision making throughout the healthcare system. Figure 2 then represents a macro view of the inter-relationships between the key players within this system as well as the sources, destinations and flows of information between these players and the pivotal role of the HCIS.

Healthcare procedures such as medical diagnostics, treatment decisions, and consequent effecting of these decisions, prevention, communication, and equipment usage can be thought of as iatric in nature (Wickramasinghe & Fadlalla, 2004). Integral to these iatric procedures is the generating and processing of information (Wickramasinghe & Fadlalla, 2004). The patient naturally provides key information at the time of a clinical visit or other interaction with his/her provider. Such a visit also generates other information including insurance information, medical history, and treatment protocols (if applicable) which must satisfy regulatory requirements, payer directives and, obviously, the healthcare organization's informational needs. Thus, we see that from a single intervention many forms and types of information are captured, generated, and then disseminated throughout the healthcare system. All this information and its flows must satisfy some common integrity characteristics such as accuracy, consistency, reliability, completeness, usefulness, usability, and manipulability. Consequently, generating a level of trust and confidence in the information's content and processes. Since the information flows across various organizational boundaries, the challenge of ensuring information integrity is further compounded because any integrity problems will propagate with ripple effects following the same trajectory as the information itself. Given the high degree of inter-relatedness between the various players, the consequences of poor quality information (such as the cost of information integrity problems) are multiplied and far reaching. This highlights the need for robust, well designed, and well managed HCIS (Wickramasinghe & Fadlalla, 2004). Such a perspective should not be limited to new systems, but rather, equally and perhaps of even more importance should be applied to existing systems as well.

Table 1. The three e-opportunity domains and their components

	Components
e-operations	• Automation of administrative processes • Supply-chain reconfiguration • Reengineering of primary infrastructure • Intensive competitive procurement • Increased parenting value
e-marketing	• Enhanced selling process • Enhance customer usage experience • Enhanced customer buying experience
e-services	• Understanding of customer needs • Provision of customer service • Knowledge of all relevant providers • Negotiation of customer requirements • Construction of customer options

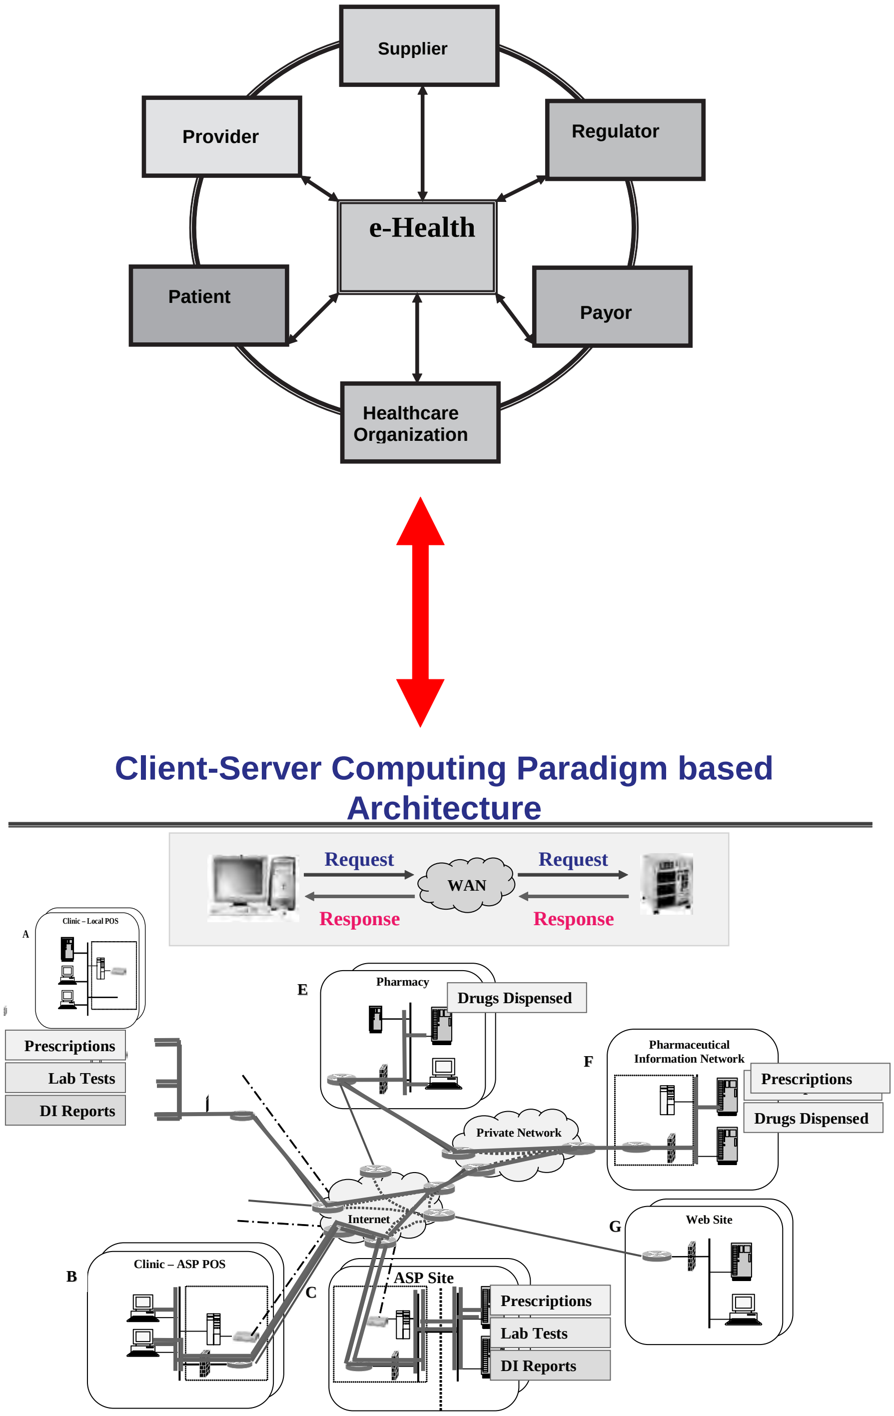
Table 2. The e-opportunities for healthcare organizations

	Components
e-operations	• Internet-based supply purchasing • Prescription writing, formulary checking, and interaction checking using hand-held devices
e-marketing	• Delivery of consumer health content and wellness management tools over the Internet • Use of consumer health profiles to suggest disease management and wellness programs
e-services	• Patient-provider communication and transaction applications • Web-based applications to support the clinical conversation between referring and consulting physicians
Crossing multiple domains	• Increasing the level of information content in the product • Increasing the information intensity along the supply chain • Increase in the dispersion of information

MODELING THE COMPETITIVE FORCES IN E-HEALTH

In order to model e-health, let us first construct a general model of the competitive forces pertaining to e-business. E-business is not simply offering traditional products and services on line. It requires broad-scale asset redeployment and process changes, which ultimately serve as the basis for a company's competitive advantage in today's Digital Economy. For this study, the e-business model could be broken into components such as; products and services, customer value, pricing component, revenue source, the cost component, and asset model as shown in Figure 3.

Figure 2. Web of e-health players adapted from Wickramasinghe et al 2004



The prime objective of business model is to make money (La Monica, 2000). The various components of business model as shown in Figure 1 work together to create profit margins for the business. First of all, the electronic business model should offer products and services online. These products and services should be differentiated with competitors by low price or unique customer value. The products are differentiated if customers perceive some value in these that other products do not have. Differentiation can be done by offering different product features, timing, location, service, product mix, linkage between functions, etc. (Afuah & Tucci, 2000). Customer value can be judged whether firm offering its customers something distinctive or at a lower cost than its competitors. The success of business model depends upon how does the firm price the value? An important part of profiting from the value that firms offer customers is to price it properly. For pricing, market shares and margins would be most critical. The good business model should strive for high market share and thus firm should devise strategies accordingly. Pricing of products depends upon the cost and asset model of the firm. The cost (fixed cost + variable cost) should be spread in a fashion that profit margins remain high. The profits in electronic business model case will not only come from sales but may come from many other sources. Therefore, revenue source is another important component for business model. The sustainability of business model can be gauged based upon non-imitable nature of products and services. How can firm continue improve market share and make more money and have competitive advantage are the kind of questions needs to answers for the sustainability of business model. For example; using simple profits equation; Profits=(P-Vc)Q-Fc , firm can assess how each of the components of business model impact profitability. If a firm offers distinctive products, it can charge premium price P for it. A good business model should keep low variable cost but should have high market share for higher profitability (Afuah et al., 2000). Taking these components of a business model into consideration, let us now map this to the healthcare domain (Figure 4).

In so doing, some of the nuances pertaining to the dynamics of healthcare become apparent; such as, the receiver of services, or the patient, is not usually the principal payer. Moreover, the model serves to underscore that for e-health initiatives to truly add value and be sustainable the dynamics

Figure 3. Generic e-business model components

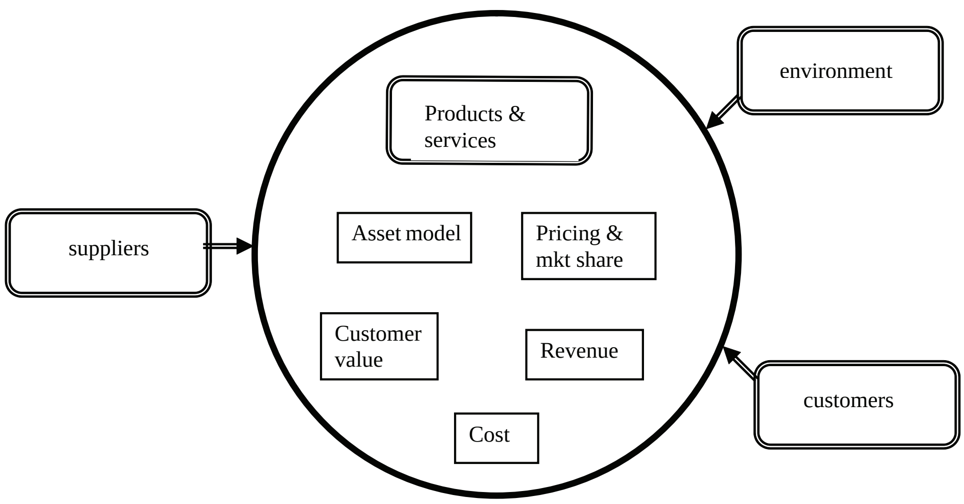


Figure 4. e-health business model components

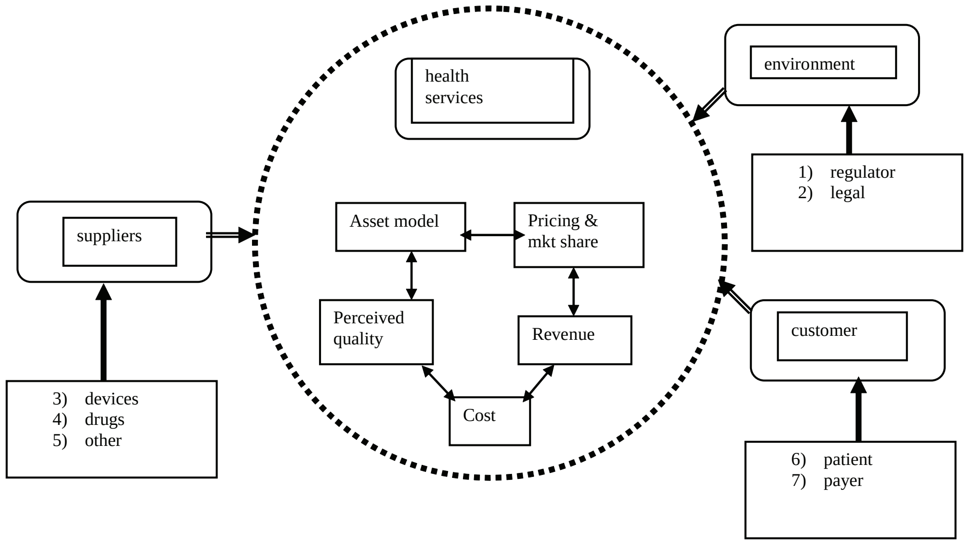

of a generic e-business model must be satisfied. Hence, some determination needs to be made regarding Vc, Fc, P, and Q in this context.

To understand these dynamics more easily let us consider a case study example of the implementation of an electronic patient record.

Case Study

The Johns Hopkins Medicine Center for Information Services Public LAN (JPL) is a computer network designed to provide patient care providers access to clinical applications. This computer network is utilized by all types of patient care providers in both inpatient and out patient services. These providers include, but not limited to, doctors, interns, fellows, nurses, unit clerks, pharmacists, nutritionists, and admission specialists. In this article, an examination of the history of the Public LAN, the current state of the LAN, and the future of the Public LAN will be examined. Since its inception the Public LAN as been the leader in efficiency and innovation for Desktop Computing Services (DCS), a division of Information Technology @ Johns Hopkins (IT@Hopkins).

Introduction of the Public LAN

During the spring of 1996, JHMCIS and a group of doctors developed an in-house application to provide patient care. This application is called Electronic Patient Record or EPR. The application was to be used in patient areas for tracking patient record. These records can then be viewed by other clinicians throughout the hospital. A second application was introduced at the same time to provide a graphical user interface to many of the hospital's mainframe and mid-range systems. This application is Host Interface Program or HIP. The challenge at this stage was to provide a computer system that could be used by the doctors that would allow EPR and HIP to be used to provide patient care and at the same time have a desktop system that was secure.

These desktops were to be deployed in medical exam rooms and the major problem was having a desktop that could provide these applications to the clinicians without allowing the clinicians or patients the ability to access the operating system and the computer configuration. This led to the development of the Public Desktop.

The Public desktop is a Microsoft Windows based desktop that has the clinical applications installed, as well as an Internet browser and the Microsoft Office suite. The challenge was managing these systems in areas with limited access during business hours as they were in use by clinicians providing patient care. The operating system was secured and limited access was given to the users. The users were not able to install any applications or download any programs.

The Public LAN started out with 70 desktops in three clinical areas. The Harriet Lane Clinic, which is an outpatient clinic for pediatrics, the neonatal intensive care unit, and the adolescent outpatient clinic. This pilot lasted approximately six months. During the next three years, the Public LAN grew to 1100 desktops.

The Growth of the Public LAN

Today the Public LAN supports over 1800 desktops and many clinical applications. During the first three years of the Public LAN, the number of systems reached over 1100 systems. Included in this growth, not only the number of devices supported, but the number of applications that were supported on these desktops. The driving forces of these changes were outdated clinical applications that were being replaced with client server applications and the millennium with applications that were not year 2000 compliant.

During this time, the application supported grew to include BDM, a new pharmacy application, Vision—a nutrition application and ClicTate, a pediatrics version of EPR. With the intention of more clinical applications moving from the mainframe and mid-range systems to client server applications, the desktops are going to need to be able to handle these additional applications.

The process of managing these systems became a challenge as well. Since the desktops were standardized, DCS was able to implement Microsoft's System Management Server (SMS). This allowed not only the ability to manage these desktops, but also distribute software, inventory the hardware, and software of a specific system, and provide remote control capabilities. SMS was included when the pilot of the Public LAN was deployed but its true value was not realized until the rapid growth of the LAN.

The Public LAN Today

The Public LAN today is well over 1800 desktops, supporting more than 30 clinical applications. Most of these applications are still accessed via HIP, however more client server applications are also supported. The additional client server applications have lead to different configurations of the desktop's application software or "flavors" of Public workstations. Currently there are currently many different configurations for the Public Workstations. These different configurations include:

- Standard configuration.
- Training configuration.
- Wilmer Eye Clinic configuration.
- Pharmacy configuration.
- Nutrition configuration.
- Provider Order Entry configuration.
- Operating room configuration.
- DCOM image viewing configuration.
- Eclypsis Point of Care configuration.
- Procedure Reporting System configuration.
- OB/GYN Configuration.

These different configurations can be on a few as 20 desktops to as many as 600, where the standard configuration is on all of the desktops. The standard configuration is:

- Windows XP Professional.
- EPR.
- HIP.
- Internet Explorer.
- Microsoft Office Suite.
- Adobe Reader.
- Calculator.

The additional configurations are based on adding additional clinical applications to the desktops. In addition, many of the systems have multiple clinical applications installed.

The Lessons Learned

During the growth of the Public LAN, many lessons have been learned. These lessons include best practices for desktops management, application management and deployment, and reduction in the total cost of ownership of a desktop.

The current network is supported by three desktop technicians, which is an average of 600 plus desktops per technician. Desktop Computing Services needed to have a way to manage these systems not only located at the East Baltimore campus, but at other campuses within the Baltimore metropolitan area. The use of Microsoft Systems Management Software (SMS) was deployed to allow desktop management. SMS allows a technician the ability to remote control in to a desktop and perform work as if they were at the desktop. This capability also allows the support staff to view the process of the user and see the error as it happened. SMS also is used to deploy application software to the desktop.

Due to the increased number of clinical applications, the number of different application software configurations increased. In order to manage this DCS used SMS for application deployment. DCS is able to determine the application software installed on the desktop and perform upgrades to the software. The upgrade to an application is preformed by using SMS to "push" and install the software on the desktop without any user intervention. Therefore, and application could be upgraded or installed without having to visit the desktop.

With the integration of SMS to manage the desktops, this has reduced the total cost of ownership of supporting the Public LAN. This decrease is realized by having a ratio of one desktop technician per 600 desktops. DCS is able to remote control the desktop; this prevents the technician from have in walk across campus to help a user. In addition, the installation of applications and upgrades to applications is completed on many systems at once without having to visit each individual desktop. Also, DCS has secured the desktop to prevent the users from accessing the operating system and the hard drive. If the users were able to access the operating system and download and install applications, including spyware, this would greatly increase the support costs of the desktop.

The Future of the Public LAN

The future of the Public LAN at Johns Hopkins Hospital is ever evolving. The needs of the clinicians for resources to provide patient care are continually changing. With patients bringing medical records in on CD-ROM to access to network resources the Public LAN must evolve to meet these needs. In order to meet these needs the Public LAN support staff is required to find clever and innovative ways to provide these resources. New hardware is being added to the Public desktops to allow viewing of clinical data on CD-ROM, the use of USB keys for file storage has been enabled and logging in with a personal account.

The ability for a clinician to login with their personal account allows them to access network resources. These resources include access to network file servers and departmental file servers. In order for a clinician to use a personal account they are required to have a timeout of their session. The timeout of the session will log the user off after a certain amount of idle time. The reason for this is to prevent others from accessing information and to prevent non Johns Hopkins employees to access data and network resources.

The future of the Public LAN is ever evolving. The Johns Hopkins Hospital is building two new clinical towers that will be state of the art. The devices that provide patient care will also need to be state of the art and provide clinicians the ability to provide patient care in a completely paperless, film-less, and wireless network. The Public LAN will be able to provide these solutions and will realize the benefits of these efforts, as patients are cared for more efficiently and effectively.

Mapping the Case to the Model

The implementation of the EPR at Johns' Hopkins represents a relatively common e-health initiative in the current healthcare environment. The EPR enables the seamless flow of patient data and thus facilitates the delivery of efficient and effective quality healthcare to the patient. This is certainly professed as a key benefit for the embracing of EPR in most instances.

The e-health sustainability model however, suggests that one must analyze the micro- and meso-dynamics more closely to actually determine the sustainability of such an initiative. Specifically, it is necessary to capture key factors including, perceived quality, fixed and variable costs, price and market share and quantity and then look at the interaction of these factors before sustainability of the initiative can be pronounced. However, this is beyond the scope of this article but will form the focus of future research.

What can be noted at this point and will be research in more detail in future work is the size or scale of the e-health initiative. Returning to the simple profit equation Profits=(P-Vc)Q-Fc, in the case scenario above, fixed costs will be constant and Vc for any EPR will be marginal given the generic nature of the program and the applications of it by various providers hence we hypothesis that the sustainability of the EPR would increase with Q the quantity or size. Thus, the larger the EPR initiative the more likely it is to be sustainable. Quantitative data to support the relationship between scope and quantity and impact of ICTs in general in healthcare settings can be found in previous studies (Wickramasinghe & Lamb, 2002; Wickramasinghe & Silvers, 2003).

DISCUSSION

In mapping the John's Hopkins case to the model in Figure 4, we can see that the reality of an e-health initiative involves the interactions of various groups of stakeholders. Knowledge management provides an umbrella under which we may discuss a number of opportunities and raise issues relative to components of the business model. The vision of collaboration between components of the business model recognized as stakeholders is one of great opportunity. Stakeholders in this case include suppliers, the firm, the customer, and the government as a key representative of the environment. Each stakeholder brings to the table talent, resources, and differentiated perspectives that, together, create a robust whole in addressing problems and projects. For example, suppliers can be a source of knowledge that can assist the firm in delivering cost effective products and services. Customers are an additional source of knowledge in terms of personal history and preferences. The firm can manage knowledge in a form that maximizes the probability of value added products and services. The government can serve as a catalyst to create an environment conducive to knowledge exchange and management.

Unfortunately, great opportunities do not always turn into reality. Collaboration successes between suppliers, the firm, and its customers much less the government can, sadly, be few and far between. In addition to strengths and distinctions, each stakeholder also brings to the table residual weaknesses and biases that can scuttle the best of collaborative intentions. For example, internal firm bureaucracy can easily drive out the best of suppler intentions and customer good will. Problems can easily be left unaddressed and efforts can easily fail as reality drives out vision. This can be exacerbated by cultural norms and historical behaviors embedded in government policies.

A case in point is the handling of SARS. Levels of suffering and unnecessary deaths were, in part, a result of lack of collaboration between stakeholders. In this case, government agencies (specifically the hospital authorities) were negligent in sharing information and allocating resources amongst hospitals. The hospitals, however, were not guilt free and were accused of withholding information to customers including patients and their families. Further, the relationship between suppliers and hospitals was insufficient to respond to the need for supplies. Shortages were evident and supplies misapplied in circumstances that could have been adverted through collaboration. The situation was further strained as lack of information sharing across governments and excessive bureaucratic delay inhibited quick action to rapidly respond to changing circumstances. In summary, stakeholder collaboration could have, arguably, avoided hardship at individual and societal levels. Unfortunately, it didn't happen and the World Health Organization (WHO) was, rightly, exasperated.

Experiences with SARS have sensitized stakeholders at all levels with respect to effectively dealing with potential pandemics e.g., H5N1-based bird flu. Over the past months, we have already seen a much higher level of information exchange and collaboration than existed in the lead-up to SARS. Governments have more readily shared information and established channels for dealing with global adversity. Hospitals have begun preparations including emergency response practice. Suppliers have opened historically propriety processes and licenses to enable extended manufacturing capability (e.g., Roche with Tamiflu, as but one example). Customers have sought (and obtained) information relative to prevention and preparation for a variety of circumstances as well as acted as a source of information back to appropriate authorities regarding infectious incidences, e.g., bird flock deaths. Numerous conferences with multiple stakeholders present have provided forums for knowledge sharing, enhanced understanding leading towards the creation of action plans. In short, bird flu threats have galvanized stakeholders in a way that was unseen in the handling of SARS, in part, as a result of witnessing and experiencing hardship.

Knowledge management provides a focus that can enhance the probability of success in encouraging and sustaining broad-based stakeholder collaboration. Formalized knowledge management promotes the ultimate desire for the benefits of stakeholder collaboration to be sufficiently well developed and supported to offset inherent weaknesses. Knowledge management plays a key role in assuring that aspects of information creation, sharing, and dissemination compatible with multiple stakeholder objectives can be successfully achieved (Alavi & Leidner, 2001). Problems are often beyond the scope of any particular stakeholder, which encourages cooperation in order for success to be attained (Van de Ven, Angle, & Poole, 2000).

The concept of suppler, firm, customer, and government collaboration is sound but operationalization is difficult and fraught with problems. This doesn't suggest that the concept should be abandoned, just managed, and supported. Sadly, this situation is not unique (Lyytinen & Rose, 2003). The missing element is often cooperative knowledge creation and exchange. Each element of the collaboration needs a better understanding and focus on cooperation. Unfortunately, this doesn't naturally exist and easily turns antagonistic. Cooperation is difficult to achieve even when linkages are in place. It is far too easy to say that "details can be worked out." Unfortunately, the "devil" is in the detail. Towards that end, stakeholder collaboration in achieving knowledge management objectives is paramount.

CONCLUSION

The underlying goal for healthcare is to provide cost effective quality treatment (i.e., realize its value proposition in this challenging environment). In order to do this healthcare needs to maximize its information management techniques and make prudent use of ICTs (Information Communication Technologies). In such a context e-health initiatives will clearly play a dominant role in healthcare delivery. This has been underscored by leaders of US and the EU as well as leading bodies such as the World Healthcare Organization (WHO) that focus on global healthcare issues and policy. Moreover, Both European and US authorities define their initiatives primarily in terms of medical information technology centering on computerized patient record [CPR] or, in more acceptable parlance, the HER electronic health record as referred to by WHO. Hence, e-health is here to stay. What becomes critical then is the sustainability of these e-health initiatives and their ability to bring benefits to the key actor in healthcare, the patient.

This article has set out to delve into the abyss of e-health sustainability. A logical starting place to us seemed to identify the primary drivers in a generic e-business model and then map them into healthcare. Our e-health sustainability model then serves to identify the critical factors and important dynamics faced by any e-health initiative. In addition, we identified the importance of scale and scope economies in this process through the mapping of case study data. Finally, we noted that it is necessary to incorporate the techniques and strategies of knowledge management if superior collaboration between the multiple stakeholders is to ensue. Through the example of SARS we underscored how important this aspect is not only to the sustainability of e-health but in order to realize effective healthcare delivery. Clearly this is only the beginning and we now need further investigation and research, which we plan to embark upon. We close by encouraging other researchers to also delve deeper into this imperative healthcare research area.

Chapter 1.4
The Telehealth Divide

Mary Schmeida
The Cleveland Clinic Foundation, USA

Ramona McNeal
University of Illinois at Springfield, USA

INTRODUCTION

In the United States, the public is accessing the Internet to provide information and deliver services, and to interact with citizens, business, and other government agencies (Bimber, 1999; Pardo, 2000; West, 2003, 2004). As with any change between citizen-government interactions, e-government is accompanied by speculation on its impact to both citizen and government. E-government capability of continual service delivery can make government efficient and transparent to the public (Norris, 1999; West, 2003), and more responsive to public needs through fast and convenient communication options (Thomas & Streib, 2003). It permits quicker material update than traditional distribution methods (Pardo, 2000).

However, other literature suggests e-government will not live up to these prospects. A separation exists among citizens that use and do not use the Internet. This separation is based on a number of factors, including inequalities in Internet access "digital divide" and technological skills, along with psychological and cultural barriers. Literature extensively shows the differences in United States Internet use to fall along important socioeconomic and demographic factors, such as age, race, education, and income (Mossberger, Tolbert, & Stansbury, 2003; Neu, Anderson, & Bikson, 1999; Pew Internet & American Life Project, 2003c; U.S. Department of Commerce, 2002; Wilheim, 2000). E-government may create inequalities in the delivery of government information and services.

Telehealth is a specific form of e-government aimed at improving the accessibility and quality of healthcare, and reducing service costs (Schmeida, 2004a). It relies on electronic information and telecommunication technology innovation (H.R. 2157, 2001). As nations contend with expensive healthcare, the promise of better healthcare service delivery at a reduced cost has made teleheath an increasingly attractive policy option in the United States and internationally.

Telehealth advancement greatly reflects the dramatic changes in the telecommunication industry. In the 1990s, we witnessed considerable advancement, such as the use of digital technology—interactive video and Internet. Interactive video, for example, can link doctors and medical students afar improving medical education. Rural citizens can interact with specialist(s) through interactive video rather than traveling great distances for a medical consultation. The Internet can bring health related information into the home for better healthcare decision-making.

Telehealth can be conceptualized as both an administrative reform policy and regulatory policy. As a hybrid policy type, it mostly exhibits the characteristics of administrative reform, such as e-government (McNeal, Tolbert, Mossberger, & Dotterweich, 2003; Schmeida, McNeal, & Mossberger, 2004) driven by the goals of cost reduction and increasing efficiency, paramount to telehealth adoption and implementation. Administrative reform policy does not involve the direct and coercive use of government power over citizens and are therefore associated with low levels of conflict (Ripley & Franklin, 1980). Regulatory policy, on the other hand tends to be politically salient among citizens as well as controversial among the actors within the policy community.

Traditionally, those interests who are regulated have been important players in the policy process. Important telehealth players are physicians, nurses, pharmacists, and health insurers. Since telehealth straddles both administrative and reform policy areas, it is difficult to predict the actors that will play the greatest role in assisting or impeding its implementation. Execution of regulatory policy is highly volatile and controversial with shifting of alliances and players. However, administrative policy innovations are low salience, and as some regulatory policies it involves technical issues, often driven by professional networks and elected officials.

TREND STUDIES ON INTERNET USE AS A HEALTHCARE TOOL

Although policy actors, cost containment and advances in technology are driving the adoption of telehealth, its impact is contingent on factors, such as Internet access among members of the public. The Internet provides information on various health and medical-related topics through government sponsored and private sector Web sites. Today, more Americans are conducting Internet health and medical-related searches. On an average day, about six million people get online to search for medical-related information (Pew Internet & American Life Project, 2002) for better decision-making on self-care and helping others (Pew Internet & American Life Project, 2003b). Across different health and medical issue topics, Pew (2003b) found online searches for information on a specific disease or medical problem leads the topic areas searched. In addition to using the Internet for health information searches, about 30% of e-mail users have e-mailed their doctors and other health professionals, thus bridging the gap between patient and doctor, particularly specialists over great distances. This elementary form of telehealth (information search, and doctor and patient correspondence) exemplifies the potential of telehealth. Yet, while becoming a commonly important healthcare tool, not all citizens including those most in need of online health and medical-related information (the elderly and poor) are taking advantage of the online services (Schmeida, 2004b).

Research on demographic groups using the Internet to search for health information is sparse and does not establish with any certainty what factors matter in predicting who is taking advantage of this form of e-government (Schmeida, 2004b). However, multivariate statistical research on computer and Internet access does exist and may help us better appreciate the barriers facing the utilization of telehealth. Mossberger, Tolbert, and Stansbury (2003) find both an Internet access and skills divide, indicating inequalities in home Internet access, e-mail use and computer ownership. The research suggests there are gaps based on race/ethnicity with whites more likely than African-Americans and Latinos to have Internet access. Inequalities were also found on education and income with higher income being associated with greater Internet and computer access and ownership. Age was also an important factor with young persons more likely to be connected (pp. 32-35). Compounding the access divide are differences in technological skills. Mossberger et al. (2003) find a skill divide exists closely mirroring the access divide with the poor, older, less educated, and non-whites less likely to have technical skill, that is, technical competence or information literacy. As important as having access at home are the technical skills for computer operations and information literacy to locate and effectively use computer information.

A TELEHEALTH DIVIDE MATCHING THE DIGITAL ACCESS DIVIDE

Do those who are least likely to have computer and Internet access match that of a potential telehealth divide? Based on literature showing disparities in Internet access and use (Mossberger, Tolbert, & Stansbury 2003; Pew Internet & American Life Project 2003a; U.S. Department of Commerce 2002), it is expected that disparities in Internet use for health searches would also exist. Using the 2000 Pew Internet & American Life (2003b) survey data and controlling for demographic factors with regression analysis, Schmeida (2004b) found several factors important in explaining which citizens are searching for health and medical information online.[1] Persons who are young, white, with a higher education and income, are more likely to search for information online.[2] Also, females and household healthcare givers are more likely to conduct searches than males and non-caregiver.[3] The findings suggest that older persons, who face more health-related problems, ironically are less likely to take advantage of these telehealth services. However, females are more likely to search online, as might be expected since they have been more active in health searches in the Pew Internet & American Life Project (2003b) study and are more likely to be caring for another person(s) at home.

Unexpectedly, race (Asian Americans and African-Americans) was not a significant predictor of a telehealth divide, differing from previous studies showing these minority groups are "have-nots" in Internet access at home. On the state level, McNeal et al. (2003) found racial diversity was not a significant predictor in percentage of state government Web sites providing services to state residents. While, Schmeida, McNeal, and Mossberger (2004) found state racial context mattered in influencing implementation of telehealth policy. This suggests that minority context may matter more for telehealth implementation. Latino (who were found significantly less likely to search for online health information) contextual barriers to computer literacy, such as entrenched resistance to acquiring computer skills (Stanley 2003) may be factors for further research.

CONCLUSION

The policy implementation literature directs us to examine factors, such as political actors, the need/demand to contain costs and increase healthcare efficiency, important to explaining the adoption and implementation of telehealth. To understand the impact of this policy, we cannot, however, lose sight of factors, such as public Internet access and use. Research statistically controlling for demographic factors on telehealth use is limited. However, using regression we control for these factors and with certainty find disparities between demographic groups searching for health information on the Internet. A telehealth divide exists and in general mirrors the contours of the digital divide. As with the digital access divide—those who are least likely to have a computer and Internet access at home are the poor, less educated, older, Latinos and African-Americans (Mossberger et al. (2003) face barriers in taking advantage of services made available by telehealth. That is, persons who are poor, less educated, older, and Latino are least likely to search online for health information than others (Schmeida, 2004b).

Persons most in need of online health information are not accessing it. These findings suggest a dilemma, those in greatest need of information, such as, the poor and elderly are not seeking it online. The ramifications are significant suggesting the "advantaged" will obtain superior healthcare and treatment than the "disadvantaged." As advanced technology replaces labor-intensive information specialists, for example, the U. S. Centers for Medicare & Medicaid Services (2004) Web site, parity between demographic groups is essential. As literature suggests that e-government will not live up to the prospects of efficiently improving healthcare for all people, our findings show that indeed e-government maybe creating inequalities in the delivery of government information and services.

Effective information technology use depends on user knowledge and skills. Technical competence, information literacy and basic literacy are required for the information age for effective use of telehealth. Today, public access cites, such as computer technology centers are giving individuals both access to computers and educational opportunities to overcome literacy barriers (Mossberger, et al. 2003). Bridging the gap may be progressed by community services and educational opportunities, yet evolving. The adoption of telehealth reminds us that with adoption of any new policy, it must be evaluated on more criteria then efficiency. Criteria, such as equality in costs, benefits and risks must also be considered.

Although this article considers policy diffusion among the United States, it has implications for the international community in terms of lesson drawing. As the literature reminds us, countries often look to their neighbors for policy ideas (Bennett, 1997; Wolman, 1992) for emulation. This has proven to be the scenario between the United States and many other nations, all-searching to improve the health of their citizens while facing rising heathcare costs.

KEY TERMS

Centers for Medicare & Medicaid Services Web site: A United States government Web site that provides information to needy groups on Medicare and Medicaid services, state children's health insurance, and clinical laboratory testing.

Digital Access Divide: Disparities between groups on demographic factors, such as gender, age, income, education, race, and ethnicity in accessing digital information technology, such as on the Internet.

Telehealth: The term is often interchanged with telemedicine. There is no consensus on its definition. However, the United States Congress defines it as the use of electronic information and telecommunications technologies to support public health and health administration, long-distance clinical healthcare, patient and professional health-related education (H.R. 2157, 2001).

Telehealth as an Administrative Reform Policy: As an administrative reform policy, telehealth is highly technical, not political charged although it may be conflictual in the policy community. Unlike regulatory and re-distributive policies, it does not involve the direct and coercive use of government power over citizens. Telehealth behaves mostly as an administrative reform, with its policy goals emphasizing greater efficiency in terms of cost savings.

Telehealth as a Regulatory Policy: Although regulatory policy may be politically salient among citizens, telehealth may be conflictual within the policy community. The regulatory aspects in this policy area may engage the participation of networks of healthcare interest groups, such as nurses, pharmacists and physicians. A moderate level of conflict over the issue may lead to some interest group activity by those who are liable to be covered by state regulations.

Telehealth Divide: Disparities between groups on demographic factors, such as gender, age, income, education, and race in using digital information technology, such as the Internet to search for public and private health and medical-related information online.

Telehealth Policy: An electronic government policy that uses the Internet to improve accessibility of public and private and non-profit healthcare services in rural and urban areas, while improving the quality of services at a lower service cost.

ENDNOTES

1. Similar question as the Pew survey is asked but demographic factors are controlled for by using negative binomial regression analysis: Have you ever looked online for any information on any of the 16 health and medical issues?" The 16 issues are: specific disease or medical problem; certain medical treatment or procedure; experimental treatments or medicines; alternative treatments or medicines; diet, nutrition, vitamins, or supplements; exercise or fitness; prescription or over the counter drugs; immunizations or vaccinations, how to quit smoking, problems with drugs or alcohol; depression, anxiety, stress or mental-health issues; environmental health hazards; sexual health; particular doctor or hospital; health insurance; and Medicare or Medicaid insurance. Our dependent variable is a count of all "yes" responses to each health and medical issue topic, ranging from 0 to 16. An individual who has searched for all 16 medical issues is coded as 16 and someone who has looked for no medical issues is coded 0 (Pew Internet & American Life Project, 2003b).
2. Age is in years, while education is a 7-point Likert scale measuring the last grade or class completed in school. Income is measured on an 8-point scale measuring the total family income from all sources before taxes in 2001 ranging from less than $10,000 to $100,000 or more (Pew Internet & American Life Project, 2003b).
3. Household healthcare giver is defined as either a primary or secondary healthcare giver to a member in their household (Pew Internet & American Life Project, 2003b).

Chapter 1.5
Health Portals:
An Exploratory Review

Daniel Carbone
Victoria University, Australia

Stephen Burgess
Victoria University, Australia

INTRODUCTION

A lack of health services has long been the thorn in the side of many communities, especially rural and regional communities. The high costs of treating ever growing chronic and complex conditions in traditional settings, where rural allied health services providers are non-existent and doctors are already overcommitted, are prompting a shift in focus to more efficient technology driven delivery of health services. Moreover, these days it is also increasingly unlikely that health professionals will encounter patients who have not used information technology to influence their health knowledge, health behaviour, perception of symptoms, and illness behaviour.

Advances in Internet technologies offer promise towards the development of an e-health care system. This article will postulate whether portal technologies can play a role facilitating the transition to such e-health care systems.

This article aims at reviewing the literature to present to the reader the barriers and opportunities out here for effective health portals. However, the article does not intend to provide a one-fits-all technical/content solution, only to make implementers and developers aware of the potential implications.

BACKGROUND

Many rural and regional communities lack the range of allied health services that are readily available in metropolitan areas, and many rural doctors who are already overcommitted, provide services that an allied health professional could readily provide (Department of Health and Ageing, 2004). The Australian Institute of Health and Welfare data shows that death and disability from chronic disease is higher in rural and regional communities, including Indigenous people. Coronary heart disease, asthma and diabetes are the biggest killers. Participants in the Regional Australia Summit highlighted chronic disease as a major menace (Department of Health and Ageing, 2004).

This state of affairs is already prompting a change in the health care system to focus more on preventive medicine and health care away from the traditional settings (Yellowlees & Brooks, 1999). According to Yellowlees and Brooks (1999), there are three major drivers for this change:

- The *economic imperative* to restrain health care costs
- *Increasing consumerism*, and the evolution of the "informed patient"
- *Changes in communication technology*, and the evolution of the Internet

PORTALS AND HEALTH

The benefits of Web portals in aggregating information from multiple sources and making that information available to various users is well known; more importantly, they can provide the services of a guide that can help to protect the user from the chaos of the Internet and direct them towards an eventual goal (Tatnall, 2005). More generally, however, a portal should be seen as providing a gateway not just to sites on the Web, but to *all network-accessible resources,* whether involving intranets (within an organisation), extranets (for special partners of an organisation), or the Internet (Tatnall, Burgess, & Singh, 2004). In other words a portal offers centralised access to all relevant content and applications (Tatnall, 2005).

The literature on health portals tells us that the Internet offers a significant amount of health information of varying quality. Health portals, which provide entry points to quality-controlled collections of Web sites, have been hailed as a solution to this problem (Glenton, Paulsen, & Oxman, 2005). However, it has been demonstrated that the information accessible through (government run and funded) health portals is unlikely to be based on systematic reviews and is often unclear, incomplete and misleading. Portals are only as good as the Websites they lead to (Glenton et al., 2005). However, irrelevant information could easily be filtered using a number of frameworks that can be used to evaluate the quality of Web-located health information. For example, Sellito and Burgess (2005) have developed a set of affirmative response evaluation features identified across four quality categories: currency/authority, accuracy, objectivity and privacy. And they are used as the basis for determining the fundamental quality of Web-located health information (Sellitto & Burgess, 2005).

THE CONSUMER AND HEALTH INFORMATION

Increasingly, consumers are accessing health information via the Web (Thompson & Brailer, 2004). It has been estimated that 6.4 million Australian adults—almost half the adult population—accessed the Internet during 2000 (Gretchen, Berland, Elliott et al., 2001). This is not just an Australian phenomenon. In the United States, 52 million Americans access health or medical information on the Web (Fox & Fallows, 2003).

The existence of health portals has made life easier for the people that need this information. However, the quality of portal interfaces as well as the portal content has many times been in doubt (Bamidis, Kerassidis & Pappas, 2005). Using popular search engines may be aesthetically appealing and easy to use, but they often provide inaccurate information (Sutherland, Wildemuth, Campbell, & Haines, 2005). What is clear however, is that while most consumers still use word-of-mouth as a primary information source for health care decisions, the use of Internet information is increasing (Snipes, Ingram, & Jiang, 2005). In Australia, for example, more Internet users search the Web for information on depression than any other health condition (Lissman & Boehnlein, 2001). This is not surprising given the high level of disability associated with depression in the community and the fact that the Web provides a convenient, anonymous means of obtaining information about the problem (Cain, Sarasohn-Kahn, & Wayne, 2000). However, much of the depression information on the Web is of low quality and originates in the United States (Jadad & Gagliardi, 1998).

SERVICE PROVIDERS AND HEALTH INFORMATION

General Practitioners (GPs)

The gap between what GPs might do (based on evidence-based clinical practice guidelines and what they actually do is wide, variable and growing. Many factors contribute to this situation. GPs are inundated with new, often poorly evidence-based and sometimes conflicting clinical information. This is particularly serious for the generalist, with over 400,000 articles added to the biomedical literature each year. Adding further pressure to the "gap" are workloads that have increased over the past decade: GPs are seeing more patients with acute and complex conditions. Rural practitioners work even longer hours, offer more medical services and perform more clinical procedures than their urban counterparts—thus facing an even greater need for up-to-date information (Davis, Ciurea, Flanagan, & Perrier, 2004).

There are four steps in incorporating research evidence in clinical decision making: *asking* answerable questions; *accessing* the best information; *appraising* the information for validity and relevance; and *applying* the information to patient care (Craig, Irwig, & Stockler, 2001). However, a study in New Zealand suggested that to make this happen, practitioners urgently need training in searching and evaluating information on the Internet and in identifying and applying evidence-based information; as well as (health) portals to provide access to high-quality, evidence-based clinical and patient information along with access to the full text of relevant items (Cullen, 2002). Many sites have been developed to help the search for quality peer-reviewed literature. These include the Cochrane Library and the U.S. National Library of Medicine's PubMed, as well as sites offering full-text access to medical journals, such as Stanford University's HighWire Press and freemedicaljournals.com (Robinson & Day, 2004). GPs can keep up to date with reliable information from readily accessible Web sites such as PubMed and HighWire Press. PubMed is part of the National Library of Medicine in the U.S. It is a useful system for retrieving clinically relevant search results. HighWire Press has a less sophisticated search engine, but is an excellent source for obtaining the full text of journal articles (Robinson & Day, 2004). However, and although increasing, access to these resources by practitioners is still low (Young & Ward, 1999).

Nurses

E-health can deliver health care services and education, via a Web portal, to older persons with chronic conditions and their caregivers and enables the patient's home to be the point of care. This growing industry is ripe for exploration by nurses who can empower the patient and caregiver to gain self-care and coping skills. Advances in information technology now make this dream a reality (Moody, 2005). However, at the American Academy of Nurse Practitioner's Conference, it was identified that information on educational options for acute care nurse practitioner (ACNP) practice was needed (Kleinpell, Perez, & McLaughlin, 2005). Information technology skills of nurse managers and staff need to be developed in order to use information technology effectively. In order to learn in a Web-based environment, everyone needs the opportunity and access to required resources. Additionally, nurse managers' experiences are important to promote wider utilisation of Web-based learning (Korhonen & Lammintakanen, 2005).

Web portals could help nursing staff in a number of ways; for example, health assessment skills are vital to professional nursing practice. Health assessment has traditionally been taught using lecture, teacher-developed tests, practice and live demonstration, and interactive and computer-based learning materials.

Student evaluation of these types of courses revealed that online assignments enabled them to pace their learning, thereby promoting greater flexibility and independence. Students were able to master the technical skills of working online with minimal difficulty and reported that working online was no more stressful than attending class. A most helpful aspect of the online course was the instructor-developed video that was digitally streamed online (Lashley, 2005).

Hospitals

International health organisations and officials are bracing for a pandemic. For example, and although the 2003 severe acute respiratory syndrome (SARS) outbreak in Toronto did not reach such a level, it created a unique opportunity to identify the optimal use of the Internet to promote communication with the public and to preserve health services during an epidemic (Rizo, Lupea, Baybourdy, Anderson, Closson, & Jadad, 2005). What was learned was that many patients are willing and able to use the Internet as a means to maintain communication with the hospital during an outbreak of an infectious disease such as SARS. Hospitals should explore new ways to interact with the public, to provide relevant health information, and to ensure continuity of care when they are forced to restrict their services (Rizo et al., 2005).

PROVIDER EDUCATION AND HEALTH PORTALS

Claire Jackson (2005), the chair of the discipline of general practice at the University of Queensland, Australia, envisioned the primary care practitioner increasingly networked with consumers, government and professional groups, such as colleges and divisions of general practice. Primary and continuing medical education needs to play a principal role in this process. Education needs a fundamental change of focus from simply delivering content to developing the ability to manage these changes. Learning to learn and learning for life should be a major guiding influence in curriculum development (Carlile & Sefton, 1998).

Portals can certainly provide practitioners easy access to these resources; however, it has been argued that student health professionals lacked the state of readiness of for Web-based learning environments. A short survey was distributed to the Medical Faculty at Sheffield and 191 valid responses were received. Only 62% of students had access to an Internet-connected computer at home. Most students (95.8%) checked their e-mail every few days or more, with slightly less (82.8%) using the Web frequently. Relevant technologies were often never used, including Internet relay chat, message forums and video conferencing. However, 66% of students had used computer aided learning packages. Future use of online continuing professional education material is likely to be limited (Stokes, Cannavina, & Cannavina, 2004). Nevertheless, various studies have shown that appropriately designed, evidence-based online continuing medical education can produce objectively measured changes in behaviour as well as sustained gains in knowledge that are comparable or superior to those realised from effective live activities (Fordis et al., 2005).

Some very recent developments has a Pfizer-sponsored educational Web portal for GPs allows the company to track the advertisements doctors look at and the Web links they visit. Believed to be the first pharmaceutical company-sponsored portal for GPs in Australia, the My E-Portal site (www.myeportal.com.au) allows GPs to drag-and-drop links to their most frequently visited sites, and provides journal and division sites, access to continuing medical information, and links to entertainment, banking and travel sites. Pfizer can then collect information about what sites are accessed, the ads and links clicked on, and the links added to the site (Limprecht, 2005).

ELECTRONIC COMMUNICATION AND PORTALS

The Internet also offers a unique means of health promotion through the use of interactive tools like chat rooms, e-mail, hyperlinks and the like (Stout, Villegas, & Kim, 2001). Looking at all these is beyond the scope of this article, however, a brief look at e-mail communication will suffice to outline some of the basic issues facing the e-health care system of the future.

In a recent American study, a Web-based communication strategy (e-mail) was used to enhance communication between patients and GPs, where a Web mail address was promoted on the telephone (Spencer, 2005). An important observation from this study is that less than half of e-mails require the direct attention of the physician. This study is also supported by other similar research findings (Griffiths & Christensen, 2002). This of course has a number of ethical issues that need to be explored before going any further (Flicker, Haans, & Skinner, 2004).

DISCUSSION

The literature is full of evidence on portal's potential use in health, but it is all compartmentalised: there are GP studies, nurses' studies, hospital studies, patient studies, communication studies and so on. Furthermore, since the inception of the computer age, and even now with the advances in online technologies, there is ample evidence to suggest that development and implementation of these tools always lie in the realm of the technologists; where the technology is the focus of the implementation rather than the user's outcome (Tatnall, Davey, Burgess, Davison, & Fisher, 2000).

The technical issues involving portals is well documented; however, portals are but one component of the larger Health Information System. This simple fact needs to be acknowledged and efforts for wider research into the many facets of online health users and their subsystems must be taken into account, not as neat individual groups as current research seems to place them, but as dynamic partners of a Health Information System.

It is with this fear that this article has been written, in the hope that somehow developers and implementers would take heed of the barriers and opportunities for cross-field efforts to develop workable online tools that would produce, in this case, positive health outcomes.

CONCLUSION

This review recognises the potential for Web information technologies to affect some of the uses of these technologies in the development of an e-health care system for communities. However, for every potential, there are lessons that need to be embraced before rushing to developing portal technologies; for example:

1. The lack of user training is usually apparent when new technologies are introduced.
2. The need to be able to appropriately filter information to instill consistency and confidence on users of the resources.
3. Not all GPs are yet convinced the evidence-based guidelines are the clinical future for the treatment of chronic and complex conditions. This is perhaps the biggest obstacle

to an uptake of Web-based resources and treatment.

4. Health communication tools like e-mail presents an interesting challenge for clinicians, clinical treatment and ethical issues.
5. The overall message from this article is *proceed with caution*. The potential for portals is definitely there, and making users adopt them is perhaps the key to it.

KEY TERMS

Broadband Incentives: The Australian federal government provided incentives to cover the cost of voluntary connection and use of broadband in general practices to improve their poor access to the Internet.

Evidence-Based Medicine (EBM): Evidence-based medicine is the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research. By individual clinical expertise we mean the proficiency and judgement that individual clinicians acquire through clinical experience and clinical practice. Increased expertise is reflected in many ways, but especially in more effective and efficient diagnosis and in the more thoughtful identification and compassionate use of individual patients' predicaments, rights, and preferences in making clinical decisions about their care. By best available external clinical evidence, we mean clinically relevant research, often from the basic sciences of medicine, but especially from patient centred clinical research into the accuracy and precision of diagnostic tests (including the clinical examination), the power of prognostic markers, and the efficacy and safety of therapeutic, rehabilitative, and preventive regimens. External clinical evidence both invalidates previously accepted diagnostic tests and treatments and replaces them with new ones that are more powerful, more accurate, more efficacious, and safer (Sackett et al., 1996).

Generalist: Refers to a general practitioner (GP) or sometimes referred to as medical doctor (MD) as opposed to specialists (cardiologist, neurologist, etc.).

General Practice (GP): Primary care is delivered by some 9,000 practices in Australia, housing some 20,000 GPs; these vary from large practices with 10-15 doctors to many single doctor practices. These are typically doctor owned and run independently as small businesses although the government has a major influence in the way services are delivered and charged.

Chapter 1.6
Semantic Web Standards and Ontologies in the Medical Sciences and Healthcare

Sherrie D. Cannoy
The University North Carolina at Greensboro, USA

Lakshmi Iyer
The University North Carolina at Greensboro, USA

ABSTRACT

This chapter will discuss Semantic Web standards and ontologies in two areas: (1) the medical sciences field and (2) the healthcare industry. Semantic Web standards are important in the medical sciences since much of the medical research that is available needs an avenue to be shared across disparate computer systems. Ontologies can provide a basis for the searching of context-based medical research information so that it can be integrated and used as a foundation for future research. The healthcare industry will be examined specifically in its use of electronic health records (EHR), which need Semantic Web standards to be communicated across different EHR systems. The increased use of EHRs across healthcare organizations will also require ontologies to support context-sensitive searching of information, as well as creating context-based rules for appointments, procedures, and tests so that the quality of healthcare is improved. Literature in these areas has been combined in this chapter to provide a general view of how Semantic Web standards and ontologies are used, and to give examples of applications in the areas of healthcare and the medical sciences.

INTRODUCTION

"One of the most challenging problems in the healthcare domain is providing interoperability among healthcare systems" (Bicer, Laleci, Dogac, & Kabak, 2005). The importance of this interoperability is to enable universal forms of knowledge representation integrate heterogeneous information, answer complex queries, and pursue data integration and knowledge sharing in healthcare (Nardon & Moura, 2004). With the recent emergence of EHRs and the need to distribute medical information across organizations, the Semantic Web can allow advances in sharing such information across disparate systems by utilizing ontologies to create a uniform language and by using standards to allow interoperability in transmission. The purpose of this article is to provide an overview of how Semantic Web standards and ontologies are utilized in the medical sciences and healthcare fields. We examine the healthcare field as the inclusion of hospitals, physicians, and others who provide or collaborate in patient healthcare. The medical sciences field provides much of the research to support the care of patients, and their need lies in being able to share and find medical research being performed by their colleagues to build upon current work. Interoperability between these different healthcare structures is difficult and there needs to be a common "data medium" to exchange such heterogeneous data (Lee, Patel, Chun, & Geller, 2004).

Decision making in the medical field is often a shared and distributed process (Artemis, 2005). It has become apparent that the sharing of information in the medical sciences field has been prevented by three main problems: (1) uncommon exchange formats; (2) lack of *syntactic* operability; and (3) lack of *semantic* interoperability (Decker et al., 2000). Semantic Web applications can be applied to these problems. Berners-Lee, Hendler, and Lassila (2001), pioneers in the field of the Semantic Web, suggest that "the semantic web will bring structure to the meaningful content of web pages". In this article published in *Scientific American*, they present a scenario in which someone can access the Web to retrieve information—to retrieve treatment, prescription, and provider information based on one query. For example, a query regarding a diagnosis of melanoma may provide results which suggest treatments, tests, and providers who accept the insurance plan with which one participates. This is the type of contextually based result that the Semantic Web can provide. The notion of ontologies can be utilized to regulate language, and standards can be used to provide a foundation for representing and transferring information. We will focus on the lack of semantic and syntactic interoperabilities in this article. The semantic interoperable concept will be utilized in the context of ontologies, and syntactic interoperabilities are referred to as standards of interoperability.

BACKGROUND

The Semantic Web is an emerging area of research and technology. Berners-Lee (1989) proposed to the Centre Europeen pour la Recherche Nuclaire (CERN) the concept of the World Wide Web. He has been a pioneer also in the concept of the Semantic Web and has expressed the interest of the healthcare field to integrate the silos of data that exist to enable better healthcare (Updegrove, 2005). He has been involved with the World Wide Web Consortium (W3C) Web site (http://www.w3.org), which offers a vast array of Semantic Web information in a variety of subject areas, including the medical sciences and healthcare. Miller (2004) states that the Semantic Web should provide common data representation to "facilitate integrating multiple sources to draw new conclusions;" and to "increase the utility of information by connecting it to its definitions and context". Kishore, Sharman, and Ramesh (2004) wrote two articles which provide detailed information about ontologies and information systems.

The concept of the Semantic Web is to extend the current World Wide Web such that context and meaning is given to information (Gruetter & Eikemeier, 2004). Instead of information being produced for machines, information will be produced for human consumption (Berners-Lee et al., 2001). There are two main aspects of Semantic Web development: (1) ontologies for consistent terminology and (2) standards for interoperability.

Ontologies

Ontologies have been defined in many ways through the areas of philosophy, sociology, and computer science. For the Semantic Web context, ontology is the vocabulary, terminology, and relationships of a topic area (Gomez-Perez, Fernandez-Lopez, & Corcho, 2004). Ontology gives the meaning and context to information found in Web resources (databases, etc.) for a specific domain of interest, using relationships between concepts (Singh, Iyer, & Salam, 2005). According to Pisnalli, Gangemi, Battaglia, and Catenacci (2004), ontologies should have:

1. *Logical consistency* and be expressed in a "logical language with an explicit formal semantics.
2. *Semantic coverage* such that it covers "all entities from its domain."
3. *Modeling precision* and represent "only the intended models for its domain of interest."
4. *Strong modularity* for the domain's "conceptual space. . .by organizing the domain theories."
5. *Scalability* so that the language is expressive of intended meanings.

The domain of an ontology should include a taxonomy of classes, objects, and their relations, as well as inference rules for associative power (Berners-Lee et al., 2001). This shared understanding of the concepts and their relationships allows a means to integrate the knowledge between disparate healthcare and medical science systems. Much of the Semantic Web research in the medical sciences area has been specific in either generating more efficient and effective information searching or to the interoperability of the EHR. Health information is inherently very tacit and intuitive, and the terminology often implies information based on physical examinations and expressions of the patient. While it uses standardized terminology, the difficulty lies in the expression of this tacit knowledge to others, especially across a network of computers. The two great needs in the medical sciences and healthcare that can be fulfilled by Semantic Web are to standardize language and to provide a consistent foundation for transferring EHR information (Decker et al., 2000).

Standards

While ontologies represent the conceptual basis for the information to be transmitted, standards allow for consistent transmission of the data between disparate systems. The data in different clinical information systems silos are in multiple formats, and relevant medical and healthcare knowledge must be accessible in a timely manner. This can be performed through interoperability standards which can enable information integration, "providing transparency for healthcare-related processes involving all entities within and between hospitals, as well as stakeholders such as pharmacies, insurance providers, healthcare providers, and clinical laboratories" (Singh et al., 2005, p. 30). The main standard for interoperability in the Semantic Web is Resource Description Framework (RDF), which is recommended by the W3C. RDF is an object-oriented based standard, which provides reusable components for data interchange over the web (Decker, Mitra, et al., 2000). It is unique in that every concept represented in RDF has a universal unique identifier (the Uniform Resource Identifier [URI]), which identifies every e-mail address, Web page, and other Web elements. This ensures no semantic ambiguity. RDF also enables knowledge representation through a series of concepts such as class, data type, and values. In order to express representations of ontologies for context, RDF allows for extensions such as the DARPA Agent Markup Language +Ontology Inference Layer (DAML+OIL) standard, which is the basis for the Web Ontology Language (OWL) standard that has recently gained popularity (Nardon & Moura, 2004).

SEMANTIC WEB APPLIED STANDARDS AND ONTOLOGIES IN THE MEDICAL SCIENCES AND HEALTHCARE

"The semantic web initiative has resulted in a common framework that allows knowledge to be shared and reused across applications" (Health Level 7, 2004) and organizations. An infrastructure of common transmission standards and terminology will enable an interconnected network of systems that can deliver patient information. There have been various calls for the decrease of medical errors via utilization of information technology, and the increase of medical information accessibility and Semantic Web technology has a critical role to play. Besides the delivery of patient information, the Semantic Web can also assist medical sciences research in providing greater accessibility and the sharing of research. In the search for information, the Semantic Web can impart a context and meaning to information so that queries are more efficient in producing results more closely related to the search terms.

Table 1 displays only a few of the main standards currently used for interoperability in the Semantic Web. The affiliated organizations are listed, showing that there are many grassroots efforts involved in generating standards. There are three main organizations that are involved in international standards for EHRs. These include the International Organization for Standardization (ISO), Committee European Normalization (CEN), and Health Level 7 (HL7)—U.S. based (HL7, 2004). Standards are also important to develop on an international basis because countries also report national health status statistics to the world community (Cassidy, 2005).

A list of ontologies in the medical domain is listed in Table 2. For clarification, a logical association to an ontology is that of the ICD-9 (ICD-10 is the new version) coding for diseases. When a patient visits the physician, the physician records a standard ICD-9 code for the diagnosis of the patient and a CPT code for the procedure that was performed on a patient. These are standardized codes that are found in manuals for medical coders; and they allow insurance companies and other medical affiliates to understand information from many different sources. For example, if a patient is seen for a mole, the mole can have many particular qualities. Is it to be removed for cosmetic purposes, or is the mole potentially cancerous? The location of the mole will be important to know, as well, because the treatment may be determined by the location. The difference in the context may determine whether the insurance company will pay for the treatment of the mole. A cancerous melanoma on the nose would have the diagnosis code of 172.3 and a benign neoplasm would be coded as 238.2. If a tissue sample were taken so that the lab could test the mole for cancerous cells, the diagnosis would be 239.9, which is unspecified until the lab results return for a firm diagnosis. The CPT procedure code for the treatment would be applied and would be determined by a number of factors including the location of the mole, amount of tissue excised, whether a modifier needs to be added to the code if the services is charged with an office visit, and the type of excision utilized. While we have CPT and ICD-9 as a vocabulary for procedure and diagnosis codes, they function only as a part of ontology's purpose. An ontology gives context to the patient's medical history and allows the diagnosis and procedure to be automatically

Table 1. Sample standards for interoperability

Name	Purpose	Associated Organization	Source
XML	eXtensible Markup Language; creation of tags		Decker et al, 2000
RDF	Standardized technology for metadata; for interpreting meaning	W3C	Nardon, 2004 Gruetter, et al, 2004

CPT Codes*	Classification of procedure codes	American Medical Association	Gillespie, 2003

linked, possibly with appropriate medications, lab tests, and x-rays. The next section discusses ways that the Semantic Web has been applied in the medical sciences field.

SEMANTIC WEB APPLICATIONS IN MEDICAL SCIENCE

Table 3 lists only a few of the sample projects being conducted in the medical science and healthcare field. Previous research in this area has dealt with two main topics: (1) efficient and effective searches of medical science information and (2) the interoperability of EHRs. Our purpose is to provide a comprehensive review of this research to understand the current status of the Semantic Web in healthcare and medical sciences and to determine what future research may be performed.

Electronic Health Records

EHRs are comprehensive patient medical records which show a continuity of care. They contain a patient's complete medical history with information on each visit to a variety of healthcare providers, as well as medical tests and results, prescriptions, and other care histories. (Opposed to EHRs, Electronic medical records [EMRs] are typically those which reside with one physician.) Figure 1 shows the main stakeholders in the healthcare industry, and thus, the necessity for enabling these partners to communicate. Physician's, hospitals, Independent Practice Organizations (IPOs), and pharmacies interact to exchange patient information for medical purposes.

The government requires that healthcare organizations report medical data for statistical analysis and so that the overall health of the nation can be assessed. Medical information is aggregated so that patient identifiers are omitted

Table 3. Sample medical Semantic Web projects

PROJECTS			
Name	***Purpose***	***Associated Organization***	***Source***
Good European Health Record Project	To produce a comprehensive multi-media data architecture for EHRs	CHIME	Nardon, 2004 http://www.chime.ucl.ac.uk/work-areas/ehrs/GEHR/index.htm
Brazilian National Health Card	Aimed at creating infrastructure for capture of encounter information at the point of care		Nardon, 2004
Artemis	Semantic Web Service-based P2P Infrastructure for the Interoperability of Medical Information Systems	Six participating entities from	Bicer et al., 2005 http://www.srdc.metu.edu.tr/webpage/projects/artemis/
Active Semantic Electronic Patient Record	Development of populated ontologies in the healthcare (specially cardiology practice) domain; an annotation tool for annotation of patient records, and decision support algorithms that support rule and ontology based checking/validation and evaluation.	LSDIS (large Scale Distributed Information Systems and AHC (Athens Heart Center)	http://lsdis.cs.uga.edu/projects/asdoc/
MedISeek	Allows users to describe, store, and retrieve medical images; metadata model		Carro et al., 2003

Figure 1. The coordination of the healthcare industry is very diverse in its information needs

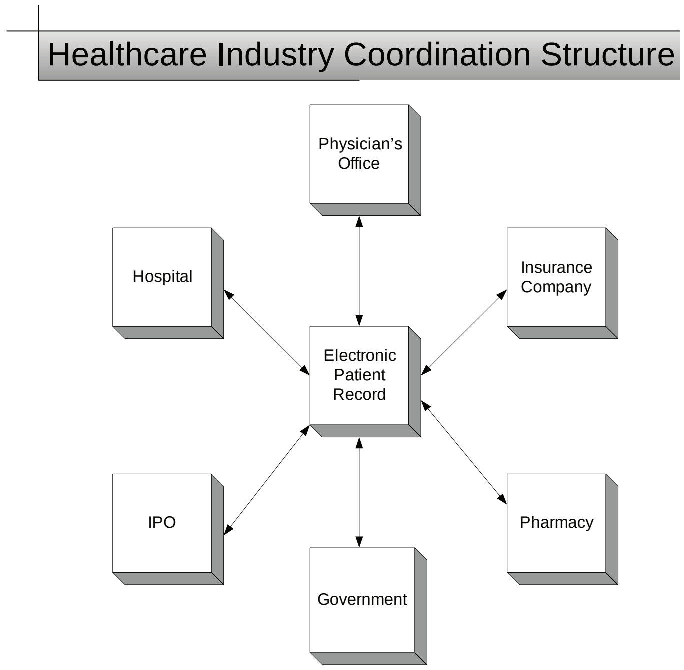

Figure 2. The sharing of information between healthcare entities can enable more efficient and effective quality of care

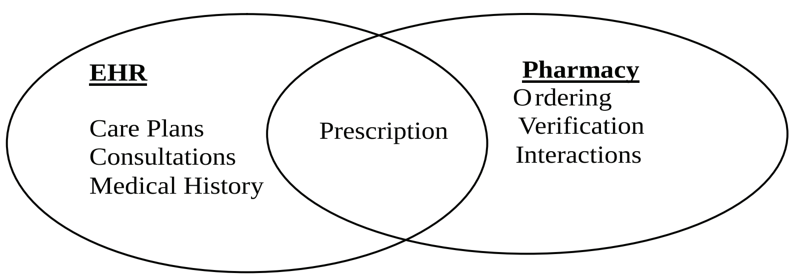

and reported to the government for public health purposes and to catch contagious outbreaks early as well as to determine current health issues and how they can be addressed. For example, cancer registries report specific aggregated cancer information, and healthcare organizations report instances of certain infectious diseases such as the Avian influenza (bird flu), for the welfare of the public. The importance of sharing this information is the improvement of patient safety, efficiency, self-health management (through access of medical information), and effective delivery of healthcare (HL7, 2005). Figure 2 shows how two entities may interact to share information (adapted from HL7).

Indeed, a commission on systemic interoperability has been established through the Medicare Modernization Act of 2003 and recommends product certification, interoperable standards, and standard vocabulary as a way of ensuring that healthcare data is readily accessible (Vijayan, 2005). At a North Carolina Healthcare Information Communications Alliance, one recurring theme was that of interoperable EHRs. Brailler (2005), the first National Health Information Technology Coordinator in the U.S., spoke about standards harmonization for EHRs. The discussion of developing standards for interoperability emphasized the need to "stitch together different efforts" put forth by organizations such as HL7, IEEE, ISO, and SNOMED. Undoubtedly, he recognized that "standards are about economic power" and they need to be analyzed to determine which standards are available for the commercial market. In doing so, the office of National Health Information Technology suggests that there be a compliance certification for EHR based on criteria such as security, interoperability, and clinical standards—basically a seal of approval that if a healthcare organization purchases such a product, it will be "guaranteed" to have specific interoperability certification. Brailler stated "if it's not certified, it's not an EHR." Given this, it has been suggested that the second generation of EHRs is being developed to communicate with structured datasets, middleware, and messaging between systems (Bernstein, Bruun-Rasmussen, Vingtoft, Andersen, & Nohr, 2005). Perhaps the third generation will provide full scale Semantic Web capabilities in which interoperability is seamless.

Currently, patient information is kept in silos across the aforementioned organizations; the Semantic Web will enable access to these silos through interoperability standards and consistent language. According to a white paper published by HL7 (2004), an organization which has developed HL7 standards for healthcare, improvements in the following five areas can be made through EHR standards: (1) interoperability, (2) safety/security, (3) quality/reliability, (4) efficiency/effectiveness, and (5) communication. To improve these areas, the standards proposed by HL7 include both standardized service interface models for interoperability, but also standardized concept models and terminologies. The current use of the HL7 standard is for the messaging of data to populate other disparate systems. For example, admissions data of a patient is also sent to the billing system. The problem with current messaging systems, such as HL7, is that they duplicate information across systems. Patient demographic information, for example, can be copied from one system to another, and maintenance of such data can create more messaging between systems (usually within an organization).

In Denmark, the examination of EHR use and interoperability has also been an issue of interest (Bernstein et al., 2005). The Danish Health IT Strategy project's goal is to analyze the variety of grassroots models for EHR information modeling and informatics. The National Board of Health is currently analyzing the SNOWMED ontology for use in its EHR. SNOWMED is an ontology that encapsulates classification systems such as ICD9. As a reference terminology, it is much more detailed in the medical concepts that it conveys. This level of detailed information allows the data to be used for quality assurance and resource utilization purposes and allows the EHR to relay more information than ICD9 coding for diagnoses. For example, there are around 13,000 ICD9 codes for diagnoses and SNOWMED contains 365,000 codes (Cassidy, 2005). Similar to the Denmark project, the Artemis project focuses on developing Semantic Web technology such as ontologies as a foundation to interoperability for medical records. Rather than standardizing the actual documents in the EHR, the goal is to standardize the accessibility of the records through wrappers, Web Services Description Language (WSDL) and Simple Object Access Protocol (SOAP) (Artemis, 2005). Bicer et al. (2005) discuss a project with Artemis in which OWL ontologies are used to map information messages from one entity to another.

Partners Healthcare uses RDF to enable medical history from EHRs to be accessible through computer models which select patients for clinical trials (Salamone, 2005). They utilized Semantic Web Rules Language (SWRL) to write decision support rules for this purpose. The advantage in using the Semantic Web approach is that the coding is concise, flexible, and works well with large databases. As Eric Neumann of the pharmaceutical company, Sanofi-Aventis suggests, "with the semantic web, you publish meaning, not just data" (Salamone, 2005).

Information Searching and Sharing

"Ontologies can enhance the functioning of the Web in many ways. They can be used in a simple fashion to improve the accuracy of Web searches" (Berners-Lee et al., 2001). The difficulties and complexities of searching for medical information are discussed by Pisnalli et al. (2004) in their research on medical polysemy. Because polysemy (a word having more than one meaning) can be critical to finding correct medical information, the application of ontologies can be of value in information searching. For example, the ontology of the term *inflammation* can vary depending on the context of its use. As Pisnalli et al. state, inflammation can include the size, shape, evolution, severity, and source. When one searches for the term inflammation, many results may be provided, but time is required to sort through the "hits" for relevance. The ON-9 ontology is utilized by Pisnalli et al. to map contexts for the term inflammation. As Nardon and Moura (2004) emphasize, the relationships among medical terminology is also essential to representation of the information in a logical format. Allowing for specific context to be interpreted through ontologies will enable more efficient and effective searching. Usually, this involves the creation of metadata to identify the relevant data elements and their relationships (Buttler et al., 2002).

Medical vocabularies used to represent data include the Unified Medical Language System (UMLS) from the U.S. National Library of Medicine and Arden Syntax. UMLS is perhaps the most frequently used ontology in the healthcare and medical sciences field. The purpose is to aid in integrating information from multiple biomedical information sources and enabling efficient and effective retrieval. It defines relationships between vocabularies and includes a categorization of concepts as well as the relationships among them. For example, the National Health Card System in Brazil contains an extensive knowledge base of 8 million patients in which complex queries can be run (Nardon & Moura, 2004). Through ontologies and UMLS, mapping of business rules can be applied to medical transactions to infer information and achieve semantic interoperability. For example, if a patient can undergo only a certain procedure once within a 30-day time period, a transaction for a patient setting up an appointment for that procedure can be mapped to business rules to infer that the same person cannot schedule the same procedure within that time period. UMLS would determine the ontology for the appointment and procedures and ensure that the patient is indeed the same, and RDF defines the business rules for sharing the information (Nardon & Moura, 2004).

When querying multiple medical data sources for research purposes, there are many medical science repositories in which data may not be in machine-processable format and stored in nonstandard ways. Most of the interfaces to search and retrieve medical sciences research require human interaction. Data extraction of such large data sources can be very complex and often the data is reused by researchers such as those in Genomics (Buttler et al., 2002). Large databases containing bioinformatics research can be unified through ontologies such as Riboweb, Generic

Human Disease Ontology, Gene Ontology (GO), TAMBIS, and LinkBase. These allow a standard vocabulary to exist over disparate ribosomal, disease, gene product, nucleic acid, and protein resources. As an example, the Generic Human Disease Ontology, currently being developed with information from the Mayo Clinic, allows a physician to search by symptom to determine the disease or for type of appropriate treatment, and researchers can search for possible causes of a disorder (Hadzic & Chang, 2005).

MedISeek is an interesting example of using semantic vocabularies to search for medical visual information, such as x-rays and other images (Carro et al., 2003). Biomedical Imaging Research Network (BIRN), a project of the National Institute of Health, examines human neurological disorders and their association with animal models. A significant aspect of their work is through brain imaging. Their goal is to make this information available to others through the Semantic Web via graphical search tools; standard identifiers through ontologies; and cross-referencing of imaging (Halle & Kikinis, 2004). The Semantic Web will enable BIRN, MedISeek, and other healthcare and medical science projects to filter out less appropriate data by searching for a context to the information. RDF is being utilized with MedISeek and BIRN to allow interoperability between metadata patterns.

CONCLUSION AND FUTURE TRENDS

Sharing of EHR information allows for improved quality of care for patients. Sharing medical science knowledge allows scientists to gather information and avoid redundant experiments. Searching for medical science information on the Semantic Web will be made more efficient and effective by the use of common ontologies and standards for transmissions. "Trusted databases exist, but their schemas are often poorly or not documented for outsiders, and explicit agreement about their contents is therefore rare." The opportunity to share such large amounts of information through the Semantic Web suggests that knowledge management can exist on a comprehensive level with ontology as a unifying resource (Hadzic & Chang, 2005).

While there has been some research in the area of medical sciences information searching on the Semantic Web, there have been few studies on how to better enable healthcare consumers to search for medical information on the Web. Lay terminology of consumers often increases the number of results returned when searching for medical information on the Web. Polysemy creates a multitude of results within which the consumer must further search. The goal should be to use Semantic Web technology to minimize the semantic distance between a search term and its polysemy of translations (Lorence & Spinks, 2004).

The future of the Semantic Web will involve important developments in the emergence of e-healthcare through the use of intelligent agents. Singh et al. (2005) suggest that emerging Semantic Web-based technologies offer means to allow seamless and transparent flow of semantically enriched information through ontologies, knowledge representation, and intelligent agents. Intelligent agents can enrich the information by interpretation on behalf of the user to perform an automated function. The example given at the beginning of this article in which someone queries for melanoma information and receives information regarding treatments, tests, and providers in that person's location which accept his insurance, shows how intelligent agents can be utilized to search the Semantic Web. Agents can also be utilized to verify the source of the information. When sharing of information occurs across the Web and is pulled automatically by agents, the source of the information needs to be verified. This is especially true in healthcare with Health Insurance Portability and Accountability Act (HIPAA) 1996 regulations. If the foundation of ontology and interoperable standards exists, intelligent agents will be able to search the Web for information within the context desired.

Legal issues associated with the dispersion of healthcare information need to be identified. With HIPAA (1996)), healthcare organizations are required to keep patient personally identifiable information secure and private. This means encryption, access control, audit trails, and data integrity must be insured in the transmission process (Jagannathan, 2001). Who has rights to the data and who "owns the data," particularly in EHRs? Similarly, there is an issue of trust involved with sharing medical science and healthcare data, and this is an area ripe for further research. How can authentication be provided so that others know the source of data is trusted and how can it be ensured that the data will be edited by a trusted entity? The area of e-commerce can be a foundation for future research in trust, as well.

Semantic Web technology can function as a foundation for the sharing and searching of information for the healthcare and medical sciences fields. Because of the intuitive nature of patient care, the Semantic Web will enable context and meaning to be applied to medical information, as well as the conveyance of relationships between data. With the generation of standards for transmission of data between disparate systems, the quality of healthcare through better research and the sharing of information between healthcare providers will be a critical step in the evolution of patient care. This will enable the third generation of EHRs to be seamlessly interoperable for more efficient and effective patient care. These innovations can lead to improved work satisfaction, patient satisfaction, and patient care (Eysenbach, 2003).

Chapter 1.7
Discussing Health Issues on the Internet

Jane Moon
Monash University, Australia

INTRODUCTION

This article provides an overview of the trend in Internet usage; in particular, the trend that relates particularly to health-information-seeking behavior. It discusses a paradigm shift in patient-doctor relationships that has resulted from social changes; that is, lack of consultation time, thirst for medical knowledge, mass-media medical information and an explosion in the number of health Web sites. The Internet has become an important medium for bridging the gap in the patient-doctor relationship.

Issues of Internet quality are explored. While the Internet can help consumers by providing immediate feedback as far as treatment and medication are concerned, without proper standards and quality assurance it can give rise to diabolical consequences (Crocco, Villasis-Keever, & Jadad, 2002). Ciolek describes information on the Internet as mediocre and argues that health information on the Internet is subject to "Multi Media Mediocrity" (MMM) (Ciolek, 1997).

General Trends of Using Internet for Health Advice

The Internet has become a vital tool for individuals, families, the health profession and the health industry. One Web site reports that there are more than 10,000 health sites on the Internet, and others report more than 100,000 health-related Web sites (Eysenbach, Sa, & Diepgen, 1999). No one knows theexact number, but what is clear is that there are numerous health sites available.

Health sites vary, from academic sites to health-provider institutions and government sites. Recently, there have been an increasing number of pharmaceutical companies disseminating information or selling products and services in a variety of ways on Web sites luring consumers (Risk & Dzenowagis, 2001).

Since the emergence of the Internet in 1991, the Internet use has grown exponentially. A recent survey shows that 86% of the 168 million American adults have visited health Web sites, compared with 55% of the 60 million in Germany. Ninety percent of American primary-care physicians have used the Internet (Risk & Dzenowagis, 2001). According to Harris Interactive consulting firm, health Internet users grew steadily from 50 million in 1998 to 69 million in 1999, 97 million in 2001 and 110 million in 2002 (Harris Interactive, 2000).

Demographical Difference

No significant difference in information-seeking habits between different age groups were found (Brodie, Flournay, Altman, Blendon, Benson, & Rosenbaum, 2000) Also, there is a direct correlation between computer usage and access to health information:

Once people gain access to the Internet, its use at home to get health information is similar across income, education, race and age. Therefore, the number of persons using the Internet to access health information should rise along with computer use. (Brodie, 2000, p.262)

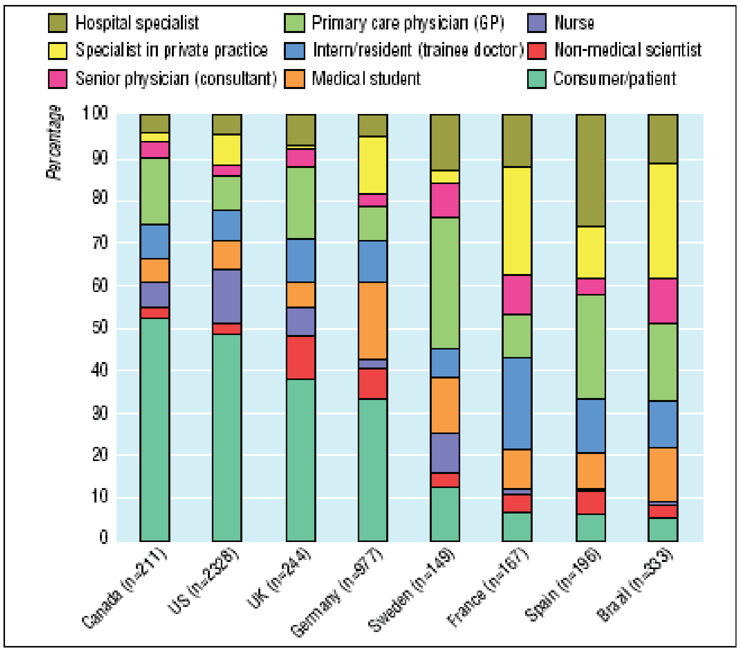
According to Brodie's report, gender, age and background do not make much difference in Internet search behavior.

A significant difference between countries is noted in research results from a questionnaire survey among the users of a dermatology atlas Web site. Pictures were used to minimize language barriers between countries (Eysenbach et al., 1999). The survey was conducted over seven months, from July 1998 to February 1999, and was answered by 6,441 users from all over the world.

Figure 1 shows the distribution of the 4,605 users who completed survey from the eight countries that showed the highest absolute numbers of users. Of those eight, Canada shows the highest percentage of users, followed by the United States (U.S.) and United Kingdom (UK), with Brazil the lowest.

There was a high proportion of general practitioners in Canada, UK, Spain and Sweden, and a high proportion of specialists in Brazil, France, Germany, Spain and U.S.

Figure 1. User profile of dermatology atlas Web site intended for health professional



A high proportion of hospital specialists were noted in Spain, Sweden, France and Brazil compared to a large number of specialists in private practice in Brazil, France and Germany. This is a reflection of the actual ratio of specialists in private practice compared with the public sector in the respective countries.

Looking at the percentage of nurses visiting the Internet, the highest percentage was noted in the U.S., Canada, UK and Sweden, as opposed to almost none in other countries, probably reflecting the differing roles and levels of responsibility nurses have in those countries.

While these data have been gathered in a specialist setting; that is, dermatology, and may be prone to self-selection bias and thus not representative of the whole, nevertheless, they tell us that there are significant differences between countries in Internet use. These differences are not only technological ones, but they also reflect differences in the health system as well as other cultural, sociological factors and economic factors—for example, capacity to afford Internet facilities (Eysenbach et al., 1999).

What causes the behavioral shift in consumers towards the Internet over traditional face-to-face contact with doctors?

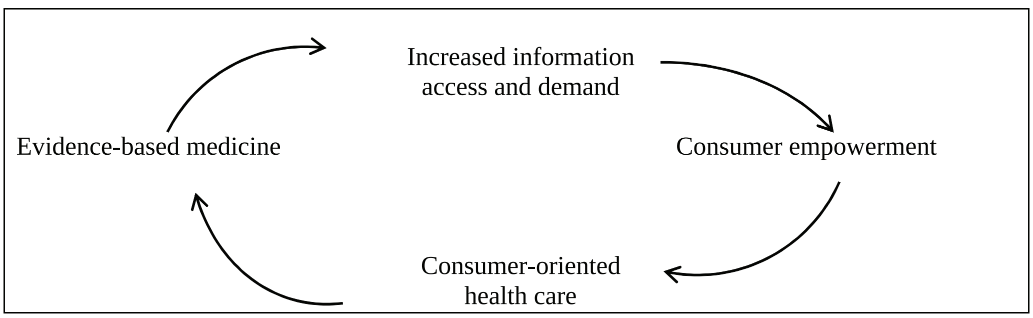
Changing Medical Practices

In the field of information technology, doctors still seem to be lagging behind other professionals. In many industrialized nations, consumers have taken a leading role in retrieving and exchanging health information (Eysenbach et al., 1999). While telemedicine (diagnostic and curative medicine) is influenced by "technological push," cybermedicine (preventive medicine and public health) is influenced by "consumer pull"; the traditional family doctor-patient relationship has to change to meet the demands of these social changes (Eysenbach et al., 1999).

Consumer Empowerment

The availability of the Internet has provided consumers with easy access to information. "The empowered, computer-literate public is exerting tremendous influence on healthcare delivery" (Ball & Lillis, 2001, p. 2). Consumers are actively seeking health information using the Internet as a major tool. Users get access to as many of the resources and databases as physicians do, although some databases are specifically available for physicians. This empowers consumers to make informed decisions and reduces their dependency on the physician. The Internet is, thus, a motor for evidence-based medicine for both physicians and consumers. It gives "increasing consumer involvement in health care decision making and increasing the pressure on caregivers to deliver high quality health services" (Eysenbach et al., 1999, p.2).

Figure 2. Positive feedback loop (Eysenbach et al., 1999)



As can be seen in Figure 2, consumers' access to health information on the Internet has increased tremendously; they have access to physicians' Web pages and databases and retrieve a wealth of knowledge on medical conditions and treatments. As computer-literate consumers become empowered, they can become involved in decision making in evidence-based medicine (Eysenbach et al., 1999).

This transformation driven by the Internet can be a challenge to physicians, as users are better informed than before (Ball & Lillis, 2001). Whether consumers are capable of making quality decisions is yet to be determined, as they can become "cyberchondriac" with more access to information on health problems. However, many consumers can challenge physicians with evidence-based information from the Internet (Eysenbach et al., 1999). The speed at which information is delivered on the Internet can cause mis-communication; for example, in Britain there was a government warning about oral contraceptives on the Internet. Some consumers found the information before physicians did (Coiera, 1996). There is a pressing need for better communication among doctors regarding information technology. Equipped with the right information, physicians can improve the quality of treatment by fostering closer partnerships with consumers.

This paradigm shift is a challenge to the doctor-patient relationship, as can be seen next.

Doctor-Patient Relationship

The term "patients" is slowly being replaced by "consumers" (Coiera, 1996). Sir William Osler (1849-1919) was a pre-eminent physician of the century whose work was based on trust and confidence, fostering a personal relationship. With the recent explosion of the Internet, the art of Osler's medical practice, which has been a fundamental to medicine, is under threat (Wheeler, 1990), as consumers challenge physicians with a "stew" of medical information they have retrieved from the Internet, and arrive at their appointments with meters of printouts challenging their knowledge (Coiera, 1996).

There is a common scenario where patients spend long hours searching for information on the Internet and bring pages of printouts to the doctor and ask questions. Such discussion can be exhausting. Some doctors have suggested, "Whatever you do, don't go on the Internet" (Ferguson, 2002, p.555). Also, the information available could be too abstruse or complex for most consumers. This health illiteracy could pose significant concerns for consumers, as they do not necessarily have sufficient medical knowledge to make informed decisions about their medical conditions (Oermann & Wilson, 2000; Wyatt, 1997).

In addition, there is an increase in litigation against doctors. The Internet transforms the traditional autocratic doctor-patient relationship into a balanced power play (Ball & Lillis, 2001).

What is very important is that, while information obtained on the Internet does support users, it cannot "replace the patient-physician relationship" (McLellan, 1998). The availability of resources to both physicians and patients could mean that consumers can get the same access to resources as the physicians. But it is often questionable whether the information is accurate or complete, which could lead to misdiagnosis and misunderstanding (Helwig, Lovelle, Guse, & Gottlieb, 1999).

National Medical Portal: Opportunities and Threats

A portal is a concept widely used within the Web. It is "a gateway or a door that provides users a single gateway to personalized information needed to make informed business decisions" (Quirk, 2001, p.2). The word "portal" has been used largely in the last two to three years and is often confused with Web sites. The difference between Web sites and portals is that the former is static and the latter is dynamic. Portals are Web-based; have dynamic links to information resources, effective information and document managers; and connect people with information (Moon & Burstein, 2004).

Medical portals provide information such as causes of diseases, medications, treatments, alternative therapies and lists of consultants. Medical portals can be either general or specific. General medical portals provide general medical information; for example, Better*Health* or Health*Insite*. Disease-specific portals provide information specific to particular disease; for example, cancer portal, breast cancer portal.

Moon and Burstein (2004) described five functional components necessary for a model of medical portal: community, personalization, quality, health services and gateway. The functional components relating to community are discussed in detail next, as it is pertinent to this article (p. 277):

- **Share medical information:** Can be done via e-mail, or by "chatting" or any other facilities such as MUD (multi-user device—through role play)
- **Promote interaction:** With doctors for receiving medical help or sharing personal experiences with other people
- **Bulletin board/newsletter:** From various stake holders can inform users of changes in the organization, such as change of member of the boards, or changes to portal sites for updates and so forth
- **Alert to new information:** With personalized settings, users can be alerted to new drugs or new research findings to a particular aspect of medical conditions
- Multimedia access via video streaming, or Web cam facilities to facilitate meetings or discussions.

Opportunities

The opportunities for users that give better empowerment are as follows:

- Better access to medical information
- New form of communication between users and care providers
- Opportunity to meet other users
- Saves time from visiting doctors
- Cheaper than visiting the doctor, as the connection fee is fairly inexpensive compared to the cost of visiting general practioners or consultants
- Not time dependent—can look for information anytime
- No geographical barrier—can find information anywhere
- New opportunity for therapy (e-therapy)
- Reduces barrier between care providers and users for second opinion
- A new medium for those who are embarrassed to see doctors for personal reasons and can find answers anonymously.

All of the above and more that can be listed add value to users and empower them to make informed decisions about their health (van Melick, Hakkenberg van Gaasbeek, & Pennings, 2001).

Threats

The Internet is anarchic in nature; that is to say that it is formless and boundless. Anyone, anywhere can write content and publish it anywhere, provided they have the software to do so. The question is not how to retrieve health information but how to retrieve relevant and accurate information (Risk & Dzenowagis, 2001). The easy access to an avalanche of health information can be an enormous threat to users if they are not properly guided.

Following is a list of some adverse effects the Internet could bring if the information is not managed with proper knowledge:

- It is not always easy to see the origin of the information, and users could be making decisions on the basis of a source that might not be quality assured

- Users are not equipped to make judgments on the basis of particular scenarios, they need to see health holistically
- Could harm users if they follow treatments that are location-specific
- Risk of making a wrong diagnosis
- Risk of taking ill advice if the discussant is not properly qualified
- Risk of Internet addiction
- Could be lured by pharmaceutical companies' advertisements
- Avalanche of information can be time-consuming and confusing.

All of the above and more add value to the users and empowers them to make informed decisions about their health (van Melick, Hakkenberg van Gaasbeek, & Pennings, 2001).

The following paragraphs discuss Internet health tools available to give guidance to consumers about the breath, depth and insightfulness of medical portals.

Internet Quality Tools

Health care information has potential benefits for many Internet users (Coiera, 1996) if they are properly educated and if the developers take quality criteria into consideration (Policy Paper, 2002). How do consumers know if a site is worthy? Many tools are available to assess the quality of content on the Internet. Wilson (2002) and Risk and Dzenowagis (2001) provide tools to classify Web sites, assisting developers to produce quality sites. They are as follows:

- **Code of conduct:** to ensure that the developers adhere to quality criteria.
- **Quality labels:** a logo or a symbol is displayed on the screen.

The most common ones are Health On the Net Foundation and Hi-Ethics code. Both of these are used on more than 3,000 Web sites.

Figure 3.

Figure 4.

Hon-code does not rate the quality of information, but it provides users the origin information and the purpose of data they are reading. It also provides ethical standards to Web site developers.

Hi-Ethics code produces quality levels for commercial sites. The uses of Hi-Ethics are: American Specialty, Health Networks, America Online HEALTHvision.

- **User guides:** provide user guidance to assess if a site meets the criteria. Web sites such as DISCERN allow users to validate the quality of written information on treatments; QUICK gives step-by-step guidance to children; NETSCORING gives guidance on all health-related topics.
- **Filters:** filter information according to a set of criteria; OMNI provides gateways to evaluate resources.
- **Third-party certification:** a seal or logo accredited by a third party, assuring consumers the site meets accepted standards for health sites. Third-party accreditors are MEDCERTAIN and TNOQMIC.

However, Wilson fails to discuss the size of the burden placed on provders, the lack of provision for educating consumers, the cost of developing and maintaining quality and the needs of developing countries. Wilson's article concentrates mostly on English-speaking countries.

FUTURE TRENDS

There is no turning back to the past. Twenty-first-century medicine has changed traditional medicine to Internet-empowered, patient-driven online support, with users controlling and managing their health (Ferguson, 2002). As more and more consumers are using the computer, it would be impossible to unwire the information. While the Internet can pose the threat of unreliable information (Oermann & Wilson, 2000), with users lured by many commercial sectors (Risk & Dzenowagis, 2001), nevertheless, it is satisfying many consumers' needs (Ferguson, 2002).

Doctors who do not recognize this trend would be losing patients to those who do understand the changes in the doctor-patient relationship. What is important is that there should be a synergy between doctors and patients (Yellowlees, 2000). The way to ensure this synergy exists, and to build trust between doctors and patients, is to make sure Web site content is reliable and that the Internet is serviceable (accessible both technically and design-wise). Doctors also need to understand consumers' needs and provide them with quality information. Given that doctors are under pressure to see more patients in a given time, leading to shorter consultation time, the Internet is an alternative for consumers to educate themselves on their health concerns.

One of the ways to ensure that consumers educate themselves is to educate the developers of portals' search engines, encouraging them to design portals that are ethical and compliant with quality standards. It is also vital to educate consumers to be cautious with the material they access on the Internet. Thus, consumers can "access health information critically" (Wilson, 2002, p.600).

CONCLUSION

The Internet presents a powerful mechanism for helping users to improve their health-care decision making by providing easy and rapid access to, and exchange and dissemination of, enormous amounts of health information. Yet, users must be aware of the potential for misinformation and recognize the critical need to assess the quality of the information provided. Content providers must be encouraged to develop and publish high-quality information, and policy makers and health-care professionals must be educated on this important health issue (Risk & Petersen, 2002).

Despite the perils of predicting the future of our health-care system, it is hard to ignore the evidence that the health system will undergo a revolution. The rapid growth of computer-based electronic communication and the fact that the new generations are comfortable with electronic transfer of health information leads to an increase of patient health management; that is, patients are taking an active role in the decision-making process (Kassirer, 1995). This trend is likely to grow and will have a substantial and hopefully positive impact (lowering the cost) on the health economy and on the well-being of consumers.

KEY TERMS

Consumer Empowerment: The users are well informed of the information thus making an informed decision.

Cyberchondriac: Those users of the Internet who are obsessively persuing the Internet in search of information.

Cybermedicine: The Internet-driven practice of medicine where patients communicate with doctors via electronic medium.

Evidence-Based Medicine: Evidence-based medicine is a new paradigm that replaces old paradigm of traditional medicine based on authority. It is based on clinical research which uses current best evidence in making decisions about the care of individual patients.

Health Portals: Includes any information on the Internet relating to health, including medical information as well as products and information that are related to well being, i.e., shampoo, diets, medicine, and alternative medicine.

Chapter 1.8
Networkcentric Healthcare and the Entry Point into the Network

Dag von Lubitz
Central Michigan University, USA

Nilmini Wickramasinghe
Illinois Institute of Technology, USA

INTRODUCTION

The concept of e-health gains rapid and wide-spread international acceptance as the most practical means of reducing burgeoning healthcare costs, improving healthcare delivery, and reducing medical errors. However, due to profit-maximizing forces controlling healthcare, the majority of e-based systems are characterized by non-existent or marginal compatibility leading to platform-centricity that is, a large number of individual information platforms incapable of integrated, collaborative functions. While such systems provide excellent service within limited range healthcare operations (such as hospital groups, insurance companies, or local healthcare delivery services), chaos exists at the level of nationwide or international activities. As a result, despite intense efforts, introduction of e-health doctrine has minimal impact on reduction of healthcare costs. Based on their previous work, the authors present the doctrine of *network-centric healthcare operations* that assures unimpeded flow and dissemination of fully compatible, high quality, and operation-relevant healthcare information and knowledge within the Worldwide Healthcare Information Grid (WHIG). In similarity to network-centric concepts developed and used by the armed forces of several nations, practical implementation of WHIG, consisting of interconnected entry portals, nodes, and telecommunication infrastructure, will result in enhanced administrative efficiency, better resource allocation, higher responsiveness to healthcare crises, and—most importantly—improved delivery of healthcare services worldwide.

BACKGROUND: CURRENT ISSUES OF E-HEALTHCARE

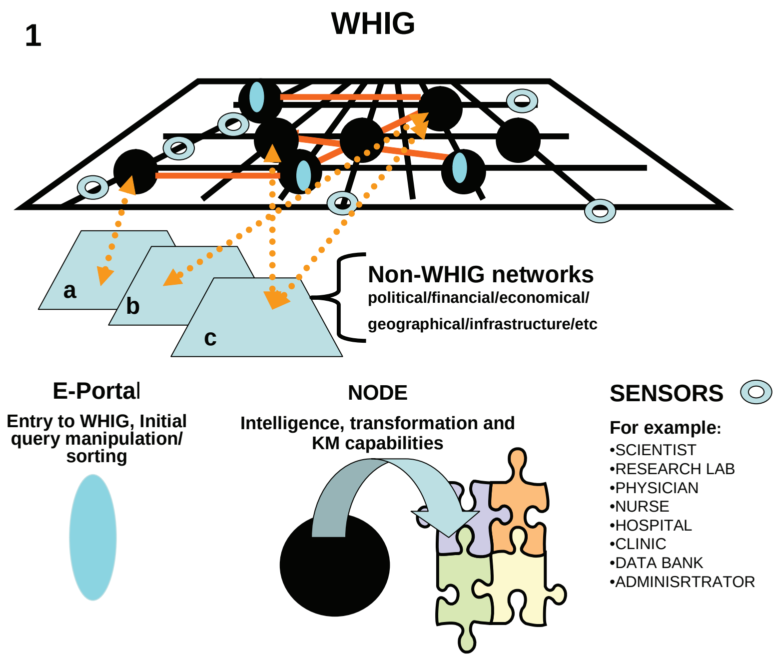
Major shifts in political and economical structure of the world that took place in the 20th century were instrumental in focusing global attention on healthcare and its importance in maintaining stability and growth of nations. At the same time, the cost and complexities of national and global healthcare operations became increasingly apparent (World Health Organization Report, 2000, 2004). In order to be efficient, healthcare providers and administrators became progressively more dependent on a broad range of information and knowledge that spans the spectrum stretching from purely clinical facts to the characteristics of local economies, politics, or geography. Consequent to the elevating demand for knowledge is the flood of a wide variety of uncoordinated data and information that emerges from multiple and equally uncoordinated sources (von Lubitz & Wickramasinghe, 2005b, 2005c). It has been hoped that vigorous use of IC^2T (Information/Computer/Communications Technology) will, in similarity to some forms of business operations, obviate the growing chaos of global healthcare. While IC^2T changed many aspects of medicine, the explosive growth of worldwide healthcare costs indicates that a mere introduction of advanced technology does not solve the problem (Fernandez, 2002: von Lubitz & Wickramasinghe, 2005). The quest for financial rewards provided by the lucrative healthcare markets of the Western world led to a plethora of dissonant healthcare platforms (e.g., electronic health records) that operate well within circumscribed (regional) networks but fail to provide a unified national or international service (Banjeri, 2004; Olutimayin, 2002; Onen, 2004). There is a striking lack of standards that would permit seamless interaction or even fusion of nonhealthcare (e.g., economy or local politics) and healthcare knowledge creation and management resources. The "inward" concentration of the Western societies on their own issues causes progressive growth of technology barriers between the West and the less developed countries, while the essentially philanthropic efforts to address massive healthcare problems of the latter continues to concentrate on "pretechnological" and often strikingly inefficient approaches (Banjeri, 2004; Olutimayin, 2002). Thus, despite the massive amount of information that is available to healthcare providers and administrators, despite availability of technologies that, theoretically at least, should act as facilitators and disseminators, the practical side of access to, and the use and administration of healthcare are characterized by increasing disparity, cost, and burgeoning chaos (Larson, 2004). Solutions to many of these acute and disturbing problems may be found in the recent approach chosen by the defence establishments of many countries to the information needs of the battlefield and to the modern, highly dynamic combat operations (von Lubitz & Wickramasinghe, 2005a).

DOCTRINE OF NETWORK-CENTRIC HEALTHCARE OPERATIONS

Our previous publications (von Lubitz & Wickramasinghe, 2005a, 2005b, 2005c) discussed the general principles and applicability of the military network-centric operations concept and its adaptation to modern worldwide healthcare activities. Network-centric healthcare operations are physically facilitated by the World Healthcare Information Grid (WHIG)—a multidimensional communications network connecting primary information collecting sources (sensors) with information processing, manipulating, and disseminating nodes. The nodes also serve as knowledge gathering, transforming, generating, and disseminating centres (Figure 1).

In similarity to the already proved attributes of network-centric military operations (Cebrowski & Garstka, 1998) of which, at the simplest level, the command centre of a joint naval task force is the simplest example and the execution of Operation Iraqi Freedom probably the most complex one, healthcare activities are characterized by multidirectional and unrestricted flow of multispectral data (von Lubitz & Wickramasinghe, 2005b, 2005c). All data, information, and node generated knowledge are characterized by fully compat-

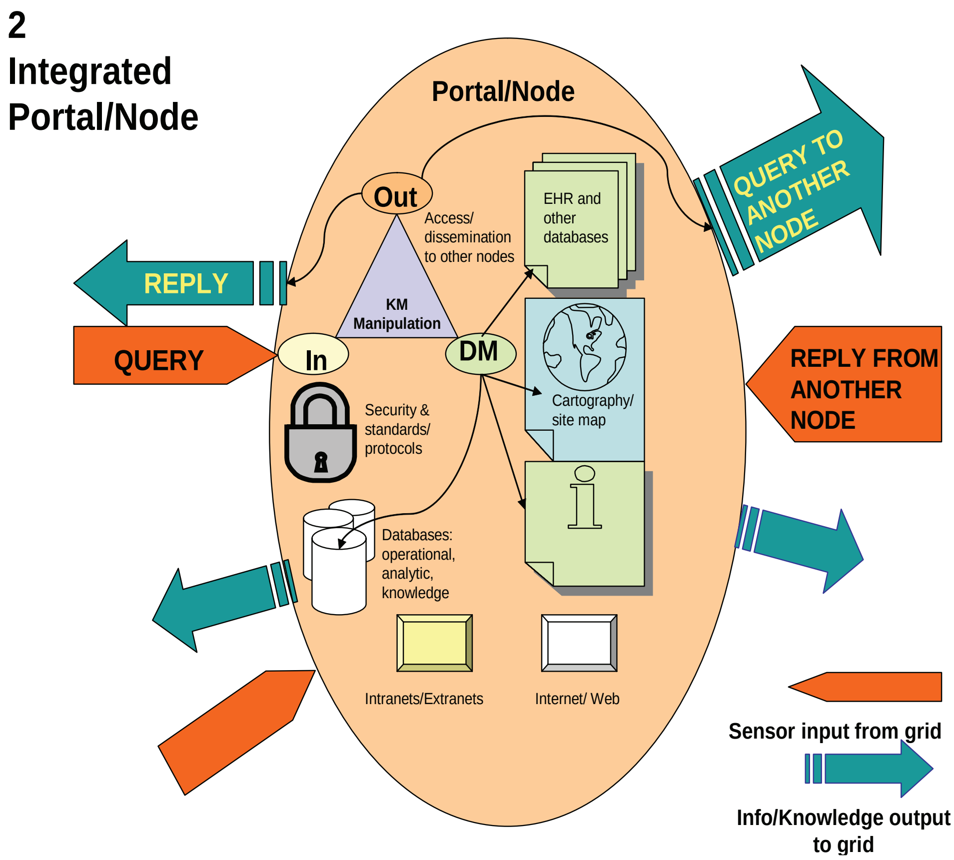
Figure 1. Schematic diagram of a WHIG segment



ible formats and standards that allow automated meshing, manipulation, and reconfiguration. Essentially, network-centric healthcare operations are based on the principles of high order network computing, where the WHIG serves as a rapid distribution system, and the nodes as the sophisticated processing centres that function not only as data/information/knowledge generating elements but also as DSS/ESS platforms providing high level, query-sensitive networkwide outputs. The nodes are also capable of extracting and analyzing data and information from healthcare-relevant sensors and electronic data sources (e.g., financial, political, military, geological, law enforcement, infrastructure level, etc.) and mesh these with the relevant biomedical elements. Incorporation of external information in healthcare operations provides readily available, rich, and necessary background that has, typically, a highly significant bearing on the success of activities that are either planned or conducted within the strict healthcare domain. The complications resulting either from the failure to include elements external to the essential healthcare activities or consequent to the exclusion caused by incompatible resource platforms have been amply demonstrated by major difficulties encountered during relief operations following tsunami-mediated destruction in December 2004.

Sensors feed raw data/information into the network through network-distributed portals. Likewise, data, information, and knowledge queries enter through portals as well. The latter provide entry level security screening and sorting/routing. Subsequent manipulation, classification, and transformation into information/pertinent knowledge is executed by interconnected nodes. Whenever required, each node can access information/knowledge existing within non-WHIG networks and databases and compare/merge the contents with the contents existing within the WHIG. While portals are associated with the nodes, implementation of ASP philosophy allows reaching the portal from anywhere within the WHIG.

Figure 2. Integrated entry portal/node



In addition to functioning as data/information/knowledge generating/manipulating/disseminating centres, the nodes also serve as the network points of entry (entry portals, Figure 2). However, contrary to the classical Web portal, where the client determines the information gathering path (O'Brien, 2004), the WHIG portal provides automated query classification, direction, and integration functions. Its operations are fuzzy logic-based, and the principal function of the WHIG portal is that of a "sorting/distribution station" which distributes the original query throughout the entire WHIG and collects and weighs the relevant outputs generated by multinodal analysis of the available resources. As the final step, the portal assigns the relevance level of the cumulative output, and provides automated pathways toward its further refinement. The WHIG portal operates thus not only as an entry point but also as either redirection station or WHIG exit site. Some of the functions of the WHIG portal are exemplified by the response to a hypothetical NGO query requiring decision support on the conduct of healthcare activities within the scope of a humanitarian relief operation in a costal region of "State X." The query will be automatically distributed within the network and the response will (equally automatically) provide multifaceted analysis of the essential medical needs of the affected population (e.g., most threatening diseases, the type and quantity of the required vaccines, need for other pharmaceuticals, tenting, water supplies, etc.). However, the response will also provide information on the local infrastructure and its nature and quality (e.g., air/sea port off loading/storage capacity, availability of beaches as the off-loading sites, capacity of local healthcare human and physical resources, quality and distribution density of roads/railways/means of transport, etc.), whether as an adverse factor, political stability/law enforcement efficiency within the region as a factor influencing distribution of aid, or movement of support teams. Clearly, even within such a simplified example, the range and complexity of factors that may significantly (and adversely) affect only one of many critical elements within a major relief operation is strikingly large. Correspondingly, the need for germane information/knowledge is equally substantial. Yet, due to the prevailing platform-centricity, despite the existence of such information, its dispersal within several, largely incompatible, systems makes it essentially inaccessible. Moreover, its retrieval demands clear awareness of the need followed by human-based/human guided search and extraction. Consequently, in situations of stress or in environments that pose acute demand for a wide range of simultaneous responses, the potential for major errors of omission and commission increases dramatically. A classical chain of such errors can be seen, for example, in the response to the events immediately preceding the destruction of World Trade Center in September 2001 (National Commission on Terrorist Attacks on the United States, 2004).

Data, information, or queries from WHIG enter through the portal where they are subjected to security/standards/protocol screening then transfer to the manipulation site (DM). The latter provides detailed sorting and redirection via intra and extra nets, and/or Internet/Web to other locations within the node, for example, patient records, information storage sites, analysis and knowledge generating sites, and so forth (unidirectional arrows). All sites within the node are capable of multidirectional communication (not indicated for the sake of clarity). Their output is transmitted to the knowledge manipulation and generation site which, in turn, generates final output stored within the node and also disseminated throughout the network (Out). If needed, the node can distribute additional WHIG-wide queries. Replies are collected, manipulated at the KM level, and incorporated into the final node output. Although neither the portal nor individual functional aspects of the node need be collocated, their operations are conducted as a single, self-contained unit; that is, none of the constituting elements can participate individually in the functions of another node. Self-containment of each node adds to its security and reduces the risk of inadvertent networkwide dissemination of integrity-compromising factors (e.g., viruses, spurious data, etc.).

FUTURE TRENDS: OPERATIONAL THEORY OF NETWORK-CENTRIC ACTIVITIES

The operational philosophy of network-centric healthcare operations is based on the principles of Boyd's (OODA) Loop (Boyd, 1987; von Lubitz & Wickramasinghe, 2005a, 2005b, 2005c) that defines the nature and the sequence of interactions with dynamic, rapidly changing environments characterized by a high degree of structural and event complexity. Accordingly to Boyd, each complex action can be subdivided into a series of consecutive cycles, loops, with the preceding cycle strongly influencing the initial stages of the following. Each revolution (cycle) of the Loop comprises four stages: observation, orientation, determination, and action. During the observation stage, all inputs describing the action environment are collected and organized into coherent entities. At the orientation stage, the organized data are converted into meaningful information that provides as complete image of the operational environment as possible based on the totality of the existing information. At this stage the weaknesses of the opposition are detected, and the centre of the future action determined. During the determination phase, the hypothesis, that is, the plan to respond to the pressure exercised by the operation environment, is formulated. The Hypothesis defines the plan of action, the required strength and nature of the response, its precise location, timing and duration, and so forth. During the Action phase, the Hypothesis is tested: the formulated plan is implemented and its results (and the consequent response of the action environment/opposition) set off the next revolution of the Loop—the new observation stage is initiated. Clearly, the nature of action determines the intervals between the stages.

Originally Boyd's Loop had been created as a tool facilitating aerial combat, where each individual stage was extremely brief (milliseconds). Nonetheless, the principles of the Loop can be applied to virtually any rapidly evolving environment. Moreover, Boyd's Loop helps to understand the critical role of the mistakes made during the initial data collection (e.g., selective or biased selection, rejection of *non-conforming* data as necessarily false, etc.) at the observation stage and their subsequent analysis (subjective analysis based on preconceived notions, influence of personal bias, inflexibility, etc.) at the orientation stage.

Errors made at these two stages influence the following two. Thus, at each subsequent cycle, error correction demands increasingly larger resources and removes them from where they should be otherwise committed—at the centre of action. Uncorrected errors compound at each new revolution of the Loop and exponentially increase the chance of failure. Probably the best example of *Loop failure* was the disastrous response of state and federal authorities to Hurricane Katrina in August 2005, while the response to Hurricane Wilma (its shortcomings notwithstanding) shows how application of Boyd's Loop-based thinking can lead to positive outcomes in situations demanding flexible, ongoing, and dynamic response to the continuously but unpredictably changing operational environment.

Clearly, to assure efficiency of action, the interval separating each individual stage of the Loop must be as short as possible, particularly when interacting with highly fluid, ultracomplex systems such as military or healthcare information. Here, the demand is not only on rapid, reliable sampling of the environment but also on a very high degree of automation at the level of multi-source data collection, analysis, manipulation, and classification into larger information/germane knowledge entities.

Contrary to the prevalent platform-centric operations, network-centricity allows vast increase in sampling speed, range, and data manipulation speed. Consequently, decision supporting outputs of the network are faster, more situation/operational environment-relevant and, most importantly, allow robustly elevated rate of stimulus-response cycle (operations "inside the Loop"). Moreover, by increasing reaction relevance and speed, network-centric operations facilitate goal-oriented manipulation of the operational environment and also increase both the level (accuracy) and predictive range of responses to environment induced pressures. Military benefits of such operations have been frequently demonstrated. However, the acceptance of Boyd's (OODA) Loop principles in the civilian world (e.g., global financial/banking operations, lean manufacturing, just-in-time supply chains, etc.) led to demonstrable gains in efficiency and productivity as well.

CONCLUSION

The preceding description is, of necessity, vastly simplified. Yet, the existence and highly efficient use of the network-centric approach to military operations has already resulted in the significant enhancement of the C^3I (Command, Control, Communications, and Intelligence) concept (Alberts, Garstka & Stein, 2000; Department of Defense, 2001). The most palpable consequences of network-centricity in warfare are increased efficiency in the use of available resources, application of resources appropriate to the operational environment, reduction of casualties, and transformation of conflict whose face changes rapidly from aggression by overwhelming force to prevention and de-escalation. Similar principles can be applied to healthcare operations, particularly in view of the already existing major technological components of the WHIG. However, in order to implement network-centricity in healthcare, a major conceptual transformation is required.

Presently, the ruling healthcare doctrine is that of e-health, which while supporting implementation of IC^2T, promotes development of individual, largely noncollaborative (particularly in the global sense) systems. While there is no doubt that the existence of such systems (for example, electronic patient records) facilitates many aspects of healthcare delivery and administration, their effect is predominantly regional. On a larger scale (national, international) most of these platforms function in isolation and major (predominantly through human interaction) effort is needed in order to extract relevant information and convert it into pertinent knowledge.

Transition to the network-centric doctrine of healthcare will greatly facilitate interoperability of multiple electronic healthcare platforms and enhance their usefulness in the broadest sense of global health. There is also no doubt that, similar to other domains in which a network-centric approach has been successfully implemented, the consequence of the proposed doctrine will be improvement of access, better delivery, increased efficiency in the use of resources, accompanied by the concomitant reduction of presently staggering expenditure.

KEY TERMS

E-Health: The application of technology, primarily Internet based technology, to facilitate in the delivery of healthcare.

Germane Knowledge: The relevant and critical knowledge, or contextualized information, required to enhance a particular decision.

Information Symmetry: The gap between the available information between two entities.

Network-Centric: In contrast to a platform-centric approach, a network-centric approach is made up of interconnecting technology grids that enable and facilitate the seamless transfer of data, information and knowledge.

OODA Loop: A framework developed by John Boyd that facilitates rapid decision making in dynamic, rapidly changing environments characterized by a high degree of structural and event complexity. Each complex action can be subdivided into a series of consecutive cycles, while each revolution (cycle) of the Loop comprises of four stages: Observation, Orientation, Determination, and Action.

Platform-Centric: Based on and exploiting the exclusive properties of an employed system or specific technology platform. Useful on a small scale but does not enable seamless transferring of information and knowledge across platforms or systems.

World Healthcare Information Grid (WHIG): The technology backbone of network-centric healthcare operations, a network of interconnecting technology grids that together contain all the necessary information for effective and efficient healthcare delivery.

Chapter 1.9
Mobile E-Health:
Making the Case

Norm Archer
McMaster University, Canada

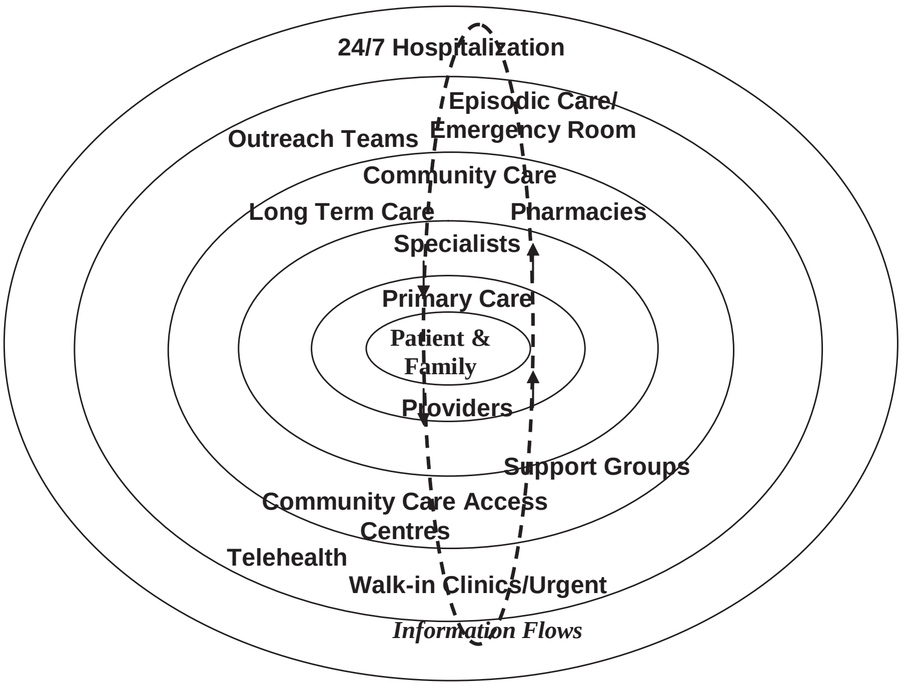
ABSTRACT

Health care is an industry with a diverse set of stakeholders: governments, private health care providers, medical practitioners (physicians, nurses, researchers, etc.), home health care providers and workers, and last but not least, clients/patients and their families. Overlapping and interacting environments include hospitals, clinics, long-term care facilities, primary care providers, homes, and so forth, involving acute, emergency, chronic, primary, and outpatient care. Patient transitions between these environments are often unnecessarily difficult due to an inability by providers to access pre-existing patient records. Mobile/wireless solutions can play an important role in supporting health care by providing applications that access health care records and reduce paperwork for clinical physicians, nurses, and other workers, community health care practitioners and their patients, or mobile chronically ill patients such as diabetics. This chapter makes the case for mobile health care and its solutions in the non-acute community health care environment, where critical issues include usability, adoption, interoperability, change management, risk mitigation, security and privacy, and return on investment. A proposed community health care application demonstrates how these issues are addressed.

INTRODUCTION

Many individuals receive their care from more than one caregiver or other provider: individual physician, group practice, hospital, long-term care facility, laboratory, pharmacy, walk-in clinic, urgent care center, work-site clinics, school clinics, and so forth. When and where choice is available, clients can select caregivers or other providers based on their proximity, bedside manner, quality and capability, cultural aptitude, or other factors. Clients/patients also must move among health care providers as their state of health changes, creating a need for their health records/histories to move with them, so each provider does not need to prepare a totally new patient history at admission (see Figure 1). Without the general existence of digital health records and some means of integration or

Figure 1. Information flows in patient-centred health care (adapted from Krull-Naraj, 2004)



interoperability, individual choice and movement leads to fragmentation of the individual's health care experience. Typically, this means that client record transfers are accomplished from one or more sources via paper, scanned digital records, and/or fax. The result is that client records may be stored on paper at a number of caregiver institutions or re-keyed into institutional databases, with no possibility of version control or compatibility. This fragmentation of records often leads to errors, duplication, lack of coordination (Brailer, 2005), conflicting approaches to a patient's health care, service and/or resource duplication and many other problems including reduced quality of care, reduced effectiveness, and increased cost to society.

Integration mechanisms have been tried in the past, although none has delivered lasting benefit. These include horizontal and vertical mergers of providers, state-sponsored networks of community care services, and so forth. However, there is theoretically no technical barrier to establishing a network of providers that would use information in an interoperable manner for integrated support of patient care, and this would not require a massive integration of physical assets and the bureaucracy required to operate it. In the U.S. alone, the potential savings from such an approach have been estimated at U.S. $77.8 billion per year (Walker, Pan, Johnston, Adler-Milstein, Bates, & Middleton, 2005). This does not include the substantial clinical and quality of life benefits from this approach. Unfortunately, it has been virtually impossible in most jurisdictions to get broad agreement on a standard and portable electronic health record (EHR) that would support this interoperability. Although the standardized EHR has a continuing focus of the health care community (Berner, Detmer, & Simborg, 2005), the process of adopting a standard would still require large investments in the database conversion process and the necessary secure communications network that would safeguard client privacy and confidentiality. However, without interoperability and health information exchange, health information will remain as it is now, in proprietary and often inaccessible silos.

The lack of a standard EHR definition, and the lack of interoperability among health care providers are both major strategic issues in information technology support for health care. No doubt at some time in the distant future both these problems will be addressed at a macro-level, but in the meantime, it is essential to make incremental improvements that will adapt to the constantly changing environment in a way that continuously improves health care support at the local level (Lenz & Kuhn, 2004). Such changes may be significant enough to be disruptive to users, so it is critical to plan and implement changes so that already overburdened health care professionals and administrative support receive relief in the most effective and efficient manner possible under the circumstances.

Health delivery practice for non-acute care in many industrialized countries is shifting toward the home. The reasons are the better possibilities for managing chronic care and controlling health delivery costs, but the appropriate infrastructure must be in place in order to maintain client quality of life through quality health services, and the need to predict and thus avoid serious complications. For this potential to be realized, new interoperable telemedicine and information technology (IT) solutions need to be implemented and integrated in the health delivery system, but these solutions need to be assessed through evidence-based medicine in order to provide solid proof for their usefulness. To ensure that quality care delivered efficiently any time and any place requires ready access to patient records and expertise from remote sources such as specialists and online databases, and mobile wireless technology can enable this support. True wireless communities where processes, technology, and people are fully aligned to mobile applications, have a great deal of potential, especially where smooth transitions by patients among the types of care they may experience, including acute, emergency, chronic, primary, and homecare, require continuing coordination among health care institutions, medical practitioners, health care workers, care givers, and the patients themselves. The real benefit of mobility support will come only when technology and process are built around a plan that embraces mobility, and where mobility is not an afterthought.

As mobile wireless unfolds, the health care world must assess both its technical and value propositions, to determine if it has a real value proposition to offer, in terms of quality of life maintenance at lower costs than existing systems. The objective of this chapter is to discuss the roles that electronic mobile solutions can play in health care, and particularly the value propositions and their evaluation that must play a role in the selection of these solutions for efficient and effective use. The concepts presented will be demonstrated by an application in a real mobile health care application.

MOBILITY

Mobility is an aspect of many environments. How mobility affects individuals tends to differ, depending on the nature of what they are doing (working, relaxing, traveling, etc.), their preferences, the form that mobility takes, and the amount of time involved. Supporting mobility through electronic solutions is having a growing impact on individuals by enabling them to carry devices that assist them to stay in constant communication with their organizations, friends, family, and advisors. This may involve using voice or data messages, paging, direct communications by telephone or teleconferencing, and database or document information access, storage, and retrieval. In working environments such as hospitals, such applications are often built upon existing e-business solutions such as corporate and operational databases, along with functional or corporate support areas and their associated networks such as LANs and Internet connectivity. The growing availability of a variety of mobile applications and technologies has encouraged the extension or replacement of existing approaches and business processes. We are only beginning to see true wireless environments where processes, technology, and people are fully aligned to a mobile environment.

Mobile Solutions

The potential selection of systems and devices for mobile support includes voice and data communications, ranging all the way from cell phones to laptop computers and PDAs (personal digital assistants). It will be assumed that end users have ready access to voice communication through cellphones, since these are rapidly becoming as ubiquitous as landline telephones. Mobile or wireless solutions discussed here may use the same networks, including and extending voice cellphone communication. Mobile solutions can be used to support hospital or clinical workers, or community health care practitioners or their patients, where the workers may be away from their home office a high percentage of the time, while traveling or meeting with clients. Others may need to travel occasionally to different sites for meetings, conferences, or training. Clients such as ambulatory care patients may also adopt mobile or monitoring devices, in order to use the services of mobile health care providers. Mobile solutions allow employment hours to be flexible and to extend beyond those hours actually spent in the office, including lunch and break time, traveling to and from work, traveling to meetings, holidays, weekends and evenings. Although this may result in an attendant increase in productivity, working with others through mobile applications may not necessarily fulfill all the needs of workers.

Pervasive Computing

Pervasive computing can be defined as personalized computing freed from the desktop, enabling information access anywhere, anytime, on demand. This provides an apt description of the objective of mobile worker support. Computing devices range from desktop (fixed), to laptops and palmtops (transportable) to handhelds and wearables (fully mobile) (Gorlenko & Merrick, 2003). Mobile devices can be differentiated according to their wireless connectivity. Content transmitted by technological solutions in the mobile wireless world can be mobile (but not wirelessly connected for synchronization with wireline content), wireless (but not mobile), or both mobile and wirelessly connected. Mobile wireless content is converging with the wireline Internet, with the result being referred to as the mobile Internet. The growing mobile wireless market demands both voice and data (text-graphics) communication services. Multimedia content is a suitable mix of the two. The content is carried through the network of a wireless network operator and a service provider. Some mobile devices are unconnected while on the move (e.g. PDAs—personal digital assistants, laptops, and palmtops) although they may be equipped for wireless connectivity in a stationary environment. Clinical, business, and technology functions are usually intertwined in a complex manner in wireless systems, it is essential to maintain patient safety and quality of life, if a health care system is to be implemented acceptably (Scalise, 2005).

Value Proposition for Mobile and Wireless Solutions in Health Care

The business model for adopting mobile solutions is the economic justification for the use of the technology, or the means by which the technology generates a value proposition. In the current wireless marketplace, with an increased system complexity that is driven by the number of players and their interactions (Olla & Atkinson, 2004), (network operators, carriers, content providers, mobile device manufacturers, etc.), the value chain is developing into linkages of partnerships for delivering value to end customers (Sabat, 2002). End customers in e-health may be individual physicians or they may be networks of health care workers who interact in such a way that mobile solutions can assist in improving their interactions cost effectively. Business partnerships involved in supporting mobile solutions continue to evolve, engage, and disengage as new technology evolves and appears, and certain business partners thrive while others fail.

It is often difficult to justify a business case for a mobile project financially. A 2002 survey by *CIO Magazine* (Worthen, 2002) indicated that the two most popular measures of ROI for wireless projects were increased productivity (54%) and improved internal customer satisfaction (40%). For mobile e-health applications, we can add an important constraint which is that the application must not decrease the quality of life of the clients, or ROI justification becomes meaningless.

One framework that has been proposed for value determination of mobile solutions, includes two dimensions: time and place—the work can be either dependent or independent of one or both these dimensions (Wiberg & Ljungberg, 2001). Mobile applications in this framework can be in one of four quadrants: anytime and anywhere; anytime and a particular place; a particular time and anyplace; and a particular time and particular place. Maglaveras et al. (2002) discuss a community-based health care support system that proved the usefulness of wireless technology in providing wireless interactivity anytime and anywhere, but also proved the necessity for restructuring educational medical knowledge for delivery to the patient. An example application of the anytime-anyplace model is in mobile support of chronically ill clients who are still able to work. Here, occurrences could be identified in all four of the quadrants, since clients have particular places where they may spend a considerable amount of time (at work and at home), and certain procedures could be specified at particular times, but there would be value in support in the "anytime and anywhere" quadrant. These concepts help in planning potential mobile support applications.

To justify mobile solutions, health care institutions that deploy wireless data solutions do so on a very selective basis, supporting only those employees who have a demonstrated need for real-time access. There are strong indications that return on investment (ROI) can be most strongly justified for specific classes of tasks in vertical markets such as health care, manufacturing, government, and transportation (Wheelwright, 2002). For example, a recent study of mobile solutions in a variety of applications in 35 major companies found hard benefits that included sales increases of 5-10%, reduced customer wait times by as much as 80%, increases in service calls of up to 32%, and service call responsiveness improvements of up to 7% (Gillott, 2002). Payback periods ranged from a few months to 30 months.

Mobility and flexibility are the biggest drivers of mobile solutions in many institutions and companies (Wheelwright, 2002). Health care companies may choose wireless solutions because they have an outbound workforce that needs to be connected within a corporate environment or when making calls on homecare clients. Cost has slowed the adoption of mobile technology in the past, although it is becoming less of a concern as prices drop and businesses recognize the benefits of offering wireless access to their workforce. Mobile portals provide convenient places where Web users can link to a set of applications that are relevant to their interests and/work (Clarke & Flaherty, 2003). Portals assist the wireless user to interact with Web-based content, and serve a valuable purpose in aggregating multiple applications and/or content providers through one Web site. They also provide a greater degree of personalization and localization than traditional Web portals.

EVALUATION OF MOBILE BUSINESS APPLICATIONS

The novelty of many of the mobile applications currently entering the marketplace, along with inexperience of business with mobile solutions, greatly increases the risks associated with adopting such solutions. For this reason, the business value proposition of proposed mobile applications must be studied with care. To that end, we have developed a process framework (Archer, 2004) that organizes the planning and evaluation process logically. This proceeds from identifying the business goals, defining potential user groups and the applications they would use, and the technical considerations that will lead to the appropriate mobility choice. When implementation issues are factored in, tempered by a variety of moderators, the application can be evaluated, along with its ROI, and compared with the existing application in terms of tangible values such as revenue, cost, and efficiency, and intangibles such as user and customer satisfaction. This process is an essential first phase in any mobile application, since it considers logically the costs and benefits of implementing the planned solution.

Key Issues for Mobile E-Health Applications

A number of key issues can affect the potential for a successful mobile e-health implementation. These include usability, adoption, interoperability, change management, risk mitigation, privacy and security, and return on investment. These are considered in more detail in the following.

- **Usability** can be defined as the quality of a system with respect to ease of learning, ease of use, and user satisfaction (Rosson & Carroll, 2002). It also deals with the potential of a system to accomplish the goals of the user. Usability is a key issue in the adoption of any information system, but it is particularly so for mobile systems, where the end-user device is often hand-held, with limited display and data entry capability (Tarasewich, 2003). Interface design and the design of the device itself have a critical impact on usability.
- **Adoption:** As in any user population, technological changes in the supporting technology for doing tasks make demands on both the quality of user interface and the functionality of mobile devices. Adoption is clearly related to usability, although it involves additional issues. The questions of interest are (Zhu, Nah, & Zhao, 2003): (1) what factors influence users' adoption of mobile computing?; (2) how does the design of mobile devices and interface affect user adoption?; and (3) to what degree do specific factors such as trust and enjoyment (in using mobile devices) play a role in adoption? Zhu et al. (2003) have proposed that perceived ease of use (input and output modalities, navigation, bandwidth), perceived usefulness (service offerings, degree of mobility, compatibility, coverage, reliability), trust (security, privacy, vendor characteristics, perceived ease of use, perceived usefulness), and enjoyment (congruence of skills and challenges, focused attention, interactivity, perceived ease of use, perceived usefulness) will affect intentions to use mobile devices, which will then influence actual usage. Evidence suggests that inadequate access to information and ineffective communication tend to be causes of error and other adverse events for in-patient care (Mendonca, Chen, Stetson, McKnight, Lei, & Cimino, 2004). Information-based handheld wireless applications at the point of care that link to clinical data can help reduce these problems.
- **Interoperability:** Interoperability with existing health care applications and/or databases is necessary, to improve or at least

avoid worsening any existing "stovepipe" characteristics that plague the health care IT field. In the absence of compatible databases or health records, separate applications may communicate through messages containing health record information using standard protocols such as HL7.[2] Supporting software could be developed with a messaging toolkit such as Chameleon,[3] or the health record information may be mapped to a particular database using Iguana.[2] Significant barriers that must also be addressed include policies on accessing and updating existing systems, due to privacy, confidentiality, legal, and regulatory concerns.

- **Change Management:** Many issues arise when technology is changed or introduced to a user population, often transforming the way users must perform their tasks. The manner with which change is introduced, irrespective of the effort invested in enabling it, will impact system adoption. There are multiple obstacles to implementing such a system. These include resistance to change by end users and IT staff, and integration with existing systems. These must be considered in advance in order to mitigate potential risks (Wang & Paper, 2005). There are two important aspects of change that must be considered. The first is in the organizational and business process structures. Not all change can be anticipated and planned in advance. Difficulties in managing change in the introduction of technology arise when the organization does not plan the management of unanticipated change. This increases the complexity of change because the organization unprepared to deal effectively unanticipated complications. For example, new technology often leads to anticipated changes in staffing levels, but there are usually psychological or social dimensions to the remaining jobs that are not anticipated.

Two types of unanticipated change include (Rivard, Aubert, Patry, Pare, & Smith, 2004):

- Emergent change, that may arise spontaneously in response to planned change, with either positive or negative impacts on the organization (for example, a requirement for new skills in analyzing data now being collected that was not previously available).
- Opportunity-based change, introduced intentionally during the change process in response to unexpected impacts. For example, the introduction of mobile technology may create new opportunities for other applications that were not previously considered possible when the mobile infrastructure was not yet in place.

The second major consideration is the technology itself. Even if the new technology offers the full functionality required, with a fully-tested interface, user compliance is far from guaranteed. Studying user interactions with the system, as well as improving it to suit their needs, can be complex, costly, and time intensive but may result in significant rewards. Simple modifications may be introduced to help users to learn and operate the system, thus increasing acceptance. Schoenberg, Safran, and Sands (2000) suggest a functionality for assessing system performance from the user perspective: acquire user information in the background and through direct survey, target population subsets of interest and avoid interrupting those who are not, invoke data acquisition methods "just-in-time" as the user interacts with the system, be as brief and concise as possible during interaction, provide incentives to compensate users for their time, and be consistent across all applications.

- **Risk Mitigation:** End-user adoption is an important issue, and this is addressed by change management, usability, and so forth. Obstacles to end-user adoption of the system must be mitigated, through training and motivation for end users and clients through improved quality of work and life. System reliability is critical in health care, and parallel testing during the test phase until there is sufficient confidence in system reliability (Mikkelsen & Aasly, 2001) is one way to develop confidence in the system.

- **Security and Privacy:** Health record privacy and confidentiality in many jurisdictions are regulated strictly by government guidelines, in terms of controlling need to know and client permission to access records. Mobile applications must adhere to these guidelines, as well as maintaining security by encoded communications and databases. An additional consideration is the reliability of the system, to ensure that information is not lost and that service interruptions are managed effectively.
- **Return On Investment:** In health service applications, ROI (return on investment) considerations are overridden by a constraint that quality of health care must be improved, or at least not reduced. In calculating ROI, cost considerations include software, hardware, installation, ongoing maintenance, and further development. Savings include some that are more easily quantifiable such as IT staff time, and employee time savings (e.g., time saved when data can be entered directly online, or reduction in errors and the associated time needed to fix them). Virtual office operations and field sales operations tend to have a higher ROI than company groups with little customer-facing work. Health services require a convincing case for the adoption of mobile applications, since there are so many other competing demands on resources. In addition, since there are typically a number of stakeholders (client, physicians and nursing staff, administrative staff, institutions—hospitals, homecare institutions, etc.), each should receive a perceived benefit in order to encourage participation.

CASE EXAMPLE: MOBILE APPLICATIONS IN HOME HEALTH CARE

Health care is the responsibility of the provincial governments in Canada, where the publicly-funded system provides universal access. In the Canadian province of Ontario, health care has been organized into a multi-tiered system. Family physicians provide primary care, typically operate as small businesses, and bill the province for services rendered. They may refer patients to specialists, who may also operate as small businesses or work as hospital employees. Acute care is supported by hospitals. Non-acute care is supported in long-term facilities or in a home environment. Laboratory testing services may be operated privately or in a public hospital. Patients are supported in the home environment by their families and friends, in addition to homecare nursing and housekeeping support that is managed and funded by the Province. To provide homecare and long-term support, the Province has chartered a number of Community Care Access Centres (CCACs) throughout the Province, that contract with private homecare providers for nursing and other patient support.

As demonstrated in Figure 1, information must flow among the various providers in order to provide continuity to patient support, and access to information that exists at many places throughout the system. Unfortunately, the number of Canadian primary care physicians that have fully digitized records is only in the neighbourhood of 5%. Although each of the types of health care institutions (hospitals, CCACs, and homecare providers) has internal digital systems and databases that support its own applications, there are no standards for health records, and little digital communication to support specific clients. Most information flows are on paper forms, usually transmitted by fax, and scanned and stored or transmitted as images. This may serve storage and legal purposes, but the information can not be retrieved in a form that can be used for management or decision support analysis. There are the usual problems in the paper-based system, resulting from delays, errors, and loss of information.

To solve some of the problems associated with current paper-based systems, a project has been proposed for Venus,[4] an Ontario county, to use wireless applications to link mobile homecare workers to centrally supported applications and databases. The Venus County Mobile E-Health Project is being planned through the collaboration of three health care organizations: Mars Home Health (provider of visiting nursing and other services), Venus County CCAC, and Jupiter Hospital. The Aquarius Research Centre plays a role in research and development, and a number of corporate vendors are also involved, including Zodiac Wireless Inc. A carefully researched process will be used to build and trial the system, with the end result being a mobile system that can be easily implemented as an ongoing commercial operation in Venus County and potentially throughout other Canadian jurisdictions.

The project is aimed at improved outpatient quality of care, while eliminating or easing routine work for health care workers. The initial focus will be on reducing or eliminating paperwork by homecare nurses accessing the remote system wirelessly onsite for client details or to enter new data. The project will be led by health care staff and professionals to maximize the chances of successful implementation. The project is incremental in approach, and undertaken in phases, with activities and outcomes carefully researched and evaluated throughout each phase. The project may be terminated or adjusted at the end of each phase. The focus will be on delivering real benefits for clients and health care providers while overcoming the barriers to information exchange among some of the entities indicated in Figure 1, without undue inconvenience to regular health care activities.

An analysis of the business case through a logical process (Archer, 2004) has predicted an approximate reduction of 50% in direct (labour and system) costs by the project. Intangible benefits include: delay until data is available online reduced from 24 to 0 hours, online availability of data increased from 10% to 100%, error rate for data entry reduced from 0.20 to 0.05 per data item, homework by homecare nurses (faxing and other work) reduced from substantial to minimal, time for client-centred care increased during nursing visits, and time required for routine work reduced.

Project Phases

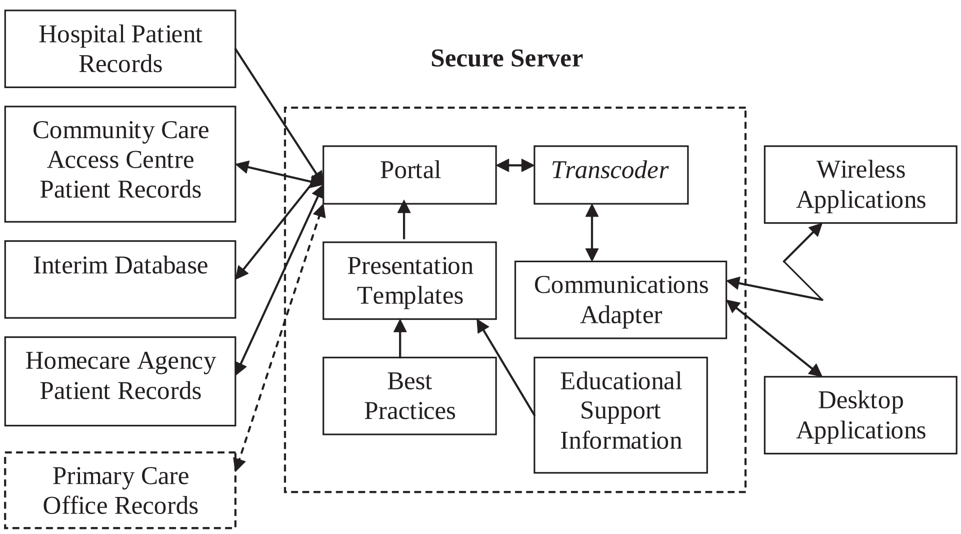
Each phase includes a research component, which will be used to plan the work, collect information, and evaluate results to ensure that the outcome of the phase is optimal from the point of view of the overall project objective. The following describes in limited detail the major phases in the project:

1. A prototype of several mobile wireless applications with a high potential impact on homecare operations, will be designed, tested, and implemented through a trial by a small group of Mars Home Health homecare nurses. Aquarius and Zodiac will be heavily involved in interface design, and a study of usability and user acceptance. The highest impact applications currently in use in paper form by homecare nurses are: supplies ordering, wound care, key path, admission, status change, and discharge. These will be implemented in the first prototype. Technical considerations include the choice of suitable end-user devices to support applications, and wireless network provision. Secure access will be available to data through both wireless mobile and office computers. Linkages

to existing databases at Mars Home Health and Venus CCAC will be designed to ensure interoperability. Figure 2 is a conceptual description of the proposed system. Interoperability challenges with existing databases require the development of an interim database for data that does not currently exist in digital form. Decision support applications for clinical and administrative use will be able to access all the digital data collected. The secure server provides application support for wireless and desktop devices. Due to the low reliability of access to wireless devices in remote areas (and sometimes in basements or other shielded areas), the devices will need to carry "fat client" applications. That is, applications will run securely on the devices rather than on the server, and data uploads and downloads will occur automatically when wireless access is available.

2. Based on a successful prototype test in phase 1, the prototype will be revised for full operations according to prototype results and learning, and rolled out as a commercial operation to the entire Mars Home Health visiting nurse population of over 120.
3. Further applications specified and required by Mars Home Health and Venus CCAC, will be designed, based on experience in Phase 1, resulting in a suite of applications based on previous and new applications. The full suite will be trialed with a small group of Mars homecare nurses, including an evaluation of the suite (usability and user acceptance) and revisions necessary for commercial operations. This will be followed by a full commercial rollout at Mars.
4. Because there will be a significant increase in data availability online, there will be an investigation into how to make use of the additional information gathered from wireless inputs available online to the health care providers, for managing and decision making. Applications will be designed and developed as appropriate, and the impact on the institutions and clients involved will be studied. An example is improved wound management data collection for monitoring and control purposes:
    - To facilitate a consistent technique in wound assessment;
    - To facilitate a consistent means of documenting wound status;

Figure 2. Data flows in mobile e-health support system



- To be a tool to infuse evidence-based practice in wound care management; and
- To provide a means of data collection that would aid in evaluation and outcome tracking.

5. The final phase will be to design and implement a wireless mobile e-health prototype to assist the three health care institutions to support newly educated Type 2 diabetics. The client process includes working through an education process in the Jupiter Hospital's Diabetes Education Centre, continuing as the clients move out of the hospital into a normal work and homecare situation over a period of several weeks. The desired end result is client self-management of diabetic condition with integrated back-up support from the health care institutions and primary care physicians.

CONCLUSIONS

Mobile health care technology has the potential for not just supporting health care in any particular health care environment (hospitals, clinics, long term care facilities, homecare), but for more easily managing transitions as patients move from or to acute, emergency, chronic, or primary care. Mobile applications can either eliminate or greatly reduce the use of paper forms, thus reducing system cost, as well as reducing errors and delays in making digital information available online. But if mobile e-health is to be introduced successfully, care must be taken to include all the stakeholders in planning and implementing mobile solutions. Critical issues that have been identified for mobile e-health applications include usability, adoption, interoperability, change management, risk mitigation, security and privacy, and return on investment.

Chapter 1.10
Mobile Telemonitoring Insights

Pantelis Angelidis
Vidavo Ltd., Greece

ABSTRACT

Technology advances create new possibilities for healthcare monitoring, management, and support, focusing on prevention rather than disease management. The provision of personalized healthcare applications is also greatly supported. Developments in the wireless and mobile markets are capitalized by the medical device industry. Services are becoming personalized and location independent to fulfill the increasing patient needs for self-empowerment and quality in the healthcare delivery away from the traditional nursing areas. This overview discusses the new opportunities for the healthcare domain in the mobile times we live.

INTRODUCTION

The healthcare industry is experiencing a substantial shift to care delivery away from the traditional nursing areas due to the convergence of several technology areas. Increasingly capable health-monitoring systems are moving the point of care closer to the patient, while the patient, better informed and aware now, undertakes an active role to self-care and/or -prevention. Emerging ICTs in conjunction with the medical device industry development (intelligent devices, biosensors, novel software, etc.) demonstrate personalized healthcare delivery's potential without geographical limitations.

The concept of prevention prevails now against disease management and treatment plans. As patient-centric processes emerge, the citizens and patients undertake an active role in monitoring their health status. Meanwhile, e-wellness evolves to address the rising expectations of the e-health consumers, who are better informed, more demanding, and empowered. The empowered, worried-well consumers require quality health services on the spot. The drivers are now connectivity, speed, and personalization (McKnight, 2000).

MOBILE HEALTHCARE PROVISION

Waves of technology incorporation and scientific discoveries have driven the sector from reliance on direct communication and physician experience to a higher reliance on technology and community information. This new Web-enabled environment has taken healthcare from local areas, where telemedicine left it, literally into the patient's home and, more recently with m-Internet, to wherever the patient might be and whenever he or she needs it (Simão, 2001).

M-Internet enables information exchange and promotes the availability of services and communication modes to serve working teams with increasing mobility requirements.

Services are becoming personalized and location independent to serve increasing patient needs for self-empowerment and quality in healthcare delivery away from the traditional nursing areas.

Furthering the new approaches in the provision of healthcare services in the frame of e-health, wireless developments create new opportunities for healthcare professionals, individuals and organizations, patients, and health authorities. The scope of mobile health addresses clinical, administrative, and consumer health-information applications and, as it could contribute to the improvement of health outcomes, m-health may be utilized to measure health status and population welfare.

Many healthcare organizations are investing in IT projects that take advantage of new technologies in the mobile healthcare application space. Functionality that augments the capture of evidence-based patient plans of care is essential and must map and bridge the information flow for both inpatient and outpatient work-flow clinical-practice guidelines. As the medical community continues to embrace these new technologies, system integrators must provide functionality that reduces costs, improves the quality of care, and improves the ease with which caregivers can perform their everyday tasks (Wolf, 2001).

The most significant challenge posed by mobile technology is the seamless integration of multiple hardware and software platforms with reliable, uninterrupted wireless services in a secure manner, which will become mission critical to successful healthcare organizations, payers, and providers (Wolf, 2001).

The current state-of-the-art technology in medical sensors allows for the easy and unobtrusive electronic measurement of several health conditions. The sensors are often stand-alone devices and sometimes comprised of two or more elements connected by a cable or wireless technology. Medical sensors have the capability to measure vital signs such as blood pressure, pulse rate, respiration frequency, and so forth. Based on these medical parameters, the medical professionals can monitor the patient's health condition and act in case of an anomaly.

The application areas of the medical-device wireless telemonitoring capabilities include the following:

1. Assistance in case of accidents and emergencies
2. Increased capacity and lower costs for hospitals
3. Assistance and monitoring in a home-care setting
4. Monitoring of chronically ill patients
5. Patient involvement in setting a diagnosis
6. Medicine dosage adjustment
7. Physical-state monitoring in sports
8. Monitoring of sporadically occurring symptoms
9. Emergency alarms (Fosse & Haug, 2003)
10. Improved health management

As a result, citizens can enjoy quality healthcare provision and an elevated quality of life. As underlined by the European Council objectives set in Lisbon, "effective integration of healthcare and related support services by electronic means, including the widespread use of telecare, could improve the quality of life of citizens by enabling safer independent living and increased social inclusion."

EVOLUTION FORCES AND CHALLENGES

Empowered patients demand advanced wireless health solutions. Similar to most authors, Lerer (2000) suggests that the e-health consumer is being empowered due to an increased ability to obtain health information and to seek health-related offerings via the Internet. A Deloitte Research (2000) study suggests the e-health consumer is a mix of an empowered and an engaged consumer. Recognizing that e-health consumers' empowerment can increase efficiency and reduce health costs, Lerer argues that consumers' education and empowerment should be a key concern for all health players. E-health consumers, he suggests, are not just the ill, but the potentially ill, the worried, and those adjacent to illness, patients, their relatives, and friends. At the first level, e-health services are information-driven activities, which are mostly "event triggered." The Deloitte Research study suggests that the demographic profile of the e-health consumer population reveals a significant population group with economic clout, information sophistication, and technological familiarity, and that is generally wealthy.

An e-health consumer is an individual who is (a) fully involved in the management of health for himself or herself and his or her family, (b) proactively educated about health issues, especially in the area of prevention, and (c) concerned about the quality of care offered by physicians and institutions, with a willingness to select the highest level of services. In short, an e-health consumer manages health, in all extents possible, as the most important asset of his or her family. The main objective is to maintain the highest level of quality of life (Lerer, 2000)

The rapid proliferation of wireless personal computers, phones, appliances, and other devices will require organizations to look beyond single-platform solutions. System-integration activities have a new level of complexity and cost to support rapidly changing technology (Wolf, 2001). Mobile-health advances generate new capabilities in patient self-care and health-practice administration and reimbursement. Cost-effective solutions minimize effort in monetary and human-input terms, while the creation of new communication modes facilitates both the healthcare professionals and the patients.

When it comes to investing in new technology solutions, affordability is a major milestone to consider. Budget allocation to mobile health applications can be easily influenced both by the technology cost and the user awareness of current and future cost benefits. The complexity and fragmentation of the overall healthcare sector (i.e., centralized vs. decentralized health systems, variations in the public and private funding mix, etc.) often leads to the implementation of fragmented and disposable technological solutions. Interoperability thus is essential for large-scale applications with international scope. Conformance to global (when available) and/or U.S. and European standards enables faster and ubiquitous communications, while also ensuring the compatibility and connectivity of systems and points of care.

According to CEN/TC 251 (2001), the present lack of standardized ICT communication, which prevents appropriate access to health records, may result in important clinical risks for the patients. This is an important safety issue that has not been recognized sufficiently.

Implemented standards are often crucial for any communication, and they are especially important for open, very complex healthcare systems with many different organizations and units, with information systems from different suppliers, providing different parts of the total ICT support.

Furthermore, the wider implementation of mobile solutions requires a robust security plan to reassure the confidentiality of sensitive medical data.

M-HEALTH POTENTIAL

The next few years will witness a rapid deployment of both wireless technologies and mobile Internet-based m-health systems with pervasive computing technologies. The increasing data traffic and demands from different medical applications and roaming applications will be compatible with the data rates of 3G (third-generation) systems in specific mobility conditions. The implementation and penetration of 4G (fourth-generation) systems are expected to help close the gap in medical care. Specifically, in a society penetrated by 4G systems, home medical care and remote diagnosis will become common, checkups by specialists and the prescription of drugs will be enabled at home and in underpopulated areas based on high-resolution image-transmission technologies and remote surgery, and virtual hospitals with no resident doctors will be realized. Preventive medical care will also be emphasized: For individual health management, data will constantly be transmitted to the hospital through a built-in sensor in the individual's watch or another item worn daily, and diagnosis results will be fed back to the individual (Istepanian et al., 2004)

A fourth-generation m-health solution builds upon the mobile information portal of a 3G solution by adding the multiple devices rendering the capability of the 2G (second-generation) solutions. Now, an end user has the ability to access any application with any device ("Going Mobile," 2001). 4G solutions embrace the distributed and loosely coupled HIS applications throughout a health unit. A 4G solution can allow for the acquisition of data from various sources and for the mobile end user to view, analyze, manipulate, graph, and merge data according to his or her needs right on the mobile device.

In the home of the future, some devices will contribute physiological information about the patient (e.g., heart rate, blood pressure), while other devices in and around the home will contribute information about the patient's environment (e.g., humidity, temperature, carbon-monoxide level). In some cases, groups of devices will have enough collective awareness to function autonomously based on sensor data.

The challenge for healthcare providers and health authorities lies in the comprehension of the end users' needs for the effective integration of new technological capabilities with existing settings in order to leverage their capacities and quality of service.

CONCLUSION

Systematically sensitizing users and providing them with specific information on new mobile and wearable computing technologies will help to discover possible fields of new applications. The initiation of a dialogue between users in healthcare and developers of mobile IT solutions eventually may lead to the identification of new application fields (i.e., medical specialties) and related practices in mobile healthcare provision.

A first step to this end is the identification and definition of mobile-activities profiles, and stakeholder profiles and their level of involvement, as well as mobile application scenarios. Technologies should be designed for people rather than making people adapt to technologies in order to capitalize on the capabilities that wireless technologies create in the healthcare domain.

KEY TERMS

3G and 4G: Third- and fourth-generation wireless Internet devices. The major distinction of 4G over 3G communications is increased data transmission rates. 4G is expected to deliver more advanced versions of the same improvements promised by 3G, such as enhanced multimedia, smooth streaming video, universal access, and portability across all types of devices. 4G enhancements are expected to include worldwide roaming capability and are likely to incorporate global positioning services (GPSs). As was projected for the ultimate 3G system, 4G might actually connect the entire globe and be operable from any location on or above the surface of the earth.

Ambient Intelligence: The concept of ambient intelligence provides a vision of the information society in which the emphasis is on user friendliness, efficient and distributed services support, user empowerment, and support for human interactions. People are surrounded by intelligent, intuitive interfaces that are embedded in all kinds of objects in an environment that is capable of recognizing and responding to the presence of different individuals in a seamless, unobtrusive, and often invisible way.

E-Health Consumer: Self-reliance and empowerment are the core characteristics of the e-health consumer, who actively pursues patient-centric quality services in a frame of information-supported activities.

Empowered Patient: A patient whose self-management is based on informed decisions and who takes into account his or her quality of life, including both physical well-being and psychological state, as well as other dimensions.

E-Wellness: The utilization of Internet capabilities (information, Web-based health services, etc.) in order to maintain a condition of good physical and mental health.

Medical Sensor: A device, such as a photoelectric cell, that receives and responds to a signal or stimulus.

M-Health: Mobile health refers to ambulatory-care provision enabled by third-generation devices that allow for the collection, management, and processing of the patient's vital data. Mobile health services range from the recording of the patient's medical signs and the synchronous or asynchronous communication with health professionals via mobile communication means, to the automatic diagnosis of the data recorded to personal sensors and alarm notices in case of an emergency. Mobile health or m-health is a step beyond electronic healthcare as it enhances ubiquitous health provision regardless of the patient's or physician's geographic location.

Telemonitoring: The science and technology of automatic measurement via medical sensors and the transmission of data by radio or other means from remote sources to receiving stations for recording and analysis. Data transfer can be achieved via wireless communications means and/or via other media, such as a telephone, a computer network, or an optical link.

Vital Signs: The pulse rate, blood pressure, body temperature, and rate of respiration of a person. The vital signs are usually measured to obtain a quick evaluation of the person's general physical condition.

Chapter 1.11
Geographic Information Systems in Health Care Services

Brian N. Hilton
Claremont Graduate University, USA

Thomas A. Horan

Bengisu Tulu
Claremont Graduate University, USA

ABSTRACT

Geographic information systems (GIS) have numerous applications in human health. This chapter opens with a brief discussion of the three dimensions of decision-making in organizations — operational control, management control, and strategic planning. These dimensions are then discussed in terms of three case studies: a practice-improvement case study under operational control, a service-planning case study under management control, and a research case study under strategic planning. The discussion proceeds with an analysis of GIS contributions to three health care applications: medical/disability services (operational control/practice), emergency response (management control/planning), and infectious disease/SARS (strategic planning/research). The chapter concludes with a cross-case synthesis and discussion of how GIS could be integrated into health care management through Spatial Decision Support Systems and presents three keys issues to consider regarding the management of organizations: Data Integration for Operational Control, Planning Interorganizational Systems for Management Control, and Design Research for Strategic Planning.

INTRODUCTION

Geographic information systems (GIS) have numerous applications in human health. At the most basic level, entire research and practice domains within health care are strongly grounded in the spatial dimension (Meade & Earickson, 2000).

Indeed, the pioneering work of Dr. John Snow in diagnosing the London Cholera Epidemic of 1854 not only launched the field of epidemiology, but did so in a manner closely linked with the visual display of spatial information (Tufte, 1997). The health care enterprise has become much more complex since the time of Dr. Snow and so have the technologies that are employed to conduct spatial analysis regarding heath care conditions and services (Dangermond, 2000).

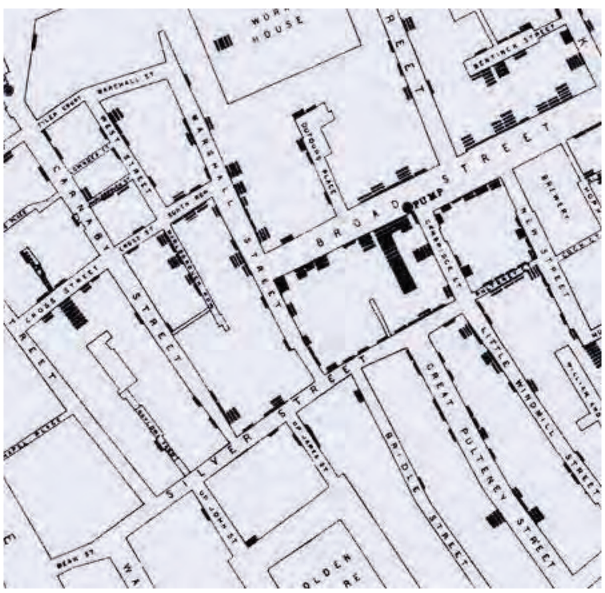
This chapter opens with a brief discussion of the three dimensions of decision-making in organizations — operational control, management control, and strategic planning. These dimensions are then discussed in terms of the case study focus of the chapter, which includes a practice-improvement case study under operational control, a service-planning case study under management control, and a research case study under strategic planning. The chapter proceeds with the analysis of GIS contributions to three health care applications: medical/disability services (operational control/practice), emergency response (management control/planning), and infectious disease/SARS (strategic planning/research). The chapter concludes with a cross-case synthesis and discussion of how GIS could be integrated into heath care management through spatial decision support systems.

BACKGROUND

One definition of a GIS is as "a group of procedures that provide data input, storage and retrieval, mapping and spatial analysis for both spatial and attribute data to support the decision-making activities of the organization" (Grimshaw, 2000, p. 33). One of the most well known models for thinking about the nature of these decision-making activities in the organization is Anthony's Model.

Anthony's Model implies a hierarchy of organizational decision-making. Here, a qualitative distinction is made between three types of decision-making: Operational Control, Management Control, and Strategic Planning (Ahituv, Neumann, & Riley, 1994). As GIS has developed,

Figure 1. John Snow's map of the Broad Street pump outbreak, 1854

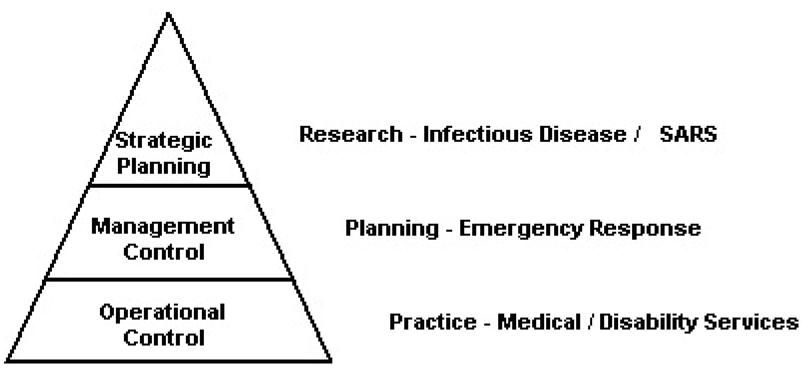


the range of applications for spatial data on human heath has grown dramatically (Cromley & McLafferty, 2002). In an effort to provide an in-depth understanding of these applications, this chapter considers three distinct application areas of GIS and Human Health: Practice, Planning, and Research. The combination of GIS and Human Health applications with the decision-making processes as defined in Anthony's Model is outlined below:

- **Operational Control** is the management of people, assets, and services using spatial information to ensure the delivery of the health care service while assuring that specific tasks are carried out effectively and efficiently. Our focus in this dimension is how spatial information can improve the *practic*e of health care.
- **Management Control** encompasses the management surrounding the health delivery system as a whole, and is specifically related to the needs and provisioning of health services, health promotion, disease prevention, and health inequalities while assuring that resources are obtained and used effectively and efficiently in the accomplishment of the organization's objectives. Our focus in this dimension is the use of spatial information to assist in the *planning* of health care services.
- **Strategic Planning** deals with the spatial distribution of diseases, their epidemiological patterns, and relation to environmental health risks and demographic characteristics while deciding on objectives of the organization, on changes in these objectives, on the resources used to attain these objectives, and on the policies that are to govern the acquisition, use, and disposition of these resources. Our focus in this dimension is how spatial-based *research* can affect the strategic design of health care delivery applications.

These combinations of GIS and Human Health applications and decision-making processes are used to present this particular series of case study summaries (*Figure 2*). The first case is an example of the *practice* of GIS regarding Disability Evaluation delivery at the Operational Control level. The second case is an example of *planning* regarding the use of a GIS for the delivery of Emergency Management Services at the Management Control level. The third case is an example of *research* regarding the conceptual design and development of a GIS as it relates to the National Electronic Disease Surveillance System at the Strategic Planning level.

Figure 2. GIS and human health decision-making and applications



RESEARCH METHODOLOGY

The research presented in this chapter draws on three case studies to illustrate various organizational scenarios in which a GIS was utilized, or could be utilized, to solve a particular Health Care Service problem.

Case Study

Case study methods can be used to explore the occurrence of a phenomenon with special attention to the context in which the case study is occurring. The most common working definition of this approach is offered by Robert Yin, who views case studies as "an empirical inquiry that investigates a contemporary phenomenon within its real-life context, especially when the boundaries between phenomenon and context are not clearly evident" (1994, p. 13). Yin's defining work and related treatments further note that there are several uses of case studies:

- **Exploratory Value** – To uncover the nature of the phenomenon of interest. This can often serve as a precursor to more quantitative analysis.
- **Explanatory Value** – To help explain a phenomenon, such as when a quantitative study has revealed statistical association between variables but a deeper understanding of why they are related is missing.
- **Causal Value** – To provide a rich explanation of phenomenon of interest, including "patterns" that are not easily discernible through more abstract and/or numerical analysis.

Case studies have been used throughout the social sciences, as well as in business studies. Single-case design often uses the *extreme* or *unique* case to illustrate those phenomenon that are acutely visible such that inferences can be easily drawn that can be generalized to less extreme cases (Yin, 1994). Pare (2001) recently summarized the widespread use of case studies to examine the influence of information technology and systems in a variety of fields. Moreover, in his work with Elam, they note the promise of building a theory of IT through multiple case studies (1997). In a similar manner, this chapter uses three case studies in an exploratory fashion to enhance the understanding of IT usage, specifically GIS usage, within the context of health care.

For each case relevant literature was reviewed. For the first and second cases, the authors obtained original empirical information as part of separate studies. In the third case, a new and timely application at the strategic level is proposed.

Case Studies

Operational Control Case Study

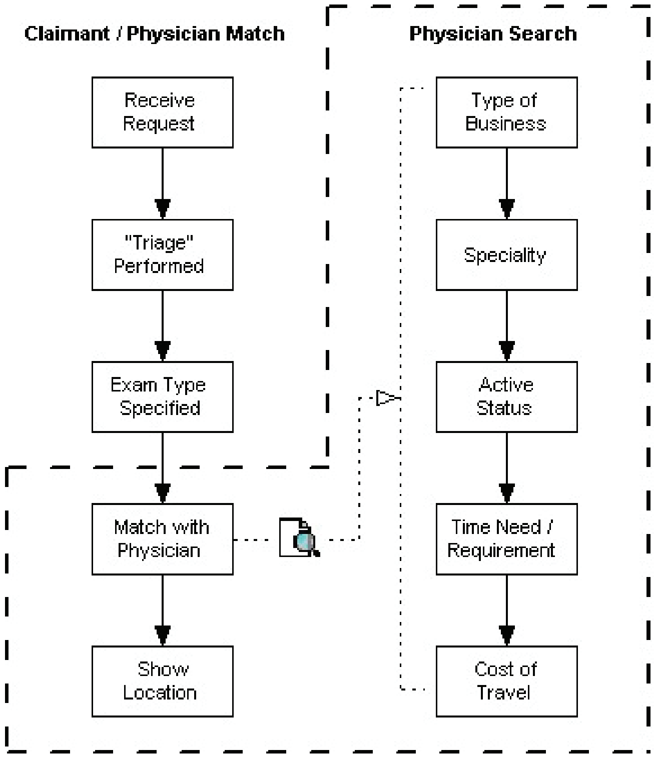
Background

One core practice area in medical services is the matching of patient/client services to providers (Cromley & McLafferty, 2002). The company in this case provides an array of disability evaluations, management, and information services nationwide. Of relevance to the subject of this chapter, this company (headquartered in Southern California) examined the use of a GIS to assist them in planning and marketing their disability evaluation services. With respect to Operational Control, this case study deals with appointment processing and the *practice* of ensuring the effective and efficient delivery of this service using spatial information.

Problem

The problem for this company was to provide an appointment for a claimant with a physician in a timely manner while meeting specific requirements and constraints. The existing workflow

Figure 3. Claim process



process was inadequate in meeting these requirements. *Figure 3* illustrates the workflow for this process, which begins when a case manager receives a request for an appointment. These requests are prioritized or "triaged" and the required exam sheets are generated using an expert knowledge base. Based on constraints such as physician specialty, availability, contract type, and location, an appointment is made for the claimant with the physician who is the "closest fit" (distance and travel-time) with minimal travel-time being the higher priority.

In this workflow process, the company was pleased with the efficiency and effectiveness of the first steps in the workflow process, which are computer-based. However, the last few steps were conducted using paper-based data sets and a number of Internet-based mapping websites (Yahoo Maps and MapQuest). As a result, these last few steps negatively impacted the amount of time a case manager interacted with a claimant, thereby increasing the company's costs in providing this service.

Solution

Using an Internet-based GIS application, a successful prototype was implemented for use within the company's Extranet. To develop this solution, a GIS planning process, also known as the GIS development cycle was employed (NYSARA & NCGIA, 1997). This process, illustrated in *Figure 4*, consists of a set of eleven steps starting with a needs assessment and ending with the on-going use and maintenance of the GIS system.

Outcome

Figures 5 through *8* provide an overview of the GIS based address-matching process that was

Figure 4. GIS development cycle

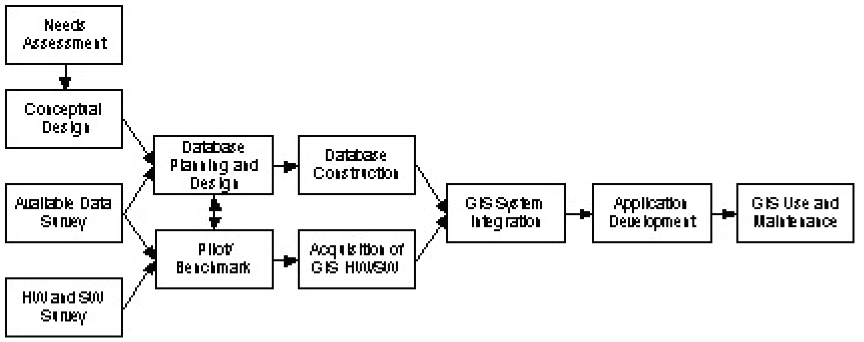


Figure 5. Step 1: Geocoding of claimant

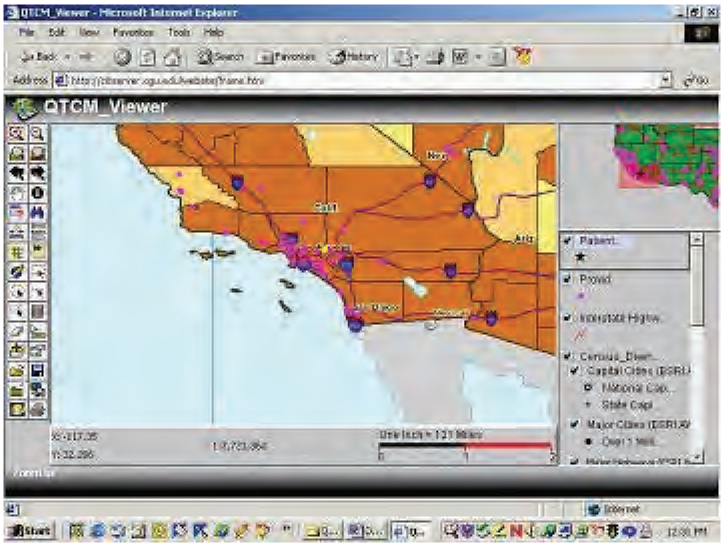

developed. Now, when a case manager receives a request for an appointment they pinpoint the location of the claimant by "geocoding" the claimant's address (*Figure 5*). With the location of the claimant identified, the case manager then performs a physician attribute search, such as physician specialty, to identify only those physicians that meet the claimants' requirements (*Figure 6*). A physician spatial search is then performed to narrow down this list even further by locating only those physicians that are within a specified proximity to the claimant (*Figure 7*). Finally, a physician is chosen from this group that most closely matches the claimants' requirements and an appointment is made (*Figure 8*). The most important outcome of this case was a reduction in time required to set an appointment location and date. An additional beneficial outcome of this case was the development of a "live" connection between this system and the company's Oracle database. This database, which is updated on a daily basis, enables the company to exchange information between geographically distributed offices in real time. Consequently, users using the new GIS are now able to view the latest data, geocoded on a map, from any company location. Another important outcome of this case is the fact that this shared information is in a visual format.

Figure 6. Step 2: Physician attribute search

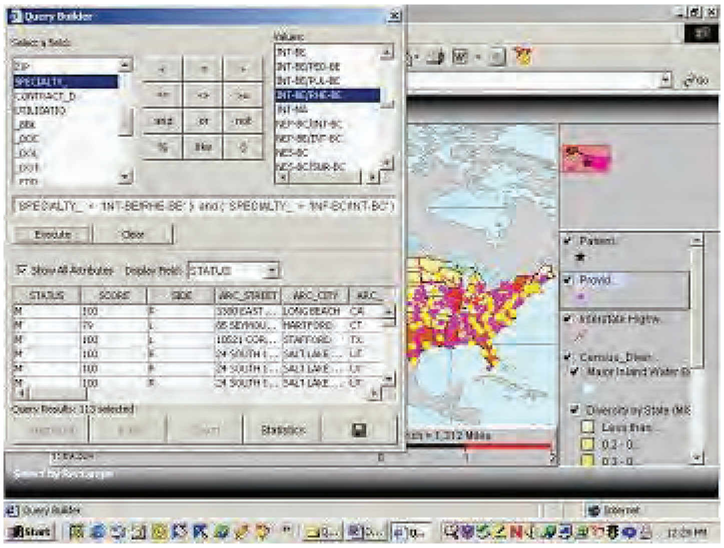

Figure 7. Step 3: Physician spatial search

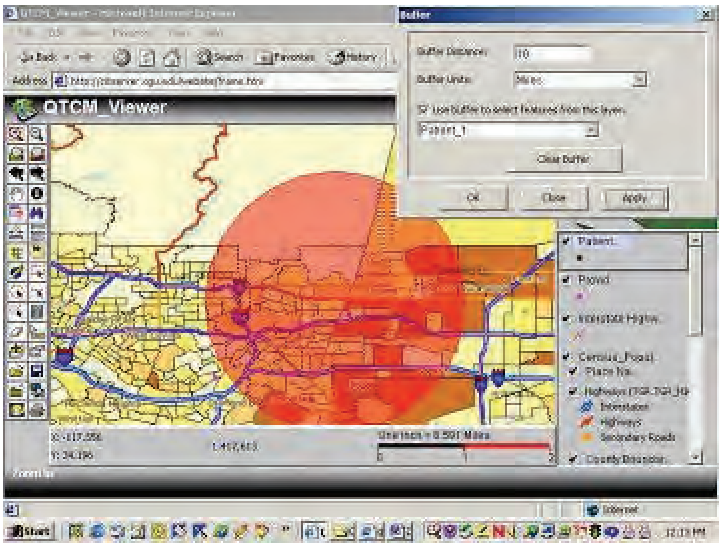
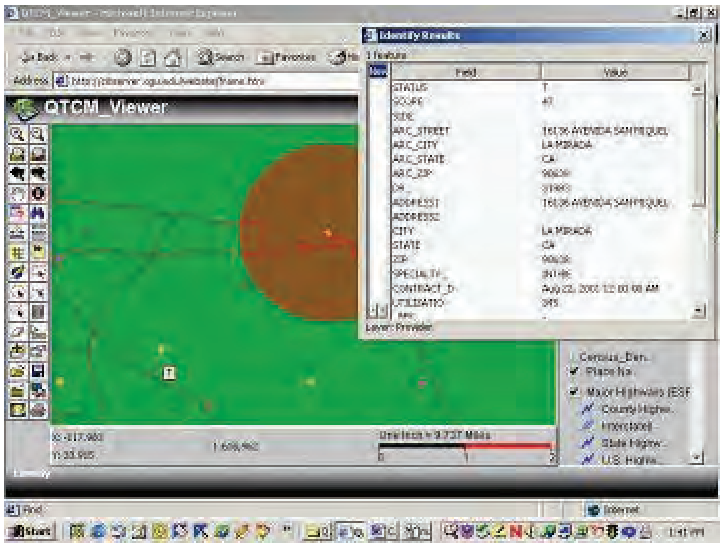


Management Control Case Study

Background

The United States Emergency 911 system, established more than 30 years ago, has become a cornerstone infrastructure for emergency management. However, the system is becoming increasingly stressed due to new wireless and digital communications technologies (Jackson, 2002; National Emergency Number Association, 2001). The original design could not anticipate the widespread use of mobile communications for emergency purposes seen today. Consequently,

Figure 8. Step 4: Final physician selection



this growth in wireless telecommunications is forcing the Emergency 911 infrastructure to change (Folts, 2002; Jackson, 2002; National Emergency Number Association, 2001). This case considers the broad development of Emergency Medical Service (EMS) systems, within the specific context of rural Minnesota. With respect to Management Control, this case encompasses the spatial properties surrounding the health delivery system as a whole, and is specifically related to the *planning* of E-911 services with the goal of assuring that wireless telecommunications services resources are obtained and used to accomplish the objectives of the State of Minnesota.

Problem

The advent of competitive sector telecommunications services in the wireless arena has played a pivotal role in the fast growth and use of the safety information network. Wireless phones have rapidly become one of our most effective tools in improving emergency response time and saving lives. A wireless 911 phone call can shave valuable minutes from the time otherwise required for a caller to find a conventional phone to access emergency medical services (Tavana, Mahmassani, & Haas, 1999). In the past 10 years, wireless phone use has grown exponentially. There are more than 120 million wireless users making approximately 155,000 emergency calls a day across the United States. The steady increase in private sector wireless subscribership and resulting mobile EMS use has created a need to better understand the implications of this rapidly growing system.

One illustration of the spatial challenges confronting EMS providers is the lack of location information regarding E-911 accessibility. The U.S. Federal Communications Commissions (FCC) has enacted mandatory requirements for wireless communications carriers to provide automatic location identification of a wireless 911 (E-911) phone call to an appropriate Public Service Answering Point (PSAP) (Federal Communications Commission, 2001). Both private carriers and public agencies are working closely together to overcome this difficult requirement. Although the technical requirements for building these systems have been thoroughly outlined, the execution of the service has materialized slowly (Christie et al., 2002; Zhoa, 2002).

One possible reason for this is the difficulty involved in committing to one of several viable technology alternatives to provide E-911. For example, one E-911 technology choice is a satellite-based system, which places a GPS-enabled chip in mobile phones along with location readers at the receiving point. With the current rate of technological change, selecting the one best solution, or combination of solutions, for long term system planning and investment is a difficult and daunting task for system administrators and designers (Proietti, 2002). The consequence of this situation is that deploying end-to-end E-911 systems will require new spatial technologies and nontraditional partnerships, particularly among wireless carriers, emergency dispatch center administrators (e.g., PSAPs), law enforcement, fire and EMS officials, automotive companies, consumers, technology vendors, and state and local political leaders (Jackson, 2002; Lambert, 2000; Potts, 2000). From a spatial perspective, the result is that location-based (E-911) services will be differentially deployed across regions, leading to a need to understand which areas are well serviced and which may require additional policy attention.

From a *planning* perspective, the need for special attention to rural areas is evident from the following statistics. According to the U.S. Department of Transportation, more than 56% of fatal automobile crashes in 2001 occurred on rural roads (National Center for Statistics and Analysis, National Highway Transportation Safety Administration, & U.S. Department of Transportation, 2002). The Minnesota Department of Transportation (MnDOT) reports that only 30% of miles driven within the state are on rural roads, yet 70% of fatal crashes occur on them (Short Elliot Hendrickson Inc. & C.J. Olson Market Research, 2000). In addition, 50% of rural traffic deaths occur before arrival at a hospital. Appropriate medical care during the "golden hour" immediately after injuries is critical to reducing the odds of lethal or disability consequences. Crash victims are often disoriented or unconscious and cannot call for help or assist in their rescue and therefore rely heavily upon coordinated actions from medical, fire, state patrol, telecommunications and other entities (Lambert, 2000).

Solution

The solution to the rural EMS program entails a combination of responses. These responses were analyzed within the context of a specific case study; an analysis of Minnesota's E-911 system (Horan & Schooley, 2003). The first activity in this case was to analyze the entire system and to construct an overall architecture of the system. This architecture, presented in *Figure 9*, illustrates Minnesota's EMS system along several key strata, technology, organizations, and policy, and identifies possible critical links (shaded gray) in the overall system. A summary of each layer follows.

- **Technology** – The top layer of the architecture illustrates some of the essential networks and communications technologies used by Minnesota EMS organizations to carry out their individual and interorganizational functions. From a GIS perspective, the GPS-equipped wireless devices and infrastructure to determine spatial location are critical elements.
- **Organizations** – The middle layer illustrates some of the public and private organizations involved in the Minnesota EMS and the general interorganizational relationships between these organizations. There is a significant geographic dimension to the organizational layer: each of the major stakeholders has distinct service boundaries (for example, there are 109 PSAPs, yet nine rural transportation operation centers).
- **Policy** – For EMS interorganizational relationships (i.e., partnerships, joint ventures, etc.) to succeed, policies need to be developed

that facilitate the interorganizational use of new and existing communications technologies. The overarching EMS technology-related policies, illustrated in the bottom layer, currently under development in the state are E-911 and 800 MHz radio. This includes the state-federal effort to develop standards and procedures for using location information received from mobile phones.

Outcomes

This case study raises several technological, organizational, and policy issues for planning EMS in rural Minnesota specifically, as well as for rural areas in general. The architecture highlights several critical areas that arose from this review and therefore have implications for future advancements. Areas, such as those denoted in gray in *Figure 9*, provide a focal point for discussing implications of this architecture for planning both EMS in general and GIS specifically.

GIS can assist greatly in understanding the extent of EMS coverage. Currently, this understanding is at a general level of detail, i.e., the level of compliance with new E-911 regulations. For example, *Figure 10* provides an example of the spatial dimension of E-911 deployment by a major provider. As displayed in this figure, the metropolitan region of Minneapolis has deployed location-identifying systems (e.g., E-911 Phase 2), while such systems have only been partially deployed in rural areas[2].

Figure 10 also provides an overview of the level of compliance with these new regulations, with lower compliance in rural areas. As shown in the figure, many regions in Minnesota are compliant with Phase 1 — the regulation requiring the provision of location-based information about mobile phones. From a service planning perspective, it will be important to monitor the spatial distribution of E-911 availability. Inadequate coverage in rural areas could give rise to the need for additional public policy regulations.

Figure 9. Interorganizational architecture for emergency management systems in Minnesota

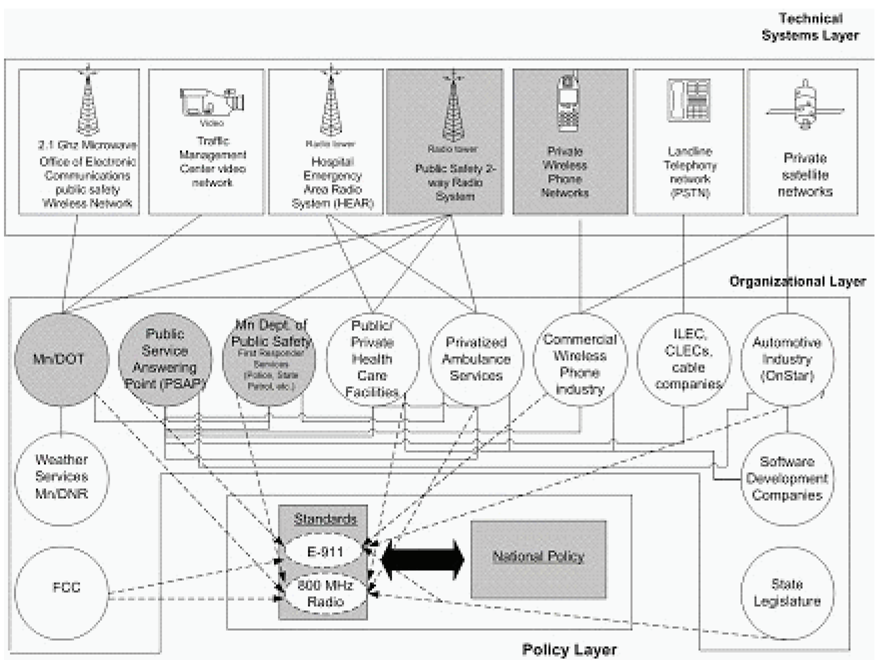


Figure 10. Spatial distribution of E-911 compliance status (Qwest)

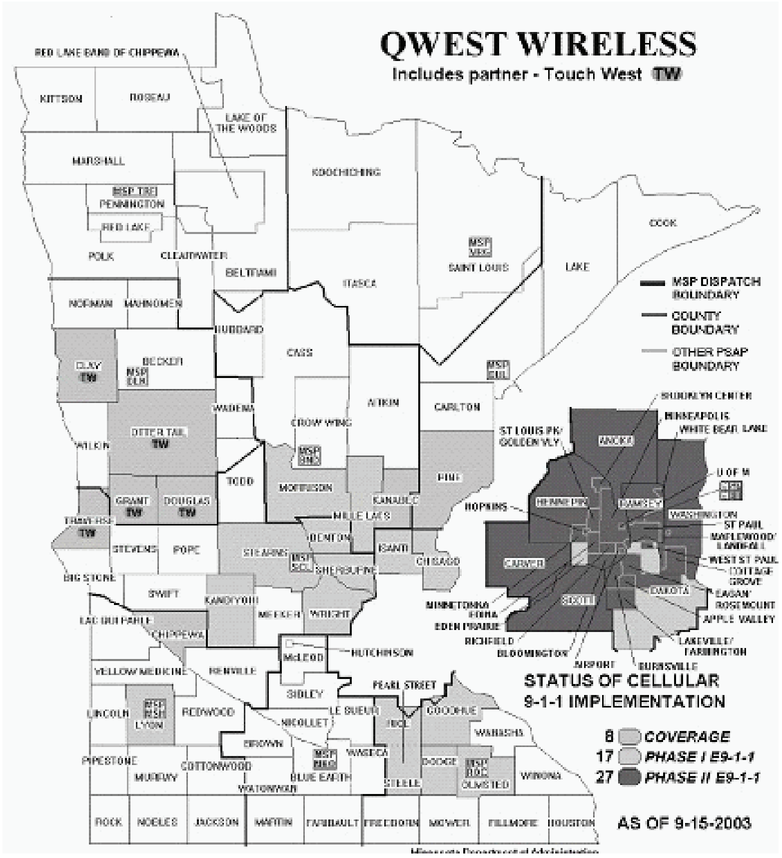
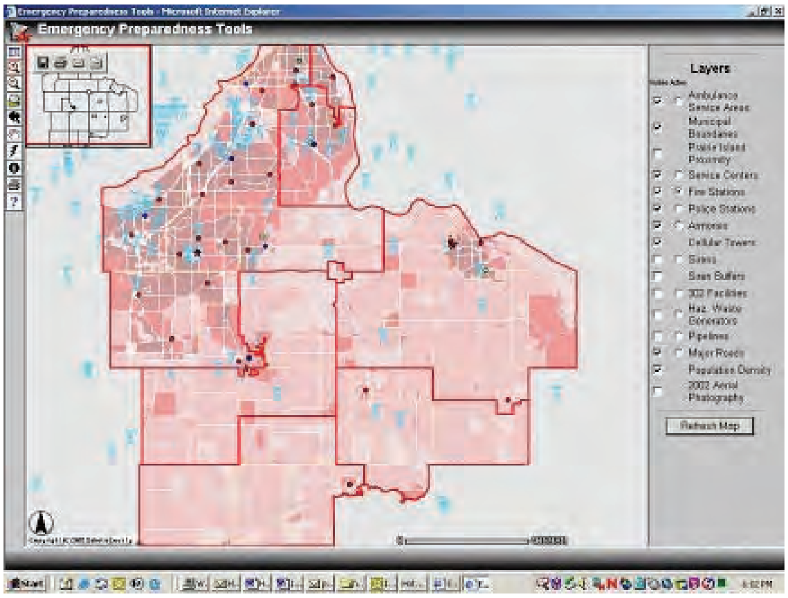


The deployment of advanced 911 capabilities is however, only one aspect of integrated EMS services. Especially with recent concerns regarding homeland security, attention is now turning to how EMS is planned as part of an overall readiness strategy. In this context, GIS can play an important role in providing a spatial platform for EMS and related emergency services. One example of this is the GIS development work underway in Dakota County, Minnesota. This county, which includes significant rural as well as urban areas, has undertaken a comprehensive GIS-based approach to emergency preparedness with an Internet-based GIS platform that integrates both EMS related factors (e.g., Ambulance Service Areas and Cellular Towers) with other civic institutions involved in emergency preparedness (e.g., Fire Stations, Police Stations, and Armories)[3]. As illustrated in *Figure 11*, the Municipal Boundaries (outlined in bold) within Dakota County and the locations of Fire Stations, Police Stations, and Armories (dots) are identified. The locations of Ambulance Service Centers (dots) and Cellular Towers (tower symbol) are identified as well.

Platforms such as this represent a critical new dimension of interactivity whereby emergency management systems can be accessed dynamically and across institutions as well as infrastructure systems. Returning to the original architecture outlined above, this platform can be used by institutions such as the departments of transportation, public safety, and emergency services to facilitate cross-agency partnerships in service and technology deployments.

Figure 11. Internet-based GIS emergency preparedness application



In summary, this case demonstrates that the planning of emergency medical services is well suited to benefit from a dynamic GIS platform. Particularly in rural areas where resources are often scarce, such a platform can provide a common database to (1) monitor the spatial deployment of services, (2) facilitate resources sharing among institutions, and (3) provide a common understanding of "conditions" against which to plan for new technologies, systems, and policies.

Over time, it will be important to monitor the rate by which rural communities improve their "readiness." GIS can assist in this monitoring, including tracking of funding expenditures, regulatory compliance, etc. Finally, it is essential that methods of planning and analysis used to determine the form, level, and location of service and resource provision reflect the geographical components underpinning the health care system, i.e., the planning process should have an explicit geographical focus (Birkin, Clarke, Clarke, & Wilson, 1996).

Strategic Planning Case Study

Background

As noted in the introduction, spatial analysis and mapping in epidemiology have a long history (Frerichs, 2000), but until recently, their use in public health has been limited. However, recent advances in geographical information and mapping technologies and increased awareness have created new opportunities for public health administrators to enhance their planning, analysis and monitoring capabilities (World Health Organization, 1999b). Moreover, effective communicable disease control relies on effective disease surveillance where a functional national communicable diseases surveillance system is essential for action on priority communicable diseases (World Health Organization, 1999a). With respect to Strategic Planning, this case considers a *research* program regarding the spatial distribution of severe acute respiratory syndrome (SARS), its epidemiological patterns, and a theory to direct health organizations objectives and policies regarding the acquisition, use, and disposition of GIS.

The National Electronic Disease Surveillance System (NEDSS) program was initiated in the United States to provide an integrated, standards-based approach to public health surveillance and to connect surveillance systems to the burgeoning clinical information systems infrastructure (U.S. Department of Health and Human Services, 2002a). It is expected that the NEDSS will improve the nation's ability to identify and track emerging infectious diseases, monitor disease trends, respond to the threat of bio-terrorism, and other scenarios where the rapid identification of unusual clusters of acute illness in the general population is a fundamental challenge for public health surveillance (Lazarus et al., 2002).

To be effective with the rapid deployment of new health information systems, it is important to maintain effective mechanisms for rapid technology transfer to occur across government, academia, and industry (Laxminarayan & Stamm, 2003). The NEDSS program articulates an architecture that will enable public health information systems to communicate electronically, thereby decreasing the burden on respondents and promoting timeliness and accuracy (U. S. Department of Health and Human Services, 2002a). Stakeholders in the NEDSS include not only the Center for Disease Control (CDC) and other agencies within Department of Health and Human Services (DHHS), but state and local public health departments, healthcare providers, laboratories, health care standards organizations, health care product vendors, and healthcare professional services organizations.

The NEDSS Base System (NBS) is an instance of the NEDSS standards for use by all stakeholders that enable systems from different CDC program areas to be integrated. Disease-specific data and processes are incorporated and integrated within the NBS using Program Area Modules (PAM). Though this modular approach allows for the sharing of these data and processes, the NEDSS standards do not provide specific guidelines to support the development of these modules. Given that "GIS provides an excellent means of collecting and managing epidemiological surveillance and programmatic information, GIS represents an entry point for integrating disease-specific surveillance approaches" (World Health Organization, 2001, p. 7). An Information System Design Theory (ISDT) approach for the development of GIS-based PAMs would provide a useful guide for the various stakeholders in the NEDSS. This approach is detailed in the following section.

Problem

Severe acute respiratory syndrome (SARS) has emerged as a serious international occupational health disease. Since the disease was first reported it has infected numerous health care workers, some fatally (Centers for Disease Control and Prevention, 2003). Consequently, early identification of SARS cases is critical, as no specific treatment protocol exists. As a result, a GIS-based PAM for SARS is needed that could be used to manage the health care services required to combat this disease.

Unfortunately, current GIS-based attempts to mitigate the spread of this disease are lacking in respect to the NEDSS; that is, they lack an integrated, standards-based approach to public health surveillance and information dissemination[4]. The objective of this case study is to propose an ISDT such that organizations meeting the requirements of this theory will, by design, develop a GIS-based PAM compliant with NEDSS standards. Geographic information science has the potential to create rich information databases, linked to methods of spatial analysis, to determine relationships between geographical patterns of disease distribution and social and physical environmental conditions. As the core of a decision support system, geographic information science also has the potential to change the way that allocations of resources are made to facilitate preventive health services and to control the burden of disease (Rushton, Elmes, & McMaster, 2000).

Information System Design Theory Approach

While the overriding methodology in this chapter is the use of case studies, the case in this section is specifically concerned with the design of GIS as systems. As such, this analysis is informed by concepts deriving from a "design" approach to information systems. As noted in the ISDT approach introduced by Walls et al. (1992), the design process is analogous to the scientific method where hypotheses are to be tested by designing and building the artifact or product. They outlined several characteristics of design theories:

- Design theories are composite theories that encompass kernel theories from natural science, social science, and mathematics.
- While explanatory theories tell "what is," predictive theories tell "what will be," and normative theories tell "what should be," design theories tell "how to/because."
- Design theories show how explanatory, predictive, or normative theories can be put to practical use.
- Design theories are theories of procedural rationality. "The objective of the design theory is to prescribe both the properties an artifact should have if it is to achieve certain goals and the method(s) of artifact construction" (p. 41). Thus, the artifact must have all the characteristics identified in the design theory.

This case study explicitly draws upon their structure for creating a design product and process. Briefly, their first component of the design product involves a set of meta-requirements that describes the class of goals to which the theory applies. Their second component is a meta-design, which describes a class of artifacts hypothesized to meet the meta-requirements. Their third component is a set of kernel theories, theories from natural or social sciences governing design requirements. Their final component of the design product is a set of testable design product hypotheses that are used to test whether the meta-design satisfies the meta-requirements.

Beyond the design product, designers of GIS would necessarily need to be concerned with principles of the design process. According to the ISDT, the first component of the design process involves a design method which describes the procedures to be used in artifact construction (Walls, Widmeyer, & El Sawy, 1992). The second component is kernel theories, theories from natural or social sciences governing design process. The last component of the design process is the testable design process hypotheses, which are used to verify whether the design method results in an artifact that is consistent with the meta-design. While ISDT is explicitly applied in this third case study, the theme of effective design holds for all: that is, there is a design need to create GIS system designs in a manner that effectively contributes to the design goal of improving human heath.

Solution

The NEDSS has identified a number of enabling technologies for each element of the NEDSS technical architecture. One of these architectural elements is Analysis, Visualization, and Reporting (AVR). AVR capabilities support the epidemiological analysis of public health data and the communication of the analytical results of that analysis (U.S. Department of Health and Human Services, 2001). The specific requirements for this architectural element include tabular and graphical reporting, statistical analysis, and geographical information analysis and display. Also included are features such as the creation of pre-defined and ad-hoc reports, the ability to share results with colleagues and the public, and the extraction of data for use with standard analysis tools. The AVR Requirements are the foundation of the GIS Meta-Requirements as well as each of the specific GIS Meta-Design elements outlined in *Table 1.*

The Meta-Requirements and Meta-Design are derived from the OpenGIS Service Architecture (Open GIS Consortium Inc., 2002). Taken as a whole, these design elements would constitute the foundation of an ISDT for GIS-based PAMs.

Table 1. ISDT for GIS-based PAMs

AVR Requirements	GIS Meta-Requirements	GIS Meta-Design
Geographical information analysis and display Tabular reporting Graphical reporting	Geographic human interaction services	Geographic spreadsheet viewer: Client service that allows a user to interact with multiple data objects and to request calculations similar to an arithmetic spreadsheet but extended to geographic data. Geographic viewer: Client service that allows a user to view one or more feature collections or coverages. This viewer allows a user to interact with map data, e.g., displaying, overlaying and querying.
Creation of pre-defined and ad-hoc reports	Geographic model/information management services	Product access service: Service that provides access to and management of a geographic product store. A product can be a predefined feature collection and metadata with known boundaries and content, corresponding to a paper map or report. A product can alternately be a previously defined set of coverages with associated metadata.
Extraction of data for use with standard analysis tools	Geographic processing services – spatial	Subsetting service: Service that extracts data from an input in a continuous spatial region either by geographic location or by grid coordinates. Sampling service: Service that extracts data from an input using a consistent sampling scheme either by geographic location or by grid coordinates.
Extraction of data for use with standard analysis tools	Geographic processing services – thematic	Subsetting service. Service that extracts data from an input based on parameter values. Geographic information extraction services: Services supporting the extraction of feature and terrain information from remotely sensed and scanned images. Image processing service: Service to change the values of thematic attributes of an image using a mathematical function. Example functions include: convolution, data compression, feature extraction, frequency filters, geometric operations, non-linear filters, and spatial filters.
Extraction of data for use with standard analysis tools	Geographic processing services – temporal	Subsetting service. Service that extracts data from an input in a continuous interval based on temporal position values. Sampling service. Service that extracts data from an input using a consistent sampling scheme based on temporal position values.
Statistical analysis	Geographic processing services – metadata	Statistical calculation service: Service to calculate the statistics of a data set, e.g., mean, median, mode, and standard deviation; histogram statistics and histogram calculation; minimum and maximum of an image; multi-band cross correlation matrix; spectral statistics; spatial statistics; other statistical calculations.
Sharing of results with colleagues and the public	Geographic communication services	Transfer service: Service that provides implementation of one or more transfer protocols, which allows data transfer between distributed information systems over off-line or online communication media.

Outcome

As seen in this case, “GIS offers new and expanding opportunities for epidemiology as they allow the informed user to choose among options when geographic distributions are part of the problem, and when used for analysis and decision-making, they become a tool with a rich potential for public health and epidemiology" (Clarke, McLafferty, & Tempalski, 1996, p. 1). GIS-based PAMs developed using the proposed ISDT would allow the sharing of common data and processes while incorporating disease-specific data and processes. As seen in *Figure 12*, a SARS-specific PAM developed in this manner would become one of many PAMs and part of the larger NBS.

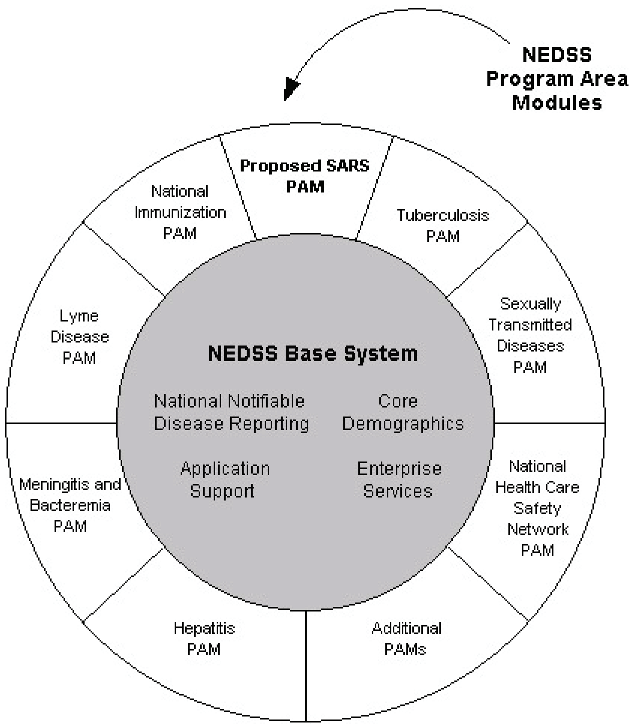
CASE STUDY SUMMARY ANALYSIS AND MANAGEMENT IMPLICATIONS

A summary of the three case studies is presented in *Table 2*. Each of the three cases presented is based on the health care service provided, specific problem type, solution generated, and final outcome.

As discussed in the introduction, the visual display of spatial information in healthcare, starting with epidemiology, has a long history. The literature reveals, as do these case studies, that the role of the private sector becomes increasingly more important as you move from the strategic planning level down to the management and operational levels. For those charged with the management of organizations, the following issues should be considered:

- **Data Integration for Operational Control:** Geospatial location is considered a valuable organizing principle for architecting and constructing enterprise data stores where interoperable geospatial technologies play a foundational role in exploiting these data

Figure 12. Conceptual picture of the NEDSS base system and program area modules



Adapted from U. S. Department of Health and Human Services (2002a) stores for enterprise missions (Open GIS Consortium Inc., 2003). As seen in the first case, this can occur at even the most basic level where demand from users at the operational level prompted the linkage of spatial and non-spatial data. As a consequence, the linkage of spatial and non-spatial databases will be among the challenges that organizations face as the spread of GIS applications and their extended functionalities drive organizations to integrate their existing structures with the increasingly important spatial dimension.

- **Planning Interorganizational Systems for Management Control:** Managing ad hoc inter-organizational networks are the nature of GIS data in health care environment. Emergency management applications are being developed in numerous areas around the country, ranging from instances where GIS-based emergency planning has been carried out by local governments, to cases where the Federal Emergency Management Agency has supported the creation and implementation of a GIS for this purpose (O'Looney, 2000). However, these diverse organizations collect spatial data for different purposes and goals. For successful planning, spatial data must be organized in such a manner as to appear as residing in one central database. Thus, the issue becomes how to successfully manage the relationship between these loosely coupled organizations that have dependence on tightly coupled systems without compromising their organizational purposes and goals.
- **Design Research for Strategic Planning:** The global implication of geographic data, as seen recently with SARS, indicates that it is no longer confined to the local or national level. Unfortunately, global geographic information is currently little more than the sum of the highly varied national parts and is not readily available (Longley, Goodchild, Maguire, & Rhind, 2001). The Global Spatial Data Infrastructure Association was formed to address this issue and is dedicated to international cooperation and collaboration in support of local, national, and international spatial data infrastructure

Table 2. Summary of case studies

Case Study	Health Care Service Provided	Problem	Solution	O utcome
Operational Control (Practice)	Disability Evaluation	Accuracy and time to schedule appointment location and date	Internet-based GIS application for use within company Extranet	Improved decision making and reduction in time required for scheduling physician appointments
Management Planning (Control)	Emergency Medical Service Delivery	Need for Ready EMS Delivery	Use GIS to provide efficient planning and management of E-911 health emergencies	Reduced EMS delay time and more rapid onset of trauma service delivery
Strategic Planning (Research)	Disease Surveillance System	Lack of Spatial Data Integration and Dissemination	Devise Inter-organizational Spatial Database for early disease detection	Program Area Module Design Theory for GIS

developments to allow nations to better address social, economic, and environmental issues of pressing importance (The Global Spatial Data Infrastructure Association, 2003). Their vision for a Global Spatial Data Infrastructure would support ready access to global geographic information. This vision would be achieved through the coordinated actions of nations and organizations through the implementation of complementary policies and common standards for the development and availability of interoperable digital geographic data and technologies to support decision-making at all scales for multiple purposes. The research challenge then is learning how to create a robust information system design process that considers spatial dimensions from global level international standard bodies to local level implementing organizations.

DISCUSSION

IS, and spatial analysis more broadly, can inform a number of pressing health care service issues, both domestically and internationally. From a domestic perspective this includes issues such as treating highly distributed populations and efficiently targeting critical services. From an international perspective, this includes developing a rapid means to detect and treat human health outbreaks in developed and developing regions as well as the creation of spatial datasets to drive international health enterprises.

Toward a Spatial Decision Support System (SDSS) for Human Health

While the geographic dimension of human health has long been recognized, the integration of GIS into the health care industry has not received the level of attention as that of more cutting-edge medical technologies. Nonetheless, as revealed in these cases as well as others that are increasingly appearing in the literature (Lang, 2000), GIS can provide a useful tool at the operational, management, and strategic levels of health care resources. For this reason, researchers such as Cromley & McLafferty (2002) have begun advocating for Spatial Decision Support Systems (SDDS) in support of health care services. Furthermore, a fairly long history of decision support systems in health care has been recognized (Shortliffe & Perrault, 2001). The new view is to integrate the spatial element into these systems. It is hoped that this chapter provides yet another indicator of the value in using spatial analysis for health care delivery.

ACKNOWLEDGMENTS

This chapter draws upon a series of research projects undertaken by the authors, as well as additional resources as appropriate. Findings related to the use of GIS and Disability Evaluations are based in part on the research conducted in collaboration with QTC, Inc. and have been reported in Hilton, Horan, & Tulu (2003). Findings related to the use of Emergency Management Systems and GIS are based in part on the research conducted in collaboration with the Humphrey Institute of Public Affairs, University of Minnesota and funded by the ITS Institute and have been reported in Horan, Kaplancali, & Schooley (2003) and Horan & Schooley (2003). The authors gratefully acknowledge the contributions of the following individuals to the chapter: Lee Munnich, Benjamin Schooley, and Dr. Subbu Murthy.

ENDNOTES

1 "Instead of plotting a time-series, which would simply report each day's bad news, Snow constructed a graphical display that provided direct and powerful testimony about a possible cause-effect relationship. Recasting the original data from their one-dimensional temporal ordering into a two-dimensional spatial comparison, Snow marked deaths from cholera on this map, along with locations of the area's 13 community water pump-wells. The notorious well is located amid an intense cluster of deaths, near the D in BROAD STREET. This map reveals a strong association between cholera and proximity to the Broad Street pump, in a context of simultaneous comparison with other local water sources and the surrounding neighborhoods without cholera" (Tufte, 1997. p. 30).

Chapter 1.12
Information Technology (IT) and the Healthcare Industry:
A SWOT Analysis

Marilyn M. Helms
Dalton State College, USA

Rita Moore
Dalton State College, USA

Mohammad Ahmadi
University of Tennessee at Chattanooga, USA

ABSTRACT

The healthcare industry is under pressure to improve patient safety, operate more efficiently, reduce medical errors, and provide secure access to timely information while controlling costs, protecting patient privacy, and complying with legal guidelines. Analysts, practitioners, patients and others have concerns for the industry. Using the popular strategic analysis tool of strengths, weaknesses, opportunities, and threats analysis (SWOT), facing the healthcare industry and its adoption of information technologies (IT) are presented. Internal strengths supporting further industry investment in IT include improved patient safety, greater operational efficiency, and current investments in IT infrastructure. Internal weaknesses, however, include a lack of information system integration, user resistance to new technologies and processes, and slow adoption of IT. External opportunities including increased use of the Internet, a favorable national environment, and a growing call for industry standards are pressured by threats of legal compliance, loss of patient trust, and high cost of IT.

INTRODUCTION

The healthcare industry faces many well-recognized challenges: high cost of operations, inefficiency, inadequate safety, insufficient access to information, and poor financial performance. For years, many have called for a fundamental change in the way healthcare is delivered. And while there is yet no clear picture of what this change will be, many believe a paradigm shift in healthcare is imminent and that information technology (IT) is the catalyst.

Increasingly, IT is seen as a way to promote the quality, safety, and efficiency of healthcare by bringing decision support to the point of care, providing vital links and closing open loop systems, and allowing routine quality measurement to become reality. IT can not only reduce operating costs, but IT can also ensure a reduction in the number of medical errors. IT in the healthcare industry provides new opportunities to boost patient confidence and reinforce patient trust in caregivers and healthcare facilities. With health insurers feeling pressure from all directions (new regulations, consumers, rising medical costs), IT is an even more important asset for carriers (Balas, 2000).

When compared to other information intensive industries, healthcare organizations currently invest far less in IT. For many years, the healthcare industry has experienced only single digit growth in terms of IT investment (Gillette, 2004). As a result, current healthcare systems are relatively unsophisticated compared to those in industries such as banking or aviation. With the many issues and variables surrounding healthcare's IT investment, a framework for better understanding of the current situation is needed before more improvements and enhancements can result. This article draws upon a comprehensive framework from the strategic planning literature to compile and summarize the major issues facing IT and the healthcare industry.

METHODOLOGY

By categorizing issues into strengths, weaknesses, opportunities, and threats, SWOT analysis is one of the top tools and techniques used in strategic planning (see Glaister & Falshaw, 1999). SWOT assists in the identification of environmental relationships as well as the development of suitable paths for countries, organizations, or other entities to follow (Proctor, 1992). Valentin (2001) suggests SWOT analysis is the traditional means for searching for insights into ways of crafting and maintaining a fit between a business and its environment. Other researchers (see Ansoff, 1965; Porter, 1991; and Mintzberg, Ahlstrand, & Lampel, 1998) agree SWOT provides the foundation to gather and organize information to realize the desired alignment of variables or issues. By listing favorable and unfavorable internal and external issues in the four quadrants of a SWOT analysis, planners can better understand how strengths can be leveraged, realize new opportunities, and understand how weaknesses can slow progress or magnify threats. In addition, it is possible to postulate ways to overcome threats and weaknesses (e.g., Hofer & Schendel, 1978; Schnaars, 1998; Thompson & Strickland, 1998; McDonald, 1999; and Kotler, 2000).

SWOT has been used extensively to aid in understanding a variety of decisions and issues including: manufacturing location decisions (Helms, 1999); penetration strategy design for export promotions and joint ventures (Zhang & Kelvin, 1999); regional economic development (Roberts & Stimson, 1998); entrepreneurship (Helms, 2003); performance and behavior of micro-firms (Smith, 1999), and strategic planning (Khan & Al-Buarki, 1992). Hitt, Ireland, Camp, and Sexton (2001) suggest that identifying and exploiting opportunities is part of strategic planning. Thus, SWOT analysis is a useful way to profile the general environmental position of a new trend, technology, or a dynamic industry.

By using SWOT analysis, it is possible to apply strategic thinking toward the implementation of IT in healthcare. By examining the internal and external factors interacting both for and against IT in healthcare, healthcare providers and supply chain organizations can formulate a strategic IT plan for developing their information resources over the next several years. By uncovering and reviewing the issues, policy makers can enact changes to make the process of IT implementation easier while simultaneously working to change the culture to foster IT benefits for institutions and the patients and other stakeholders they serve.

In SWOT analysis, strengths act as leverage points for new strategic initiatives, while weaknesses are limiting factors. Specifically applied to IT in healthcare, strengths should indicate areas where either IT or healthcare is particularly strong, (i.e., the technical skills of IT professionals or the quality of existing healthcare information systems). Weaknesses should display areas where either IT or healthcare requires improvement, and may range from personnel issues within IT to limited healthcare applications beyond routine transaction processing. The threats and opportunities identified during the external analysis should be both factual and attitudinal issues that must be addressed in any strategic plan being formulated, and should include both healthcare and IT issues (Martin, Brown, DeHayes, Hoffer, & Perkins, 2005). The following section presents the internal strengths and weaknesses currently confronting the implementation and proliferation of IT in healthcare.

INTERNAL STRENGTHS

Improved Patient Safety

Patient safety, as expressed in the Hippocratic Oath (Classical Version)—"I will keep them from harm and injustice"—is an underlying principle of professional healthcare throughout the world. Improving patient safety is a primary objective at all levels of the healthcare industry. The strategic initiative to increase the role of IT in healthcare can advance the cause of greater patient safety by enhancing the quality of that care. With comprehensive data available in a timely manner, healthcare providers can make better decisions about their patients' care, thereby reducing errors due to incomplete or insufficient information at the point of decision (Goldberg, Kuhn, & Thomas, 2002). Lenz (2007) agrees IT has a huge potential to improve the quality of healthcare and that this aspect has not been fully explored by current IT solutions. Advanced process management technology is seen as a way to improve IT support for healthcare processes by improving the quality of those processes.

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) established the Healthcare Information Technology Advisory Panel in 2005 to focus attention on the improvement of patient safety and clinical processes as new healthcare information systems are implemented. Members of the panel include researchers, physicians, nurses, chief information officers, educators and leaders of healthcare organizations, as well as representatives from the Office of the National Coordinator for Health Information Technology, the American Health Information Management Association, the Agency for Healthcare Research and Quality, the Veterans Health Administration, and the Healthcare Information and Management Systems Society. The panel was formed to recommend ways JCAHO's accreditation process and the widespread use of technology can be used to help re-engineer patient care delivery and result in major improvements in safety, quality and efficiency. The panel was also charged with the task of examining such topics as the effect of electronic health records on performance benchmarking and public reporting capabilities. Based on the panel's recommendations, JCAHO will evaluate its strategic plan and future direction relative to healthcare information technology (Anonymous, 2005b).

Two examples of existing information technologies and computer-based information systems contributing to improvements in patient safety through better quality of care and reduction of errors are smart cards (and/or compact discs) and computerized physician order entry (CPOE) systems. Smart cards containing a patient's entire medical history can be designed to be accessible only by devices in a hospital, doctor's office, or other medical facility. They not only eliminate the problems of lost and comprised hard copies of patient records, but also enable more secure electronic transfers of patient information to other healthcare providers and insurers (Anonymous, 1997). The technology for Java-based cards can securely support applications for multiple health-care facilities and be combined with biometric measures for identification purposes (Sensmeier, 2004). With complete information available, physicians are able to make better decisions for the care of the patient, and order appropriate tests and treatments (Goldberg et al., 2002).

Several studies indicate medication errors are the most likely type treatment error to occur because drug therapy is one of the most widely used interventions in healthcare (Kohn, 2001). Computerized physician order entry (CPOE) systems eliminate transcription errors and can warn of allergies and drug interactions. Such systems reduce errors by more accurately dispensing the correct dosage of the correct medication for the correct patient (Bates, Teich, Lee, Seger, Kuperman et al., 1999;Kuperman, Teich, Gandhi, & Bates, 2001; Mekhjian, Kumar, Kuehn, Bentley, Teater et al., 2002; Order Entry Rules, 2002; Scalise, 2002; Shane, 2002).

Computerized Physician Order Entry (CPOE) systems reduce medication errors by 80%, and errors with serious potential patient harm by 55% (Bates et al., 1999).

In pharmaceuticals, e-prescribing, or the electronic transmission of prescription information from the prescribing physician to a pharmacist can reduce medical errors. Since Americans receive more than three billion prescriptions yearly and pharmacists have to call these physicians 150 million times a year because they cannot read or understand the prescriptions, e-prescribing could reduce injuries from medication errors (Brodkin, 2007).

Technology-enabled improvements could also aid disease prevention and management. Other benefits could include lowering age-adjusted mortality by 18% and reducing annual employee sick days. Lieber (2007) stresses shared experiences regarding pandemic diseases can provide the best solutions and this is aided by IT solutions and global information exchange.

When medical records are available electronically, patients too can have access to their personal health records. Five large U.S. employers have funded an institute where their current and retired employees and their families can have access to and maintain their lifelong personal health records (Five Large Companies, 2007). With access to longitudinal and comprehensive records, patient safety can continue to improve.

A recent example of IT and improved patient safety is the North Mississippi Medical Center (NMMC) in Tupelo, Mississippi. Serving 24 rural counties, NMMC is the largest rural hospital in the country and the 2006 winner of the Malcolm Baldrige National Quality Award in the Healthcare Category. NMMC's recognition was due largely to their success in utilizing IT. Patients' electronic medical records can be accessed by nurses, by partner community hospitals, by physicians in their offices, and even by specialists and primary care providers in remote sites, reducing medical errors and duplication of effort. These enhancements have earned NMMC the distinction of one of the most wired facilities in the country. The organization has a shared radiography information system for all its hospitals and clinics which reduces report preparation time. For example, patients can have a radiology procedure, see their doctor, and obtain their results the same day (Baldrige Award Recipient, 2006; Anderson, 2007).

Greater Efficiency of Operation

Information technology, or the digital world of bits and bytes, delivers information faster, smarter, and cheaper (Conger & Chiavetta, 2006). In healthcare, IT has improved operational efficiency and increased productivity by reducing paperwork, automating routine processes, and eliminating waste and duplication. Lieber (2007) reports the use of electronic health records could save as much as $8 billion yearly in California alone through improvements in delivery efficiency.

Picture archival and communication systems (PACS) not only save providers' costs for file room, storage space and film supplies, but also decrease time spent reporting, filing and retrieving records. Web access enables physicians to view radiological images from their offices, homes, or other remote facilities. IT provides emergency rooms with tools for electronic prescriptions, order entry, provider documentation, and aftercare instructions for patients and their family. Updating electronic instructions is quick and easy. Purchasing departments are aided by the ability to buy products for specialty areas, such as anesthesia, infection control, substance-abuse programs, and home healthcare. Increased productivity and positive return on investment are seen in many areas of IT and are continuously improving (Parker, 2004b).

Three other important technological advances for improved productivity are voice-technology systems, two-way communications systems, and radio-frequency identification (RFID). Voice-technology systems can significantly reduce the time nurses and admissions personnel spend on pre-authorizations and pre-certifications required by third-party payer plans. Within six months of implementing a phone-based voice-technology system, Erlanger Hospital in Chattanooga, Tennessee, reported a greater than 50% drop in phone transaction times. Moreover, in May, 2006, after four years in operation, Erlanger reported a total payback of $920,201, decreased percentages in days denied, and the reassignment of three full-time equivalent employees to other departments within the hospital (Bowen & Bassler, 2006). Automated two-way communications systems for scheduling can greatly improve workflow by managing automatic appointment reminders, waiting lists, and cancellation notices. These systems call patients, and in a pleasant voice, remind them of a doctor's appointment, ask them to confirm their intention to keep the appointment, and report the information to the provider's office (Sternberg, 2005). RFID technology, particularly in the areas of human and material resources, offers healthcare facilities a way to measure and control their resources as well as the relevant workflow processes (Janz, Pitts, & Otondo, 2005).

Some healthcare providers suggest Emergency Department Information Systems (EDIS) can improve operations efficiency in this extremely time-critical area by facilitating the flow of patients through the emergency department, eliminating redundant patient records, promoting information sharing, and providing quicker access to laboratory test results and radiology films (Parker, 2004a). Because electronic medical records allow tracking of patients' conditions and medications, emergency room providers and hospitals have immediate access to detailed information; both patients and providers have a better sense of what occurred and when. Both groups also report increased satisfaction with the process. Interoperability of systems also makes patient information available across budgetary and functional units, thereby providing greater continuity of patient care (Cohen, 2005).

Lopes (2007) agrees it is more efficient when an internal medicine physician can consult with a cardiologist electronically while viewing a patient's medical work-up and history. Such systems create efficiencies, have a positive return on investment, and there are no misfiled lab results.

IT tools and software are being developed to meet the growing needs of the healthcare community. As an example, VHA, Inc. recently introduced an updated version of a Comparative Clinical Measurement tool to give member hospitals flexibility in both collecting and reporting clinical improvement data. VHA, Inc. has worked with the Joint Commission on Accreditation of Healthcare Organizations to include their measures into the new tool (VHA, 2007).

Current Investment in IT

Is there a hospital in the United States that has not already made an investment in their IT infrastructure? Probably not. In the past ten years, advances in health information technologies have occurred at an unprecedented rate and healthcare organizations have responded by increasing their IT investments "threefold" (Burke & Menachemi, 2004). Today, albeit at varying levels of sophistication, all hospitals use IT to run their core administrative and clinical application systems, that is, patient accounting, insurance billing, human resources, staff and facilities scheduling, pharmacy, laboratory results reporting, and radiology (Cohen, 2005). Most healthcare organizations in the U.S. are spending between 2.1% and 10% of their capital operating budget on IT (Conn, 2007c). Within this spending on IT, healthcare providers cite electronic health record development as a top priority followed by development and implementation of clinical IT systems to improve patient care capability (Conn, 2007b).

According to the U.S. Department of Health and Human Services (HHS), approximately 13% of the nation's 4,000+ hospitals use electronic medical records and 14% to 28% of the 853,000 U.S. physicians are wired (Swartz, 2005). A recent study reported, on average, hospitals have acquired 10.6 clinical application systems, 13.5 administrative application systems, and 50.0 strategic application systems (Burke & Menachemi, 2004). Some healthcare organizations including the Cincinnati Children's Hospital, Baylor Healthcare System in Dallas and The Heart Center of Indiana are going beyond their core systems to develop, acquire, and integrate applications for decision support, benchmarking, facilities management, and workflow processes (Cohen, 2005; Kay & Clarke, 2005).

If predictions are correct, by 2015 the electronic medical records market is expected to grow to more than $4 billion, up from $1 billion in 2005. The Kalorama Information Research firm, after studying the healthcare, diagnostics, pharmaceuticals, and medical devices markets, predicts the surge will be led by the increase in IT budgets of hospitals, physicians' offices and other U.S. healthcare organizations (Study: U.S., 2007).

Healthcare organizations, having already made investments in their computing and communications hardware and software, application software, and personnel, can leverage their existing IT investments as they expand their IT infrastructure to meet growing demands to achieve more efficient operations and more effective levels of healthcare. Whether or not the IT investments meet the ROI goals of financial departments, hospitals are going to implement IT, according to a survey by the Healthcare Information and Management Systems Society. Some 88% of hospitals have adopted electronic medical records and 24% already have them in place. Some 36% are implementing them and 28% have plans to. Only 12% lack IT plans (Greene, 2007).

INTERNAL WEAKNESSES

Lack of System Integration

Integrated systems offer seamless data and process integration over diverse information systems (Landry, Mahesh, & Hartman, 2005). Since a patient's treatment involves receiving services from multiple budgetary units in a hospital, information system integration should exist between the computer-based applications within a single hospital. When healthcare organizations coordinate and integrate their internal data, they can improve operations and decision making; however, most healthcare organizations are not yet at this level of system integration. Clinical, administrative, and financial systems are not linked, and as a result, many healthcare institutions are not yet maximizing their IT potential (Cohen, 2005).

Moreover, system integration need not be confined to applications within a single facility. There are many types of healthcare providers and healthcare-related agencies in the complex healthcare network. Since a patient's treatment usually involves receiving services from multiple providers and interacting with various other healthcare-related entities, information system integration should also exist between the computer-based applications of those separate agencies. Immediate benefits of information sharing between different agencies include the elimination of duplicate work in gathering and inputting the data, the immediate availability of the information, a lower probability of error, and greater convenience for the patient. Called a "vision of unsurpassed information technology integration," The Heart Center of Indiana, a joint venture between St. Vincent Health, The Care Group, and CorVasc, reports improved quality of care at lower costs through its IT partnership (Kay & Clarke, 2005).

System integration between agencies could also take increased efficiency to the industry or national level. A report issued by the Foundation of Research and Education of the American Health Information Management Association supports a fully integrated fraud management system which it believes could help address the growing problem of healthcare fraud (Swartz, 2006a).

User Resistance

User resistance, more commonly termed *user acceptance* in the information systems literature, is nothing new to IT. The original Technology Acceptance Model (TAM) put forth by Davis (1989) states a user's level of system acceptance is explained by two factors: the system's perceived usefulness and its perceived ease of use. Perceived usefulness is defined as the degree to which a person believes that using a particular system would enhance job performance, while perceived ease of use is defined as the degree to which a person believes that using a particular system would be free of effort. Subsequent research across a variety of research settings confirms perceived usefulness as the strongest predictor of user acceptance (Adams, Nelson, & Todd, 1992; Taylor & Todd, 1995; Venkatesh & Davis, 1996; Mahmood, Hall, & Swanberg, 2001). Some believe that IT implementations in the healthcare environment, however, encounter more resistance than in any other environment (Adams, Berner, & Wyatt, 2004).

The healthcare-related literature suggests physician resistance is a key weakness existing in the doctor's office and at the hospital. Consistent with Davis' (1989) principle of perceived usefulness, physician acceptance of new IT systems at the hospital is linked to the system's impact on patient safety (Rhoads, 2004), while physician acceptance of new IT at their office largely depends on cost (Chin, 2005). Healthcare literature suggests nurse acceptance of new IT has steadily improved as applications demonstrate increased support of the practice of nursing and improvement of patient safety resulting from the reduction of human error (Sensmeier, 2005; Simpson, 2005).

A study of 12 critical access hospitals found barriers to health information technology included funding, staff resistance to change, staff adaptation to IT and workflow changes. Other user resistance was noted by the time constraints on small staff, facility and building barriers, and lack of appropriate IT support. While all agree that IT will improve safety and reduce errors, barriers to implementation are numerous and must be addressed (Hartzema, Winterstein, Johns, de Leon, Bailey, McDonald, & Pannell, 2007).

Slow IT Adoption

Traditionally, healthcare has been slow to adopt IT and has lagged significantly behind other industries in the use of IT (Ortiz & Clancy, 2003; Adams et al., 2004). A 2005 report from the National Academy of Engineering and the Institute of Medicine agrees healthcare's failure to adopt new strategies and technologies has contributed to the list of problems now associated with the industry: thousands of preventable deaths a year, outdated procedures, billions of dollars wasted annually through inefficiency, and costs rising at roughly three times the rate of inflation. Lack of competition, resistance to change, and capital costs are among the major causes for healthcare's slowness to adopt IT (Hough, Chen, & Lin, 2005).

There are signs of progress, however, which offer promise of accelerated change. Many hospitals and physician groups are now digitizing their medical records and clinical data (Hough et al., 2005). As noted earlier, some hospitals like Cincinnati Children's Hospital, Baylor Healthcare System in Dallas, and The Heart Center of Indiana have adopted IT at advanced levels (Cohen, 2005; Kay & Clarke, 2005). These hospitals are models for the industry, forging a path for other healthcare organizations to follow, and emerging as healthcare leaders in IT whose techniques can be benchmarked, emulated and implemented. As the healthcare technologies are developed to greater sophistication and functionality, it will be possible for other healthcare organizations to "leapfrog" over the slow, expensive evolutionary learning process experienced by the leaders (Conger & Chiavetta, 2006).

The following section outlines external opportunities and threats facing IT and healthcare. Specific opportunities are the Internet, the national environment, and industry standards. Key threats include legal compliance, loss of patient trust, and the costs of IT systems, training, implementation, and support.

EXTERNAL OPPORTUNITIES

The Internet

Across the industry, healthcare facilities and providers are in various stages of incorporating the Internet into their operations to allow new ways to communicate with the general public, specific patients, patient groups, physicians, other providers, and employees. Notable Web-based services include public Web sites, various telemedicine applications for targeted patient audiences, physician portals, physician education sites, and facility intranets which serve an organization's internal audiences. Generally, there is an increased focus throughout the healthcare industry to improve all Web-based applications (Sternberg, 2004).

Through their public Web sites, hospitals and other healthcare agents provide medical information to the general public (Natesan, 2005). E-Health Web portals offer healthcare services and education to people with chronic conditions and to their caregivers (Moody, 2005). Through various telemedicine initiatives, the healthcare industry has reached significant numbers of people living in rural areas, providing access to expert advice and reducing their health risks (Harris, Donaldson, & Campbell, 2001). Web-based patient support systems educate patients and allow them better participation in their own care. Patients can research detailed information for their particular conditions, medications, and treatments to understand what is happening and to reduce their anxiety. Online surgery videos and graphics can be presented in user-friendly formats to assist patients in procuring information. The Internet has also had a major impact in the delivery of information and education to healthcare professionals (Kiser, 2001). Numerous organizations have Web sites for disseminating new medical information to physicians. Various Web-based physician education services have been established. Some hospitals offer physician portals allowing physicians to access patients' medical records, lab results, and radiological images and reports from their offices, homes, or other remote locations (Cohen, 2005).

The Internet is also redefining communication channels between doctors and patients, as well as between healthcare providers and other healthcare-related agencies. DeShazo, Fessenden, and Schock (2005) suggest the top two emerging trends in healthcare are (1) online patient/physician communication and (2) secure connectivity and messaging among hospitals, labs, pharmacies, and physicians. Advances in home technology coupled with the aging of the baby-boom generation have created the demand for better communications with patients about their on-going care and monitoring. Improving the communication between the patient's at-home technology and the provider's technology is also a growth opportunity. Based on the adequacy of information transmitted to the healthcare provider, the physician saves appointment times and patients are freed from excessive office visits, thereby lowering transaction costs (Flower, 2005).

The Internet and other advances in IT have enabled new models for electronic delivery of a variety of healthcare services. Kalyanpur, Latif, Saini, and Sarnikar (2007) describe the market forces and technological factors that have led to the development of Internet-based radiological services and agree the Internet has provided the platform for cost-effective and flexible radiological services. Wells (2007) agrees the practice of evidence-based medicine requires access to the Internet, mobile devices, and clinical decision-support tools to assist practitioners in improving preventable medical errors.

Favorable External Environment

There is growing support worldwide for the utilization of more IT in healthcare (Caro, 2005). Reports from Australia, Great Britain, India, Italy, and Norway, for example, document local, regional and national healthcare projects and initiatives utilizing IT (Sharma, 2004; Grain, 2005; Marino & Tamburis, 2005; Bergmo & Johannessen, 2006; Fitch & Adams, 2006).

In the U.S., more funds are being made available in the form of grants and demonstration projects by the Federal government to encourage greater adoption of IT in healthcare. In 2004, officials of the U.S. Department of Health and Human Services (HHS) disclosed a ten-year healthcare information infrastructure plan, the "Decade of Health Information Technology," to transform the industry from a paper-based system to an electronic one. More than 100 hospitals, healthcare providers, and communities in 38 states were awarded $96 million over three years to develop and use IT for healthcare. Awards were focused on communities and small and rural hospitals. Five states, Colorado, Indiana, Rhode Island, Tennessee, and Utah, were awarded $25 million over five years to develop secure statewide networks for accessing patient medical information. The National Opinion Research Center at the University of Chicago was awarded $18.5 million to create a National Health Information Technology Resource Center to provide technical assistance, tools, and a best-practices repository as well as provide a focus for collaboration to grantees and other federal partners. In all, HHS awarded nearly $140 million in grants to promote the use of IT, develop state and regional networks, and encourage collaboration in advancing the adoption of electronic health records (Swartz, 2005).

In 2005, the Agency for Healthcare Research and Quality, part of HHS, awarded over $22 million in grants to 16 institutions in 15 states to aid in implementing healthcare IT projects emphasizing patient safety and healthcare quality. The grants were designed to encourage the sharing of information among providers, labs, pharmacies, and patients, with the specific goal of decreasing medication errors and duplicate testing. Eleven of the 16 grants were awarded to small and rural communities (Anonymous, 2005c).

In his 2004 State of the Union address, President Bush called for the transformation of electronic health records within the next ten years in the United States and urged more healthcare organizations to consider implementing such health information technologies as electronic healthcare records (EHR), computerized ordering of prescriptions and medical tests, clinical decision support tools, digital radiology images, and secure exchange of authorized information, emphasizing that all of these technologies have been shown to improve patient care quality and reduce medical errors (Abrahamsen, 2005). In President Bush's 2008 budget proposal, there is funding for a healthcare system and IT is the starting point for the system. Carolyn Clancy, Director of the Agency for Healthcare Research and Quality, agrees the data generated from the healthcare system could answer various medical inquiries and could draw on the data of EHRs of millions of individuals to advance the evidence base for clinical care. She further suggests the data could reveal why costs are increasing and what risks and benefits are associated with particular prescription drugs (Lubell, 2007).

Industry Standards

The development of industry standards for both data communications and data taxonomies may be the most profound of all the opportunities currently facing healthcare. As a crucial first-step in modernizing the U.S. healthcare system, all industry participants—providers, payers, and regulators—are being urged to adopt interoperable systems and common data standards for existing federal, state, and health networks along with standard practices to promote data sharing and protection of patient privacy (Swartz, 2006b). Standard data communications technology and standard data definitions are essential for such health information technologies as electronic health records and e-prescribing (Brailer, 2004).

A recent study of several disability compensation programs within the U.S. found each program uses its own terminology and disability definitions causing non-standard interpretation of terms, misinterpretation of data, and delay in the disability evaluation process. The study suggests defining and adopting a standard for disability evaluation could not only eliminate process inefficiencies in determining disabilities but could also facilitate innovative disability technology practices (Tulu, Hilton, & Horan, 2006).

Some standardization of data has been introduced with the Health Insurance Portability and Accountability Act (HIPPA) legislation, but for the most part, standardization projects are voluntary and lack assurances the standards will be adopted by all parties. The National Quality Forum (NQF) endorsed a voluntary consensus standard for patient safety events and has been adopted by more than 260 healthcare providers, consumer groups, professional associations, federal agencies, and research and quality improvement organizations. The taxonomy is the first standardized, integrative classification system adopted by a group of medical agencies, organizations, providers, and U.S. states. The standard establishes a common taxonomy for healthcare errors and other patient safety problems. It can be used to classify data collected in different reporting systems, allowing the data about patient safety events to be combined and analyzed (Anonymous, 2005d).

Standardization can result in greater levels of system integration, increased sharing of data between healthcare partners, greater information continuity throughout the healthcare industry, and more powerful data mining. Enterprise Resource Planning (ERP) systems can offer more online processing to all users and function, automate routine job processes, and redefine existing work processes (Landry et al., 2005). With integration of systems and standardization of data taxonomies, the healthcare industry will experience changes similar to those in other industries where "enterprise" systems have been adopted. Others agree a seamless support of information flow for healthcare processes that are increasingly distributed requires the ability to integrate heterogeneous IT systems into a comprehensive system (Lenz, Beyer, & Kuhn, 2007).

System standards resulting in a greater level of systems integration is a pressing need. Conn (2007a) reports the compromise reached by two rival standards groups for data communications standards can help to bridge the gap between physicians' offices and hospitals in the electronic health record systems they use. The Continuity of Care Document standard combines the independent works by two standards development organizations on creating electronic summaries of care for discharged patients.

EXTERNAL THREATS

Legal Compliance

The Health Insurance Portability and Accountability Act (HIPAA), enacted by Congress in 1996, is the most significant Federal legislation affecting the U.S. healthcare industry since the Medicare and Medicaid legislation of 1965. Title I of HIPAA legislates improved portability and continuity of health insurance coverage for American workers. Title II addresses "administrative simplification" requiring the development of standards for the electronic exchange of personal health information (PHI). Administrative simplification requires rules to protect the privacy of personal health information, the establishment of security requirements to protect that information, and the development of standard national identifiers for providers, health insurance plans, and employers. Two significant sections of HIPAA are (1) the Privacy Rule and (2) the Security Rule.

The Privacy Rule legislates in detail the collection, use, and disclosure of personal health information. To be in compliance with the Privacy Rule, covered entities must notify individuals of uses of their PHI, keep a record of all disclosures of PHI, and document and disclose their privacy policies and procedures. Covered entities must have designated agents for receiving complaints and they must train all members of their workforce in proper procedures.

The Security Rule complements the Privacy Rule and presents three types of security safeguards designated as administrative, physical, and technical. For each type, the Rule identifies various security standards and names (1) *required implementation specifications* which must be adopted and implemented as specified in the Act and (2) *addressable implementation specifications* which are more flexible and can be implemented by the covered entities as deemed appropriate.

Covered entities face potentially severe penalties for failure to comply with the complex legalities of HIPAA and this has caused much concern throughout the industry. Physicians, medical centers, and other healthcare providers have experienced increased paperwork and cost to incorporate the requirements of this legislation into their current methods of operation. Future adoptions of new information technologies will be subject to its specifications as well (American College of Physicians, 2006).

Loss of Patient Trust

The Institute of Medicine (IOM) of the National Academy of Sciences released a report in 1999 that caused much attention to be focused on the U.S. healthcare industry. The report stated medical errors caused between 44,000 and 98,000 preventable deaths annually, and medication errors alone caused 7,000 preventable deaths (Kohn, Corrigan, & Donaldson, 1999). Within two weeks of the report's release, Congress began hearings and the President ordered a government-wide feasibility study for implementing the report's recommendations for (1) the establishment of a Center for Patient Safety, (2) expanded reporting of adverse events, and (3) development of safety programs in healthcare organizations. According to a study by Healthgrades, a leading healthcare ratings organization, during the period 2000–2002 the estimated number of accidental deaths per year in U.S. hospitals had risen from the 98,000 reported by the IOM in 1999 to 195,000 (Shapiro, 2006).

On July 29, 2005, President Bush signed into law the Patient Safety and Quality Improvement Act, establishing a federal reporting database. This was the first piece of patient safety legislation since the 1999 IOM report. Under this act, hospitals voluntarily report "adverse patient events" to be included in the database, and "patient safety organizations" under contract with the Federal government, analyze the events and recommend improvements. The reports submitted by the hospitals remain confidential and cannot be used in liability cases. The most recent Healthgrades report (April 7, 2007) covering the period 2003–2005, indicates that patient safety incidents have increased over the previous period to 1.16 million among the 40 million hospitalizations covered under the Medicare program.

Healthcare must utilize all available means to maximize patient safety and retain patient trust. Healthcare is an information intensive industry and the delivery of high quality healthcare depends in part on accurate data, available at the point of decision. Handwritten reports, notes and orders, non-standard abbreviations, and poor legibility all contribute to substantial errors and injuries (Kohn et al., 1999). A doctor needs to know a patient's medical history, ancillary providers need to be able to read the doctor's orders and patients need to be able to understand what the doctor expects of them. IT solutions are available that address many of the data accuracy and availability problems in healthcare records (Poston, Reynolds, & Gillenson, 2007); however, the level of adoption for these technologies is not impressive. For example, a 2005 report predicts that by the end of 2007, only 59% of all medical groups will have implemented an Electronic Health Record (EHR) system (Gans, Kralewski, Hammons, & Dowd, 2005). And although Computerized Physician Order Entry (CPOE) systems reduce medication errors by 80% (Bates et al., 1999), a 2004 survey by Leapfrog found only 16% of hospitals, clinics, and medical practices expected to be utilizing CPOE by 2006.

Cost

One of the most immediate barriers to widespread adoption of technology is the high cost of implementation. A report by the Annals of Internal Medicine estimated that a National Health Information Network (NHIN) would cost $156 billion in capital investment over five years and $48 billion in annual operating costs. Approximately two-thirds of the capital costs would be needed to acquire the functionalities and one-third for interoperability. The present level of spending is only about one-fourth of the amount estimated for the model NHIN. While an NHIN would be expensive, $156 billion is equivalent to 2% of annual healthcare spending for 5 years (Kaushal et al., 2005). Industry reports from Datamonitor, Gartner, and Dorenfest & Associates predict increased spending on IT by healthcare providers at an annual rate of between 10% and 15% (Broder, 2004). A study conducted by Partners Healthcare System, Boston, concluded that a national healthcare information system would cost $276 billion, take 10 years to build, and require another $16.5 billion annually to operate. However, the study also concluded that such a system would save U.S. hospitals $77.8 billion annually because of more efficient communication (Anonymous, 2005a).

According to a study by RAND Health (Health Information Technology, 2005), the U.S. healthcare system could save more than $81 billion annually, reduce adverse healthcare events, and improve quality of care if it were to widely adopt health information technology. Patients would benefit from better health and payers would benefit from lower costs; however, some hospitals fear loss of revenue due to reduced patient length of stay. A recent study in Florida suggests that this fear may be unfounded. The results of the study suggest that there is a significant and positive relationship between increased levels of IT use and various measures of financial performance. The results indicated that IT adoption is consistently related to improved financial outcomes both overall and operationally (Menachemi, Burkhardt, Shewchuk, Burke, & Brooks, 2006).

Lopes (2007) agrees that fully integrated electronic medical records systems can replace paper records and allow hospitals and physicians to share medical information electronically to improve response and lower costs from duplication. However, the adoption of such systems is slowed by the high cost of new technology, the complexity of the systems, training, and an unwillingness to adapt work processes to include new information technologies.

DISCUSSION AND CONCLUSIONS

Table 1 summarizes the current SWOT analysis of IT implementation in the healthcare industry in the U.S. The healthcare industry faces multi-faceted challenges to improve patient safety and assure information security while containing costs and increasing productivity. The key area for addressing these concerns is more investment in IT to facilitate the flow of information and offer access to providers and partners along the healthcare supply chain, reduce medical errors, and increase efficiency. Implementation of IT networks to achieve the required level of information and data communications is complicated by the variety of systems already used by provider organizations as well as the lack of system integration within provider organizations.

Various benchmarking studies are helping to educate healthcare providers about IT expenditures and offer comparison reports on expenditures. The availability of systems far exceeds the budget of most organizations to adopt them. However, the improved revenue cycles and cost-benefit offered by IT investments are becoming easier to quantify in faster turnaround and processing of patient-related transactions, shared data, reduced duplication of efforts, and increased provider and customer satisfaction.

Information technology can help take the paper chart out of healthcare, and eliminate error, variance and waste in the care process. IT can help connect the appropriate persons, knowledge, and resources at the appropriate time and location to achieve the optimal health outcome, increase customer service and patient care with industry leading medication fill rates and timely deliveries, cut operation costs through advanced warehouse management, reduce internal labor costs, and improve enterprise efficiencies of healthcare organizations, all through tightly integrated applications.

Table 1. SWOT Analysis

Strengths • Improved Patient Safety • Greater Efficiency of Operation • Current Investment in IT	**Weaknesses** • Lack of System Integration • User Resistance • Slow IT Adoption
Opportunities • The Internet • Favorable External Environment • Industry Standards	**Threats** • Legal Compliance • Loss of Patient Trust • Costs

IT can ultimately transform the healthcare industry. Along with improved safety and greater patient trust, adopting IT in healthcare can only improve current conditions and help the United States improve healthcare in general. Concerns remain about how smaller practices can afford the costs of new systems that require them to move their paper medical records to electronic media. These costs and start-up expenses mean an unequal playing field for small practices versus larger healthcare systems with more money to spend on IT integration.

AREAS FOR FUTURE RESEARCH

IT applications in healthcare are reaching the growth phase of the lifecycle. The strengths, weaknesses, opportunities, and threats at this stage of the life cycle are clear, but few solutions have been proposed. Research is needed to forecast the SWOT issues as IT in healthcare moves from growth to maturity. Case studies in both large and small physician practices as well as in large and small healthcare systems are needed to better understand the IT implementation timeframe and costs. Studies that address ways to overcome human barriers to implementation are also needed.

Using the supply chain model, the healthcare information system needs to be studied as to access and applicability for other providers including pharmacists, dietitians, insurance companies, home health service and equipment providers, and other vendors to healthcare. If the healthcare system it to be truly integrated, these additional players must be included. Protection of patient medical information, access to information, data security, and assurances of privacy should also be studied. International suppliers and other options for outsourcing should be investigated as a cost containment strategy.

With the growing body of patient-related medical and healthcare data, other applications should be studied. Data is available to postulate ways to improve lifelong health and reduce the incidences of various diseases and ailments. Such data mining should be studied by those in the management information systems area to determine cause and effect and recommend changes. As employers seek to contain healthcare costs of their employees, such data can aid in more active involvement in reducing health risks and making lifestyle changes (i.e., smoking cessation programs, dietary counseling, healthy cafeteria food, work-place gyms).

Choosing the best approach to implement IT systems in healthcare settings is also an area for further study. These systems should meet healthcare goals in addition to functionality and integration criteria. Involving physicians and other clinicians in selecting IT systems can increase their support and lessen their resistance to technology. In fact, the more stakeholders are involved in IT selection and implementation planning, the greater their acceptance and rate of adoption will be.

Studies in IT implementation outside the healthcare industry need to be reviewed and analyzed to determine where other industries have had success in implementation or have developed tools that could aid the healthcare arena. Human resource studies of executive ownership and accountability can help the healthcare industry better prepare physicians and other practice managers to overcome the user resistance to IT.

Chapter 1.13
The Core Governmental Perspectives of E-Health

Antti Syväjärvi
University of Lapland, Finland

Jari Stenvall
University of Lapland, Finland

INTRODUCTION

Public healthcare is facing huge future challenges in order to deal with rising costs, growing demands of customers, information flow, demographic changes, and aging population. The healthcare service sector can be seen as an information intensive area during an era of innovation and information technology (cf. Bellamy & Taylor, 1998). According to McLaughlin, Rosen, Skinner, and Webster (1999), it is common to assume that technological interventions are almost inevitable and it is humans' duty, at least to some extent, to follow the suggested development. In the organizational level of public healthcare, high expectations about the technology and its new possibilities are introduced. Additionally, the customers can seek support and advice for their healthcare needs from thousands online connections at any time of a day (e.g., Silber, 2003). The European Commission (2004) states how "eHealth offers European citizens important opportunities for improved access to better health systems" (p. 22). This trend has implications to human beings and governments.

The electronic health services produced by the information and communication technology (ICT) belong to the era of e-government. The e-government can be seen as an electronic exchange of information and services between different actors (cf. Mälkiä, Anttiroiko, & Savolainen, 2004; Oliver & Sanders, 2004). The development of information society throughout the last decades has brought up possibilities to adapt, modify, and reorganize healthcare practices and services (e.g., Gallivan, 2001; Turner, Fraser, Muir Grau, & Toth, 2002). The ICT has been used as a tool to reorganize best organizational practices, information management, and government. The ICT has also given a possibility to produce tailored healthcare services and to gain improvements in cost-effectiveness, access, safety, and quality of public healthcare services (Bates et al., 2001; Whitten et al., 2002).

In the future, the healthcare organizations in public sectors will confront many challenges by means of the ICT implementation. This situation is considered here both as the function of healthcare organizations and as the supply of knowledge intensive public health services. The current viewpoint presumes a paradigm that is structured on the basis of specific conceptualization. The purpose of this article is to conceptualize the complex topic of e-health from the governmental viewpoint and to clarify the best organizational practices. Special notation is also given for human resources, information management and the ICT implementation. Finally, some future trends are shortly discussed.

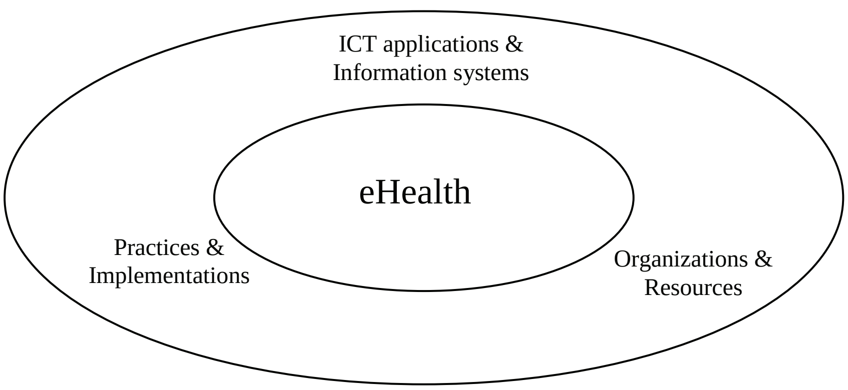
BACKGROUND

Experts define e-health differently and the term has some overlapping conceptual views. The term "e-health" is derived from the term "electronic commerce" (i.e., e-commerce), which was introduced in the mid-1990s to reflect the growing commercial use of the Internet. The e-health (cf. Eysenbach, 2001; European Commission, 2004; Silber, 2003), when recognized as a governmental issue, refers to the use of ICT applications or information systems to improve or enable health and healthcare services. Now it also refers to the main organizational and resource based factors before, during, and after an introduction of ICT. Finally, the term refers to best practices and implementations produced or needed to confront and manage with the ICT-based healthcare. The e-health concerns customers, patients, professionals, but additionally the whole primary healthcare, home care, and organizations like hospitals. It engages the terms like telemedicine, telematics, telehealth, medical and health informatics, interactive health communication, and so forth. To conclude, the e-health as a governmental concept give good reason for to describe the abovementioned combination by the means of three conceptual dimensions.

CONCEPTUAL DIMENSIONS OF THE E-HEALTH PARADIGM: THE GOVERNMENTAL PERSPECTIVE

In the first dimension, the e-health connection can be found by referring to ICT applications and information systems in healthcare and in supporting functions (cf. McGinnis, 1997; Turban, McLean, & Wetherbe, 1999). In many cases, this has included telemedicine and health informatics as patients have been informed, examined and treated over distance by using appropriate applications (e.g.,

Figure 1. E-health concept according to the core governmental dimensions



Hailey, Roine, & Ohinmaa, 2002). The e-health is seen now through issues like information system, standardization, and system quality (e.g., digital referrals, data security, access, and privacy, etc.). Also, the usability or user-friendly orientation should be placed under a close scrutiny. Hence, the applications and systems require understanding about technology and its effect on organizational structures, processes, and actors.

Secondly, it is considered that by e-health it is possible to renew and to produce more effective healthcare practices and implementations. Now the e-health is studied typically in conjunction with key processes like the management of ICT applications and information (Plsek & Wilson, 2001; Tachakra, El Habashy, & Dawood, 2001; Walker & Whetton, 2002) and by the means of best practices or ICT implementations in healthcare (e.g., Paré & Elam, 1999). The introduction of technology may support or change operational practices in organizations. The operational aspect engages also electronic healthcare services as the e-health services are multileveled. Services represent, for example, the possibility of consumers to interact online, the possibilities for institution-to-institution data transmissions, and the possibilities for peer-to-peer communication of consumers. However, the overall question is about the best practices and implementations in order to successfully complete the e-health in service sector.

As third dimension, the organization and its various resources (e.g., economical and humanistic) have been under intensive study. For example, Parente and Dunbar (2001) found that hospitals with integrated information systems have higher total and operating financial margins than those without these systems. Whitten et al. (2002) did a systematic review and found no good evidence that telemedicine is cost-effective. Additionally, the e-health can be seen in terms of human resources. This is the case, for example, with the acceptance of ICT-based organizational solutions (Mathieson, Peacock, & Chin, 2001) and with the professional human resources (e.g., Syväjärvi, Stenvall, Harisalo, & Jurvansuu, 2005). The interest has also been in health services and in policy to provide a diverse range of services (e.g., Silber, 2003; Turner et al., 2002). Both customers and professionals can be seen as key actors, because they use applications and participate in electronic service interaction (e.g., Hailey et al., 2002).

Hence, the e-health from governmental perspective can be defined as health service and information delivered through different technologies. Applications of the ICT and information systems support health, healthcare, and health services. In case of current governmental perspective, the dimension of ICT applications and information systems concentrates mainly on technological system, standardization, and usability issues. The ICT applications can be seen as architectures to understand and plan information system components in the form of an organizational infrastructure. The most crucial questions are the standardization of information systems and their usability in organizational environment.

It seems worldwide that open technical standards to provide e-health are lacking. McGinnis (1997) studied health informatics and stated the critical importance of data exchange standards for communication between healthcare providers. The usability instead is traditionally defined (cf. Isomäki, 2002) by attributes like learnability, efficiency, memorability, errors and satisfaction. However, without neglecting the human factors like learning, sensation, and perception, memory, problem solving, and so forth. An optimal system should be easy to learn, it should be efficient to use, the system should be easy to remember, the error rate with the system should be low, and the system should be pleasant to use. Corresponding arguments of usability and human-centered design are also offered by ISO quality standards.

Second governmental dimension of e-health was about practices and implementations. E-health as practices and implementations emphasizes the need to combine knowledge and the use of ICT in various ways. In this article, the management as an organizational process has the viewpoint of ICT-based e-health. McLaughlin et al. (1999) claimed that in hospitals it is needed a wider perspective than social, since managers and users need to have a commitment to longtime innovative process. Clark (1995) suggested that leaders have the main responsibility for development work, because the problem with technological changes was frequently that people and technology didn't meet or people didn't participate.

The management has also direct link to best practices in organization and its health service production. Martin (2000) claimed that the quality of public services and cost-effectiveness depend on management. Smith (2004) studied how to inspire and motive professional service teams and indicated the importance of discussion and collective responsibility. The e-health can be seen as a part of knowledge intensive public services in a knowledge intensive society. The previous conceptualization invoked to describe the current e-health practices and implementations more generally as seminal goals for public healthcare organizations. However, it should be reminded that information technology does not necessarily lead so radical organizational changes as expected (Bellamy & Taylor, 1998; Nicholson, 2003).

The third governmental dimension of e-health involved organizations and resources. The governments try to manage with the increasing costs of public administration. Simultaneously the need to improve the cost-effectiveness of public healthcare has become apparent. One way to resolve the dilemma has been the use of electronic health services. However, the results have been controversial. Whitten et al. (2002) made a massive evaluation and they included 24 of 612 identified articles presenting cost-benefit information. About 30% of those 24 tried to solve the economic function of telemedicine without a clear outcome.

However, in public organizations the ICT has had often a transformative role. The e-health is understood and projected as being able to reshape the way healthcare services are delivered. The demands set by stakeholders are obvious. Governments want accountability to ensure that the funds are used effectively. Healthcare providers want a better quality of work life through the ICT tools. Patients and customers want access to the high quality healthcare service. One response has been the virtual life of organizations (cf. Nicholson, 2003). The virtual life in current context can be defined as a group of people or organizations that interact through interdependent task guided by common good purpose. In addition, the actors have learned to interact across space, time and inter-professional or organizational boundaries by using the ICT-based e-health solutions (Syväjärvi et al., 2005).

ORGANIZATIONS AND E-HEALTH: IMPLEMENTATION AND HUMAN RESOURCES AS CRUCIAL FACTORS

Numerous organizational e-health projects with various goals are ongoing worldwide under public administration. For example, the European Commission launched an Action Plan for a European eHealth area in 2004. The aim is to support EU member states to materialize the benefits available from e-health, and to respond to the growing need for coordinated activities of e-health (European Commission, 2004). These kinds of activities denote a coherent agenda for the implementation of e-health. Hence, the e-health implementation may cause changes in organizational design and such changes typically require new organizational structures, processes, and personnel arrangements. From governmental perspective, the e-health either allows or forces an organization to rearrange especially its human resources. The focus is thus to analyze the relationship between e-health implementation and HR-centered organizational practice. Human resources are considered as a key area of e-health implementation.

Human resources have indeed an essential function both in knowledge intensive healthcare practices and in knowledge innovative services. The implementation of e-health has indeed organizational effects as it should concurrently support the patient mobility, facilitate the citizen-centered healthcare, but particularly to provide healthcare professionals new tools to sustain or improve the quality of public healthcare service. The implementation should allow greater flexibility, for example in case of inter-professional and organizational practices, to enhance information and knowledge exchange between humans. It is given here a synopsis of e-health implementation that contains previous governmental dimensions.

Many nations worldwide are known as countries with high technology. The extensive use of ICT and the adoption of various technological solutions represent everyday practice. In these knowledge intensive nations, the public policy has been largely based on the assumption that society will develop and succeed by focusing on ICT. For example in many European countries the information technology has been harnessed to promote social welfare. The ICT has been used for strengthening and developing the welfare society. The public service organizations and citizens thus have confronted the wave of e-government (e.g., Mälkiä et al., 2004; Oliver & Sanders, 2004). At the same time research has concentrated on the possibilities, quality, and costs of technology. However, what the implemented information technology means to public health service sector, public organizations, and especially to organizational human resources has usually received less attention. Under the issues of e-government and public services, there are several approaches to the human-centered e-health implementation.

Firstly, from the point of how the employees' attitudes and approval affect the success of implementation (Mathieson et al., 2001). This kind of approach has produced theoretical models to explain how implementation depends on reasoned action of humans and the technology acceptance. Considering a more professional view, for example, the doctors who have received training in technology and understand technological concepts are more likely to grasp the positive impact of technology in healthcare (Paré & Elam, 1999). Burge, Creps, and Wright (2001) assumed that doctors are key persons to adopt technology in healthcare organizations, however, the doctors are not enthusiastically accepting the technology if it does not help everyday work. Tachakra et al. (2001) suggest that telemedicine includes the ability to rearrange the distribution of work; especially concerning the tasks of doctors and nurses. The ICT-based e-health seems not to be a question of single profession as it reflects over entire professional work society.

Secondly, the ICT has been studied by the innovative theories. Again models have been presented how a technological innovation is adopted in an organization through various phases. Gallivan (2001) developed a frame of references how to merge a technical innovation into the organizational operation. Thus, there are themes like management support, high resources, organization culture, own responsibility of learning, broad work roles, work security, and individual characteristics, which either increase or decrease the innovative implementation. These studies argue that the success of information technology in organizations more generally reflects the systems of innovations' advance in organizations. Finally, as technology is implemented to organization more clear and exact strategies accompanied with leading spokesmen are required (Walker & Whetton, 2002).

Thirdly, the setup "e-health vs. implementation" stimulates the leadership and management dimensions. Clark (1995) suggests that the use of ICT is an organizational issue that needs efforts in the direction of change. The leaders have thus a responsibility to create and sustain participation, but also trust (cf. Harisalo & Stenvall, 2004). In good accordance, Plsek and Wilson (2001) found complexity in leadership and management of healthcare organizations. They assumed that leaders should found ways to make the change more attractive and meaningful for workers. This is done by securing the open information flow of good practices. The earlier observation about the complexity of knowledge intensive health services denotes the importance of information management. The information management refers to interdisciplinary procedures designed to provide and improve the appropriate information systems and resources by planning, organizing, executing, and evaluating necessary management operations. Thus, the human resource perspective both involves multi-professional diversity practices and presupposes the proper activities of human resource management (Syväjärvi et al., 2005).

Fourthly, the human resource centered ICT implementation considers the development of information systems according to usability factors, organizational practice, and the humanization of computerized information systems (Cummings & Worley, 2001; Isomäki, 2002). The usability of information systems is included in this framework. The information system development (ISD) can be introduced by different phases. It is stressed that the ISD tasks must be completed with knowledge concerning users and contextual analyses. Isomäki (2002) found that only a few information system designers have potential to contribute to the humanization of information systems. Cummings and Worley (2001) considered organizational change as a function of implementation process. They indicated how implementation causes organizational change and this can be controlled throughout singular phases like by information or system contracting and gathering, familiarizing, planning and accomplishing, evaluating and stabilizing. The humanization and e-health-based information system development can be seen as a part of organizational development (OD). Organization development in public health service sector applies this kind of knowledge and practice in order to help organizations to achieve effectiveness and social quality of work life.

The fifth and final aspect to comprise human resource and e-health implementation consists of the cognitive human capacity and service administration. The human capacity indicates the multilevel competencies of professionals. The service administration indicates both the service knowledge and management, which are approached in a customer-centered way. The e-health services are a challenge for both individuals and collective work society. Hence, individual, collective, and organizational competencies (e.g., Hamel & Prahalad, 1994; McLagan, 1997) are clearly required in different phases of the implementation. These competencies represent the foundation of service knowledge, which denotes the ability to arrange and manage both professionally and organizationally with the electronic public services. In present context this entirety (i.e., professional and organizational practices), the e-health implementation and customer relationships can be supported by appropriate and flexible service management. The public service management can comprise, for example, the dimensions of project management, human resource management, network management and customer relationship management. The concept of service management can be also seen as one value creator for service innovations or improvements, and with modifications, as a suitable management approach for organizations from various sectors (cf. Boyne, Martin, & Walker, 2004; Fitzsimmons & Fitzsimmons, 2004; Martin, 2000).

FUTURE TRENDS

In the near future organizations will once again face a dynamic and turbulent environment. That requires flexible and fast response ability from the healthcare organizations and public services. The ongoing era of e-government has enabled organizations to acquire such structures and processes that support new or additional ways of interaction between electronic service providers and customers. Hence, the future trends of e-health indicate implications for health service users, service suppliers and entire society. The purpose of this section is to discuss shortly some essential future trends of e-health. The future possibilities and needs of e-health are introduced according to present literature and reflected alongside the three main dimensions described in current conceptualization. Thus, the final section is based on future prospects and e-health's relationship to e-government.

The present view indicated that the public healt care services will be going through major electronic turnarounds. The e-health revolution accompanied with the future possibilities are far away from straightforward. Many different issues have to be considered in order to make successful ICT-based transitions in public services. In case of organizations and resources there is going to be a further increase in information intensity of the e-health. Public institutions and human actors are stressed and challenged over again with more sophisticated, and hopefully with more user-friendly and appropriate information technology. There will be a need for competent health professional as continuous cognitive pressure is evident. A clear e-health challenge for public healthcare organizations seems to be how to manage with differences in processes, with strong professional culture of healthcare personnel, with cognitive pressure set by ICT, and with hierarchical or traditional structures.

These prospects as seen as future trends of e-health indicate cooperation, but also knowledge and information integration both in organizational and professional level. For example, healthcare professional will probably have fast and unhindered access to the latest knowledge and to the other relevant information needed in clinical practice. It is also assumed that the number of virtual organizations and new innovative services will be increased. The organizational and resource-based future of e-health has to be affected more by customers and patients. The e-health services are targeted as support for the customers (i.e., for those who daily cope with individual health). Thus, as the impact of ICT on healthcare professionals is extensive, similarly the e-health should be harmonized to the specific needs of the users. For example, citizens will increasingly have an opportunity to access their own health data and to contact directly to health professional (e.g., online booking, e-prescribing, home-care monitoring, health information bank, etc.). It is expected that the customer-centered approach will be even more vital as a resource for the future development of e-health. In knowledge intensive society, more demanding customers can be recognized.

In the future, the applications appear to be even more plentiful for consultations with other organizations, professionals, and patients. Portable and mobile tools will be increasingly adopted in healthcare settings together with many web-based gateways or portals. For example, the question can be about the new innovative e-health systems for retrieval, feedback, participation, clinical data management, and in general about the electronic health recording systems (EHR). There will be quite many views about the needs of e-health-based information systems and probably only a few will get it right. The challenge will be the standardization of ICT applications and information systems. Also the users themselves should be equal partners in development teams. As indicated before, people will probably found themselves in the era of virtual life. This indicates the increasing use of collaboration-support information systems.

Finally, the e-health future has implication in the dimension of practices and implementations. The ICT can be seen as a powerful change agent for the whole healthcare sector and it is important to recognize the importance of non-ICT factors in e-health. In this sense, alongside the system implementation it seems to be significant to concentrate on workplace practices and implementations. The best practices and implementations will be valued even more in the complex future of e-health. The e-health interventions based on ICT re-engineering, human-centered information systems, human resource and change management, and practical work innovations will play crucial roles for wellness in workplaces.

It seems that practical work tools or models that support decision making, management, preparation and processes will have an enormous importance. Public healthcare organizations will continue to invest huge amounts of resources into the latest ICT. It seems that new investments on organizational practices and implementations should support both professionals and customers. For example, one challenge is to combine multi-professional practices and service security for the customers benefit. During the continuing era of e-government, the e-health concept will be even more inevitable and natural part of the public healthcare service.

CONCLUSION

The current governmental perspective of e-health has focused into three core dimensions. Current conceptualization has indeed some overlapping areas, but it is important that the approach to e-health is not done only by means of ICT factors or some single science. Hence, the e-health should follow the multi-scientific paradigm as the concept itself has been adopted by the experts of medicine, health science, applied information technology, social science, information and communication science, and by governmental and management science.

It was found how rich the topic of e-health is. The e-health was studied through the ICT implementation and human resources in the knowledge intensive healthcare service organizations. Hence, the implementation of e-health was recognized as a function of various practices and human resources together with future organizational possibilities in public service sector. Alongside the implementation procedures, the human resource was found to be fundamental. Thus, professional, inter-professional and customer perspectives were critical factors. Current perspectives go under the e-government. It combines the perspectives of governmental and management science, social science, health science, and applied information technology. The future trends of e-health thus involve various combined implications to customers and professionals, to service and system suppliers, and to organizations.

KEY TERMS

E-Government: An electronic exchange of information and services between different actors. Usually refers to local or state government activities that take place by digital processes and various networks.

E-Health: Health services and information delivered through different technologies in order to improve or enable health, healthcare and services with variable contents and transactions (cf. Eysenbach, 2001).

E-Health Usability: The design and technical features that allow electronic healthcare applications and information systems to be suitable for intentional use in a user friendly way.

Health Informatics: Knowledge, skills, and tools to support the delivery of healthcare information and services (cf. Silber, 2003).

Health Information System: An ICT-based routine constructed for the purposes of delivering health and medical care. Information system can be seen as physical process that supports an organization by providing information to achieve goals.

Information Management: Interdisciplinary procedures designed to provide and improve appropriate information systems and resources. Refer to planning, organizing, executing, and evaluating the necessary management operations.

Standardization of E-Health: The method to reduce or eliminate inconsistency, potential added costs and quality problems in applications and information systems of the electronic healthcare.

Chapter 1.14
Differences in Computer Usage for U.S. Group Medical Practices:
1994 vs. 2003

Marion Sobol
Southern Methodist University, USA

Edmund Prater
University of Texas at Arlington, USA

ABSTRACT

Research on the use of information technology in healthcare has focused on hospitals and Health Management Organizations (HMOs). However, little has been done to study the use of IT in group medical practices. In 1994, we conducted a pilot study of group medical practices and then repeated this pilot study in 2003 to obtain a longitudinal picture of the IT services used by these private practices. Researchers can use this to form ideas of the important issues and changes involved in IT usage in group medical practices over the past decade thus providing a needed benchmark to fill a gap in the existing literature and that can be used to compare domestic as well as international practices. For example, an expanded form of this study will be conducted in Taiwan this summer.

INTRODUCTION

Studies of the introduction of computer technology in medical settings have focused on hospitals (Griffith & Sobol, 2000; Sobol, Humphrey, & Jones, 1992; Sobol & Smith, 2001) and more recently on HMOs. In these studies, such issues as barriers to the introduction of technology in hospitals, returns to adoption of technology, and the market status of the adoption of different technologies have been studied. It was found that there are many barriers to the adoption in hospitals. The longitudinal issues of what the changes have been in the last decade have been studied with the results that certainly there has been an increase in adoptions over the past decade. These increases have occurred in both transactional, informational, and strategic uses of technology (Sobol & Woods, 2000). This trend is expected to increase. A survey in 2002 by Sheldon I. Dorenfest & Associates of Chicago indicated that IT spending on healthcare in 2002 would be $21.6 billion (Dorenfest, 2002).

While the focus has been hospitals and HMOs, very little has been done to study the use of IT in group medical practices both small and large. This is the case even though researchers have for years trumpeted the impact of IT on physician's practice (Rodger, Pendharkar, & Paper, 1996; Shine, 1996). In 1994, we conducted an initial study of group medical practices of three or more doctors; we completed a later study in 2003 to obtain a longitudinal picture of the IT services used by these private practices. While this is not yet the definitive study of IT in group medical practices, it can be used to form ideas of the important issues and changes involved in IT usage in the smaller group medical practices over the past decade thus providing a needed benchmark to fill a gap in the existing literature and to start an intensive study of changes in IT usage.

In this article, we look at the differences in computer usage, computer facilities, sources of computer information, and the satisfaction with computer usage in group medical practices from 1994 to 2003. We compare these characteristics and the amount of time spent on business issues by size of practice and years in practice for group medical practices studied in 1994 and 2003.

BACKGROUND

There has been a great deal of research on IT as well as healthcare. Unfortunately, much of this has been of limited use to practicing physicians. From the computer science side of research, most work has been done on theoretical computing structures. This includes work such as neural net applications of drug/plasma levels (Tolle, Chen, & Chow, 2000) or parsing methods for biomedical texts (Leroy, Chen, & Martinez, 2003). When trying to overlap IT and near term healthcare concerns, the research has tended to focus on public policy (Magruder, Burke, Hann, & Ludovic, 2005) or on hospitals. This includes work done on hospitals and adoption of computer-based IT (Sobol et al., 1992; Sobol & Woods, 2000), as well as the impact of IT use on hospital staffing and payroll (Sobol & Smith, 2001). Other work has focused on the barriers to IT adoption within healthcare (*Economist*, 2005; Sobol, Alverson, & Lei, 1999).

On the other end of the spectrum, some research has been conducted on issues surrounding IT in private practices. This research has tended to be very specific in nature, however. This includes whether or not medical practices should hire an IT person or outsource (Lowes, 2005) or the use of electronic billing systems by private practices (Burt, 2005). Other research tends to focus on a hot technology that is currently being embraced such as electronic medical records (Miller & Sim, 2004; Palattao, 2004). What is lacking is an overall benchmark or "snapshot" of overall IT use by private practice physicians. That is the goal of this research.

METHODOLOGY

In the summer of 1994, a mail survey was sent to a sample of 270 multiple physician groups within Maricopa County, Arizona, who were chosen from lists of a value-added reseller. These practices were medical groups containing three or more physicians. A total of 65, or a response rate of 24%, of usable replies were received. This is a good response for a mail survey. In the summer of 2003, 54 physicians were surveyed in group practices of three or more in the Arlington/Mansfield area of Tarrant County, Texas. The surveys were given to the business managers' offices and were returned by mail. Thus, in essence both were mail surveys utilizing the same questionnaire. Both counties (Maricopa and Tarrant) included large metropolitan areas (Phoenix and Fort Worth), were 71 to 77% white and had median per capita income of approximately $22,250 to $22,500. In both counties, 65 to 69% of the people were in the labor force. These statistics show both interview sites to be similar Southwestern areas. The group practices in Tarrant County were randomly chosen from a list of 525 physicians in group practices and provided a sampling rate of 10%. The size of the practices and the years in practice in both surveys were well-distributed over a wide spectrum of sizes and age of practice. In the following paragraphs, we will look at the use of computers in the group medical practice with the primary perspective of assessing how this usage has changed over the last decade.

First, we will use rank order correlation to determine if the orders of importance for various technologies (hardware and applications) have remained the same over the decade. Spearmans' rho was chosen for this because it makes no assumptions about the shape of the relationship between variables. Secondly, we will employ tests of the differences in proportions for software and hardware adoptions, important types of technology and applications, time spent on business applications, and sources of computer information, comparing 1994 and 2003. These tests will be developed for whole groups and will also focus on differences by the size of the practice (number of doctors) and the number of years in practice.

SURVEY RESULTS

Characteristics of the Samples

The practices in the 1994 sample tended to be larger in terms of the number of physicians than the 2003 sample. As we can see from Table 1A, about one quarter of the group practices in 1994 were less than five while 60.4% of those in 2003 were less than five. If we look at practices of less than 10, 50% of the 1994 sample can be compared to 75% of the 2003 group. Why this disparity? There are many different factors. For example, the Arlington area is a fast-growing area and new start-up practices are forming. However, these are

Table 1. Characteristics of samples, 1994 vs. 2003

A. Number of Physicians In Practice	1994	2003
Less than 5	24.1%	60.4%
5 but < 10	25.9	15.7
10 but < 25	31.6	15.7
25 but < 50	18.4	8.2
	100%	100%
B. Years in Practice		
0-5	23.1%	17.3%
6-10	16.9	11.5
11-15	18.5	17.3
16-20	12.3	17.3
21+	27.7	36.6
No answer	1.5	0.0
	100%	100%

Table 2. Current computer systems, 1994 vs. 2003

System	1994	2003
Individual PCs (not connected)	15.4%	17.5%
Network connected PCs	35.4	61.4*

not just new physicians but include older practices that are moving to the faster-growing areas. In addition, during the past 10 years, many practices have become part of hospital-based groups in order to save on costs. This leveraging of resources among a large hospital network has meant that there is less of a need to have larger individual practices in order to distribute costs. There may be other factors, but these are hard to delineate. Because of this, for the studies in this paper, we will look at the variables by practice size so we can study small vs. large practices.

In terms of years in practice, the samples are similar. In Table 1B, we see that in 1994, about 23.1% of the practices had been in business five years or less, while 17.3% of the 2003 practices had been in practice 5 years or less. If we look at 6 to 10 years in practice, 16.9% of the 1994 group as opposed to 11.5% had been in practice 6 to 10 years. Adding these groups to form groups in practice 0 to 10 years we get 40% for 1994 and 27.8% for 2003. Thus, the 2003 practices tended to be smaller and somewhat older. To account for these differences, we will separate a number of our analyses by practice size and years in practice.

Current Computer Systems

The computer systems used have changed over the last decade. We can see from Table 2 that in 1994, 15.4% used individual PCs (non-connected, in even a local area network) while 17.5% in 2003 used individual PCs (non-connected). This remained about the same. However, there has been a big move to network-connected PCs.

Types of Business Applications Used

We have examined the types of computer equipment in group practice offices; we now turn to the types of applications used by these offices. This is important because when the doctors were asked if they were satisfied that the applications used met their business requirements, 86.7% of doctors in 1993 were. In 2003, the level of satisfaction had risen slightly to 91.0%. So while there have been complaints that physicians are not open to using information technology in hospital settings (Florien, 2003), physicians apparently are satisfied using IT in their own practices. Table 3 indicates the types of uses of computer applications for the 1994 and 2003 samples. The rank order of overall uses in 2003 is highly correlated with uses in 1994.

Since the earlier sample contained a larger number of larger medical practices, we will separate the study by group size to make the statistics more comparable (see Table 4). Generally, the order of importance of the usage of applications has

Table 3. Applications used in group medical practice, 1994 vs. 2003

Percent Who Used Application Applications	1994	2003
Personnel Scheduling	48.3%	26.9%*
Facility Scheduling	21.7	28.8

† Spearman's Rank Order Correlation Coefficient rho = .949, p = .00001

** Significant at 0.05 level.*
*** Reflects differences in available services.*
**** Reflects the fact that practices were automatically networked.*
† There were at least three possible ways to compare the percentages: Spearmans' rho, Kendall's tau and gamma. Since the questions were the same but the samples were not paired, Spearman's rho was chosen.

Table 4. Application used by group practice size, 1994 vs. 2003

Applications	Groups Less Than 10		Groups 10 or Greater	
	1993	2004	1993	2004
Personnel Scheduling	42.3%	13.3%	48.0%	32.4%
Facility Scheduling	15.4	33.3	28.0	27.0
Patient Scheduling	53.8	53.3	50.0	56.8
Insurance Billings	100.0	100.0	92.0	81.1
Practice Billing	84.6	73.3	80.0	83.8
Business Record Keeping	80.8	53.3	80.0	70.3
Patient Record Keeping	34.6	66.7	52.0	48.6
Practice Networking	19.2	33.3	36.0	59.5
Hospital Networking	3.8	46.7	24.0	27.0
Vendor Networking	7.7	6.7	12.0	10.8
Use of Expert System	3.8	20.0	16.0	8.1
Imaging Technology	3.8	13.3	28.0	10.8
Voice Recognition	0	6.7	0	0
	rho = .767 p = .002		rho = .925 p = .00006	

remained the same (r = 0.949). This should come as a surprise since the basic business aspects of managing a business/practice have not changed. In 1995, a survey of physician managers found that the key issues they needed support in were personnel management, computing, budgeting, and financial management issues (Cordes, Rea, Rea, & Vuturo, 1995).

Practice networking is higher for large groups and seems to have risen for all groups since 1994. Hospital networking by computer for groups of less than 10 physicians *has risen considerably*

Table 5. Applications used by years in practice 1994 vs. 2003

Applications	Years in Practice					
	0 - 10		11 - 20		21 Plus	
	1994	2003	1994	2003	1994	2003
Personnel Scheduling	71.4%	13.3%	38.9%	38.9%	35.3%	26.3%
Facility Scheduling	33.3	33.3	11.1	33.4	17.6	21.1
Patient Scheduling	60.9	53.3	50.0	61.1	35.3	52.6
Insurance Billings	95.8	100.0	94.4	83.4	94.1	78.9
Practice Billing	87.5	73.3	77.8	83.4	88.2	84.2
Business Record Keeping	83.3	53.3	66.7	88.9	77.8	52.6
Patient Record Keeping	54.2	66.6	27.8	66.7	42.9	31.6
Practice Networking	37.5	40.0	27.8	72.3	17.6	47.4
Hospital Networking	8.3	46.7	11.1	38.9	17.7	15.8
Vendor Networking	12.5	6.7	11.1	11.1	5.8	10.5
Use of Expert Systems	0	20.0	16.7	11.1	17.7	10.5
Imaging Technology	16.7	13.3	16.7	5.6	17.6	15.8
Voice Recognition	4.2	0	0	16.7	0	5.3
	rho = .719		r ho = .771		r ho = .828	
	p = .00561		p= .003 p		= .00048	

from 3.8% to 46.7%. Vendor networking seems to have stayed the same.

We now consider the relationship between years in practice and usage of different computer applications (Table 5). We used rank order correlation to compare the relative amount of use of each of these applications by years in practice (Table 5), and the rankings have remained similar over the decade. However, different applications show differing amounts of use.

Importance of Different Types of Savings with Respect to Business Aspects of the Medical Practice

We then looked at the overall rankings of the importance of different types of savings or improvements to business practice that could be achieved by utilizing computers (Columns 5 & 6, Table 6). We asked respondents to rank the importance of different types of savings from computer adoptions on a scale from 1 to 5 (with 5 being very important). In more recent years (2003), respondents have been inclined to say that different savings are very important. On every one of 13 categories in Table 6, columns 5 and 6, the 2003 sample is 15% to 35% higher than their counterparts were in 1994. In both years, improving insurance claim processing was ranked as most important. In 1994, 70.2% said this, but by 2003, 85.8% found this type of savings most important. Other important savings issues in 2003, with 70% or more ranking them as important, were improving patient record keeping, access to patient or hospital information, increasing cash flow, and reducing administrative overhead.

The next area was the comparison of the importance of different types of savings by the age of the practice (see Table 7). These could be cost reduction or quality improvements. In Table 6, we classified the savings. Overall, the three groups (0 to 10, 11 to 20, 21+) order of importance (by use) of the applications was the same although the individual usage percentages differed widely.

Time Spent on Business Aspects of Practice

A very striking difference in the decade was the increased amount of time being spent by doctors on the business aspects of their practices. In 1994, 64.6% of the doctors said that they spent

Table 6. Importance of different types of savings from computer adoptions, 1994 vs. 2003 by a number of people in the group

CR = cost reduction QI = quality improvements

less than 10% of their time on business aspects, while in 2003, only 23.1% spent less than 10% on business, indeed they spent far more time on these aspects. About a quarter of the doctors in 1994 said they spent up to 25% of their time on business, and 21.2% of the 2003 sample recorded this answer. The striking difference was that, in 2003, 55.7% of the doctors spent *more than 25%* of their time on business as compared to only 9.2% of the doctors in 1993, reporting that they spent more than 25% of their time on business issues (see Table 8).

Table 9 shows the importance of different types of savings by time spent on business aspects. One of the key changes from 1994 to 2003 was that, in 1994, both groups sited insurance claims processing as most important. On the other hand, in 2003, access to patient and hospital information had become most important thus reflecting a key shift in focus.

Table 7. Importance of different types of savings from computer adoptions, 1994 vs. 2003 by years in practice

	0 – 10 Years		11 – 20		21+

Correlating 2003 (< 10% vs. 10%+), rho = 0.957, p = 0.0000003

Sources of Information on Running Business Aspects of Their Practice

The doctors in both surveys were asked, "Where do you get the information you need to run the business aspects of your practice?" This question suggested sources and allowed doctors to fill in blank lines. Also, it allowed respondents to check many answers. We will compare overall answers for the two surveys (Table 10). The ranking stayed approximately the same for 2003 as it had been in 1994 (rho = 0.813, p = 0.04). However in 2003, there was more reliance on associations and professional meetings and on professional journals. Use of consultants had tapered off, but vendors were more likely to be relied upon for information.

DISCUSSION

In viewing Table 2, we see that, in 1994, 35.4% of the offices had network-connected PCs while, in 2003, 61.4% had network-connected PCs. In 1994, 16.9% of the offices had mid-range or mini-computers while, in 2003, only 8.8% had these large computers. No doubt this is due to the enhanced capacities of today's PCs. No one in 2003 reported a network of PCs and mainframes, while, in 1994, about 7.7% used these facilities. The past decade has also shown a difference between the computing services that are available for physicians to use. For example, in 2003, 8.8% of the practices reported that they used outside service bureaus to handle their computer needs. Application Service Providers (ASPs) were not commonly available in 1994.

Table 10. Sources of information to run business

Percent Who Checked Answers Sources	1994	2003
Colleagues	55.4%	53.1%
Associations/Professional Meetings	46.2	67.3*
Professional Journals	46.2	59.2*

Vendors	21.5	38.8*
Other (CPAs, Billing Companies, Business Managers)	13.8	10.2
	rho = .813	
	p = .040	

Table 3 shows that, in general, the rank orders for application usage by practice size has remained the same in the last decade (rho = 0.767 and 0.925 respectively). Personnel scheduling by computer is done more often on the computer by large firms, but has gone down over the decade. Facility scheduling has gone up and patient scheduling has stayed the same or increased slightly. It seems that insurance billings for large firms using computers have decreased somewhat but for smaller firms 100% of insurance billing is done by computer. This difference may be due to age differences of physicians (older physicians tending to be in larger groups). We will assess the impact of age on IT usage later.

Looking at Table 4, we see the use of expert systems has gone up considerably in small practices from 3.8% to 20%. This is due to the fact that decision support systems have played an increasingly widespread role as the healthcare industry has embraced managed care (Dutta & Heda, 2000). This was predicted by McCauley and Ala (1992). One other area that has seen change is that of imaging technology. This may be due to the impact of telemedicine. In the early 1990s, imaging technology was very expensive, and only large groups and hospitals could afford it. Today, there is a minimal cost associated with it and new applications such as remote or telemedicine has attracted new physicians (Prater & Roth, 2003).

If we look at Table 5, we see that different applications have grown and fallen in importance depending on the age of the practice. The younger practices (0 to 10 years in practice) were more likely to use hospital networking, patient record keeping, and expert systems than their counterparts were in 1994 and 2003. They were less likely to use the computer for personnel scheduling, probably because they were in smaller practices. If we look at the middle group, 11 to 20 years in practice, they were more likely to do patient scheduling, patient record keeping, and practice networking than were their counterparts in 1994. So relatively new (10 years or less) and intermediate-aged practices (11 to 20 years) were more likely to use computers than the older practices (21+ years). In most other areas, the applications listed were utilized by the same percentage or less for each of the years in practice groups in 2003 as compared to 1994.

Table 6 shows that except for access to patient or hospital information, the same issues were very important in 1994 as in 2003 but not at the 70% level. No doubt because there was relatively little networking capacity in 1994, this issue was only ranked as very important by 38.4% of the sample. Assessing the importance of savings with relation to practice size (Table 6, Columns 1-4), the three most important issues for smaller practices (less than 10 physicians) in 2003 are improving insurance claims processing, improving patient record keeping, and access to patient hospital information. In 1994, the smaller practices chose improving insurance claims processing, increasing cash flow, and financial performance controls. So they were stressing the importance of the computer for billing and financial purposes. The smaller practices were not as likely to rank order these types of savings in the same orders in 1994 as they did in 2003 (rho = 0.44, p = 0.133). For the larger practices (10 or more physicians) in 2003, the most important savings were increasing cash flow, improving insurance claims processing, and reducing administrative overhead. For 1994, the top importance (for large practices) was for improving insurance claims processing. There were four other savings that tied for second place, improving patient record keeping, access to patient and hospital information, increasing cash flow, and financial performance controls. Uses devoted to quality improvements (QI) almost doubled in importance from 1994 to 2003. On the other hand, uses aimed at cost reduction increased in importance by 15 to 20 percentage points. Thus, it seems that early computer introductions were primarily devoted to cost reductions while later introductions may be more focused on quality improvements such as enhancing professional image, access to patient hospital information, and improving patient record keeping. Looking at the younger practices (0 to 10 years), we see that here again improving insurance claims processing was the most important issue in 1994 and 2003. Reducing administrative overhead was next in importance in 1994 and then increasing cash flow ranked third. In 2003, improved patient record keeping and access to patient and hospital information tied for second place. Thus in 2003, the informational and strategic uses of IT (such as long-term planning and marketing improvement) are becoming as important as transactional uses. However, the top uses were mainly those that led to cost reductions rather than quality improvements.

Using Table 7, and looking at the mid-term practices (11 to 20 years), again insurance claims processing was most important in both years, reduction of administrative overhead came in second in 1994 and third in 2003. Tying for first in 2003 was increased cash flow, and improving insurance claim processing. Tying for third in 2003 was a new variable enhanced professional image, and access to patient or hospital information. Here, we see the older doctors starting to focus on quality improvements. Finally, when we look at the older practices (21 years or more), increased cash flow comes out first for 2003 with improving claims processing, business management of the practice and business training for support or staff and financial controls vying for second place. Evidently, the older firms were sensing the need for updates and for more training and better business management practices. In 1994, the older practices ranked increasing cash flow first and improving insurance claims processing second. So over the years, the older practices have sensed the need for better business management and quality improvements. This need has probably been instrumental in the encouragement of the recent developments in management training and executive education for doctors and dentists (Glasser, 1997; Lazarus, 1999; Lipson, 1997).

With respect to the data from Table 8, we see that in 1994, 65% of the doctors spent less than 10% of their time of the business aspects of their practice. By 2003, 55.7% of the doctors reported that they spent more than 25% of their time on business aspects. With all of the different current issues such as HMOs, health insurance, Medicare, Medicaid, and so forth, doctors must personally make more decisions and consult with third parties to justify the use of medical techniques and billing. So we see that a decade ago, “physician” and “administrator” referred to two different people. Today, physicians realize that they have to embrace both titles, and their separate (and sometimes opposing) strategies (Lazarus, 1999; Lipson, 1997).

When we look at the importance of savings from computer adoptions and compare doctors who spend less than 10% of their time on the business aspects of their practice, we find that there is no correlation between the importance of various types of usage in the 1994 vs. 2003 (Table 9). In 1994, the three most important savings were improving insurance claims processing, increasing cash flow, and reducing administrative overhead. In 2003, access to patient hospital information, increasing cash flow, improving patient record keeping, and use of computer technology was the highest. Thus, the doctors in 2003 who spent little time on business stressed the patient information and record keeping. When we look at the doctors spending more than 10% of their time on business aspects in 1994 and 2003, we also find little correlation between the various types of usage. In fact, we find a somewhat negative correlation in what they found as the most important savings. In 1994, improving insurance claim processing, reducing administrative overhead, increasing cash flow, and financial performance controls were most important. In 2003, access to hospital patient hospital information and increasing cash flow were first and second in importance, and the use of computer technology came in third. These doctors in 2003 were also interested in reducing service bureau costs and image storing of patient records, which were not concerns for their counterparts in 1994 since image storage was not common in the early 1990s. Moreover, patient record keeping has grown tremendously in importance probably due to the new HIPPA legislation (Jonietz, 2003).

If we compare the two groups (under 10% and 10% plus) for 2003, there is a very high correlation (rho = 0.957 and p = 0.0000003, bottom of Table 9). Thus, for each year, separately, the time spent by doctors on business matters doesn't seem related to the importance they accord to different business aspects. However, over the decade, different business aspects have become more important.

This last assessment seems to be the overarching theme of the data. The changes that have occurred in IT usage during the last decade have been in response to physicians trying to adapt to greater business demands on them. Physicians are becoming more aware of this with new programs in medical schools focusing on business. Texas Tech, for example has instituted a combined MD and MBA program. As physicians become businesspeople as well as healers, they have had to embrace information technology in different ways. Apparently, the profession as a whole is adapting to this change. This is seen in Table 10, where the amount of business information provided by associations/professional meetings, professional journals and vendors has increased statistically significantly from 1994. On the other hand, the use of consultants has decreased significantly from 1994, where it was the number one source of information. This shows that physicians no longer have to pay experts to provide business information to them but are being supported by their profession.

CONCLUSION

Since the 1970s, researchers and practitioners have attempted to apply IT to the practice of medicine in order to increase efficiencies and decrease costs; however, the work is far from over. Technological leaps such as the Internet and the World Wide Web have been born and begun to impact medicine (Prater & Roth, 2002). The medical industry still has no clear common goals for IT and very few universally accepted standards. More than 90% of the $30 billion in health transactions are carried on via phone, fax or paper (Shine, 1996). As an example, in only 22% of clinics in North America can a clinician call up a medical record, input information, and enter orders (2002). To quote Tommy Thompson, the former

U.S. Secretary of Health and Human Services, “some grocery stores have better technology than our hospitals and clinics” (Turner, 2004). Other researchers have argued that we are beginning to see the first-level benefits of digitization such as increases in speed, control, accountability, and cost containment (Flower, 2003). This line of thinking is supported by the new federal 10-year initiative to “use Medicare as a vehicle for pilot programs ranging from handling prescriptions electronically to moving patient records online so that caregivers and patients can refer to them regardless of time or place” (Turner, 2004). Our paper shows that physicians have, in increasing numbers, embraced the use of IT in these areas. Thus, one of the benefits of this paper is to show the growth and trend lines of the various types of IT use by physicians for the past decade. We have also noted the move from primarily transactional uses of IT to informational and strategic uses.

Also, we have been able to look at the changes in infrastructure for group medical practices over the past decade. We have compared the different applications used over the decade by different-sized practices and by relatively new versus old practices. We have also measured the importance of different types of savings from computer adoptions and shown that, especially for small practices, the importance of these types of savings have changed significantly. Finally, we have shown the tremendous increase in time that physicians must devote to the business aspects of their practices.

We see a trend from the use of IT in transactional uses such as billing and insurance company dealings to more informational uses as patient record and contact with hospitals (Dutta & Heda, 2000). There has also been an increase in strategic emphasis of IT. This would include such uses as enhancing professional image use of expert systems and business planning, which have significantly increased in importance over the decade (Tables 3, 6). Moreover, we see big changes in infrastructure as discussed by Weill and Broadbent (1998). The number of practices with network-connected PC’s has doubled. Mainframe and mini-computers, which were used in 30.7% of practices in 1994, were used in only 12% of practices in 2003. Thus, the role of computers and the type of computer facilities employed in group medical practices have appreciably changed over the past decade.

One of the major problems of moving to IT systems is cost. A recent article in *USA Today* (Schmit, 2004) points out that wider use of computer software and hardware costs $10,000 to $20,000 per doctor and most of the benefits go to the insurers and hospital records. Doctor productivity drops 20% during the first 3 to 6 months after computer installation. Some possibilities for improvement are suggested by Bridges to Excellence, an employer coalition including GE and Ford Motor formed last year, which pays eligible doctors $50 per patient, per year, to use technology to improve healthcare.

While this paper provides a benchmark for the past decade’s use of IT by physicians, its best use is as a foundation for further research. First of all the consequences of the new HIPPA legislation may lead to more informational uses of IT in the physician’s offices (Jonietz, 2003). Second, while the overall use of IT in key clinical functions remains low (Networks, 2000, 2001), new technologies are being developed on an almost daily basis. Electronic patient records are being utilized more frequently (Hassey, Gerrett, & Wilson, 2001; Mondl, Szolonits, & Kohane, 2001). There is a need to determine the use of computerized physician order entry (CPOE) systems, disease registries, and pharmaceutical surveillance systems. Patient-centered Internet applications are expanding. An example is PatientSite, which allows access to patient’s medical records (except for clinical notes). It also allows patients to schedule appointments online. Other systems tie in hospital-based IT with private practitioners. An example would be eICUs where hospital specialists can remotely track as many as

105 patients in intensive care. If problems arise, direct intervention can be signaled to the patient's on-site medical staff, while the personal physician is being called (Turner, 2004). Another example is hospitals that provide online prescription renewal. These examples compose just a partial list. The key issue is that physicians are just beginning to utilize IT. In a recent study by BCG reported in the *Wall Street Journal* (Landro, 2002), only 42% of U.S. physicians are using electronic records or plan to do so in the near future. However, others have argued that, "at the end of the day, a physician's value will depend on whether he or she can still connect to patients in this cyberspace odyssey" (Healy, 2004).

So will the majority of physicians end up going the same route as the early movers or will they demand new IT capabilities? Will these new applications of IT come from the U.S. or overseas? Given that IT is interconnecting the world and governments worldwide strive to provide excellent medical services while containing costs, there is a need to glean information from worldwide practices. As of now, we do not know, but we will be applying an expanded form of this study in Taiwan this summer. The benchmarking done in this study, combined with periodic research assessing changes will provide the tools that researchers and practitioners need to best anticipate and manage the changes in medical practices that the future holds.

INTRODUCTION

As with many disciplines, the fields of healthcare in general and medicine, in particular, have made vast strides in improving patient outcomes and healthcare delivery. But, have healthcare professionals and medical academia been able to maximize the utilization of new technologies to improve the delivery of the right knowledge, to the right people, at the right time across geographical boundaries? In order to provide the best quality of care, regardless of patient or provider location, specific issues must be addressed.

Healthcare consumers and providers recognize that the system is often over worked, time constrained, poorly funded and desperately in need of a means to maintain up-to-date knowledge and efficient skills in order to deliver the best quality of care (Health Canada, 1998). We also know that there is a large disparity in both the quality and types of healthcare available between developed and developing countries (Lown, Bukuchi & Xavier, 1998). Within a single country there are also differences in healthcare services based upon location (rural vs. urban areas), wealth, age, gender and a host of other factors (Health Canada, 2004). However, because Information and Communication Technologies (ICT) can be a simple and cost effective tool, it can make desperately needed medical knowledge available to developing countries (Pakenham-Walsh, Smith & Priestly, 1997). Furthermore, it is becoming more difficult to get physicians and extended healthcare professionals to participate in face-to-face seminars in order to learn about the progress and changes in the delivery of healthcare. Time, travel requirements and cost are the biggest barriers to overcome. For rural areas and developing countries these issues are even more evident (Ernst and Young, 1998). Today, many institutions and countries are exploring and implementing ICT solutions to help reduce these inequities. The fact remains however that in the case of developing countries, a critical shortage of healthcare professionals remains (Fraser and McGrath, 2000). Adding to the problem is the fact that the telecommunications network, the backbone of ICT, in Africa is the least developed in the world (Coeur de Roy, 1997)

This article concentrates on two main aspects of ICT. First, it examines ways in which ICT can assist in information and knowledge transfer and second, it explores the challenges of ICT implementation.

ICT AND ITS ROLE IN MEDICAL EDUCATION

Providing the right medical knowledge and training to healthcare professionals can be a challenge in the best of circumstances. In developing countries dissemination of the best clinical practice protocols at an affordable cost regardless of the location of the targeted audience is even more daunting. While technology such as CD-ROM-based learning can be tremendously efficient in helping medical students learn fast and well, there may be a lack of individual access to the necessary infrastructure such as equipment and power. In these cases the material is often used in classrooms and the goal of facilitating individual learning and allowing students to go at their own pace may not be met (Pakenham-Walsh, 2003). It is important to keep in mind that even developed countries have, in spite of relatively easy access to the necessary technology, difficulties in properly managing its introduction and use in medical schools (Greenhalgh, 2001).

Tele-education can help in reaching remote communities in developing countries. However, in many regions, technological compatibility and training remain a challenge (Pakenham-Walsh, 2003). The birth of the Internet, in spite of its many imperfections, has dramatically changed the way information, communication and learning are delivered. Although there still exists an imbalance (Davison, Harris, Vogel & Vreede, 1999), in many ways the Internet Age can reduce the gap between developed and developing countries in terms of access to all types of information (United Nations ICT Task Force-1, 2004). While the full potential of the Internet as an ICT tool has yet to be defined it does allow access to information at a speed, quality, and cost previously unseen and defies the notion of geographical boundaries. The Internet allows access to medical information through online articles, video presentations, videoconferences, e-mail-based information and communication. Today, a medical student or healthcare practitioner in India, Africa or any developing country can gain access to the latest medical information from around the world. This new reality has set the foundation for a truly worldwide medical and healthcare community of practice. However, the lack of technological infrastructure and training in developing countries can affect the delivery and use of this health care information (Lown et al., 1998).

As mentioned earlier, users of ICT in the healthcare field face many challenges. Yet despite these challenges, we are at the beginning of a marvelous adventure that has the potential to create a healthcare arena for all with unrestricted access to information and knowledge for practitioners around the world. While this could be viewed by some as simple, utopian rhetoric, the group "Doctors without Borders (Medecins sans Frontières)" already demonstrates the willingness of medical communities to create a vast exchange of information and knowledge (Orbinski, 2000). The term "doctors without borders" captures the spirit of the new world order and sets the future stage for sharing healthcare information. This growing global community of healthcare workers may bring about the desperately needed improvement in the availability of healthcare information around the world (Jareg & Kaseje, 1998).

Despite the great potential, we need to both understand and address the limitations of ICT as a tool in the acquisition and transfer of information and knowledge. The Achilles' heel of the ICT user is not, in our opinion, in terms of access to information, but rather in terms of prior training in healthcare, possession of the necessary technical skills, and an efficient infrastructure (United Nations ICT Task Force-2, 2004). These are the basic requirements in understanding and transforming the rich information that is available into meaningful and useful medical knowledge. When the introduction of ICT is paired with proper access and training, it can lead to the successful creation of a community ready, willing and able to use the ICT to its fullest extent possible (United Nations ICT Task Force-2, 2004).

While such a community can create, share and apply important healthcare knowledge on a wide range of issues, it has to be done accurately and in a timely manner in order to be beneficial (Using ICT to Empower Communities, 2003).

An additional benefit of ICT is the degree to which it can help reduce the sense of isolation often felt by healthcare professionals, especially in rural areas. As a result, staff morale can be improved (Using ICT to Empower Communities, 2003; Ballantyne, 2003).

At this point, the question arises: Can a viable knowledge community exist through the use of ICT?

Before answering, one must differentiate between ICT as a tool on the one hand and the knowledge it can help foster and transfer across boundaries on the other hand. Unlike Marshall McLuhan, who stated that the medium was the message (McLuhan, 1994), we say that ICT is not the knowledge, but only its channel.

FOSTERING A KNOWLEDGE COMMUNITY

Up until now we have discussed the use of ICT as a method of sharing information and knowledge. However, there are conflicting opinions regarding the differences between information and knowledge and the transferability of knowledge (Wilson, 2002).

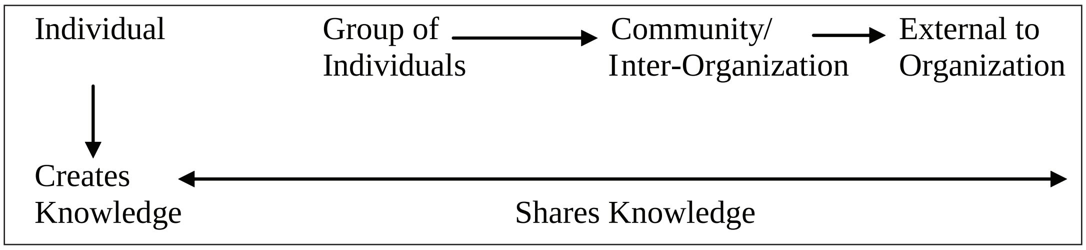
Exploring the Definition of Knowledge

What is knowledge? How can it be defined? These questions have been posed for thousands of years and answered with varying degrees of clarity. Plato described knowledge as justified true belief. Other definitions have been as simple and direct as what we know (Wilson, 2002), or as detailed as a mix of experience, values, information and insights that are applied in the minds of individuals as well as embedded in organizations (Davenport & Prusak, 2000).

Related to knowledge, but not interchangeable, are data and information. Although they are sometimes used interchangeably with each other and with knowledge, they are different. Data is considered the most basic level of discrete facts. Information is more sophisticated than data in that it is a set of related facts. Both data and information, while important, are not knowledge. They generally have no meaning attached to them and they are much more likely to be objectively measured and agreed upon by those preparing and using them. They are also likely to be more generally available than knowledge.

While related to each other, these three concepts are not interchangeable. Rather, there is a hierarchy. It is possible to have data and informa-

Diagram 1. Hierarchy of knowledge creation and sharing within a community



tion without knowledge but *it is not possible to have knowledge without data and information*.

If there is no knowledge without first having access to data and information, then ICT, by allowing the transfer of data and information anywhere, anytime, allow individuals across the world to have the fundamental resources needed for the creation of knowledge. This makes ICT a critically important aspect of knowledge creation and transfer.

Diagram 1 describes a hierarchy of knowledge creation and sharing within a community. Note that knowledge also flows back to the individual.

In this paradigm, ICT, although not perfect, becomes the arteries of a mega community linked by these common objectives.

Classical medical education activities delivered through traditional means such as seminars, perceptorships, residency programs, and workshops seem quite inefficient and costly, poorly coordinated, supply driven, and the content of the information and learning provided is frequently not relevant to the diverse needs of today's rural healthcare workers, especially in the third world (Ballantyne, 2003).

ICT, by allowing healthcare professionals to interact together and with the public, can dramatically change the way medicine is practiced by allowing the timely and unlimited exchange of an ever-increasing quality and quantity of information and knowledge. The role of ICT in the healthcare domain has been so important that in some countries, such as Malaysia, it has been regulated and important financial and material support is provided (Minges & Gray, 2004). The number of online programs of continuing medical education has, for example, increased by 110% in 1999 compared to 1998 (Reynolds, 2002). This shows a definite trend towards the acceptance and use of ICT in the field.

In addition to providing fast and easily accessible information, ICT helps create ties across geographical borders. When asked about their expectations of the use of ICT, healthcare professionals ranked sharing of information and experience number one (Roundtable on ICT for Continuing Medical Education, 2003). The act of sharing helps to create a deeper sense of community (Bwalya, 2003; Grunwald, 2003; Roos, 2001).

Moreover, when it comes to poorer and rural areas, ICT can assist in reducing costs by minimizing redundancy and mismanagement of treatment by enabling healthcare professionals to have readily available clinical information about their patients. An economic argument can be made for greater use of ICT tools in that it will lead to more efficient use of available healthcare resources (Denz, 2003).

In rural areas of developing countries, the successful implementation of ICT requires addressing the management, maintenance and user support issues (Verboom, 2003) which are obviously important aspects and may be easier to deal with in cities and developed countries.

ICT has completely and forever changed the way healthcare education can be delivered (Finkelstein, 2003; Greenhalgh, 2001).

In order to be successful, the use of ICT tools in the healthcare field must be driven by a vision and by policies that recognize the potential. As well, the involvement and buy in of the multiple stakeholders-medical academia, governments at national, regional and local levels, and healthcare practitioners and consumers is critical.

CHALLENGES FOR ICT IN DEVELOPING COUNTRIES AND RURAL AREAS

Table 1 summarizes some of the critical ICT issues faced by developing countries.

The inequities described in Table 1 undoubtedly create a digital divide (Cullen, 2003) making an efficient use of ICT difficult in developing countries (Moghaddan & Lebedeva, 2004). In healthcare, this is unacceptable as it could mean the difference between life and death. Healthcare professionals as a community without borders must be accepted and supported and ICT tools must be developed and made available by international agencies. Access to information is instrumental to the success of healthcare systems in developing and transitional economies (Pakenham-Walsh, 2000). In developed countries however, resistance to change seems to be the main issue where older generations of healthcare professionals are less familiar with the use of ICT and sometimes prefer not to use them (Peterson, 1999).

CONCLUSION

ICT tools are indispensable in providing desperately needed information and knowledge to healthcare professionals regardless of their geographical location. Much has been done and, while improvements continue, more remains to be accomplished (Dash, Gowman, Traynor, Jones & Tait, 2003).

The creation of an international task force to encourage access to ICT tools by healthcare professionals across the world is essential. It will help reduce the gap in medical knowledge, improve infrastructure and quality of care among rural and urban areas as well as amongst developing and developed countries. Quality of care should become a right, not a privilege. We must always keep in mind the patient and improved patient outcomes on a worldwide scale (Towle, 1998).

We believe that healthcare ICT communities will be instrumental in achieving this objective.

Table 1. Critical ICT issues faced by developing countries

-Scarcity and/or costs of telephone lines -Unreliability of telephone lines and Internet connectivity -Lack of skilled workers to properly use the technology -Lack of vision and support from policy makers -Political instability leading to: Prohibitive costs Poor infrastructure Poor funding Electricity shortage -Low priority for ICT against the urgent need to spend the money on medication instead

KEY TERMS

CD-Rom (Compact Disc Read-Only Memory): Optical data storage medium using the same physical format as audio compact discs, readable by a computer with a CD-ROM drive.

CME (Continuing Medical Education): All learning by healthcare providers, after basic training.

Community:A unified body of individuals, people with common interests living in a particular area.

Digital Divide: The phrase has been applied to the gap that exists in most countries between those with ready access to the tools of information and communication technologies (ICT), and those without such access or skills.

E-Health: Used to characterize not only "Internet medicine," but also virtually everything related to computers and medicine.

Information Technology (IT) or Information And Communication Technology (ICT): The technology required to convert, store, process, transmit, and retrieve information.

Internet, The: The vast collection of interconnected networks that all use TCP/IP protocols.

Preceptorship: Teaching or tutoring.

System: A group of devices or an artificial objects or an organization forming a network, especially for distributing something or serving a common purpose.

Telehealth: The use and transmission of video, voice and text data for a multitude of health–related issues, including, health management, patient care, and health worker training and education, individual and patient education on health maters.

ABSTRACT

Healthcare organizations are facing many challenges in the 21st Century due to changes taking place in global healthcare systems. Spiraling costs, financial constraints, increased emphasis on accountability and transparency, changes in education, growing complexities of biomedical research, new partnerships in healthcare and great advances in IT suggest that a predominant paradigm shift is occurring. This shift is necessitating a focus on interaction, collaboration and increased sharing of information and knowledge which is in turn leading healthcare organizations to embrace the techniques of Knowledge Management (KM) in order to create and sustain optimal healthcare outcomes. This chapter describes the importance of knowledge management systems for healthcare organizations and provides an overview of knowledge management technologies and tools that may be used by healthcare organizations.

INTRODUCTION

Knowledge Management (KM) is an essential tool in today's emerging healthcare system. Hospitals that seek to deploy KM systems need to understand the human element in the process. Earlier, success factors were only restricted to a few healthcare variables such as patient care and cost, but over the years, technology (both clinical and administrative) has evolved as a differentiating variable, thus redefining the doctrines of competition and the administration of healthcare treatments. For example, in today's healthcare environment we are now treating patients with an emphasis on prevention and managing the patient through good health throughout their life. Such an approach requires significant investment in knowledge assets. One of the key objectives of a KM system is to insulate a hospital's intellectual knowledge from degeneration (Elliot, 2000).

Most hospitals are unaware of their acquired knowledge base. Further, knowledge capital is often lost from a hospital through employee attrition, high turnover rates, cost-saving measures and improper documentation (Chase, 1998). Specific KM tools and metrics help focus the hospital on acquisition, retrieval and storage of knowledge assets both tangible and/or other for activities such as learning, strategic planning and decision making (Oxbrow, 1998). This goes a long way in crafting a coherent and well-designed growth plan for the hospital (Allee, 1997, 1999). KM treats intellectual capital as a managed asset. Improved patient care is directly proportional to a hospital's intellectual assets. The tactical expertise and experience of individual workers should be fully captured and reflected in strategy, policy and practice at all levels of the hospital management and patient care activity (Conklin, 1998). The intangible asset of knowledge of the employee can nurture radical innovation in advance planning, change management, hospital culture and well balanced approaches. Fostering a knowledge-sharing attitude and competency of patient care processes are vital for any KM program in healthcare (Burca, 2000; Matheson, 1995). Hospitals managing and sharing their knowledge assets effectively will have benefits of cycle time reduction, cost reduction, improved return on investment, higher satisfaction index, and better medical and paramedical education levels (Antrobus, 1997; Atkins et al., 2001).

KNOWLEDGE MANAGEMENT

Knowledge Management (KM) is an emerging, interdisciplinary business model dealing with all aspects of knowledge within the context of the firm, including knowledge creation, codification, sharing and how these activities promote learning and innovation (Choo, 1998). Unfortunately there's no universal definition of KM, just as there's no agreement as to what constitutes knowledge in the first place (Beckman, 1999). For this reason, it's best to think of KM in the broadest context:

KM is a discipline that promotes an integrated approach to identifying, managing, and sharing all of an enterprise's information assets, including database, documents, policies and procedures, as well as unarticulated expertise and experience resident in individual workers (Wickramasinghe, 2003). There are many dimensions around which knowledge can be characterized such as storage media, accessibility, typology and hierarchy. Each of these dimensions is explained in this chapter (Brailer, 1999; Broadbent, 1998; Skyrme, 2001, 1999, 1998; Davenport & Prusak, 1997, 1998).

Knowledge Storage Media

There are several media in which knowledge can reside including: the human mind, an organization, a document and/or a computer. Knowledge in the mind is often difficult to access; organizational knowledge is often dispersed and distributed; document knowledge can range from free text to well-structured charts and tables; while computer knowledge can be formalized, sharable and often well structured and well organized. In order to effectively manage KM it is important to pay careful attention to the most useful storage media.

Knowledge Accessibility

Intellectual and knowledge-based assets fall into one of three major categories (Nonaka, 1994; Nonaka & Nishguchi, 2001; Sharma & Wickramasinghe, 2004):

- *Tacit (human mind, organization):* accessible indirectly only with difficulty through knowledge elicitation and observation of behavior.
- *Implicit (human mind, organization):* accessible through querying and discussion, but informal knowledge must first be located and then communicated.
- *Explicit (document, computer):* readily available, as well as documented into formal knowledge sources that are often well organized, often with the help of IT.

In order for effective KM to ensue, it is necessary to understand these categories of knowledge as well as their subtle nuances.

Knowledge Typologies

Typologies are defined, characterized and described in terms of knowledge type-conversion, structural features, elementary properties, purpose and use, and conceptual levels. Knowledge typologies play an integral role in a robust KM system.

Knowledge Hierarchy

A further dimension considers the premise that knowledge can be organized into a hierarchy. Several authors draw distinctions between data, information and knowledge (Allee, 1997; Devenport & Prusack, 1998; Leonard, 1998).

- *Data:* Facts, images and sounds.
- *Information:* Formatted, filtered and summarized data.
- *Knowledge:* Instincts, ideas, rules and procedures that guide action and decisions and are context dependent.

Strictly speaking, KM is a process that identifies and creates knowledge assets. In healthcare, KM optimally utilizes these assets to fulfill the core healthcare objectives. Knowledge assets in hospitals are intangible but they can be defined as knowledge that a medical/paramedical/non-medical person has with respect to patient care, medical needs, operating environment and technologies, something that he or she can utilize in routine medical and healthcare management. KM identifies and maps intellectual assets within the hospital, thereby generating precious knowledge capital for competitive advantage within the medical institution. Since knowledge is dynamically imbedded in organizational and healthcare networks and processes as well as in the staff that use them, hospitals need to have a built-in KM system that "crisscrosses" with its healthcare networks (Jackson, 2000). The result is that employees will then be better informed and continuously updated on the latest tools and best practices. It is important that the techniques adopted to enable KM must take into account some basic factors such as the type of hospital, its culture and its needs to ensure a successful KM system for a healthcare setting (Gokce, 2002; Johnson, 1998; Keeling & Lambert, 2000).

THE NEED FOR KM IN HEALTHCARE

The health sector is large, accounting for between 6% to 12% of GDP across OECD countries. Though the use of healthcare services varies between nations, public expectations of them globally have risen dramatically everywhere since 1950 and the trend is still upwards. Fresh demands arise from the appearance of new drugs and the invention of new technology, from advances in prevention and diagnosis as well as therapy, and from new categories of demand, such as care of the elderly (Eisenberg, 2002). The health sector is complex and includes a range of key actors: patients, providers, practitioners, payers, purchasers, pharmaceutical industry, and professors. The interaction among these actors shapes what counts as relevant knowledge as well as how it is produced, mediated, and used (Conner, 2001). Further, the domain of medical knowledge has expanded to such a degree that a human mind can no longer retain it all. There are now some 20,000 medical journals in the world. A professor of medicine spends on average one day a week to remain abreast of studies in his/her field of interest as well as for his/her research. What can a generalist physician do? How much time can he/she devote to "keeping up"? In France, there are some 7,000 prescription drugs based on some 3,500 active ingredients. A physician has the right to prescribe them all. Can he/she be familiar with all of them? He/she must also be aware of some 300 medical references, some 800 biological tests, more than 1,000 imagery tests, and more than 1,500 surgical interventions. If he/she prescribes six drugs, he/she must also be aware of some 720 potential sources of interaction. The figure reaches 3,328,800 if 10 drugs are prescribed. In addition to the therapeutic value of each molecule, the physician should also know their price and potential effect on specific population groups (diabetics, the obese, children, the elderly, etc. The growth in knowledge has necessarily led to specialization, which too has meant "balkanization" and lack of coordination, especially in hospitals but also in private practice (Halpern, Perry & Narayan, 2001; Dean, 2002). As knowledge is shared, responsibility and decisions about treatment should be shared as well (Eisenberg, 2002). Hospital Information Management (HIM) professionals, like other healthcare personnel, have always sought, used, and valued knowledge about their practice. Managers hire experience because they understand the value of knowledge that has been developed and proven over time. Unfortunately, they are bombarded each day with information in the form of e-mails, voice mails, faxes, reports, memos, and so on — much of which is repetitive or simply not useful. On the other hand, the same professionals spend a great deal of time looking for the information they need by accessing the Web, sending e-mails, making phone calls, and scouring computerized reports. It is in this process that KM can make a difference. Studies have shown that managers get two-thirds of their information from face-to-face meetings or phone conversations. Only one-third comes from documents or other knowledge bases. Unlike material assets, which decrease in value as they are used, the value of knowledge increases with use. For example, new ideas on records storage or retrieval breed other new ideas, and shared knowledge stays with the giver while it enriches the receiver (Jadad, Haynes, Hunt & Browman, 2000). The potential for new ideas arising from the store of knowledge in any healthcare organization is to provide a common entry point for corporate knowledge, such as formularies, clinical road maps, and key financial indicators (Einbinder, Klein & Safran, 1997). Thus what we can see is that the need for KM in healthcare is critical and becomes significant when it begins to focus on the needs of individual users, departmental indicators, and key processes in order to capture and display relevant, useful, and usable knowledge in a customized fashion (Sorrells & Weaver, 1999a, 1999b, 1999c).

APPROACHES TO CAPTURE, STORE AND SHARE KNOWLEDGE

For companies that need to leverage their corporate knowledge, the following four initiatives may help you establish a knowledge sharing system of your own. These initiatives draw upon a predominate, repository model but are also relevant to other models (Morrissey, 1998).

Build the Infrastructure Using Appropriate Technology

Technology enables connectedness to take place in ways that have never before been possible. Harnessing intellectual capital can be expedited through a network-computing infrastructure. Technology has emerged to support each different approach to knowledge management. Document management systems expedite document storage and retrieval. Web-casts allow synchronous communication between experts while discussion groups enable asynchronous interaction. Learning management systems track an employee's progress with continuous learning while data warehousing mines powerful SQL databases, which organize and analyze highly structured information. Paramount to the successful use of these technologies is naturally a flexible, robust IT infrastructure (Sharma & Wickramasinghe, 2004).

Build a Conceptual Infrastructure with Competencies as the Backbone

Technology is important in harnessing intellectual assets, but integrated solutions encompass more than that. You must rethink the conceptual infrastructure of your business. For example, you may need to: ensure intellectual assets reflect your vision and values; articulate the theoretical framework for your processes; establish a taxonomy or categorization scheme to organize your information; create cross references that reflect relationships between entries; or index your information using attributes or meta-tags. The notion of competence plays a critical role in knowledge indexing and sharing. Karl Erik Sveiby, noted Swedish expert on managing and measuring knowledge-based assets, observes, "The concept of competence, which embraces factual knowledge, skills, experience, value judgments and social networks is the best way to describe knowledge in the business context." Once competencies or target proficiencies are defined, they become the backbone, which connects users to useful, relevant knowledge.

Create a Repository of Reusable Components and Other Resources

Before the Industrial Revolution, products were handcrafted; each piece was unique and couldn't be reused. The genius of the Industrial Revolution centered on making reusable parts and components became standardized and interchangeable. The Information Revolution is similar. Instead of crafting a unique solution each time, knowledge sharing creates a warehouse of "stored parts" — e.g., standardized and interchangeable components which can be reused and adapted: skills, best practices, models and frameworks, approaches and techniques, tools, concepts, specific experiences, presentation aids, white papers, etc. Adding to this, resources such as directories of experts indexed by their field can help you gain access to knowledge outside of your core competencies.

Set High Standards for Quality and Usability

Ensure that your information complies with high quality standards because it is the foundation upon which to build a knowledge-centric healthcare organization. In addition, it is important to make sure that the system meets the users' needs, which may involve reworking or restructuring information. Leonard Caldwell observed: "Critical information must first be reorganized so that information is presented in a way that mirrors users' needs and parallels a thought process occurring within a job function or task." Establishing consistent patterns helps end-users find information quickly. Online coaching can provide users with tips and techniques on how to modify, customize, or tailor information. Leveraging organizational knowledge is not an option — it is an imperative if one is to flourish in the marketplace. It can lead into a new phase of quality and innovation.

It will reduce cycle time and gives a competitive advantage as a company. The synergy will also contribute to growth as individuals. Companies who have the foresight to manage their knowledge capital now will have an advantage in the future (Herbig, Bussing & Ewert, 2001).

KM TOOLS AND TECHNOLOGIES

The paraphernalia of the information revolution — computers, communications networks, compact discs, imaging systems and so on — are now widely expected to make a vital contribution to helping doctors and other medical professionals do their work better (Gokce, 2002). New information technologies include:

- Electronic patient records, which are more up to date, easier to access, and more complete than paper ones;
- Standardized medical terminologies and languages, both within and across natural language communities;
- Methods and tools to support faster dissemination of information via the Internet that leads to new scientific understanding of diseases and their treatment;
- More timely and reliable methods and tools to support better communication and coordination among members of healthcare teams;
- A creative approach to KM can result in improved efficiency, higher productivity and increased revenues in practically any business function.

The technical goal of KM initiatives is to give the organization the ability to mine its own knowledge assets, which could include creating such tools as a centralized search capability, automatic indexing and categorization, content analysis and preparation, data analysis, and customizable features integrated in a digital dashboard. Process improvement is a precursor to providing a knowledge-centered environment. Before an organization can foster collaboration and knowledge sharing, the organization must possess an understanding of information flows and of the overall knowledge infrastructure. There is no such thing as the perfect KM product. Instead, different tool sets can be integrated with the organization's legacy systems (Heathfield & Louw, 1999). Technical issues that KM projects must address include:

- Setting up electronic delivery strategies for information
- Identifying information sources and services
- Building decision support tools and data-mining templates
- Establishing enterprise-wide business rules
- Implementing process improvement techniques

Knowledge Mapping

Knowledge management is rapidly becoming a critical success factor for competitive organizations. Carrying out knowledge management effectively in an industrial environment requires support from a repertoire of methods, techniques and tools, in particular knowledge engineering technology adapted for knowledge management. Knowledge mapping creates high-level knowledge models in a transparent graphical form. Using knowledge maps, management can get an overview of available and missing knowledge in core business areas and make appropriate knowledge management decisions. Knowledge mapping is a good example of a useful knowledge management activity with existing knowledge acquisition and modeling techniques at its foundations (Strawser, 2000). Knowledge mapping is a technique rather than a product. A knowledge map could be used as a visual example of how information is passed from one part of an organization or group to another and is usually a good place to start understanding what types of intellectual assets the organization has at its disposal. Most organizations that have implemented KM applications provide a context and framework for the way knowledge is gained. KM is usually an integral part of continuous quality improvement or total quality management projects. Several consultants offer knowledge-mapping methodologies (Heathfield & Louw, 1999).

Process-Based Knowledge Map

A process-based knowledge map is essentially a map or diagram that visually displays knowledge within the context of a business process. In other words, the map shows how knowledge should be used within the processes and sources of this knowledge. The overview of the business process is prepared before the knowledge and the sources are mapped to this process. Any type of knowledge that drives the process or results from execution of the process can be mapped. This could include tacit knowledge (knowledge that resides in people such as know-how, experience, and intuition) and explicit knowledge (codified knowledge that is found in documents); customer knowledge; knowledge in processes; etc.

Intelligent Agents

In the early days of online information retrieval systems, individuals met with search intermediaries who were trained to use the online systems. The intermediaries were often knowledgeable about the information seeker's area of interest. Today, technology in the form of personal computers and the Internet provides users with the means to access the online databases from their own offices. However, distributed sources of online information, e.g., the World Wide Web (WWW), compound the problem of information searching. Both novice and experienced users still need support with the search process and the integration of information. To address this problem, agents have been developed for information management applications. The goal of intelligent search agents is to allow end-users to search effectively, be it either a single database of bibliographic records or a network of distributed, heterogeneous, hypertext documents. The approaches range from desktop agents specialized for a single user to networks of agents used to collect data from distributed information sources. Intelligent agents use a combination of profiling techniques, search tools, and recognition algorithms to "push" information to the decision maker on a regular basis. Because intelligent agents use a standard Web analogy, users can quickly set up "net casts" of internal information to automatically receive knowledge bases when they become available. For example, a physician can request that lab results be forwarded to his or her individual dashboard as soon as the lab has completed the procedure. One cautionary note: using push technologies can result in an information flood if filters are not configured to reduce unwanted or unnecessary data (Strawser, 2000).

Web Browsers

Web browsers such as Microsoft's Internet Explorer are practical because of their cost and relative ease of use, and they have become the preferred presentation layer for accessing knowledge bases. The productivity potential inherent in browsers is similar to that of wireless phones. The freer the knowledge worker is of place, time, medium, and device, the less time is spent on the process of messaging, and the more time is available for results. The less time spent on process, the shorter the knowledge cycle, which can be a significant productivity advantage (Strawser, 2000).

KM Applications

Most new KM applications consist of two major elements (often integrated into one interface): a means for employees looking for specialized knowledge to hook up with other people in the organization with the same knowledge (usually via a web application), in other words, an easy way for employees to tap into tacit knowledge resources (people); and a means for employees looking for specialized knowledge to search relevant documents/data (also usually via a web application), in other words, an easy way for employees to tap into explicit knowledge. KM applications are usually designed to support a particular information set in an organization, such as length-of-stay margin management, physician profitability, or accounts receivable recovery. Some consulting firms offer a base set of templates as a core application, focusing on desktop applications, whereas others have developed information sets that provide encyclopedic knowledge of a particular healthcare segment, such as physician issues (Strawser, 2000).

Workflow Applications

In the software world, and in particular in the imaging subset of that world, the need arose to send a particular (bit-mapped) document to a particular workstation or users on a network. This simple routing and distribution was called "workflow." It was quickly learned that these work items could be "tracked," which allowed the accumulation of data about not only where an item had been but also on what happened to it along the way. Who worked on it, how long it was there, the status it had leaving a point, and where it went next was starting to look much more like the manufacturing model. If data was also accumulated about the workers in this operation (how many did they complete, to what status, how long did it take for each) the model was complete. Workflow applications, such as Lotus Notes or Outlook 2000, also play an important role in a KM implementation. For example, a KM solution based on Office 2000 could serve as a nurse triage application, integrating automatic call distribution and transaction-processing systems, in concert with a knowledge base of typical responses to patient questions and symptoms (Strawser, 2000). These described technologies and tools can be exploited to create data banks, knowledge banks and a KM software as shown in *Table 1*, which will be a great help for providing better solutions for healthcare.

These data banks can be readily accessed through a network (Internet or intranet) if the user has at his/her disposal a workstation, software, and passwords that give access to these networks and their different sites. The system should be made flexible so that it can be adaptable in time and space, and can be customized: each physician can, when he/she wishes, consult one of the

Table 1. Data banks, knowledge banks and KM software

Data banks	(Involving text and images as well as figures) which act as medicine's memory to be used for research (clinical, pharmaceutical, epidemiological, etc.)
Knowledge banks	(Bibliographies, sites for exchanges among professionals, etc.), which make it possible to have access at any moment to the state of the art and can help in making medical decision (diagnosis or treatment)
Software	To help with diagnosis and prescribing which does not replace the physician but acts to extend their knowledge

banks or receive specific information on the fields which he/she has chosen in advance. Access need not be limited to physicians alone, but can also be made available to health professionals and the public, and the latter could adapt behavior to help prevent the onset of illness. Of course, these data banks have to be organized, updated continuously and meet users' expectations by allowing them to ask questions and to engage in discussions among themselves, so that it is always possible to evaluate the quality of the information consulted (Fitchett, 1998). The knowledge bank can make it possible to consult experts located elsewhere and to transmit images and other elements of a patient's file to a colleague to obtain an opinion, a practice currently known as "tele-medicine" (Hansen & Nohria, 1999). Software can help to offer software diagnostic and prescription aids to extend this knowledge (Confessore, 1997; Wyatt, 2000; Timpson, 1998).

CONCLUSIONS

Until recently, most of the knowledge experience and learning about KM had been accessible to only a few practitioners. However, during the past three years an explosion of interest, research, and applications in KM has occurred. There is some concern among the practitioners that KM might suffer a fate similar to business reengineering, artificial intelligence, and total quality management. That is, interest in the discipline must last long enough to iron out the bugs while simultaneously delivering significant business value. The irony is that just when the discipline works well, potential users often have lost interest in the fad, point to the inevitable early failures, and thus miss out on the real benefits. Unless the very ambitious and interesting KM initiatives in healthcare evolve differently, even if they work in a technical sense, they will not work in the economic sense and the healthcare system will continue to be what it is today: an immense apparatus for reimbursing healthcare costs. However, there will still be a health/social services network and a medical profession that is familiar with the tools and power of the Internet. The experience will not be totally negative, even if it is likely to reach goals that are different from those set at the outset. Although considerable progress has been achieved in KM across a broad front, much work remains to fully deliver the business value that KM promises. Ultimately, in order to realize the enormous potential value from KM, organizations must motivate and enable creating, organizing and sharing knowledge.

This chapter has served to highlight the need for healthcare in general to embrace the strategies, protocols, tools, techniques and technologies of knowledge management in order to contend with key challenges pertaining to access, quality and value of healthcare delivery. The following chapters in the book will highlight specific areas within the healthcare industry and key issues regarding knowledge management that are pertinent. This will serve to develop a detailed understating of the essential requirements for creating knowledge-based healthcare organizations.

Chapter 1.17
Healthcare Knowledge Management

Kostas Metaxiotis
National Technical University of Athens, Greece

INTRODUCTION

The healthcare environment is changing rapidly, and effective management of the knowledge base in this area is an integral part of delivering high-quality patient care. People all over the world rely on a huge array of organizations for the provision of healthcare, from public-sector monoliths and governmental agencies to privately funded organizations, and consulting and advisory groups. It is a massive industry in which every organization faces a unique combination of operational hurdles. However, what every healthcare system has in common is the high price of failure. Faced with the prospect of failing to prevent suffering and death, the importance of continuously improving efficiency and effectiveness is high on the agenda for the majority of healthcare organizations (Brailer, 1999). Taking also into consideration that the amount of biological and medical information is growing at an exponential rate, it is not consequently surprising that knowledge management (KM) is attracting so much attention from the industry as a whole.

In a competitive environment like the healthcare industry, trying to balance customer expectations and cost requires an ongoing innovation and technological evolution. With the shift of the healthcare industry from a central network to a global network, the challenge is how to effectively manage the sources of information and knowledge in order to innovate and gain competitive advantage. Healthcare enterprises are knowledge-intensive organizations which process massive amounts of data, such as electronic medical records, clinical trial data, hospitals records, administrative reports, and generate knowledge. However, the detailed content of this knowledge repository is to some extent "hidden" to its users, because it is regularly localized or even personal and difficult to share, while the healthcare data are rarely transformed into a strategic decision-support resource (Heathfield & Louw, 1999). KM concepts and tools can provide great support to exploit the huge knowledge and information resources and assist today's healthcare organizations to strengthen healthcare service effectiveness and improve the society they serve.

The key question which remains is the following: *How can we make knowledge management work in healthcare?* The answer is given in the following sections.

The Healthcare Industry: A Brief Overview

The health care industry is one of the largest single industries all over the world and the largest one in the United States. It has increased by over 65% since 1990 and is expected to double by the year 2007.[1] The IT industry is strategically positioned to become a powerful ally to the healthcare industry as it strives to adopt well-managed cost-efficient strategies. Advanced information technologies can give healthcare providers the opportunity to reduce overall healthcare expenses by lowering the costs of completing administrative and clinical transactions. Nevertheless, in comparison to other industry sectors, the healthcare industry has been slow to embrace e-business solutions and other advanced information technologies, as presented in Table 1.

The same study revealed that the healthcare industry spends substantially more on overhead and computer facility maintenance than other industry sectors. In 1997, for instance, the healthcare industry allotted 12% of its budget to maintain existing infrastructure—6% more than the industry norm. The high level of investment in this area by healthcare organizations indicates that many providers operate with the aid of old systems, which require constant repair and maintenance.

At this stage, it is worth emphasizing that the healthcare context differs from other information systems application domains in that it often concerns sensitive and confidential information and leads to critical decisions on people's lives (or quality of life). Thus, stakeholder conflicts have more of an impact than in other areas such as business, trade, and manufacturing. Healthcare is an area with quite intense differences of values, interests, professional backgrounds, and priorities among key stakeholders. Given the complexity of the context, health informatics in general cannot simply focus on technical or information systems aspects alone. It has to take account of their relationship with clinical and managerial processes and practices, as well as deal with multiple stakeholders and organizational cultures and accompanying politics.

Concluding, it should be stressed that healthcare is not only a significant industry in any economy (Folland, Goodman, & Stano, 1997), but also a field that needs effective means to manage data as well as information and knowledge. Man-

Table 1. Percentage of IT implementation in industry (Computer Economics, 1999)

Industry Sector	% in Place
Transportation	57.2
Banking and Finance	52.9
Insurance	48.1
State & Local Government	37.5
Trade Services	36.8
Retail Distribution	35.5
Process Manufacturing	34.9
Discrete Manufacturing	33.3
Wholesale Distribution	33.3
Utilities	26.9
Federal Government	25.0
Healthcare	21.8
Professional Services	21.7

aged care has emerged as an attempt to stem the escalating costs of healthcare (Wickramasinghe & Ginzberg, 2001) and improve the quality of services.

THE BACKGROUND OF KM IN HEALTHCARE

An increasing concern with improving the quality of care in various components of the healthcare system has led to the adoption of quality improvement approaches originally developed for industry. These include *Total Quality Management* (Deming, 1986), an approach that employs process control measures to ensure attainment of defined quality standards, and *Continuous Quality Improvement* (Juran, 1988), a strategy to engage all personnel in an organization in continuously improving quality of products and services. Nowadays, the importance of knowledge management is growing in the information society, and medical domains are not an exception. In Yu-N and Abidi (1999), managing knowledge in the healthcare environment is considered to be very important due to the characteristics of healthcare environments and the KM properties. We should always keep in mind that medical knowledge is complex and doubles in amount every 20 years (Wyatt, 2001).

The healthcare industry is nowadays trying to become a knowledge-based community that is connected to hospitals, clinics, pharmacies, physicians, and customers for sharing knowledge, reducing administrative costs, and improving the quality of care (Antrobus, 1997; Booth, 2001). The success of healthcare depends critically on the collection, analysis, and exchange of clinical, billing, and utilization information or knowledge within and across the organizational boundaries (Bose, 2003).

It is only recently that initiatives to apply KM to the healthcare industry have been undertaken by researchers. Firstly, in the second half of the 1980s, several authors tried to apply artificial intelligence (AI)—with doubtful success—to medicine (Clancey & Shortliffe, 1984; Frenster, 1989; Coiera, Baud, Console, & Cruz, 1994; Coiera, 1996). MYCIN is probably the most widely known of all medical (and not only) expert systems thus far developed (Shortliffe, 1976). And this is despite the fact that it has never been put into actual practice. It was developed at Stanford University solely as a research effort to provide assistance to physicians in the diagnosis and treatment of meningitis and bacteremia infections. PUFF, DXplain, QMR, and Apache III are also some of the most well-known medical expert systems that were developed and put into use (Metaxiotis, Samouilidis, & Psarras, 2000).

De Burca (2000) outlined the conditions necessary to transform a healthcare organization into a learning organization. Fennessy (2001) discussed how knowledge management problems arising in evidence-based practice can be explored using “soft systems methodology” and action research. Pedersen and Larsen (2001) presented a distributed health knowledge management (DKM) model that structures decision support systems (DSSs) based on product state models (PSMs) among a number of interdependent organizational units. The recurrent information for the DSS comes from a network-wide support for PSMs of the participating organizations.

Ryu, Hee Hp, and Han (2003) dealt with the knowledge sharing behavior of physicians in hospitals; their study investigated the factors affecting physicians’ knowledge sharing behavior within a hospital department by employing existing theories, such as the Theory of Reasoned Action and the Theory of Planned Behavior. Torralba-Rodriguez and colleagues (2003) presented an ontological framework for representing and exploiting medical knowledge; they described an approach aimed at building a system able to help medical doctors to follow the evolution of their patients, by integrating the knowledge offered by physicians and the knowledge collected from intelligent alarm systems. Also, Chae, Kim, Tark, Park, and Ho (2003) presented an analysis of healthcare quality indicators using data mining for developing quality improvement strategies.

Reviewing the literature, it is concluded that a KM-based healthcare management system should have the following objectives (Shortliffe, 2000; Booth & Walton, 2000):

- To improve access to information and knowledge at all levels (physicians, hospital administrators and staff, consumers of health services, pharmacies, and health insurance companies) so that efficiencies and cost reductions are realized.
- To transform the diverse members (care recipients, physicians, nurses, therapists, pharmacists, suppliers, etc.) of the healthcare sector into a knowledge network/community of practice.
- To enable evidence-based decision making to improve quality of healthcare.

Table 2 presents important Web sites dedicated to the promotion and application of KM to healthcare.

THE KNOWLEDGE MANAGEMENT PROCESS IN HEALTHCARE

In order to examine whether knowledge management can really succeed in healthcare, we can analyze this proposition in terms of examining the knowledge management process and the likelihood of success for the healthcare organizations in achieving these steps in the process. The KM process consists of four key stages, as shown in Figure 1 (Schwartz, Divitini, & Brasethvik, 2000).

Knowledge identification and capture refer to identifying the critical competencies, types of knowledge, and the right individuals who have the necessary expertise that should be captured. Then, this captured knowledge is shared between individuals, departments, and the like. The knowledge application stage involves applying knowledge—which includes retrieving and using knowledge—in support of decisions, actions, and problem solving, and which ultimately can create new knowledge. As new knowledge is created, it needs to be captured, shared, and applied, and the cycle continues.

Knowledge Identification and Capture in Healthcare

One way to identify the critical knowledge that should be captured and determine the experts in the healthcare organization who have the knowledge on a specific issue (e.g., disease, therapy) is to conduct a knowledge audit. The knowledge audit helps to identify the types of knowledge needed and the appropriate sources (e.g., patient records, medical research literature, medical procedures, drug references) in order to develop a knowledge management strategy for the organization.

On the other hand, the use of intranets is suggested as basic tools for the capture of implicit knowledge. St Helens & Knowsley Health Informatics Service—which covers 320,000 patients—designed and developed an intranet structure with the aim to generate the potential to capture organizational implicit knowledge (Mimnagh, 2002). The real challenge has been to create a health- community- wide intranet that implements directory services, communities of practice, and lessons learnedt in a way which builds on existing activity and looks for the synergistic effect of adding a KM focus to ongoing work.

Vast amounts of medical knowledge reside within text documents, so that the automatic extraction of such knowledge would certainly be beneficial for clinical activities. Valencia-Garcia and colleagues et al. (2004) presented a user-centered approach for the incremental extraction of knowledge from text, which is based on both

Table 2. Important Web sites dedicated to KM in healthcare

Web Site	Description
www.nelh.nhs.uk/knowledge_management.asp	The National Electronic Library for Health has a link dedicated to knowledge management. It describes how to manage explicit knowledge and outlines revolutions in KM in healthcare.
www.who.int	The World Health Organization has launched the Health Academy, which aims to demystify medical and public health practices, and to make the knowledge of health specialists available to all citizens through Web-based technology. The academy will provide the general public with the health information and knowledge required for preventing diseases and following healthier lifestyles.
www.cochrane.org	The Cochrane Collaboration is an international non-profit and independent organization, dedicated to making up-to-date, accurate information about the effects of healthcare readily available worldwide. The major product of the collaboration is the Cochrane Database of Systematic Reviews, which is published quarterly.
www.AfriAfya.org	AfriAfya, African Network for Health Knowledge Management and Communication, is a consortium formed by well-known agencies such as Aga Khan Health Service in Kenya, CARE International, SatelLife HealthNet, PLAN International, and the Ministry of Health in Kenya to harness the power of information and communication technology for community health.
www.hc-sc.gc.ca/iacb-dgiac/km-gs/english/kmhome.htm	The goal of knowledge management at Health Canada is to use the knowledge that resides in the department—in the minds of its staff, in the relationships they have with other organizations, and in their repositories of information—to fulfill their mission: to help the people of Canada maintain and improve their health.
www.ucl.ac.uk/kmc/index.html	The Knowledge Management Centre is part of the School of Public Policy of University College London (UCL). The Knowledge Management Centre's aim is to improve clinical practice, patient outcomes, and health service innovation and efficiency by promoting better health knowledge management by serving as a resource center and making efficient use of its resources internally and across a network of collaborators.

knowledge technologies and natural language processing techniques. The system was successfully used to extract clinical knowledge from texts related to oncology and capture it.

Concluding, a key question is whether people would be willing to give up their competitive edge to have their knowledge captured via online repositories, lessons learned, best practices, and the like. This possible dilemma is especially valid in the healthcare sector.

Knowledge Sharing in Healthcare

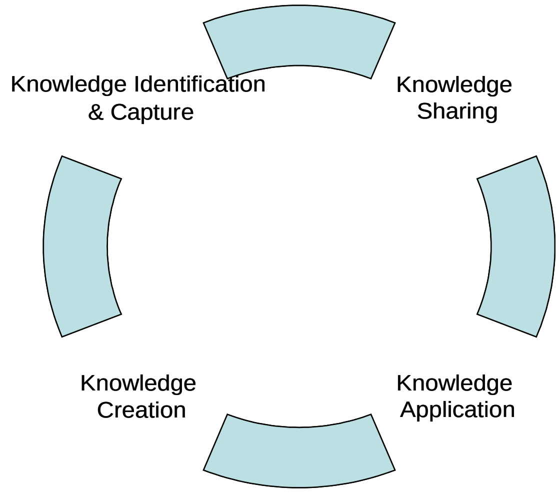
Productive organizations have the ability to create an environment where specialized knowledge, skills, and abilities of all employees are leveraged to achieve advancements in service industry. However, healthcare organizations cannot be considered as a good example of such organizations. A healthcare organization is a collection of professional specialists who contribute to the delivery of patient care, but also often act competitively inside the organization, without being willing to transfer knowledge because of associated status and power within the organization and the society.

Taking also into account that people in general are not likely to share their knowledge unless they think it is valuable and important, it becomes clear why doctors and physicians are not willing to share and transfer their knowledge. In addition, due to minimal interdisciplinary training, the transfer of tacit knowledge which occurs through apprenticeship style work patterns—for example, internships where junior doctors work alongside a senior clinician in surgery or intensive care—remains problematic (Beveren, 2003).

Effective knowledge management requires a "knowledge sharing" culture to be successful. Especially in healthcare, it is crucial that doctors and physicians understand the benefits of knowledge sharing on a number of levels: benefits to the organization, benefits to patients, and benefits to them personally. The more you can clearly demonstrate these benefits, the more people are likely to be open to change. Doctors and physicians need to be recognized and rewarded in a formal way (e.g., promotions, cash awards) to make knowledge sharing a reality in healthcare.

The Wisecare (Workflow Information Systems for European Nursing Care) project—an EC-funded initiative (1997-1999)—has promoted knowledge sharing using the Internet and online communities. Wisecare provided nurses with a vast amount of information and knowledge about clinical practice through both the Wisecare Web site and data collection tool. This information has been specifically selected to meet their clinical needs and meant nurses had access to relevant knowledge extremely quickly.

Figure 1. The knowledge management process cycle



Lesson learned systems can also be an effective knowledge sharing approach to be used in healthcare (Yassin & Antia, 2003).

Knowledge Application in Healthcare

Knowledge application refers to taking the shared knowledge and internalizing it within one's perspective and worldviews. For the healthcare organizations the reality is that technology can only fulfill some of their needs. And how well it fulfills them depends critically on managing the knowledge behind them—content management, assigning knowledge roles, and so forth. Tom Davenport (2002), a prominent author on knowledge management, is often quoted as offering the following rule of thumb: your investment in technology in terms of both cost and effort should stay under one-third of the total knowledge management effort—otherwise you are going wrong somewhere.

Knowledge-enabling technologies which can effectively be applied to healthcare organizations are:

- Groupware
- Intranet
- Collaborative tools (e.g., discussion boards, videoconferencing)
- Portals
- Taxonomies

Abidi (2001) presented the Healthcare Enterprise Memory (HEM) with the functionality to acquire, share, and operationalize the various modalities of healthcare knowledge. Davenport (2002) outlined how Partners Health Care System in Boston implemented an enormously successful expert-intervention KM solution. Case studies from the UK's National Health Service (NHS) and the Department of Health illustrated the drive towards modernization and more effective collaborative working among public-sector healthcare systems (Ark Group, 2002).

Knowledge Creation in Healthcare

In general, knowledge creation may take the form of new products or services, increased innovation, and improved customer relationships. In the healthcare setting, knowledge creation can take place in terms of improved organizational processes and systems in hospitals, advances in medical methods and therapies, better patient relationship management practices, and improved ways of working within the healthcare organization. Given the various constraints and barriers occur in the healthcare sector, it takes longer for a new idea to be implemented in the healthcare setting versus that in the business sector.

A few examples of knowledge creation technologies that can be used in healthcare are:

- **Data Mining:** Tools that analyze data in very large databases, and look for trends and patterns that can be used to improve organizational processes.
- **Information Visualization:** Computer-supported interactive visual representations of abstract data to help improve understanding.

CONCLUSION

Knowledge is a critical tool for health, and knowledge management is the capacity to translate research results (knowledge) into policies and practices that can improve the quality of life and lengthen survival. Managing knowledge in a healthcare organization is like trying to knit with thousands of strands of knotted wool; data is held in a number of locations, managed by a variety of people, and stored in every imaginable format. Perhaps in no other sector does knowledge management have such a high promise.

Delivering healthcare to patients is a very complex endeavor that is highly dependent on information. Healthcare organizations rely on information about the science of care, individual patients, care provided, results of care, as well as its performance to provide, coordinate, and integrate services. The traditional single physician-patient relationship is increasingly being replaced by one in which the patient is managed by a team of health care professionals each specializing in one aspect of care. Hence, the ability to access and use the electronic healthcare record (EHCR) of the patient is fundamental. In addition, the transformation of healthcare data into a strategic decision-support resource is fundamental too.

KM can be approached in numerous ways to serve particular needs and conditions. Successful KM practices typically need to be supported by complementary efforts in different domains. IT-related support activities and infrastructures are very important. They serve vital functions, are complex, costly, and often take time to design and implement. In the case of healthcare, building the infrastructure for a KM practice requires extensive effort due to the peculiarities of the health sector (e.g., legal and ethical issues, complex procedures for provision of healthcare, doctors' behavior, etc.).

Coming back to the original question—*How can we make knowledge management work in healthcare?*—and by examining the knowledge management process, we can see that there are positive and negative points as to whether KM will truly work in the healthcare sector. Some people in healthcare think that KM is a passing fad like Total Quality Management, Business Process Reengineering, and other administration-backed initiatives. It is unfortunate to think in this light, as knowledge sharing should be encouraged so that lessons can be learned. KM solutions can facilitate the transfer of patient medical information, access to new treatment protocols as they emerge, knowledge exchange among experts, and so on.

Future research needs to be devoted to measuring the success of KM in healthcare organizations, showing quantitative benefits, and producing a "Return on Investment" index. Measurement is the least-developed aspect of KM because of the inherent difficulty to measure something that cannot be seen, such as knowledge (Bose, 2004). However, this is a very crucial issue since the future usage of KM is heavily dependent on both the quality of the metrics and whether output generated by this metric management would provide tangible value addition to the healthcare organizations. Integration of KM with e-health is also another direction for further research.

KEY TERMS

Collaborative Tools: Electronic tools that support communication and collaboration—people working together; essentially they take the form of networked computer software.

Distributed Knowledge Management Model: The model which combines the interdependence of one partial product state model to others with the idea of knowledge acquisition rather than just the operational exchange relationship.

Evidence-Based Medicine: Healthcare based on best practice which is encoded in the form of clinical guidelines and protocols.

Groupware: Specific software which allows groups of people to share information and to coordinate their activities over a computer network.

Healthcare Enterprise Memory: A KM info-structure which supports the functionality to acquire, share, and operationalize the various modalities of knowledge existent in a healthcare enterprise.

Information Visualization: Computer-supported interactive visual representations of abstract data which help improve understanding.

Taxonomy: A hierarchical structure for organizing a body of knowledge; it gives a framework for understanding and classifying knowledge.

Chapter 1.18
Knowledge Management in Hospitals

Kevin C. Desouza
University of Illinois at Chicago, USA

ABSTRACT

The medical field in recent years has been facing increasing pressures for lower cost and increased quality of healthcare. These two pressures are forcing dramatic changes throughout the industry. Managing knowledge in healthcare enterprises is hence crucial for optimal achievement of lowered cost of services with higher quality. The following chapter focuses on developing and fostering a knowledge management process model. We then look at key barriers for healthcare organizations to cross in order to fully manage knowledge.

INTRODUCTION

The healthcare industry is information intensive and recent trends in the industry have shown that this fact is being acknowledged (Morrissey, 1995; Desouza, 2001). For instance, doctors use about two million pieces of information to manage their patients (Pauker, Gorry, Kassirer & Schwartz, 1976; Smith, 1996). About a third of doctor's time is spent recording and combining information and a third of the costs of a healthcare provider are spent on personal and professional communication (Hersch & Lunin, 1995). There are new scientific findings and discoveries taking place every day. It is estimated that medical knowledge increases fourfold during a professional's lifetime (Heathfield & Louw, 1999), which inevitably means that one cannot practice high quality medicine without constantly updating his or her knowledge. The pressures toward specialization in healthcare are also strong. Unfortunately, the result is that clinicians know more and more about less and less. Hence it becomes difficult for them to manage the many patients whose conditions require skills that cross traditional specialties. To add to this, doctors also face greater demands from their patients. With the recent advances of e-health portals, patients actively search for medical knowledge. Such consumers are increasingly interested in treatment quality issues and are also more aware of the different treatment choices and care possibilities.

Managing knowledge in healthcare enterprises is hence crucial for optimal achievement of lowered cost of services with higher quality. The fact that the medical sector makes up a large proportion of a country's budget and gross domestic product (GDP), any improvements to help lower cost will lead to significant benefits. For instance, in 1998 the healthcare expenditure in the US was $1.160 billion, which represented 13.6% of the GDP (Sheng, 2000). In this chapter, we look at the knowledge management process and its intricacies in healthcare enterprises.

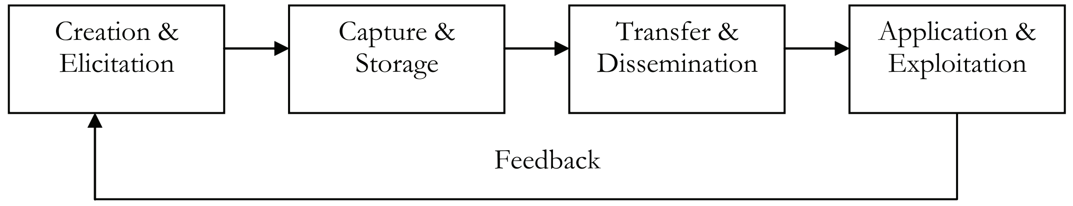
KNOWLEDGE MANAGEMENT PROCESS

Knowledge management from a process perspective is concerned with the creation, dissemination, and utilization of knowledge in the organization. Therefore, a well-structured process needs to be in place to manage knowledge successfully. The process can be divided into the following steps: beginning with knowledge creation or elicitation, followed by its capture or storage, then transfer or dissemination, and lastly its exploitation. We now elaborate on the various stages of the process:

Creation and Elicitation

Knowledge needs to be created and solicited from sources in order to serve as inputs to the knowledge management process. For the first scenario where knowledge has to be created, we begin at the root — data. Relevant data needs to be gathered from various sources such as transaction, sales, billing, and collection systems. Once relevant data is gathered, it needs to be processed to generate meaningful information. Transaction processing systems take care of this task in most businesses today. Just like data, information from various sources needs to be gathered. An important consideration to be aware of is that information can come from external sources in addition to internal sources. Government and industry publications, market surveys, laws and regulations, etc., all make up the external sources. Information once gathered needs to be integrated. Once all necessary information is at our disposal, we can begin analyzing it for patterns, associations, and trends — generating knowledge. The task of knowledge creation can be delegated to dedicated personnel, such as marketing or financial analysts. An alternative would be to employ artificial intelligence-based computing techniques for the task such as genetic algorithms, artificial neural networks, and intelligent agents (Desouza, 2002a). Data mining and knowledge discovery in data bases (KDD) relate to the process of extracting valid, previously unknown and potentially useful patterns and information from raw data in large data bases. The analogy of mining suggests the sifting through of large amounts of low grade ore (data) to find something valuable. It is a multistep, iterative inductive process. It includes such tasks as: problem analysis, data extraction, data preparation and cleaning, data reduction, rule development, output analysis and review. Because

Figure 1. Knowledge management process



data mining involves retrospective analyses of data, experimental design is outside the scope of data mining. Generally, data mining and KDD are treated as synonyms and refer to the whole process in moving from data to knowledge. The objective of data mining is to extract valuable information from data with the ultimate objective of knowledge discovery.

Knowledge also resides in the minds of employees in the form of know-how. Much of the knowledge residing with employees is in tacit form. To enable for sharing across the organization, this knowledge needs to be transferred to explicit format. According to Nonaka and Takeuchi (1995), for tacit knowledge to be made explicit there is heavy reliance on figurative language and symbolism. An inviting organizational atmosphere is central for knowledge solicitation. Individuals must be willing to share their know-how with colleagues without fear of personal value loss and low job security. Knowledge management is about sharing. Employees are more likely to communicate freely in an informal atmosphere with peers than when mandated by management. Desouza (2003b) studied knowledge exchange in game rooms of a high-technology company and found significant project-based knowledge exchanged.

Capture and Storage

To enable distribution and storage, knowledge gathered must be codified in a machine-readable format. Codification of knowledge calls for transfer of explicit knowledge in the form of paper reports or manuals into electronic documents, and tacit knowledge into explicit form first and then to electronic representations. These documents need to have search capabilities to enable ease of knowledge retrieval. The codification strategy is based on the idea that the knowledge can be codified, stored and reused. This means that the knowledge is extracted from the person who developed it, is made independent of that person and reused for various purposes. This approach allows many people to search for and retrieve knowledge without having to contact the person who originally developed it. Codification of knowledge, while being beneficial for distribution purposes, does have associated costs. For instance, it is easier to transfer strategic know-how outside the organization for scrupulous purposes. It is also expensive to codify knowledge and create repositories. We may also witness information overload in which large directories of codified knowledge may never be used due to the overwhelming nature of the information. Codified knowledge has to be gathered from various sources and be made centrally available to all organizational members. Use of centralized repositories facilitates easy and quick retrieval of knowledge, eliminates duplication of efforts at the departmental or organizational levels and hence saves cost. Data warehouses are being employed extensively for storing organizational knowledge (Desouza, 2002a).

Transfer and Dissemination

One of the biggest barriers to organizational knowledge usage is a blocked channel between knowledge provider and seeker. Blockages arise from causes such as temporal location or the lack of incentives for knowledge sharing. Ruggles' (1998) study of 431 US and European companies shows that "creating networks of knowledge workers" and "mapping internal knowledge" are the two top missions for effective knowledge management.

Proper access and retrieval mechanisms need to be in place to facilitate easy access to knowledge repositories. Today almost all knowledge repositories are being web-enabled to provide for the widest dissemination via the Internet or intranets. Group Support Systems are also being employed to facilitate knowledge sharing, with two of the most prominent being IBM's Lotus Notes and Microsoft's Exchange. Security of data sources and user friendliness are important considerations that need to be considered while providing access to knowledge repositories. Use of passwords and secure servers is important when providing access to knowledge of a sensitive nature. Access mechanisms also need to be user-friendly in order to encourage use of knowledge repositories.

Exchange of explicit knowledge is relatively easy via electronic communities. However, exchange of tacit knowledge is easier when we have a shared context, co-location, and common language (verbal or non-verbal cues), as it enables high levels of understanding among organizational members (Brown & Duguid, 1991). Nonaka and Takeuchi (1995) identify the processes of socialization and externalization as means of transferring tacit knowledge. Socialization keeps the knowledge tacit during the transfer, whereas externalization changes the tacit knowledge into more explicit knowledge. Examples of socialization include on-the-job training and apprenticeships. Externalization includes the use of metaphors and analogies to trigger dialogue among individuals. Some of the knowledge is, however, lost in the transfer. To foster such knowledge sharing, organizations should allow for video and desktop conferencing as viable alternatives for knowledge dissemination.

Exploitation and Application

Employee usage of knowledge repositories for purposes of organizational performance is a key measure of the system's success. Knowledge will never turn into innovation unless people learn from it and learn to apply it. The enhanced ability to collect and process data or to communicate electronically does not — on its own — necessarily lead to improved human communication or action (Walsham, 2001). Recently the notion of communities of practice to foster knowledge sharing and exploitation has received widespread attention. Brown and Duguid (1991) argued that a key task for organizations is thus to detect and support existing or emergent communities. Much of knowledge exploitation and application happens in team settings and workgroups in organizations, hence support must be provided. Davis and Botkin (1994) summarize the six traits of a knowledge-based business as follows:

1. The more *they* (customers) use knowledge-based offerings, the smarter *they* get.
2. The more *you* use knowledge-based offerings, the smarter *you* get.
3. Knowledge-based products and services adjust to changing circumstances.
4. Knowledge-based businesses can customize their offerings.
5. Knowledge-based products and services have relatively short life cycles.
6. Knowledge-based businesses react to customers in real time.

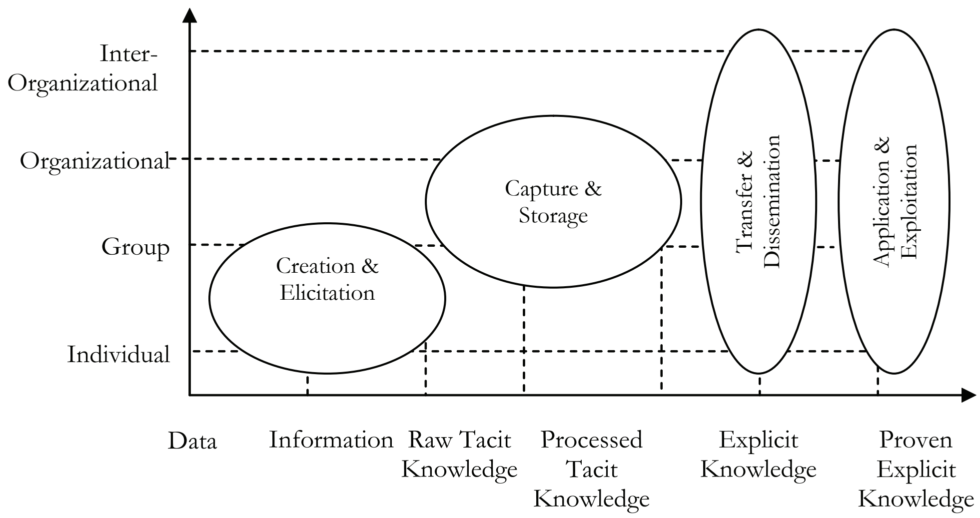
KNOWLEDGE MANAGEMENT IN HOSPITALS

We now apply the generic discussion of knowledge, knowledge management, and the process in the context of healthcare enterprises. For purposes of this chapter, we focus our attention on hospitals, although much of the discussion can be applied to other healthcare enterprises, such as pharmaceutical companies, insurance providers, etc.

Knowledge in Hospitals

In healthcare, we have the presence of both explicit and tacit forms of knowledge. Explicit knowledge is available in medical journals, research reports, and industry publications. Explicit knowledge can be classified under: internal and external. Internal are those that are relevant to the practice of medicine, such as medical journals and research reports. External are legal, governmental, and other publications that do not directly affect patient treatment methodology but govern general medical practices. Three dimensions in health information outlined by Sorthon, Braithewaite and

Figure 2. Staged look at knowledge management



Lorenzi (1997) include management information, professional information, and patient information. Overlap and commonalties are identified, but fundamental differences exist in the types of information required for each dimension, the way the information is used, and the way standards are maintained. The achievement of a comprehensive and integrated data structure that can serve the multiple needs of each of these three dimensions is the ultimate goal in most healthcare information system development. Tacit knowledge is found in the minds of highly specialized practitioners, such as neurosurgeons or cardiac arrest specialists. Much of tacit knowledge resides in the minds of individuals. Seldom does efficient knowledge sharing take place. One exception to this is where practitioners exchange know-how at industry or academic conferences. This, however, happens on an all-too-infrequent basis.

Knowledge Management in Hospitals

In the following section we step through the various stages of the knowledge management process.

Knowledge Creation and Elicitation

Creation and elicitation of knowledge can be handled in one of two modes: controlled or free form. In the controlled scenario, we can have an individual department responsible for overseeing knowledge gathering from the various functional areas. This department can be in lieu of the current medical records department in most hospitals, which are responsible for centrally storing patient information. We can also have a variation in which control is divested to each department. In this method, each department will be responsible for coordinating knowledge-sharing efforts from their constituents. For instance, a person in the pharmaceutical department will be responsible for gathering all knowledge on drugs administered to patients. In the second approach, i.e., free form, each individual is responsible for contributing to the organization's knowledge resource. A strong locus of control is absent. Individuals as end users of organizational resources share equal burden to contribute into the asset. A variation of the free-form strategy can be one in which each group, rather than individuals, are responsible for knowledge creation and sharing. An example would be a group of neurosurgeons that research new knowledge on surgical practices. Each of the above-mentioned strategies has associated pros and cons. For instance, with a controlled strategy, we need to have dedicated individuals responsible for knowledge creation and elicitation from group members. In the free-form strategy, while we do not have the overhead of a dedicated person, we lose a structured knowledge-creation process. Choosing a given strategy is a function of the hospital's resources. Along with soliciting internal knowledge, a hospital should also acquire relevant knowledge from external entities such as government, regulatory bodies, and research organizations. Gathering of external knowledge is crucial for hospitals due to the high nature of external pressures and their involvement in day-to-day operations.

As portrayed in *Figure 2*, knowledge creation and elicitation takes place at the individual and group level. Much of the elements gathered at this stage might be raw data, which after processing, becomes information. Information is then applied on experiences, learned associations, and training of employees to generate knowledge. This knowledge remains in tacit form until it is called upon for sharing with peers. Tacit knowledge stored with employees is raw to a large degree, as it is has not been checked for quality or validated against standards.

The other option in the healthcare industry is to generate knowledge through discovery. Data mining and other statistical techniques can be used to sift through large sets of data, and discover hidden patterns, trends, and associations. For instance, in the medical domain all resources are not only very expensive but also scarce. Optimal planning and usage of them is, hence, not a luxury but a requirement. To illustrate this let us take the case of simple blood units. Annually well over 12 million units of blood are transferred to patients (Clare et al., 1995; Goodnough, Soegiarso, Birkmeyer & Welch, 1993) with a cost-per-unit ranging from $48 to $110 with a national average of $78 (Sheng, 2000; Forbes et al., 1991; Hasley, Lave & Kapoor, 1994). Ordering of excess units of blood for operations is the primary cause of waste and corresponding increases in transfusion costs (Jaffray, King & Gillon, 1991). Blood ordered that is not used takes it out of supply for at least 48 hours (Murphy et al., 1995). Even though blood can be returned, it needs to be tested and routed which costs on average $33. In recent years, supply of blood has been decreasing in recent years due to an aging population and increased complexity of screening procedures (Welch, Meehan & Goodnough, 1992). Given these circumstances, any improvements in blood-need prediction can realize significant benefits. Data mining techniques such as artificial neural networks have been employed to sift through large medical databases and generate predictive models which can better forecast blood transfusion requirements. Kraft, Desouza and Androwich (2002a, 2002b, 2003a, 2003b) examine the discovery of knowledge for patient length-of-stay prediction in the Veterans Administration Hospitals. Once such knowledge is generated, it can be made available to external sources.

Knowledge Capture and Storage

Once gathered, knowledge needs to be captured and stored to allow for dissemination and transfer. Two strategies are common for capture and storage: codification and personalization. The codification strategy is based on the idea that knowledge can be codified, stored and reused. This means that the knowledge is extracted from the person who developed it, is made independent of that person and reused for various purposes. This approach allows many people to search for and retrieve knowledge without having to contact the person who originally developed it (Hansen et al., 1999). Organizations that apply the personalization strategy focus on dialogue between individuals, not knowledge objects in a database. To make the personalization strategies work, organizations invest heavily in building networks or communities of people. Knowledge is shared not only face-to-face, but also by e-mail, over the phone and via videoconferences. In the medical domain, the codification strategy is often emphasized, because clinical knowledge is fundamentally the same from doctor to doctor. For instance, the treatment of an ankle sprain is the same in London as in New York or Tokyo. Hence it is easy for clinical knowledge to be captured via codification and to be reused throughout the organization.

Knowledge capture has been one of the most cumbersome tasks for hospitals. Until rather recently much of the patient knowledge was stored in the form of paper reports and charts. Moreover, the knowledge was dispersed throughout the hospital without any order or structure. Knowledge was also recorded in different formats, which made summarization and storage difficult.

Recently we have seen advancements in the technology of Electronic Medical Records (EMRs). EMRs are an attempt to translate information from paper records into a computerized format. Research is also underway for EMRs to include online imagery and video feeds. At the present time they contain patients' histories, family histories, risk factors, vital signs, test results, etc. (Committee on Maintaining Privacy and Security in Healthcare Applications of the National Information Infrastructure, 1997). EMRs offer several advantages over paper-based records, such as ease of capture and storage. Once in electronic format, the documents seldom need to be put through additional transformations prior to their storage.

Tacit knowledge also needs to be captured and stored at this stage. This takes place in multiple stages. First, individuals must share their tacit know-how with members of a group. During this period, discussions and dialogue take place in which members of a group validate raw tacit knowledge and new perspectives are sought. Once validated, tacit knowledge is then made explicit through capture in electronic documents such as reports, meeting minutes, etc., and is then stored in the knowledge repositories. Use of data warehouses is common for knowledge storage. Most data warehouses do have web-enabled front-ends to allow for optimal access.

Knowledge Transfer and Dissemination

Knowledge in the hospital once stored centrally needs to be made available for access by the various organizational members. In this manner knowledge assets are leveraged via diffusion throughout the organization. One of the biggest considerations here is security. Only authorized personnel should be able to view authorized knowledge. Techniques such as the use of multiple levels of passwords and other security mechanisms are common. However, organizational security measures also need to be in place. Once the authorized users get hold of the knowledge, care should be taken while using such knowledge, to avoid unscrupulous practices. Moreover, employees need to be encouraged to follow basic security practices, such as changing passwords on a frequent basis, destroying sensitive information once used, etc. Ensuring security is a multi-step process. First, the individual attempting to access information needs to be authenticated. This can be handled through use of passwords, pins, etc. Once authenticated, proper access controls need to be in place. These ensure that a user views only information for which he or she has permission. Moreover, physical security should also be ensured for computer equipment such as servers and printers to prevent unauthorized access and theft.

Disseminating healthcare information and knowledge to members outside the organization also needs to be handled with care. Primarily physicians, clinics, and hospitals that provide optimal care to the patients use health information. Secondary users include insurance companies, managed care providers, pharmaceutical companies, marketing firms, academic researchers, etc. Currently no universal standard is in place to govern exchange of healthcare knowledge among industry partners. Hence, free flow of healthcare knowledge can be assumed to a large degree. From a security perspective, encryption technologies should be used while exchanging knowledge over digital networks. Various forms are available such as public and private key encryptions, digital certificates, virtual private networks, etc. These ensure that only the desired recipient has access to the knowledge. An important consideration while exchanging knowledge with external entities is to ensure that patient identifying information is removed or disguised. One common mechanism is to scramble sensitive information such as social security numbers, last and first names. Another consideration is to ensure proper use by partners. Knowledge transferred outside the organization (i.e., the hospital) can be considered to be of highest quality as it is validated multiple times prior to transmittal.

Medical data needs to be readily accessible and should be used instantaneously (Schaff, Wasserman, Englebrecht & Scholz, 1987). The importance of knowledge management cannot be stressed enough. One aspect of medical knowledge is that different people need different views of the data. Let us take the case of a nurse, for instance. He or she may not be concerned with the intricacies of the patient's condition, while the surgeon performing the operation will. A pharmacist may only need to know the history of medicine usage and any allergic reactions, in comparison to a radiologist who cares about which area needs to be x-rayed. Hence, the knowledge management system must be flexible to provide different data views to the various users. The use of intelligent agents can play an important role here through customization of user views. Each specialist can deploy customized intelligent agents to go into the knowledge repository and pull out information that concerns them, thus avoiding the information overload syndrome. This will help the various specialists attend to problems more efficiently instead of being drowned with a lot of unnecessary data. Another dimension of knowledge management is the burden put on specialists. A neurosurgeon is paid twice as much, if not more, than a nurse. Hence, we should utilize their skills carefully to get the most productivity. Expert systems play a crucial role here in codifying expertise/knowledge. When a patient comes for treatment, preliminary test and diagnosis should be handled at the front level. Expert systems help by providing a consultation environment whereby nurses and other support staff can diagnose illness and handle basic care, instead of involving senior-level doctors and specialists. This allows for the patients that need the care of experts to receive it and also improves employee morale through less stress.

Knowledge Application and Exploitation

The last stage, and the most important, is the application and exploitation of knowledge resources. Only when knowledge stored is used for clinical decision-making does the asset provide value. As illustrated in *Figure 3*, knowledge application and exploitation should take place at all levels from the individual to inter-organizational efforts. We draw a distinction here between application and exploitation. Applications are predefined routines for which knowledge needs are well defined and can be programmed. For instance, basic diagnosis when a patient first enters the hospitals, these efforts include calculation on blood pressure, pulse rates, etc. Knowledge needed at this level is well defined and to a large extent is repetitive. On the other hand, exploitation calls for using knowledge resources on an ad-hoc basis for random decision-making scenarios. For instance, if a hospital wants to devise an optimal nurse scheduling plan, use of current scheduling routines, plus knowledge on each individual's skill sets can be exploited for devising the optimal schedule. Decisions like these, once handled, seldom repeat themselves on a frequent basis.

With knowledge management being made easy and effective, quality of service can only increase. A nurse, when performing preliminary tests on a patient, can provide them with better information on health issues through consultation with an expert system. Primary care doctors normally refer patients for hospital care. Some of the primary care doctors may work for the hospital (Network) and the rest are independent of the hospital (Out-of-Network). Today there are a lot of inefficiencies associated with referring patients to hospitals. If a patient is referred, he or she has to contact the hospital personnel who then first take in all patient information and then schedule an appointment. The normal wait time can be any where from one to four weeks depending on seriousness. With the Internet revolution today, all patients, doctors, and hospitals can improve the process tremendously through the deployment of dedicated intelligent agents. Each doctor can be provided with a log-on and password to the hospital's web site. Upon entry to the web site, the doctor can use search agents to browse through appointment schedules, availability of medical resources, etc. These agents can then schedule appointments directly and electronically receive all documentation needed. Hospitals within a certain location can set up independent networks monitored by agents whereby exchange of medical knowledge and resources can take place. Patients can use search agents to browse through hospital web sites, request prescriptions, learn about medical treatments, view frequently asked questions, etc. Intelligent agents can also be trained to learn patient characteristics. Once this takes place, they can be deployed to monitor various medical web sites and send relevant information to the patient in the form of e-mails. Expert systems can be deployed to help the user navigate through the various knowledge bases through recommendations. If a user chooses the main category of "common cold," the expert system can ask for symptoms, suggest medications, etc. Patients can then use these notifications to improve the quality of their health. Intelligent agents also help in improving quality of service through providing only relevant decision-making information. Personnel can then act quickly and reduce time lags. An added benefit of a successful knowledge management system is less burden and stress on personnel. Hospitals are characterized for being highly stressful and always "on pins and needles" when it comes to employees. Through artificial intelligence, much of the routine details can be automated. This reduces the burden on personnel. Also, specialists and highly valued personnel can concentrate efforts on selected matters, the rest can be handled by junior level staff and intelligent systems. This makes for a more welcoming atmosphere.

IMPENDING BARRIERS TO KNOWLEDGE MANAGEMENT

The medical field has to overcome a few hurdles in order to realize the potential benefits of open connectivity for knowledge sharing among the partners of the supply chain and internal personnel such as doctors, surgeons, nurses, etc. We now highlight three of the most prominent issues:

Unified Medical Vocabulary

The first barrier is the development of a unified medical vocabulary. Without a unified vocabulary, knowledge sharing becomes close to impossible. There is diversity of vocabulary used by medical professionals, which is a problem for information retrieval (Lindberg, Humphreys & McCray, 1993). There are also differences in terminology used by various biomedical specialties, researchers, academics, and variations in information accessing systems, etc. (Houston, 2000). To make matters more complex, expertise among users of medical information also varies significantly. A researcher in neuroscience may use precise terminology from the field, whereas a general practitioner may not. Medical information also must be classified differently based on tasks. Researchers may need information summarized according to categories, while a practitioner or doctor may need patient-specific details that are accurate (Forman, 1995).

To help bridge some of the gap in terminology, we have two main medical thesauri in use. Medical Subject Headings (MeSH) and Unified Medical Language System (UMLS) are meta-thesauri developed by the National Library of Medicine (NLM) (Desouza, 2001). UMLS was developed in 1986 and has four main components: meta-thesaurus, specialist lexicon, semantic net, and information sources map. The meta-thesaurus is the largest and most complex component incorporating 589,000 names for 235,000 concepts from more than 30 vocabularies, thesauri, etc. (Lindberg et al., 1993). Approaches to organizing terms include human indexing and keyword search, statistical and semantic approaches. Human indexing is ineffective as different experts use varying concepts to classify documents, plus it is time-consuming for large volumes of data. The probability of two people using the same term to classify a document is less than 20% (Furnas, Landauer, Gomez & Dumais, 1987). Also different users use different terms when searching for documents. Artificial Intelligence-based techniques are making headway in the field of information retrieval. Houston et al. (2000) used a Hopfield network to help in designing retrieval mechanism for the CANCERLIT study. The issue of standardization of terminology continues to be a great debate. The Healthcare Financing Association (HCFA) is adopting some Electronic Data Interchange (EDI) standards to bring conformity to data (Moynihan, 1996). We can expect more standards to be released in the next few years to enable sharing of data.

Security and Privacy Concerns

With sharing of data comes the inherent risk of manipulation and security issues. Security of patients' data and preventing it from entering the wrong hands are big concerns in the field (Pretzer, 1996). Strict controls need to be put in place before open connectivity can take place. Patients' data are truly personal and any manipulation or unauthorized dissemination has grave consequences. Sharing of patient-identifiable data between members of the healthcare supply chain members is receiving serious scrutiny currently. Government and other regulatory bodies will need to set up proper laws to help administer data transmission and security (Palmer et al., 1986). The recent Health Insurance Portability and Accountability (HIPPA) Act can be seen as one of many governmental interventions into the healthcare industry for the protection of consumer privacy rights. Enterprises will have to go to the basics of ethics and operate carefully.

Organizational Culture

In every organization we can see the application of the 20/80 rule. Knowledge providers make up 20% of the workforce, as they possess experiences and insights that are beneficial to the organization. The remaining 80% are consumers of this knowledge (Desouza, 2002a). The providers are often reluctant to share and transfer knowledge as they fear doing so will make them less powerful or less valuable to the organization (Desouza, 2003a, 2003b). Between departments we also find knowledge barriers, in which one group may not want to share insights collected with the other. To help alleviate some of these issues, management should strive to provide incentives and rewards for knowledge-sharing practices. A highly successful approach is to tie a portion of one's compensation to group and company performance, thus motivating employees to share knowledge to ensure better overall company performance. Additionally, Foucault (1977) noted the inseparability of knowledge and power, in the sense that what we know affects how influential we are, and vice versa our status affects whether what we know is considered important. Hence, to alleviate this concern, an enterprise-wide initiative should be carried out making any knowledge repository accessible to all employees without regard to which department or group generated it.

A key dimension of organizational culture is leadership. A study conducted by Andersen and APQC revealed that one crucial reason why organizations are unable to effectively leverage knowledge is because of a lack of commitment of top leadership to sharing organizational knowledge or there are too few role models who exhibit the desired behavior (Hiebeler, 1996). Studies have shown that knowledge management responsibilities normally fall with middle managers, as they have to prove its worth to top-level executives. This is a good and bad thing. It is a good thing because normally middle-level managers act as liaisons between employees and top-level management, hence they are best suited to lead the revolution due to their experience with both frontline, as well as higher-level authorities. On the other hand it is negative, as top-level management does not consider it important to devote higher-level personnel for the task. This is changing, however. Some large companies are beginning to create the position of chief knowledge officer, which in time will become a necessity for all organizations. A successful knowledge officer must have a broad understanding of the company's operation and be able to energize the organization to embrace the knowledge revolution (Desouza & Raider, 2003). Some of the responsibilities must include setting up knowledge management strategies and tactics, gaining senior management support, fostering organizational learning, and hiring required personnel.

It is quite conceivable that healthcare enterprises will start creating the positions of chief knowledge officers and knowledge champions. Top management involvement and support for knowledge management initiatives cannot be underestimated. This is of pivotal importance in hospitals, as their key competitive asset is medical knowledge.

CONCLUSIONS

Some researchers and practitioners have expressed concern about knowledge management being a mere fad (Desouza, 2003b). To deliver promised values, knowledge management must address strategic issues and provide for competitive advantages in enterprises. McDermott (1999) noted that companies soon find that solely relying on the use of information technology to leverage organizational knowledge seldom works. The following chapter has introduced knowledge management and its process. We have also applied it to healthcare enterprises focusing on hospitals. Finally, we justified the knowledge management process by looking through two main strategic frameworks.

Knowledge management initiatives are well underway in most healthcare enterprises, and we can expect the number and significance of such efforts to increase over the next few years. Areas of future and continued research include: automated search and retrieval techniques for healthcare information, intelligent patient monitoring systems, and optimal knowledge representation semantics.

Chapter 1.19
An Overview of Efforts to Bring Clinical Knowledge to the Point of Care

Dean F. Sittig
Medical Informatics Department, Kaiser Permanente Northwest, USA
Care Management Institute, Kaiser Permanente, USA
Oregon Health & Sciences University, USA

ABSTRACT

By bringing people the right information in the right format at the right time and place, state of the art clinical information systems with imbedded clinical knowledge can help people make the right clinical decisions. This chapter provides an overview of the efforts to develop systems capable of delivering such information at the point of care. The first section focuses on "library-type" applications that enable a clinician to look-up information in an electronic document. The second section describes a myriad of "real-time clinical decision support systems." These systems generally deliver clinical guidance at the point of care within the clinical information system (CIS). The third section describes several "hybrid" systems, which combine aspects of real-time clinical decision support systems with library-type information. Finally, section four provides a brief look at various attempts to bring clinical knowledge, in the form of computable guidelines, to the point of care.

To be effective, (clinical decision support) tools need to be grounded in the patient's record, must use standard medical vocabularies, should have clear semantics, must facilitate knowledge maintenance and sharing, and need to be sufficiently expressive to explicitly capture the design rational (process and outcome intentions) of the guideline's author, while leaving flexibility at application time to the attending physician and their own preferred methods. (Shahar, 2001)

INTRODUCTION

By bringing people the right information in the right format at the right time and place, informatics helps people make the right clinical decisions. Cumulatively, these better decisions improve health outcomes, such as quality, safety, and the cost-effectiveness of care. This improvement has been a mantra of informatics at least since the landmark article by Matheson and Cooper in 1982. This chapter provides an overview of the efforts over the years to develop systems capable of delivering such information at the point of care. Such an overview should help illustrate both the opportunities and challenges that lie ahead as we struggle to develop the next generation of real-time clinical decision support systems for use at the point of care.

VISION TO ACHIEVE

The ultimate goal is to provide patient-specific, evidence-based, clinical diagnostic and therapeutic guidance to clinicians at the point of care; this guidance should be available within the clinical information system (CIS) that defines their current workflow. In addition, we must have the tools necessary to enable clinicians, without specialized programming knowledge, to enter, review, and maintain all the clinical knowledge required to generate this advice. Finally, we must have the ability to rapidly change the clinical knowledge, test it, and make it available to clinicians without having to wait for a regular CIS updating schedule.

Questions That Must Be Answered Prior to Creating Such Systems

What information or knowledge is required to help the clinician make the right decision to achieve the desired health outcome?

Who will be the information's recipient (e.g., physician, nurse, pharmacist, or even a specific individual such as the patient's primary care physician)?

When in the patient care process is the intervention applied, for example, before, during (which can be broken down into sub-activities such as order entry or progress note creation) or after the patient encounter?

How is the intervention triggered and delivered? For example, does the system or the clinician initiate it? How much patient-specific data (if any) is needed to trigger system-initiated interventions? How much is the intervention output customized to the clinical workflow stage, the clinician, and or the patient? For system-initiated interventions, how can the threshold be set to minimize nuisance alerts? How intrusive should the information be (Krall, 2001)?

Will the clinicians find the information useful (Krall, 2002a, 2002b)? What can we do to minimize the number of false positive alerts?

Where will the clinician be when receiving the intervention, for example, with the patient at the bedside or in the office? What should happen if the information becomes available at some future point when the clinician is no longer with the patient to whom the information pertains?

Which medium will be used to convey the message, for example, e-mail inbox, wireless and/or handheld device, pager, CIS/CPOE screen, or printed pre-visit encounter sheet?

Is there a demonstrable return on investment (ROI) that is due exclusively to the clinical decision support intervention or feature?

BACKGROUND

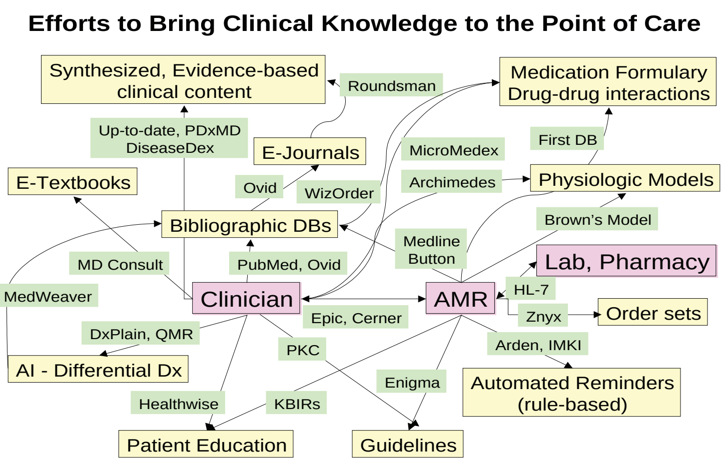
Where Do We Stand?

Numerous attempts have been made to bring various forms of clinical information to the clinician at the point of care. One way to solve this problem is to develop computer applications that stand alone, although often network accessible, and are available to the clinician upon his/her request. Another way is to incorporate the clinical knowledge directly into the clinical information system used by clinicians while giving care. Once it is there, the CIS system can automatically prompt the clinician or the clinician can request help. Recently, a third model for system development has been proposed that enables the clinician to request help from an outside source. Often several patient-specific data items are included in the request. Using such a system, a clinician is still completely in-charge of making the request for information and the information can be automatically configured based on a subset of patient information (Cimino, 1996). In addition, it is now possible to embed medication or procedure codes along with instructions that tell the CIS how to handle this information that allows a clinician to place an order directly into the patient's electronic medical record from the externally available information resource (Tang & Young, 2000).

The following diagram (Figure 1) is an attempt to illustrate both the key types of information or knowledge that investigators have focused on along with their mode of interaction [i.e., directly to the clinician or through the clinical information system (CIS)]. The boxes (yellow) represent the type of knowledge and the labels on the links (green) represent some of the key projects or concepts vendors have focused on this particular form of clinical decision support. The aim of this figure is to highlight the myriad attempts that have been made to develop clinical knowledge management applications and to help everyone understand how different clinical knowledge resources and applications are both related in terms of what they are trying to accomplish and different in the resources they utilize. Although this diagram is fairly complex, it is only a small, imperfect and incomplete representation of the entire clinical decision support landscape.

The following sections briefly review each of the projects or concepts. The first section focuses on "library-type" applications that enable a clinician to look up information in an electronic document. The second section describes a myriad of "real-time clinical decision support systems". These systems generally deliver clinical guidance to clinicians at the point of care within the CIS. The third section describes several "hybrid" systems, which combine aspects of knowledge-based

Figure 1. An overview of the numerous efforts researchers have made to bring pertinent clinical knowledge to clinicians at the point of care



clinical decision support systems with library-type information. Finally, section four looks at various attempts to bring clinical knowledge in the form of computable guidelines to the point of care.

LIBRARY-TYPE APPLICATIONS: FRONT-ENDS TO APPLICATIONS THAT DIRECTLY INTERACT WITH CLINICIANS

Bibliographic Databases (DBs)

Biomedical bibliographic databases contain on the order of millions of records, each representing a unique scientific journal article that has been published. Each record typically contains the title of the article, the authors, their affiliation(s), and the abstract of the article. In addition, several metadata tags may have been applied by human indexers to improve the likelihood that each document will be retrieved when and only when it is relevant to the user's query.

For the last 30 years, the National Library of Medicine has maintained the MedLine database, the most common bibliographic database used in clinical medicine. During that period, various attempts have been made to develop easy to use and reliable interfaces to this vast resource including Grateful Med (Cahan, 1989) and COACH (Kingsland, 1993). Currently, PubMed is the most widely used of all these interfaces. PubMed relies on a sophisticated free-text query processor to map freetext user queries to MeSH terms, when appropriate, and returns a highly relevant set of documents.

In addition to PubMed, several commercial vendors have created proprietary interfaces to the MedLine database in an attempt to improve either the recall or precision of the user's queries. For example, Ovid has developed an interesting MeSH mapper and query expander that has gathered outstanding reviews from highly trained librarians. Knowledge Finder has developed a fuzzy mapping algorithm that has also generated some good reviews. Unfortunately, none of these systems consistently enables clinicians to retrieve more than half of all the relevant articles on any particular topic (Hersh, 1998). In addition to these variations on a search interface, several projects have used automated differential diagnosis generators, such as DxPlain, as an interface to the bibliographic DBs. Finally, the Science Citation Index uses the reference list at the end of every scientific article published to generate linked lists of references. Such a scheme can also identify particularly noteworthy articles since these articles are referenced many more times. Interestingly, the Google search engine uses this same concept to generate its index of relevant web sites. It does this by keeping track of the number and quality of referring web sites rather than references at the end of the article (Brin, 1998).

Other Clinical Reference Materials

In addition to access to the bibliographic literature, clinicians could use other clinical reference information. For example, various systems exist to provide clinicians with access to the complete text and figures contained in textbooks (e.g., MD Consult) or journals (e.g., Ovid) in electronic form. In addition, several commercial companies have begun developing synthesized, evidence-based clinical summaries of the diagnosis and treatment of common clinical conditions [e.g., Up-to-Date, CliniAnswers, DiseaseDex, PDxMD (see http://www.informatics-review.com/KnowMan/Examples.html for other examples)].

REAL-TIME CLINICAL DECISION SUPPORT SYSTEMS

Real-time clinical decision support systems (RCDSS) are fundamentally different from "library" applications in that they interact with the clinician through the CIS. Rather than relying on the user to interpret the text and then make a decision, RCDSS combine the patient's clinical data with the clinical knowledge to help the clinician reach a decision. At least six distinct methods can provide this type of RCDSS:

1. Medication formularies and drug-drug interaction checkers provide routine checks of all orders entered into the EMR. They can recommend alternative medications based on the formulary and check for potential drug-drug interactions automatically following entry of a medication order assuming they have access to the patient's list of current medications. FirstDataBank, Micromedex, and Multum are examples of commercial providers of drug-drug interaction checking databases.
2. Automated rule-based reminders are used most commonly to remind clinicians to perform routine health maintenance procedures. The Arden syntax is currently the only "standard" means of encoding these rule-based systems (Arden, 2003). The Institute for Medical Knowledge Interchange (IMKI), another recent entry into this field (IMKI, 2003), recently scaled back their operations while they seek additional funding and support.
3. Condition-specific order sets and charting templates help clinicians remember and facilitate the entry of all related orders or answers to questions asked of a patient with a particular condition. Zynx, a recently formed company, is developing these ready-to-use, condition-specific order sets. In addition, most of the commercially available CISs either offer ready-to-use order sets or provide tools to help clinicians construct these order sets (Franklin, Sittig, Schmiz, Spurr, Thomas, O'Connell, & Teich, 1998).
4. Integrated clinical guidelines allow a clinician to compare a specific patient's clinical data against a guideline and automatically receive a recommendation. The most advanced example of this type of application is Enigma's PREDICT application. In an early attempt to develop this sort of functionality, Epic Systems created their "Active Guidelines" application. A major distinguishing feature between the Active Guidelines (AG) effort and that of Enigma is that the AG user is still required to search for, read, interpret, and then decide which portion of the large, text-based guideline document applies to a specific patient and then select the appropriate recommendation. Enigma's PREDICT automatically does all of this work and simply presents the clinician with the appropriate suggestions. Another recent entry into this market space is Theradoc, a small company located in Salt Lake City, Utah (www.theradoc.com).
5. Complex, physiologic models incorporate our best current understanding of human physiology along with evidence-based results of randomized clinical trials to generate patient- or population-specific predictions of future events. Archimedes, a complex model of diabetes and the entire healthcare system, is currently configured to allow specially trained clinicians to access this resource (Schlessinger, 2002). Jonathan Brown, from Kaiser Permanente's Center for Health Research in Portland, has recently begun working on a method to automatically link therapeutic suggestions generated by his Global Diabetes Model to a specific patient's clinical data from an EMR or clinical data warehouse (Brown, 2000).
6. Artificial Intelligence (AI) systems have been developed to help clinicians complete their differential diagnosis list. To date these systems have not had wide-spread acceptance by clinicians, even though they have been shown to be at least as good and often better than un-aided clinicians (Bankowitz, 1989; Berner, 1994). DxPlain, QMR,

and Weed's Problem Knowledge Couplers (Weed, 1986) are the best examples of these types of systems.

HYBRID APPLICATIONS

In addition to each of these fairly straightforward attempts to link clinical knowledge to the point of patient care, several companies have attempted to combine various clinical knowledge resources and applications to generate even more useful applications. MedWeaver (Detmer, 1997) was an early attempt to combine DxPlain, an AI-based differential diagnosis (DDx) system with a bibliographic database. The DDx in conjunction with the Unified medical Language system (UMLS) act as an automatic query expander and presents the user with information related to all the known items on the patient's differential diagnosis.

Geissbuhler and Miller (1998) developed WizOrder, a system to automatically generate potential drug-drug interaction reminders when clinicians order medication through the system. These reminders are based on the co-occurrence of clinical term frequencies[1] that are a part of the UMLS's Metathesaurus database. Rennels, Shortliffe, Stockdale, and Miller (1987) developed Roundsman, a prototype system, to automatically extract evidence-based recommendations from on-line structured journal articles.

Cimino (1996) developed the concept of the "InfoButton" which allows a clinician to automatically generate queries to a variety of clinical information resources to answer a set of generic concept-specific questions such as, "What's the treatment for X?", where X can be any clinical condition. Recently, the HL-7 Clinical Decision Support Task Force has begun efforts to develop a standard for such queries.

COMPUTABLE GUIDELINES

Current State of the Art

Various research and commercial efforts are underway in an attempt to create systems to achieve the vision outlined above. The distinguishing feature of computable guideline systems is that they are more than a simple application of "if-then-else" rules to generate alerts and reminders at the point-of-care. All of the systems described below are attempting to go one step further with multi-step clinical algorithms at the point-of-care. The more complex algorithms attempt to track a patient's treatments and progress over time, while the alerts and reminders serve only to look at what is best at each point in time. Therefore, I did not include the efforts of the Institute for Medical Knowledge Interchange (IMKI) or the Arden group to create libraries of rules and systems to facilitate their incorporation in various clinical information systems.

The following sections overview several attempts and describe which parts of the vision they either have or are currently focusing on. I also point out the strengths and weaknesses of each approach.

ACADEMIC RESEARCH EFFORTS

GLEE is a system for execution of guidelines encoded in the Guideline Interchange Format v3 (GLIF3) (Wang, 2002). GLEE provides an internal event-driven execution model that can be hooked up with the clinical event monitor of a local clinical information system environment. It was developed at Columbia University and is currently only a research prototype. No tools exist for knowledge maintenance other than those proposed by the GLIF3 organization.

GLARE (GuideLine Acquisition, Representation and Execution) is a domain-independent system for the acquisition, representation and execution of clinical guidelines (Terenziani, 2001). GLARE provides expert physicians with an "intelligent" guideline acquisition interface. The interface has different types of checks to provide a consistent guideline: syntactic and semantic tests verify whether or not a guideline is well-formed. GLARE technology has been successfully tested in different clinical domains (bladder cancer, reflux esophagitis, and heart failure), at the Laboratorio di Informatica Clinica, Azienda Ospedaliera S. Giovanni Battista, Torino, Italy. Currently, this application is not available for use by people outside of the research team. See: www.openclinical.org/gmm_glare.html#aimj01

COMMERCIAL VENDORS

Therapy Edge (http://www.therapyedge.com/) is a condition-specific, stand-alone, web-based, EMR with extensive clinical decision support for HIV patients. It is a stand-alone tool, that is, it has no integration with the existing CIS; it is only for HIV patients; and has no tools for knowledge based maintenance.

PRODIGY is a guideline-based decision support system in use by a large number of General Practitioners in the United Kingdom (Purves, 1999). The evaluation of PRODIGY 3 is currently underway and Phase 4 is being planned. PRODIGY I and PRODIGY II were implemented as extensions to proprietary UK electronic patient record systems. The PRODIGY system includes a proprietary guideline model, which in PRODIGY II was used to implement guidelines for the management of acute diseases. See: http://www.prodigy.nhs.uk/ClinicalGuidance/ReleasedGuidance/GuidanceBrowser.asp for a demo.

PREDICT is a decision support system for delivering evidence-based care directly to clinical practitioners desktops or handhelds. PREDICT integrates with existing clinical information systems using standard internet communication protocols, and allows clinicians to create new disease modules and manage their own guideline content. See: http://www.enigma.co.nz/framed_index.cfm?fuseaction=ourknowledge_products for more info.

eTG complete is an easy-to-use, HTML-based product, available for use on stand alone or networked PC or Mac computers. It covers over 2000 clinical topics and will be updated at regular intervals (three to four times per year). They do not even mention the possibility of integrating their work with any commercially available EMR products. See: http://www.tg.com.au/complete/tgc.htm for an online demonstration. This is just one of many examples of stand-alone, proprietary format, internet-based, guideline presentation systems. In my opinion, none of these are significantly better than what the USA's National Guideline Clearinghouse (www.guideline.gov) or the New Zealand Guidelines Group (www.nzgg.org.nz) are doing by simply creating a large database of clinical guidelines that are arranged by clinical condition.

AREZZO is a decision support technology (based on PROforma), for building and running clinical applications. AREZZO applications are designed to provide patient-specific advice, guiding the user through data collection, clinical actions and decision making. Applications can be quickly modeled and tested, using the AREZZO Composer, and instantly deployed on the Internet. AREZZO is capable of supporting the development of multi-disciplinary care pathways (customized for local circumstances); its safety-critical and task-based features support the rigor needed for clinical protocols. Currently the system is limited to supporting decisions on pain control in cancer, but this will be expanded in the future to include pain control in much more general terms (for example, arthritis, chronic pain, etc.) See: http://www.infermed.com/ds_arnocs.htm for more information.

SUMMARY AND CONCLUSIONS

Library-type applications that provide users with easy access to the latest medical knowledge in the form of journal articles or textbooks will not be going away in the near future. Even with our increasing understanding of how to build intelligent computer systems that can recognize the current patient context and suggest potentially relevant clinical information resources, the users must still have a means of getting directly to the knowledge resources so they can look up additional information. Therefore, work based on the Medline Button, as described by Cimino (1996) must continue. In fact, an effort is now underway within the HL-7 Clinical Decision Support Technical Committee to develop a standard interface that will facilitate further development of these types of applications.

The use and utility of real-time clinical decision support systems (RCDSS) will continue to grow exponentially. As more and more pressure is placed on clinicians to practice evidenced-based medicine and do it as inexpensively as possible, these RCDSSs will proliferate. A recent publication by the Health Information Management Systems Society (HIMSS) entitled, the "Clinical Decision Support Implementers' Workbook" is now freely available on the internet (Osheroff, 2004). This workbook and others should lead to increased use of various clinical decision support systems. Although little work is currently underway on the development of new hybrid systems, I believe that these types of systems will soon reappear and provide users with significant additional functionality that cannot be achieved using any other means. Finally, as healthcare delivery systems choose and implement commercially available clinical information systems, clinicians and researchers alike could gain valuable knowledge by beginning work on various clinical knowledge management projects with one or more of the vendors or research groups listed above. At the present time, this field has no clear-cut winner. In fact, no system is beyond the advanced research prototype stage. As such, there will be considerable changes in whichever solution is ultimately successful. I believe it is in everyone's best interest to be a part of the effort in defining and experimenting with these types of systems. Only then will we truly understand what is really useful and how we should proceed.

ACKNOWLEDGMENTS

I would like to thank Jerry Osheroff, M.D. for his comments on an early draft of this paper. A preliminary version of this chapter was presented at a health informatics conference in Auckland, New Zealand (2003).

ENDNOTE

1. The UMLS contains the co-occurrence relationships for the number of times concepts have co-occurred as key topics within the same articles, as evidenced by the Medical Subject Headings assigned to those articles in the MEDLINE database. Co-occurrence relationships have been also computed for different ICD-9-CM diagnosis codes assigned to the same patients as reflected in a discharge summary database. In contrast to the relationships asserted within source vocabularies, the statistical relationships in the Metathesaurus can connect very different concepts, such as diseases and drugs. There are specific Metathesaurus files for the co-occurrence relationships (MRCOC. RRF and MRCOC in ORF).

Chapter 1.20
Issues in Clinical Knowledge Management:
Revisiting Healthcare Management

Raouf Naguib
Coventry University, UK

ABSTRACT

The objective of this chapter is to examine some of the key issues surrounding the incorporation of the Knowledge Management (KM) paradigm in healthcare. We discuss whether it would it be beneficial for healthcare organizations to adopt the KM paradigm so as to facilitate effective decision-making in the context of healthcare delivery. Alternative healthcare management concepts with respect to their ability in providing a solution to the above-mentioned issue are reviewed. This chapter concludes that the KM paradigm can transform the healthcare sector.

INTRODUCTION

In today's information age, data has become a major asset for healthcare institutions. Recent innovations in Information Technology (IT) have transformed the way that healthcare organizations function. Applications of concepts such as Data Warehousing and Data Mining have exponentially increased the amount of information to which a healthcare organization has access, thus creating the problem of "information explosion". This problem has been further accentuated by the advent of new disciplines such as Bioinformatics and Genetic Engineering, both of which hold very promising solutions which may significantly change the face of the entire healthcare process from diagnosis to delivery (Dwivedi, Bali, James, Naguib, & Johnston, 2002b).

Until the early 1980s, IT solutions for healthcare used to focus on such concepts as data warehousing. The emphasis was on storage of data in an electronic medium, the prime objective of which was to allow exploitation of this data at a later point in time. As such, most of the IT applications in healthcare were built to provide support for retrospective information retrieval needs and, in some cases, to analyze the decisions undertaken. This has changed healthcare institutions' perspectives towards the concept of utility of clinical data. Clinical data that was traditionally used in a supportive capacity for historical purposes has today become an opportunity that allows healthcare stakeholders to tackle problems before they arise.

Healthcare Management Concepts

Healthcare managers are being forced to examine costs associated with healthcare and are under increasing pressure to discover approaches that would help carry out activities better, faster and cheaper (Davis & Klein, 2000; Latamore, 1999). Workflow and associated Internet technologies are being seen as an instrument to cut administrative expenses. Specifically designed IT implementations such as workflow tools are being used to automate the electronic paper flow in a managed care operation, thereby cutting administrative expenses (Latamore, 1999).

One of the most challenging issues in healthcare relates to the transformation of raw clinical data into contextually relevant information. Advances in IT and telecommunications have made it possible for healthcare institutions to face the challenge of transforming large amounts of medical data into relevant clinical information (Dwivedi, Bali, James, & Naguib, 2001b). This can be achieved by integrating information using workflow, context management and collaboration tools, giving healthcare a mechanism for effectively transferring the acquired knowledge, as and when required (Dwivedi, Bali, James, & Naguib, 2002a).

Kennedy (1995, p. 85) quotes Keever (a healthcare management executive) who notes that "Healthcare is the most disjointed industry…in terms of information exchange... Every hospital, doctor, insurer and independent lab has its own set of information, and … no one does a very good job of sharing it." From a management perspective, these new challenges have forced healthcare stakeholders to look at different healthcare management concepts that could alleviate the problem of information explosion. The following are some of the new paradigms and concepts that have caught the attention of healthcare stakeholders.

EVIDENCE BASED MEDICINE (EBM)

EBM is defined as the "conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients" (Cowling, Newman, & Leigh, 1999, p. 149). A typical EBM process starts with an identification of knowledge-gaps in current healthcare treatment processes, followed by a search for the best evidence. This is then succeeded by a process to aid in the selection of appropriate electronic data/information sources and IT applications that focus on clinical competencies in the context of the best evidence generated.

The next step is to carry out a critical appraisal of the best evidence identified by carrying out checks for accuracy and diagnostic validity of the procedure/treatment identified by the best evidence generated. The costs and benefits of alternative procedures (i.e., the current best evidence procedure/treatment being recommended) are then considered. The last step is its application to patients' healthcare which calls for integration of the best evidence with the General Practitioners' (GP) clinical expertise so as to provide best treatment and care (Cowling et al., 1999).

MODEL OF INTEGRATED PATIENT PATHWAYS (MIPP/IPP)

Schmid and Conen (2000) have argued that the model of integrated patient pathways (MIPP/IPP) is a more comprehensive concept for healthcare institutions. As the acronym suggests, IPPs aim to enable better support for healthcare institutions by focusing on the creation of clinical guidelines for commonly accepted diagnostic and therapeutic procedures at a defined level of quality. This would lead to cost-efficient treatment. It could be argued that IPP calls for in-house development of standardized clinical treatment procedures for some pre-defined diagnoses and treatments.

Schmid & Conen (2000) elaborate that IPP aims to ensure that patients receive the right treatment which is based upon best practice guidelines that have sufficient evidence to warrant the label of "best practice" and which have been proven to be clinically adequate. They argue that when a hospital tries to implement IPP, it will automatically go through a circular chain process that calls for identifying sources of best practice, converting them to worldwide implementation practices and then, based upon their performance, converting them to benchmarks. Deliberation on current health reform is centered on two competing objectives: expanding access and containing costs. The challenge is to find an acceptable balance between providing increased access to healthcare services while at the same time conserving healthcare resources.

Pryga and Dyer (1992) have noted that, in the USA, hospitals receive a fixed amount per patient for each Medicare patient admission. As such, they have an objective of providing essential medical services whilst physicians are remunerated on the basis of the clinical service provided. The situation emerges where the physician and healthcare managers can have conflicting goals; such a dilemma is bound to affect formulation of best care practices particularly for preventive care.

CLINICAL GOVERNANCE (CG)

Clinical governance (CG) was first introduced in the UK by way of a National Health Service (NHS) white paper (Firth-Cozens, 1999) and calls for an integrated approach to quality, team development, clinical audit skills, risk management skills, and information systems. A typical CG process can be delineated into a sequential process that calls for (a) the means to disseminate knowledge about relevant evidence from research, (b) best treatments rather than focusing just on recognition of poor treatments, (c) better appreciation of what IT led solutions can do for clinical governance, and (d) knowing what data/information is available so as to provide baselines for best care and treatments.

Melvin, Wright, Harrison, Robinson, Connelly, and Williams (1999) have remarked that the NHS has witnessed the incorporation and development of many approaches that support and promote effective healthcare, but in practice, none of them have been successful. Research by Zairi and Whymark (1999) submits that the problem lies in the lack of proper systems to support the measurement of organizational effectiveness (i.e., clinical) in a healthcare delivery context.

According to Sewell (1997), one of the biggest challenges in having concise summaries of the most effective clinical practices is establishing what is meant by "quality in healthcare" (i.e., a measurement standard for clinical effectiveness). Sewell (1997) elaborates that measurement standards in clinical practice will change from each context and that this is attributed to the linkage between measurement standards and values and the expectations of the individual healthcare stakeholders (which, in turn, originate from the shared values and expectations to which all the healthcare stakeholders subscribe).

Melvin, et al. (1999) have noted that, in the UK, the NHS has started to support the concept of clinical governance by identifying individual best effective clinical practices. This process provides concise summaries of the most effective clinical practices in all key clinical areas. Summaries that are successfully substantiated are then disseminated throughout the NHS. Sewell (1997) has noted that the USA, Canada, Australia and New Zealand have adopted a formal accreditation system for the healthcare sector based upon the ISO 9000 approach.

COMMUNITY HEALTH INFORMATION NETWORKS (CHIN)

Modern day healthcare organizations have realized that in the future their survival would depend upon their ability to give the caregiver access to such information that would enable the caregiver to deliver personalized clinical diagnosis and treatment in real-time in very specific clinical contexts, a process termed Information Therapy (Dwivedi et al., 2002a). This vision has been translated into concepts such as Integrated Delivery System (IDS) and Community Health Information Networks (CHIN) (Lang, 1997; Mercer, 2001; Morrissey, 2000).

IDS refers to a Healthcare Information System (HIS), a business model based on computing technologies such as Object Orientation (OO) "to share key data, with partners and providers, that will allow faster and more accurate decision making … to deliver care to a broader population with fewer requirements for expensive and scarce resources" (Lang, 1997, p.18).

CHINs are integrated healthcare institutions based upon a combination of different technology platforms connected to enable support for data sharing amongst different healthcare providers (Mercer, 2001). Both IDS and CHIN are very similar in nature and both refer to an integrated network for allowing the delivery of personalized healthcare. CHINs were founded on the premise that patient information should be shared by competitors (Morrissey, 2000). The main aim of CHIN was to enable hospitals and other healthcare stakeholders to electronically exchange patient encounter summaries and medical records between emergency departments and related departments.

Another factor responsible for emphasis on CHIN was the perception in the healthcare industry that, for small-scale players to survive as individual entities, it was essential for them to form some sort of technological alliances (Huston & Huston, 2000). The original technological objective of CHIN was to enhance data-sharing capabilities amongst different healthcare stakeholders. The original technological infrastructure supported the creation of "point to point" connections. This did not succeed primarily due to limitations in technology coupled with the high amount of financial resources required to establish the "point to point" technological infrastructure (Morrissey, 2000).

The objective behind the incorporation of the CHIN concept is that it allows users to collect data which could be used to formulate "best practice protocols for effective treatment at a low-cost", that is, clinical best evidence practices for both healthcare diagnosis and delivery (Kennedy, 1995). It was anticipated that the advent of CHINs in conjunction with Internet technologies would empower healthcare stakeholders to provide healthcare to patients in real time whilst being in geographically distinct locations (Kennedy, 1995).

KM TAXONOMIES

KM has become an important focus area for organizations (Earl & Scott, 1999). It has been argued that KM evolved from the applications of expert systems and artificial intelligence (Liebowitz & Beckman, 1998; Sieloff, 1999). Almost all of the definitions of KM state that it is a multi-disciplinary paradigm (Gupta, Iyer & Aronson, 2000) that has further accentuated the controversy regarding the origins of KM. One of the main factors behind widespread interest in KM is its role as a possible source of competitive advantage (Havens & Knapp, 1999; Nonaka, 1991). A number of leading management researchers have affirmed that the Hungarian chemist, economist and philosopher Michael Polanyi was among the earliest theorists who popularized the concept of characterizing knowledge as "tacit or explicit" which is now recognized as the accepted knowledge categorization approach (Gupta et al., 2000; Hansen, Nohria & Tierney, 1999; Zack, 1999).

The cornerstone of any KM project is to transform tacit knowledge to explicit knowledge so as to allow its effective dissemination (Gupta et al., 2000). This can be best met by developing a KM framework. Authors such as Blackler (1995) have reiterated that the concept of knowledge is complex and, in an organizational context, its relevance to organization theory has not yet been sufficiently understood and documented. This is one of the fundamental reasons why KM does not have a widely accepted framework that can enable healthcare institutions in creating KM systems and a culture conducive to KM practices.

KM is underpinned by information technology paradigms such as Workflow, Intelligent Agents and Data Mining. According to Manchester (1999), a common point about software technologies such as (1) information retrieval, (2) document management and (3) workflow processing is that they blend well with the Internet and related technologies (i.e., technologies which focus on dissemination of information). Deveau (2000, p. 14) submits that: "KM is about mapping processes and exploiting the knowledge database. It's taking people's minds and applying technology." Deveau (2000) also noted that information technology puts the organization in a position to state the currently available information in the organizational knowledge base. At this point, the role of IT ends and the role of KM commences.

As KM deals with the tacit and contextual aspects of information, it allows an organization to know what is important for it in particular circumstances, in the process maximizing the value of that information and creating competitive advantages and wealth.

APPLICABILITY OF THE KM PARADIGM IN HEALTHCARE

A KM solution would allow healthcare institutions to give clinical data context, so as to allow knowledge derivation for more effective clinical diagnoses. In the future, healthcare systems would see increased interest in knowledge recycling of the collaborative learning process acquired from previous healthcare industry practices. This chapter puts forward the notion that this sector has been exclusively focused on IT to meet the challenges described above and reiterates that this challenge cannot be met by an IT led solution.

KM initiatives should be incorporated within the technological revolution that is speeding across healthcare industry. There has to be balance between organizational and technological aspects of the healthcare process, that is, one cannot exist without the other (Dwivedi et al., 2001a). This chapter emphasizes the importance of clinicians taking a holistic view of their organization. Clinicians therefore need to have an understanding of IT in a healthcare context and a shared vision of the organization. Clinicians and healthcare administrators thus need to acquire both organizational and technological insights if they are to have a holistic view of their organization.

The KM paradigm can enable the healthcare sector to successfully overcome the information and knowledge explosion, made possible by adopting a KM framework that is specially customized for healthcare institutions in light of their ICT implementation level. Adoption of KM is essential for healthcare institutions as it would enable them to identify, preserve and disseminate "best context" healthcare practices to different healthcare stakeholders.

PREFATORY ANALYSIS OF ALTERNATIVE HEALTHCARE CONCEPTS

The failure of some healthcare management concepts propelled a new stream of thought that advocated the incorporation of the KM paradigm in healthcare (Health Canada, 1999; Mercer, 2001). KM could allow healthcare organizations to truly take advantage of the driving forces behind the creation of the CHIN concept. However, very few organizations have adopted a comprehensive healthcare KM system. The main reason attributed is the failure of healthcare stakeholders in properly creating a conducive organizational culture. Based on a literature review above, a preliminary conceptual analysis of alternative healthcare management concepts is presented in Table 1. As can be seen from the table, healthcare stakeholders are searching for alternative paradigms that support collaboration in order to synergistically learn from others' experiences, training and knowledge within specific organizational cultures. Healthcare institutions have realized that existing concepts such as EBM and CG do not enable healthcare stakeholders to achieve this challenge as they do not holistically support effective integration of IT within specific organizational cultures and processes. Contemporary concepts such as EBM, CHIN, ICHDS and IPP focus on IT at the expense of having too little emphasis on people. This is further aggravated by the presence of dysfunctional organizational processes in the majority of healthcare institutions.

CONCLUSION

For any healthcare organization to succeed, it needs to excel in a number of key processes (i.e., patient diagnosis, care treatment, etc.) that are necessary for it to achieve its mission. If the processes are repetitive, automation is possible via the use of IT. Modern IT applications in healthcare are not sufficient in meeting the information needs of current healthcare institutions as they lack the ability to deliver precise, accurate and contextual information to the desired caregiver at the desired time.

This chapter has presented an analysis of alternative healthcare management concepts with respect to their ability in providing a solution to the issue of information management. Furthermore, this chapter has examined the feasibility of the KM paradigm in solving the problem of information explosion in healthcare and has found validation for the proposition that the current focus on technological solutions will aggravate the problem of explosion in clinical information systems for healthcare institutions.

Table 1. Prefatory analysis of alternative healthcare concepts

Concept	Support for People	Support for Process	Support for Technology	Limitations
CG	Present	Insufficient	Present	Policy initiative
EBM	Insufficient	Insufficient	Present	Tacit Processes?
CHIN	Insufficient	Absent	Present	Limited Trials
IHCDS	Insufficient	Insufficient	Present	Technology focus
IPP	Insufficient	Present	Present	Tacit Knowledge?
KM	Present	Present	Present	Not validated

The chapter has also presented the key requirements for creating a KM framework, which can act as a template in enabling healthcare institutions in their attempts to initiate KM projects. This chapter concludes that any potential solution has to come from a domain that synergistically combines people, organizational processes and technology, thereby enabling healthcare stakeholders to have a holistic view of the entire healthcare continuum. This chapter further concludes that KM is the only paradigm that combines the above-mentioned perspectives (i.e., people, organizational processes, and technology) into healthcare and as such, KM is the next indispensable step for integrated healthcare management.

Chapter 1.21
Interactive Information Retrieval as a Step Towards Effective Knowledge Management in Healthcare

Jörg Ontrup
Bielefeld University, Germany

Helge Ritter
Bielefeld University, Germany

ABSTRACT

The chapter shows how modern information retrieval methodologies can open up new possibilities to support knowledge management in healthcare. Recent advances in hospital information systems lead to the acquisition of huge quantities of data, often characterized by a high proportion of free narrative text embedded in the electronic health record. We point out how text mining techniques augmented by novel algorithms that combine artificial neural networks for the semantic organization of non-crisp data and hyperbolic geometry for an intuitive navigation in huge data sets can offer efficient tools to make medical knowledge in such data collections more accessible to the medical expert by providing context information and links to knowledge buried in medical literature databases.

INTRODUCTION

During the last years the development of electronic products has lead to a steadily increasing penetration of computerized devices into our society. Personal computers, mobile computing platforms, and personal digital assistants are becoming omnipresent. With the advance of network aware medical devices and the wireless transmission of health monitoring systems pervasive computing has entered the healthcare domain (Bergeron, 2002).

Consequently, large amounts of electronic data are being gathered and become available online. In order to cope with the sheer quantity, data warehousing systems have been built to store and organize all imaginable kinds of clinical data (Smith & Nelson, 1999).

In addition to numerical or otherwise measurable information, clinical management involves administrative documents, technical documentation regarding diagnosis, surgical procedure, or care. Furthermore, vast amounts of documentation on drugs and their interactions, descriptions of clinical trials or practice guidelines plus a plethora of biomedical research literature are accumulated in various databases (Tange, Hasman, de Vries, Pieter, & Schouten, 1997; Mc Cray & Ide, 2000).

The storage of this exponentially growing amount of data is easy enough: From 1965—when Gordon Moore first formulated his law of exponential growth of transistors per integrated circuit—to today: "Moore's Law" is still valid. Since his law generalizes well to memory technologies, we up to now have been able to cope with the surge of data in terms of storage capacity quite well. The retrieval of data however, is inherently harder to solve. For structured data such as the computer-based patient record, tools for online analytical processing are becoming available. But when searching for medical information in freely formatted text documents, healthcare professionals easily drown in the wealth of information: When using standard search engine technologies to acquire new knowledge, thousands of "relevant" hits to the query string might turn up, whereas only a few ones are valuable within the individual context of the searcher. Efficient searching of literature is therefore a key skill for the practice of evidence-based medicine (Doig & Simpson, 2003).

Consequently, the main objective of this chapter is to discuss recent approaches and current trends of modern information retrieval, how to search very large databases effectively. To this end, we first take a look at the different sources of information a healthcare professional has access to. Since unstructured text documents introduce the most challenges for knowledge acquisition, we will go into more detail on properties of text databases considering MEDLINE as the premier example. We will show how machine learning techniques based on artificial neural networks with their inherent ability for dealing with vague data can be used to create structure on unstructured databases, therefore allowing a more natural way to interact with artificially context-enriched data.

SOURCES OF INFORMATION IN HEALTHCARE

The advance of affordable mass storage devices encourages the accumulation of a vast amount of healthcare related information. From a technical point of view, medical data can be coarsely divided into structured and unstructured data, which will be illustrated in the following sections.

Data Warehouses and Clinical Information Systems

One major driving force for the development of information processing systems in healthcare is the goal to establish the computer-based patient record (CPR). Associated with the CPR are patient registration information, such as name, gender, age or lab reports such as blood cell counts, just to name a few. This kind of data is commonly stored in relational databases that impose a high degree of structure on the stored information. Therefore, we call such data "structured." For evidence based medicine the access to clinical information is vital. Therefore, a lot of effort has been put into the goal to establish the computer-based patient record (CPR) as a standard technology in healthcare. In the USA, the Institute of Medicine (1991) defined the CPR as "an electronic patient record that resides in a system specifically designed to support users by providing accessibility to complete and accurate data, alerts, reminders, clinical decision support systems, links to medical knowledge, and other aids." However, as Sensmeier (2003) states, "this goal remains a vision [...] and the high expectations of these visionaries remain largely unfulfilled." One of the main reasons why "we are not there yet" is a general lack of integration.

A recent study by Microsoft[1] identified as much as 300 isolated data islands within a medical center. The unique requirements of different departments such as laboratory, cardiology, or oncology and the historical context within the hospital often results in the implementation of independent, specialized clinical information systems (CIS) which are difficult to connect (McDonald, 1997). Consequently, main research thrusts are strategies to build data warehouses and clinical data repositories (CDR) from disjoint "islands of information" (Smith & Nelson, 1999). The integration of the separated data sources involves a number of central issues:

1. Clinical departments are often physically separated. A network infrastructure is necessary to connect the disparate sites. Internet and Intranet tools are regarded as standard solutions.
2. Due to the varying needs of different departments, they store their data in various formats such as numerical laboratory values, nominal patient data or higher dimensional CT data. Middleware solutions are required to translate these into a consistent format that permits interchange and sharing.
3. In the real world, many data records are not suitable for further processing. Missing values or inconsistencies have to be treated: Some fields such as blood cell counts are not always available or data was entered by many different persons, and is thus often furnished with a "personal touch." Cleaning and consistency checks are most commonly handled by rule-based transformations.
4. Departmental workflow should not be strained by data copying tasks. Automated script utilities should take care of the data migration process and copy the data "silently in the background."

None of the steps above is trivial and certainly it requires a strong management to bring autonomous departments together and to motivate them to invest their working power for a centralized data warehouse. But once such a centralized repository of highly structured data is available it is a very valuable ground for retrospective analysis, aggregation and reporting. Online analytical processing (OLAP) tools can be used to perform customized queries on the data while providing "drill downs" at various levels of aggregation. A study with an interactive visualization framework has shown that it can massively support the identification of cost issues within a clinical environment (Bito, Kero, Matsuo, Shintani, & Silver, 2001). Silver, Sakata, Su, Herman, Dolins, and O'Shea (2001) have demonstrated that data mining "helped to turn data into knowledge." They applied a patient rule induction method and discovered a small subgroup of inpatients on the DRG level which was responsible for more than 50 percent of revenue loss for that specific DRG (diagnoses related group). The authors describe a "repeatable methodology" which they used to discover their findings: By using statistical tools they identified regions and patterns in the data, which significantly differentiated them from standard cases. In order to establish the *reason* for increased costs in those regions, they found it necessary that a human expert further analyzes the automatically encircled data patterns. Therefore, a closed loop between clinical data warehouse, OLAP tool and human expert is necessary to gain the maximum of knowledge from the available data.

A recently proposed data mart by Arnrich, Walter, Albert, Ennker, and Ritter (2004) targets in the same direction: Various data sources are integrated into a single data repository. Results from statistical procedures are then displayed in condensed form and can be further transformed into new medical knowledge by a human expert.

UNSTRUCTURED DATA IN BIOMEDICAL DATABASES

As the discussion on hospital information systems shows, interactive data processing tools form a large potential to extract hidden knowledge from large structured data repositories. A yet more challenging domain for knowledge acquisition tasks is the field of unstructured data. In the following we will briefly present the two premier sources of unstructured data available to the healthcare professional.

Narrative Clinical Data

Many hospitals do not only store numerical patient data such as laboratory test results, but also highly unstructured data such as narrative text, surgical reports, admission notes, or anamneses. Narrative text is able to capture human-interpretable nuances that numbers and codes cannot (Fisk, Mutalik, Levin, Erdos, Taylor, & Nadkarni, 2003). However, due to the absence of a simple machine-parsable structure of free text, it is a challenging task to design information systems allowing the exchange of such kind of information.

In order to address the interoperability within and between healthcare organizations widely accepted standards for Electronic Health Records (EHR) are important. Health Level 7 (HL7)—an ANSI accredited organization, and the European CEN organization both develop standards addressing this problem. The HL7 Clinical Document Architecture (CDA) framework "stems from the desire to unlock a considerable clinical content currently stored in free-text clinical notes and to enable comparison of content from documents created on information systems of widely varying characteristics." (Dolin, Alschuler, Beebe, Biron, Boyer, Essin, Kimber, Lincoln, & Mattison,, 2001). The emerging new standard based on HL7 version 3 is purely based on XML and therefore greatly enhances the interoperability of clinical information systems by embedding the unstructured narrative text in a highly structured XML framework. Machine-readable semantic content is added by the so-called HL7 Reference Information Model (RIM). The RIM is an all-encompassing look at the entire scope of healthcare containing more than 100 classes with more than 800 attributes. Similar to HL7 v3, the European ENV 13606 standard as defined by the TC 251 group of the CEN addresses document architecture, object models and information messages. For a more detailed discussion on healthcare information standards see Spyrou, Bamidis, Chouvarda, Gogou, Tryfon, and Maglaveras (2002).

Another approach to imprint structure on free text is the application of ontologies to explicitly formalize logical and semantic relationships. The W3C consortium has recently (as of May 2004) recommended the Web Ontology Language (OWL) as a standard to represent semantic content of web information and can therefore be seen as a major step towards the "semantic Web" (Berners-Lee, Hendler, & Lassila, 2001). In the medical domain, the Unified Medical Language System (UMLS) uses a similar technology to represent biomedical knowledge within a semantic network (Kashyap, 2003). Once an ontology for a certain domain is available, it can be used as a template to transfer the therein contained explicit knowledge to corresponding terms of free text from that domain. For example, the term "blepharitis" is defined as "inflammation of the eyelids" in the UMLS. If a medic professional would search for the term "eyelid" within the hospital's EHRs, documents containing the word "blepharitis" would not show up. However with knowledge from the UMLS, these documents could be marked as relevant to the query. However, the tagging of free text with matching counterparts from an ontology is either a cost intensive human labor or requires advanced natural language processing methods. We shall see below, how computational approaches could address the problem of adding semantics to free narrative text.

Biomedical Publications

For most of the time in human history, the majority of knowledge acquired by mankind was passed on by the means of the written word. It is a natural scientific process to formulate new insights and findings and pass them to the community by publishing. Consequently, scientific literature is constantly expanding. It is not only expanding at growing speed, but also increasing in diversification, resulting in highly specialized domains of expertise.

The MEDLINE database at the U.S. National Library of Medicine (NLM) has become the standard bibliographic database covering the fields of medicine, nursing, veterinary medicine, dentistry, pharmacology, the healthcare system, and the preclinical sciences. The majority of publications in MEDLINE are regular journals and a small number of newspapers and magazines. The database is updated on a regular daily basis from Tuesdays to Saturdays and on an irregular basis in November and December. At the time of this writing, MEDLINE contains approximately 12 million references to articles from over 37,000 international journals dating back to 1966. In 1980 there were about 100,000 articles added to the database, and in 2002 the number increased to over 470,000 newly added entries. That means, currently over 50 new biomedical articles are published on an hourly basis. Clearly, no human is able to digest one scientific article per minute 24 hours a day, seven days a week. But the access to the knowledge within is lively important nonetheless: "The race to a new gene or drug is now increasingly dependent on how quickly a scientist can keep track of the voluminous information online to capture the relevant picture … hidden within the latest research articles" (Ng & Wong, 1999).

Not surprisingly, a whole discipline has emerged which covers the field of "information retrieval" from unstructured document collections, which takes us to the next section.

COMPUTATIONAL APPROACHES TO HANDLE TEXT DATABASES

The area of information retrieval (IR) is as old as man uses libraries to store and retrieve books. Until recently, IR was seen as a narrow discipline mainly for librarians. With the advent of the World Wide Web, the desire to find relevant and useful information grew to a public need. Consequently, the difficulties to localize the desired information "have attracted renewed interest in IR and its techniques as promising solutions. As a result, almost overnight, IR has gained a place with other technologies at the center of the stage" (Baeza-Yates & Ribeiro-Neto, 1999).

Several approaches have shown that advanced information retrieval techniques can be used to significantly alleviate the cumbersome literature research and sometimes even discover previously unknown knowledge (Mack & Hehenberger, 2002). Swanson and Smalheiser (1997) for example designed the ARROWSMITH system which analyses journal titles on a keyword level to detect hidden links between literature from different specialized areas of research. Other approaches utilize MeSH headings (Srinivasan & Rindflesch, 2002) or natural language parsing (Libbus & Rindflesch, 2002) to extract knowledge from literature. Rzhetsky, Iossifov, Koike, Krauthammer, Kra, Morris, Yu, Duboue, Weng, Wilbur, Hatzivassiloglou, and Friedman (2004) have recently proposed an integrated system which visualizes molecular interaction pathways and therefore has the ability to make published knowledge literally visible.

In the following sections we go into more detail and look how computational methods can deal with text.

Representing Text

The most common way to represent text data in numerical form such that it can be further processed by computational means is the so-called "bag of words" or "vector space" model. To this end a standard practice composed of two complementary steps has emerged (Baeza-Yates & Ribeiro-Neto, 1999):

1. **Indexing**: Each document is represented by a high-dimensional feature vector in which each component corresponds to a term from a dictionary and holds the occurrence count of that term in the document. The dictionary is compiled from all documents in the database and contains all unique words appearing throughout the collection. In order to reduce the dimensionality of the problem, generally only word stems are considered (i.e., the words "computer", "compute", and "computing" are reduced to "comput"). Additionally, very frequently appearing words (like "the" & "and") are regarded as *stop words* and are removed from the dictionary, because they do not contribute to the distinguishability of the documents.
2. **Weighting**: Similarities between documents an then be measured by the Euclidean distance or the angle between their corresponding feature vectors. However, this ignores the fact that certain words carry more information content than others. The so-called *tf-idf* weighting scheme (Salton & Buckley, 1988) has been found a suitable means to deal with this problem: Here the *term frequencies (tf)* in the document vector are weighted with the *inverse document frequency idfi* = $\log(N/s^d_i)$, where N is the number of documents in the collection, and s^d_i denotes the number of times the word stem s_i occurs in document d.

Although the "bag of words" model completely discards the order of the words in a document, it performs surprisingly well to capture its content. A major drawback is the very high dimensionality of the feature vectors from which some computational algorithms suffer. Additionally, the distance measure typically does not take *polysemy* (one word has several meanings) and *synonymy* (several words have the same meaning) into account.

Evaluating Retrieval Performance

In order to evaluate an IR system, we need some sort of quality measure for its retrieval performance. The most common and intuitively accessible measures are *precision* and *recall*. Consider the following situation: We have a collection of *C* documents and a query *Q* requesting some information from that set. Let *R* be the set of relevant documents in the database to that query, and *A* be the set of documents delivered by the IR system as answers to the given query *Q*. The *precision* and *recall* are then defined by

$$precision = \frac{|R \cap A|}{|R|} \text{ and } recall = \frac{|R \cap A|}{|R|},$$

where $R \cap A$ is the intersection of the relevant and the answer set, that is, the set of found relevant documents. The ultimate goal is to achieve a precision and recall value of one, that is, to find only the relevant documents, and all of them. A user will generally not inspect the whole answer set *A* returned by an IR system—who would want to click through all of the thousands of hits typically returned by a web search? Therefore, a much better performance description is given by the so-called *precision-recall-curve*. Here, the documents in *A* are sorted according to some ranking criterion and the precision is plotted against the recall values obtained when truncating the sorted answer set after a given rank—which is varied between one and the full size of A. The particular point on the curve where the precision equals the recall is called *break even point* and is frequently used to characterize an IR system's performance with a single value.

Therefore, the quality of a search engine which generates hit lists is strongly dependent on its ranking algorithm. A famous example is PageRank, which is part of the algorithm used by Google. In essence, each document (or page) is weighted with the number of hyperlinks it receives from other web pages. At the same time the links themselves are weighed by the importance of the linking page (Brin & Page, 1998). The higher a page is weighted, the higher it gets within the hit list. The analogue to hyperlinks in the scientific literature are citations, that is, the more often an article is cited, the more important it is (Lawrence, Giles & Bollacker, 1999).

The Role of Context

So, we can handle unstructured text and measure how good an IR system works, but a critical question was not answered yet: How do we determine, which documents from a large collection are actually *relevant* to a given query? To answer this question, we have to address the role of *context.*

User Context

Consider the following example: A user enters the query "Give me all information about jaguars." The set of relevant documents will be heavily dependent on the context in which the user phrases this query: A motor sports enthusiast is probably interested in news about the "Jaguar Racing" Formula 1 racing stable, a biologist probably wants to know more about the animal. So, the context—in the sense of the situation in which the user is immersed—plays a major role (Johnson, 2003; Lawrence, 2000).

Budzik, Hammond and Birnbaum (2001) discuss two common approaches to handle different user contexts:

1. Relevance feedback: The user begins with a query and then evaluates the answer set. By providing positive or negative feedback to the IR system, this can modify the original query by adding positive or negative search terms to it. In an iterative dialogue with the IR system, the answer set is then gradually narrowed down to the relevant result set. However, as studies (Hearst, 1999) have shown, users are generally reluctant to give exhaustive feedback to the system.
2. Building user profiles: Similar to the relevance feedback, the IR system builds up a user profile across multiple retrieval sessions, that is, with each document the user selects for viewing, the profile is adapted. Unfortunately, such a system does not take account of "false positives", that is, when a user follows a link that turned out to be of no value when inspecting it closer. Additionally, such systems integrate short term user interests into accumulated context profiles, and tend to inhibit highly specialized queries which the user is currently interested in.

Budzik, Hammond & Birnbaum (2001) presented a system that tries to guess the user context from open documents currently edited or browsed on the work space. Their system constitutes an "Information Management Assistant [which] observes user interactions with everyday applications and anticipates information needs […] in the context of the user's task." Another system developed by Finkelstein and Gabrilovich (2002) analyzes the context in the immediate vicinity of a user-selected text, therefore making the context more focused. In an evaluation of their system both achieved consistently better results than standard search engines are able to achieve without context.

Document Context

Context can also be seen from another point of view: Instead of worrying about the user's intent and the context in which a query is embedded, an information retrieval system could make the context in which retrieved documents are embedded more explicit. If each document's context is immediately visible to the information seeker, the relevant context might be quickly picked out. Additionally, the user might discover a context he had not in mind when formulating the query and thus find links between his intended and an unanticipated context. In the following we describe several approaches that aim in this direction.

Augmenting Document Sets with Context

Text Categorization

One way to add context to a document is by assigning a meaningful label to it (Le & Thoma, 2003). This constitutes a task of text categorization and there exist numerous algorithms that can be applied. The general approach is to select a training set of documents that are already labelled. Based on the "bag of words" representation, machine learning methods learn the association of category labels to documents. For an in depth review of statistical approaches (such as naives Bayes or decision trees) see Yang (1999). Computationally more advanced methods utilize artificial neural network architectures such as the support vector machine which have achieved break even values close to 0.9 for the labelling of news wire articles (Joachims, 1998; Lodhi, 2001).

However, in the medical domain, 100 categories are seldom adequate to describe the context of a text. In case of the MEDLINE database, the National Library of Medicine has developed a highly standardized vocabulary, the Medical Subject Headings (MeSH) (Lowe & Barnett, 1994). They consist of more than 35,000 categories that are hierarchically organized and constitute the basis for searching the database. To guarantee satisfactory search results of constant quality, reproducible labels are an important prerequisite. However, the cost of human indexing of the biomedical literature is high: according to Humphrey (1992) it takes one year to train an expert the task of document labelling. Additionally, the labelling process lacks a high degree of reproducibility. Funk, Reid, and McGoogan (1983) have reported a mean agreement in index terms ranging from 74 percent down to as low as 33 percent for different experts. Because the improvement of index consistency is such demanding, assistance systems are considered to be a substantial benefit. Recently, Aronson, Bodenreider, Chang, Humphrey, Mork, Nelson, Rindflesh, and Wilbur (2000) have presented a highly tuned and sophisticated system which yields very promising results. Additionally to the bag of words model their system utilizes a semantic network describing a rich ontology of biomedical knowledge (Kashyap, 2003).

Unfortunately, the high complexity of the MeSH terms makes it hard to incorporate a MeSH-based categorization into a user interface. When navigating the results of a hierarchically ordered answer set it can be a time-consuming and frustrating process: Items which are hidden deep within the hierarchy can often only be obtained by descending a tree with numerous mouse-clicks. Selection of a wrong branch requires backing up and trying a neighboring branch. Since screen space is a limited resource only a small area of context is visible and requires internal "recalibration" each time a new branch is selected. To overcome this problem, *focus and context* techniques are considered to be of high value. These are discussed in more detail below.

The Cluster Hypothesis

An often cited statement is the *cluster hypothesis*, which states that documents which are similar in their bag of words feature space tend to be relevant to the same request (van Rijsbergen, 1979). Leuski (2001) has conducted an experiment where an agglomerative clustering method was used to group the documents returned by a search engine query. He presented the user not with a ranked list of retrieved documents, but with a list of clusters, where each cluster in turn was arranged as a list of documents. The experiment showed, that this procedure "can be much more helpful in locating the relevant information than the traditional ranked list." He could even show that the clustering can be as effective as the relevance feedback methods based on query expansion. Other experiments also validated the cluster hypothesis on several occasions (Hearst & Pedersen, 1996; Zamir & Etzioni, 1999). Recently the *vivisimo*[2] search engine has drawn attention by utilizing an online clustering of retrieval sets, which also includes an interface to PubMed / MEDLINE.

Visualizing Context

Another way to create context in line with the spirit of the cluster hypothesis is by embedding the document space in a visual display. By making the relationship between documents visually more explicit, such that the user can actually *see* inter-document similarities, the user gets *(i)* an overview of the whole collection, and *(ii)* once a relevant document has been found, it is easier to locate others, as these tend to be grouped within the surrounding context of already identified valuable items. Fabrikant and Buttenfield (2001) provide a more theoretical framework for the concept of "spatialization" with relation to cognitive aspects and knowledge acquisitions: Research on the cognition of geographic information has been identified as being important in decision making, planning and other areas involving human-related activities in space.

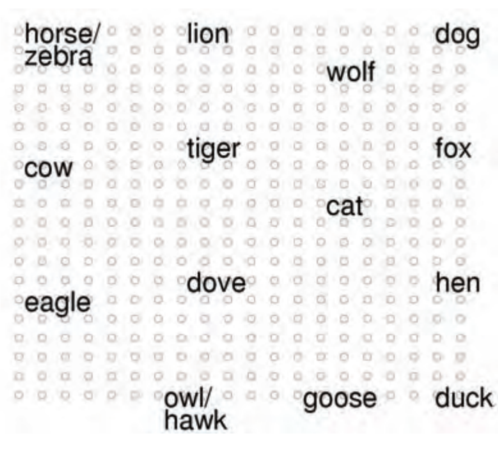
In order to make use of "spatialization", that is, to use cognitive concepts such as "nearness" we need to apply some sort of transformation to project the documents from their high-dimensional (typically several thousands) bag-of-words space onto a two dimensional canvas suitable for familiar inspection and interaction. The class of algorithms performing such a projection is called *multi dimensional scaling* (MDS). A large number of MDS methods such as Sammon mapping, spring models, projection pursuit or local linear embeddings have been proposed over the years. Skuping and Fabrikant (2003) provide an excellent discussion of the most common MDS variants in relation to spatialized information visualization.

Self-Organizing Maps

The notion of the self-organizing map (SOM) has been introduced by Kohonen (1982) more than 20 years ago. Since then is has become a well-accepted tool for exploratory data analysis and classification. While applications of the SOM are extremely wide spread—ranging from medical imaging, classification of power consumption profiles, or bank fraud detection—the majority of uses still follows its original motivation: to use a deformable template to translate *data similarities* into *spatial relations.*

The following example uses a simple toy dataset to demonstrate the properties of the SOM

Figure 1. A map of animals



algorithm. Consider a 13-dimensional dataset describing animals with properties such as s*mall, medium, big, two legs, hair, hooves, can fly, can swim, and* so on. When displaying the data as a large table, it is quite cumbersome to see the interrelationship between the items, that is, animals. The map shown in Figure 1 depicts a trained SOM with neurons placed on a 20x20 regular grid. After the training process, each animal is "presented" to the map, and the neuron with the highest activity gets labelled with the corresponding name. As can be seen in the figure the SOM achieves a semantically reasonable mapping of the data to a two-dimensional "landscape": birds and non-birds are well separated and animals with identical features get mapped to identical nodes.

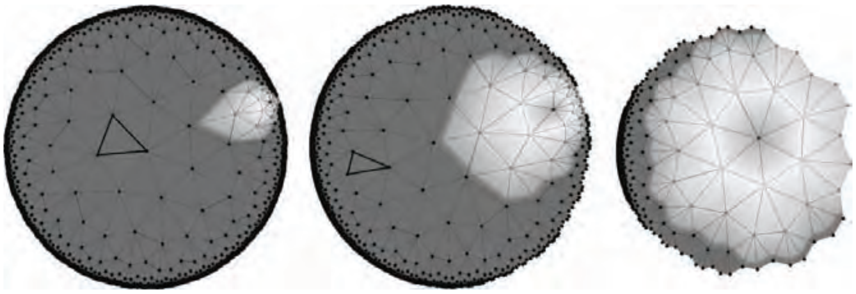
There have been several approaches to use the SOM to visualize large text databases and relations of documents therein. The most prominent example is the WEBSOM project. Kohonen, Kaski and Lagus, (2000) performed the mapping of 7 million patent abstracts and obtained a semantic landscape of the corresponding patent information. However, screen size is a very limited resource, and as the example with 400 neurons above suggests, a network with more than one million nodes—2500 times that size—becomes hard to visualize: When displaying the map as a whole, annotations will not be readable, and when displaying a legible subset, important surrounding context will be lost. Wise (1999) has impressively demonstrated the usefulness of compressed, map-like representations of large text collections: His *ThemeView* reflects major topics in a given area, and a zoom function provides a means to magnify selected portions of the map—unfortunately without a coarser view to the surrounding context.

Focus & Context Techniques

The limiting factor is the two dimensional Euclidean space we use as a data display: The neighborhood that "fits" around a point is rather restricted: namely by the square of the distance to that point. An interesting loophole is offered by *hyperbolic space*: it is characterized by uniform negative curvature and results in a geometry, where the neighborhood around a point increases *exponentially* with the distance. This exponential behavior was firstly exploited (and patented) by the "hyperbolic tree browser" from Lamandpng & Rao (1994), followed by a Web content viewer by Munzner (1998). Studies by Pirolli, Card and van der Wege (2001) showed that the particular *focus & context* property offered by hyperbolic space can significantly accelerate "information foraging".

Naturally, it becomes apparent to combine the SOM algorithm with the favorable properties of hyperbolic space (Ritter, 1999). The core idea of the hyperbolic self-organizing map (HSOM) is to employ a grid of nodes in the hyperbolic plane H^2. For H^2 there exists an infinite number of tessellations with congruent polygons such that each grid point is surrounded by the same number of neighbors (Magnus, 1974). As stated above, an intuitive navigation and interaction methodology is a crucial element for a well-fitted visualization framework. By utilizing the *Poincaré* projection and the set of *Möbius* transformations (Coxeter, 1957) a "fish-eye" fovea can be positioned on the HSOM grid allowing an intuitive interaction methodology. Nodes within the fovea are displayed with high resolution, whereas the surrounding context is still visible in a coarser view. For further technical details of the HSOM see (Ritter, 1999; Ontrup & Ritter, 2001). An example for the application of the fish-eye view is given in Figure 2. It shows a navigation sequence where the focus was moved towards the highlighted region of interest. Note, that from the left to the right details in the target area get increasingly magnified, as the highlighted region occupies more and more display space. In contrast to standard zoom operations, the current surrounding context is not clipped, but remains gradually compressed at the periphery of the field of view. Since all operations

Figure 2. Navigation snapshot showing isometric transformation of HSOM tessellation. The three images were acquired while moving the focus from the center of the map to the highlighted region at the outer perimeter. Note the "fish-eye" effect: All triangles are congruent, but appear smaller as further they are away from the focus.



are continuous, the focus can be positioned in a smooth and natural way.

Browsing MEDLINE in Hyperbolic Space

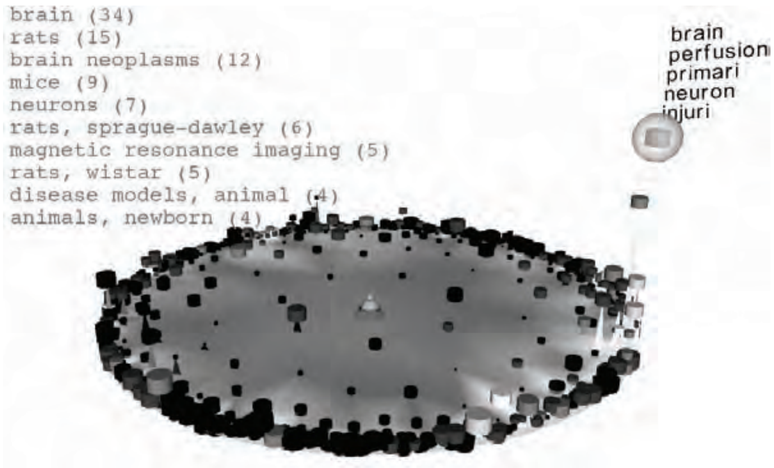
The following example presents a HSOM framework that combines the aspects of information retrieval, context enrichment and intuitive navigation into a single application. The following images show a two dimensional HSOM, where the nodes are arranged on a regular grid consisting of triangles similar to those in Figure 2. The HSOM's neurons can be regarded as "containers" holding those documents for which the corresponding neuron is "firing" with the highest rate. These containers are visualized as cylinders embedded in the hyperbolic plane. We can then use visual attributes of these containers and the plane to reflect document properties and make context information explicit:

- The container sizes reflect the number of documents situated in the corresponding neuron.
- A color scale reflects the number of documents which are labelled with terms from the *Anatomy* hierarchy of MeSH terms, i.e. the brighter a container is rendered, the more articles labelled with *Anatomy* MeSH entries reside within that node.
- The color of the ground plane reflects the average distance to neighboring nodes in the semantic bag-of-words space. This allows the identification of thematic clusters within the map.

Figure 3 shows a HSOM that was trained with approximately 25,000 abstracts from MEDLINE. The interface is split into two components: the graphical map depicted below and a user interface for formulating queries (not shown here). In the image below, the user has entered the search string "brain". Subsequent to the query submission, the system highlights all nodes belonging to abstracts containing the word "brain" by elevating their corresponding nodes. Additionally the HSOM prototype vectors—which were autonomously organized by the system during a training phase—are used to generate a key word list which annotate and semantically describe the node with the highest hit rate. To this end, the words corresponding to the five largest components of the reference vector are selected. In our example these are: *brain, perfusion, primari, neuron,* and *injuri*. In the top left the most prominent MeSH terms are displayed, that is, 34 articles are tagged with the medical subject heading "brain", 15 are tagged with "rats", and so on.

The map immediately shows that there are several clusters of brain-related articles in the

Figure 3. MEDLINE articles mapped with the HSOM. The user submitted the query string "brain" and the corresponding results are highlighted by the system.



right part of the map. Moving the focus into this area leads to the situation shown in Figure 4. By selecting single neurons with the mouse, the user can selectively retrieve key words of individual containers. Additionally, the MeSH terms of the selected node are displayed. As can be seen from the keyword distribution, all nodes share semantically related characteristics. The two leftmost labelled nodes do not contain key words like "brain" or "neuron", but the labelling with "cord", "spinal", "eeg", and "gamma", respectively, indicates a close relation to the selected "brain-area".

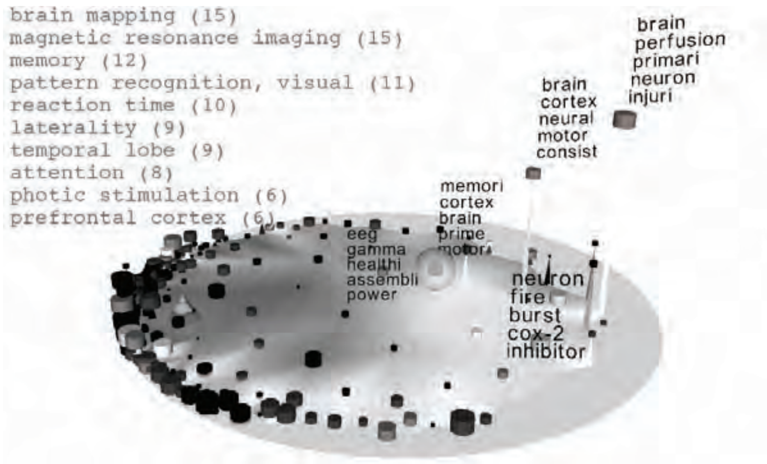
The drill-down process to the document level combines the strengths of the graphical and the textual display: After zooming-in on a promising region, the titles of documents pertaining to a particular node can be displayed by a double mouse click. Note, that due to the ordering process of the SOM algorithm these documents are typically very similar to each other—and in the sense of the clustering hypothesis therefore might all provide an answer to the same query. A further double click on a document title then displays the selected abstract on the screen. In this way, the hyperbolic self-organizing map can provide a seamless interface offering rapid overview of large document collections while allowing at the same time the drill down to single texts.

BENEFITS FOR A HOSPITAL INFORMATION SYSTEM

In the framework of a hospital information system, such a context enriched interactive document retrieval system might be of great benefit to the clinical personal. According to Chu and Cesnik (2001) a hospital may generate up to five terabytes of data a year, where 20 to 30 percent of such data are stored as free text reports such as medical history, assessment and progress notes, surgical reports or discharge letters. Free text fields in medical records are considered of invaluable importance for medical relevance (Stein, Nadkarni, Erdos, & Miller, 2000). By using document standards like the CDA as briefly discussed in Section 2.2, the clinician is able to browse and retrieve the data according to the structure provided by the document framework. However, many existing information systems do not yet take advantage of the complex CDA or the even more substantial Reference Information Model—because it is a very time consuming task to transfer documents to the new standards and to fit the enormous mass of model objects to free text data.

Nevertheless, these systems store valuable information—just in a format which cannot be

Figure 4. The user has moved the focus into the target area and can now inspect the context enriched data more closely.



directly analyzed by structured methods. In order to provide access by content, the aforementioned Information Retrieval methodologies can significantly contribute to facilitate these tasks: a self-organizing map creates structure and context purely on the statistical word distributions of free text and thus allows a semantic browsing of clinical documents. This in turn offers the possibility to gain a problem orientated perspective on health records stored in information systems, that is, as Lovis et al (2000) have noted: "intelligent browsing of documents, together with natural language emerging techniques, are regarded as key points, as it appears to be the only pertinent way to link internal knowledge of the patient to general knowledge in medicine."

CONCLUSION

Recent advances in hospital information systems have shown that the creation of organization-wide clinical data repositories (CDR) plays a key role for the support of knowledge acquisition from raw data. Currently, many case studies are published which emphasize that data mining techniques provide efficient means to detect significant patterns in medical records. Interactive OLAP tools support best practice and allow for informed real time decision-making and therefore build the solid foundation for further improvements in patient care.

The next step to further broaden the knowledge base in healthcare environments will be the integration of unstructured data, predominantly free narrative text documents. The nature of this type of data will demand for new approaches to deal with the inherently vague information contained in these documents. We have shown how artificial neural networks with their ability for self-organization of non-crisp data provide an almost natural link between the hard computational world and the soft-computing of the human brain. We believe that interactive information retrieval methodologies that account for the rich context of natural language will significantly contribute to knowledge acquisition through text analysis.

Chapter 1.22
Key Performance Indicators and Information Flow:
The Cornerstones of Effective Knowledge Management for Managed Care

ABSTRACT

It is paradoxical that, although several major technological discoveries such as Magnetic Resonance Imaging and Nuclear Medicine and Digital Radiology, which facilitate improvement in patient care, have been satisfactorily embraced by the medical community, this has not been the case with Healthcare Informatics. Thus, it can be argued that issues such as Data Management, Data Modeling, and Knowledge Management have a long way to go before reaching the maturity level that other technologies have achieved in the medical sector. This chapter proposes to explore trends and best practices regarding knowledge management from the viewpoint of performance management, based upon the use of Key Performance Indicators in healthcare systems. By assessing both balanced scorecards and quality assurance techniques in healthcare, it is possible to foresee an electronic healthcare record centered approach which drives information flow at all levels of the day-to-day process of delivering effective and managed care, and which finally moves towards information assessment and knowledge discovery.

INTRODUCTION

The advantages of the introduction of Information and Communication Technologies (ICT) in the complex Healthcare sector have already been depicted and analyzed in the Healthcare Informatics bibliography (Eder, 2000; Englebardt & Nelson, 2002; Harmoni, 2002; Norris, Fuller, Goldberg, & Tarczy-Hornoch, 2002; Shortliffe, Perreault, Wiederhold, & Fagan, 2001; Stegwee & Spil, 2001). It is nevertheless paradoxical that, although several major technological discoveries such as Magnetic Resonance Imaging, Nuclear Medicine and Digital Radiology, which facilitate improvement in patient care, have been satisfactorily embraced by the medical community, this has not been the case with Healthcare Informatics. Thus, it can be argued that issues such as Data Management, Data Modeling, and Knowledge Management have a long way to go before reaching the maturity level that other technologies have achieved in the medical sector.

A variety of reasons could be proposed for this issue, though with a short analysis it becomes rather clear that modern ICT present integration problems within the healthcare sector because of the way the latter is organized. Healthcare is a strongly people-centered sector in which ICT has been considered more as an intruder, as a "spy" to the healthcare professionals' way of doing things and as a competitor to this people-centered model. Thus, if ICT intend to prove its advantages towards establishing an information society, or even more a knowledge society, it has to focus on providing service-oriented solutions. In other words, it has to focus on people and this has not been the case in most of the circumstances. It is common knowledge that in order to install any type of information system in healthcare, especially if it involves knowledge management, six main groups of issues have to be dealt with (Iakovidis, 1998, 2000):

1. The organizational and cultural matters related to healthcare. This issue is rather important, regardless of any information system, since organizational models and culture do not endorse the continuity of care or any type of structured data collection. Issues such as mistrust between different specialists, between the different healthcare structures or between doctors and nurses prevent in many cases the effective sharing of information. Health reforms are currently under way in many countries stressing the will to deal with this problem.
2. The technological gap between healthcare professionals and information science experts. Doctors are often reluctant to use information systems that they believe are not designed for them. From another point of view, Healthcare Informatics have been introduced in healthcare institutions mostly on pilot-based projects aiming at addressing specific issues and have proposed solutions addressing a small number of healthcare practitioners, resulting in establishing a complex map of information niches. This approach is the consequence of applying information technology to procedures that where not designed for it, thus creating a panspermia of information models which are neither compatible nor interoperable, even within a single institution's environment. Efforts in creating interoperability standards and protocols such as HL7 are proposing solutions to address this issue, thus enabling data manipulation and knowledge management.
3. The legal requirements on the confidentiality of personal and patient related data and on data privacy. It is clear that if this issue is not addressed at a managerial and procedural level by imposing suitable policies to meet these requirements, there is little chance that medical data will be kept digitally in a structured manner (thus allowing the transition from digital islands of clinical data towards a structured electronic healthcare record). The implementation of an information system, where the electronic healthcare record is considered to be the core of the system (patient-centered model), is the only way

to drive data management towards creating new knowledge. The complexity of the problem can be explained if one just observes the course of implementation of both the Health Information Privacy and Accountability Act (HIPAA) in the US and Directive 95/46/EC in the EU. The issues seem to have been dealt with at the strategic level, but still a lot has to be done in the implementation and setup of those strategies.

4. The industrial and market position of Healthcare Informatics. In general, the healthcare market is seen by the industry as large in size but not highly profitable, mainly due to the lack of standards in implementing and interoperating healthcare informatics products. As a consequence, the industry has focused on creating mostly small-scale products (i.e., Laboratory Information Systems, Radiology Information Systems, Clinical Information Systems) and not on evangelizing the production of information system that are dealing with healthcare as a whole. The lack of end-to-end solutions is dealt with by interconnecting heterogeneous information systems (a rather complex task with constant change management issues) and by introducing solutions from other business sectors (i.e., ERP, SCM, CRM) that have often been rejected by "key users" as non-compliant with their job description. Nevertheless, the new Web technology approaches (Web services, XML, etc.) and the new information technology strategies (i.e., service oriented architecture) could be the drivers towards merging information technology and healthcare services and thus enabling the establishment of knowledge management products.
5. The lack of vision and leadership of healthcare managers and health authorities, and the lack of willingness to re-engineer healthcare processes for the benefits of efficiency and quality of care delivery. Some countries are in the process of introducing or implementing such Business Process Reengineering projects in order to address healthcare delivery in a more information flow conformant way. This is a key point in reaching knowledge management, knowledge re-use and sharing, and finally proposing a solution for the knowledge-based society of tomorrow. This issue should be dealt with by proposing strategies that focus on processes and by establishing key performance indicators, balanced scorecards, or other metrics that are the upper level of a structured information flow-based model.
6. User acceptability and usability of the proposed information systems. This issue is the one most strongly related to the problem of dealing with the people-centered approach of the healthcare sector. This issue deals with information systems' user friendliness, with usability issues such as the time to reach a data entry point, the speed of information retrieval, the quality of information retrieval, the complex security procedures, and so on. In order to implement information systems and knowledge management systems, education and training must be addressed with high priority since user acceptability is strongly related to them. Service oriented models and patient-centered information systems have a higher chance of passing the user acceptability test. A system that is not accepted by the user is often a system with poor data quality (or no data at all) and knowledge management, business intelligence or data warehousing solutions are consequently inoperable and unsuccessful.

Taking all of the above issues into consideration, this chapter proposes to explore trends and best practices regarding knowledge management from the viewpoint of performance management, based upon the use of Key Performance Indicators (KPI) in healthcare systems. By assessing both balanced scorecards (Kaplan/Norton) and quality assurance techniques in healthcare (Donabedian), it is possible to foresee an electronic healthcare record centered approach which drives information flow at all levels of the day-to-day process of delivering effective and managed care, and which finally moves towards information assessment and knowledge discovery (both with administrative and medical data). KPIs should be regarded as the strategic assessment tool, for both the executives and the clinical decision-makers, that will lead healthcare delivery to excellence and to knowledge discovery and assessment.

BACKGROUND

Knowledge Management as a Transformation Driver in Healthcare

Today, Knowledge Management (KM) is on everyone's mind. Healthcare organizations are no exception and are accepting the challenge to more effectively share knowledge both internally and externally (Strawser, 2000). The growth of KM projects (i.e., decision support systems, data mining tools, business intelligence solutions) signals a growing conviction that managing institutional knowledge is crucial to business success and possibly business survival. When the hype and confusion are stripped away, it is apparent that KM initiatives can profoundly change a healthcare enterprise for the better, and bring numerous advantages to Healthcare Information Management (HIM) professionals. For HIM professionals, KM is worthy of special attention because it informs them not only on how to do things, but also on how they might do them better. In order for this to happen, data should be provided in specific patterns and should be based upon a strategy that will empower a healthcare system by gaining knowledge of its processes, its outcomes, and its structures.

Despite the obvious advantages, many healthcare decision makers view the idea of a KM initiative with scepticism, possibly because of an incomplete or incorrect understanding of the tools needed to achieve it. Many of the tools and strategies associated with implementing KM are not new; what is new is a cohesive approach to KM design and implementation. Certainly there are pitfalls and limitations in using information technology for KM—trying to force fluid knowledge into rigid data structures, for example, or focusing too much on the tools and not enough on the content. But networks and computers, with their ability to connect people and store and retrieve virtually unlimited amounts of information, can dramatically improve departmental efficiencies. Some examples of knowledge management applications are listed below:

- **Data Mining tools** enable decision makers to search and analyze large sets of data by using specific querying methods and tools (Standard Query Language, Rough Data set, On Line Analytical Processing).
- **Document and Content Management systems** are widely used to store and archive files of any type (text, images, video, etc.) and correlated them with keywords that have a business meaning to the end user.
- **Knowledge Maps** are graphical or other representations of how and by whom a specific set of information is created, distributed and assessed. Knowledge Maps are very important tools in Total Quality Management projects.
- **Intelligent Agents** use a combination of profiling techniques, search tools, and recognition algorithms to provide up to date specific information to the end user. For example, intelligent agents could be used to forward completed test results to the corresponding physicians of a patient.
- **Web Browsers** are the most commonly used tools for searching information in an intranet

or the Internet. As such, Web browsers are increasingly becoming the most common graphical user interface, even for specific software products such as financial accounting and patient order entry systems.

- **Business Intelligence tools and Data Warehouses** enable the decision maker to have predefined access to specific information of interest regardless of the physical location of the data. Such systems are ideal for performance management and executive reporting and serve as the technological base for supporting the idea of a digital dashboard of indicators.
- **Workflow applications** play a very important role in KM since knowledge is created during the process-based operations that take place in a healthcare institution. A computerised patient order entry system is a classic example of a process-based operation in healthcare that requires the constant monitoring of the workflow status.
- **E-learning and collaboration tools** are part of the knowledge distribution process, which is extremely important in healthcare, since continuous education is a key factor in effective practice of care.

The essence of effective knowledge management does not rely on the use of one or more existing or forthcoming information technology tools. It is mostly about people, about processes and about capturing the results of people following processes, about transforming information into knowledge (explicit or tacit) and reusing it within a healthcare framework.

Performance Management: Monitor and Manage Healthcare

In order to persuade healthcare decision makers to assess the added value of KM tools, the latter should initially be used to propose new performance measurement and performance management techniques at all levels of a healthcare system (Hurst & Jee-Hughes, 2001). In that sense, performance management has long been considered as a tool for controlling spending and for increasing the efficiency of healthcare systems (Oxley & MacFarlan, 1994). There are three broad goals that governments generally pursue in the healthcare area:

- Equity: where citizens should have access to some incompressible minimum level of healthcare and treatment based on the need for care rather that solely on income.
- Micro-economic efficiency: where quality of care and consumer satisfaction should be maximized at minimum cost.
- Macroeconomic cost control: where the healthcare sector should consume an "appropriate" share of GDP.

In addition, healthcare systems are often facing factors that put pressure on the system. As a consequence, an effective performance management framework is the only solution towards controlling factors such as:

- Population aging
- Increased income and higher demand for healthcare services;
- Increased access to healthcare services; and
- Increase of high technology usage which in turn increases the healthcare services usage creating sometime unnecessary demand (from a medical point of view).

Most existing policies for controlling the performance of healthcare systems were based upon financial assessment of past results (macroeconomic control of spending and micro-efficiency improvements) by giving incentives to payers and providers of a healthcare system. By its very nature the financial measurements are not forward looking and are exclusionary to non-financial measures. In addition, the emergence of the Information Society in the late 90s rendered many of the fundamental performance management assumptions obsolete. Information Society has brought a new set of assumptions that institutions have to include into their strategy. Amongst others we could refer to:

- The cross functional aspects of processes based upon specialisation, increased skills and high technology
- The integration of processes in the healthcare sector from the suppliers to the patient and the ability to manage and monitor materials upon requests and needs
- The ability to offer specific services to patients in accordance to their needs while being able to constraint costs of this customised care. In fact this is the essence of managed care: providing satisfactory and high quality of care at a reasonable cost.
- The global scale of healthcare: This sector is no exception to any other global marketplace, thus making healthcare delivery more comparable at a national or regional level and within accepted standards (e.g., clinical procedure guidelines)
- Innovation, which has been a key driver towards quality of care and quality of life for many years in the healthcare sector
- Knowledge workers: the increasing complexity of medicine and technology has created a need for highly skilled personnel at every level of a healthcare institution. Employee empowerment is driven by knowledge as it is created in the daily process of delivering healthcare services.

Nowadays, performance measurement is moving towards the adoption of a set of objectives for a healthcare system. To our knowledge, there is no complete agreement on what is meant by "performance" of health systems and many sets of objectives are generally proposed. The use of Key Performance Indicators (KPI) helps to establish this set of objectives more thoroughly by focusing on the real needs.

Using Balanced Scorecards

In order to address the issue of creating a set of KPIs , the Balanced Scorecard (BSC) framework (Kaplan, 2001; Norton & Kaplan, 1996) initially proposed by Kaplan and Norton for the strategic management of financial organizations in the mid 1990s, is one of the most suited approaches in that direction. This model has now proven its value and since it is a generic framework it is applicable to the healthcare sector. The BSC concept involves creating a set of measurements and objectives for four strategic perspectives:

- Financial: financial performance measures typically indicate whether a proposed strategy implementation and execution is contributing to bottom line improvements, based upon an accurate summary of economic consequences of actions already taken.
- Customer (i.e., the Patient): this perspective is a set of objectives that focuses on identifying the patient's needs, the targeted market (this could be the case of a specialised institution) and on measuring the performance of each specific business unit (i.e., a department) that has some influence on how the patient sees the healthcare organization.
- Internal Business Process. This perspective should gather all objectives related to processes and the way these are monitored and fine-tuned in order to achieve both excellence in financial accomplishments and patient satisfaction. In that sense, the BSC approach is a constant business process reengineering process based upon specific goals to meet and not on improving de facto established processes.
- Learning and Growth (innovation and vision). This is an important perspective of

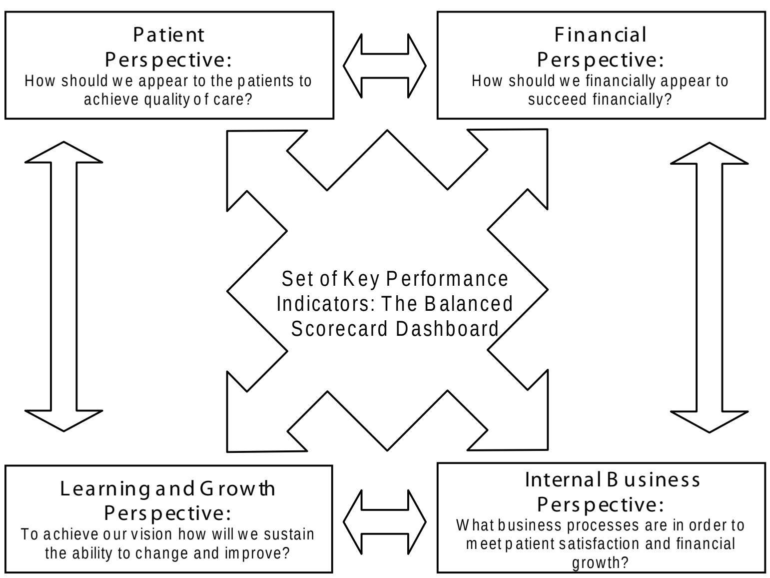
a BSC implementation because it focuses on the objectives and goals to achieve the incorporation of business innovation (e.g., installing a Positron Emission Tomography Device) and the continuous education of medical and administrative staff. In that sense, this perspective identifies measurable tasks in order to build long-term growth and improvement. In the healthcare sector, improvement is also measured by assessing the outcome of treatment and care.

These four perspectives comprise a framework, meaning that they must be assessed and populated in accordance to each business case. In order to achieve this, one has to set for each category a list of objectives that can be feasibly measured. To each objective, a specific target should be set and the initiative to reach that target well described.

The BSC approach retains the "traditional" financial perspective, which mostly focuses on reporting about past events. Financial figures, even if prospected in the future by statistical means, are inadequate for guiding and evaluating the journey that healthcare institutions must make to create future value through innovation, knowledge, patient satisfaction, employee empowerment, process refinement, technology assessment and material management. In that sense, the three other cited perspectives are completing the puzzle in order to create a more valid and future-oriented performance management strategy. In recent years, there have been some implementations of BSC frameworks in the healthcare sector mostly on a single institution base (i.e., a hospital, a clinic, an information technology component). Readers are encouraged to read and assess the best practices, cited as references to this chapter (Aidermark, 2001; Castaneda-Mendez, Mangan, & Lavery, 1998; Forgione, 1997; Freeman, 2002; Gordon & Geiger, 1999; Inamdar, Kaplan, & Bower, 2002; Oliveira J, 2001; Pink, Mc Killop, Schraa, Preyra, Montgomery, & Baker, 2001; Tarantino, 2003; Weber, 1999)

The model in Figure 1 enables decision makers to also value how the latter three perspectives have worked and thus it enables the measurement of intangible aspects of a system. The measurements focus on a single strategy that can be easily broken

Figure 1. A healthcare oriented BSC framework



down to the various levels of depth, depending of the organization type. Thus, by using BSC one can create a top-to-bottom design of a system, starting up from the needed strategy (what is the market, who are the customers, what are the critical processes, what is required by the stakeholders) going down to design metrics, processes, structures and finally the needed technical and functional specification to create an information system and a knowledge management framework capable of producing the right data and serve the strategy.

QUALITY ASSURANCE IN HEALTHCARE AND THE ROLE OF INFORMATION TECHNOLOGY

Known Problems and Issues of the Healthcare Sector

It is rather of common knowledge that the healthcare sector is not a sector without problems. Especially in Europe, the great majority of healthcare organizations are state funded. This means that institutions have in some cases very restricted budgets to satisfy their needs thus making performance management a critical issue in their daily routine. Other common problems are increased bed coverage (some institutions are almost at 100 percent), long length of stay, increased waiting lists, poor facilities, and so on. Taking all this into account and adding the life-related processes, one can clearly see that healthcare organizations are difficult to manage even for experienced managers of other sectors. One could list some of the major issues that healthcare stakeholders are confronted with:

- Diversity of cases
- Need of high technology medical devices
- Public Policy Restrictions (e.g., payment by per day quotas that do not cover the inpatient treatment costs)
- High lengths of stay
- Increased waiting times
- Obsolete facilities
- Restricted funds for training
- Restricted funds for maintenance
- Increased number of medical errors (sometimes fatal)
- Erroneous drug prescription and intake (sometime fatal)
- Geographical issues (too many patients, too few nurses and medical staff)
- Large lists of materials to be managed (more than 3000 on average)
- Excessive waste management (10 m^3 per day on average)

Quality Assurance and Performance Management

The application of a BSC framework will not by itself solve any of the aforementioned problems and issues. One could even say that BSC projects often fail as a consequence of misunderstanding or of not using a BSC strategy. BSC projects also fail because the variables of the scorecard are incorrectly identified as the primary drivers and because the improvement goals (the targeted objectives) are negotiated across an institution instead of being based upon stakeholders' requirements, fundamental processes and improvement process capabilities. They also fail because there is no deployment system installed to disseminate, maintain and promote the BSC framework, or because some very important KPIs are not used, or metrics are poorly defined.

Furthermore in order to create a structure that can be monitored the KPIs should not be more that 10 for each perspective, while non financial metrics should overcome the financial metrics by approximately six to one (Schneiderman, 1999). In order to support any BSC framework, a deployment and maintenance system based upon quality assurance specially designed for Healthcare should be established. Traditionally in healthcare, Quality Assurance (QA) has been meant to apply predominantly to healthcare itself as provided directly to patients by legitimate healthcare practitioners. We also include other services that directly affect the ability of practitioners to perform well, meaning services such as radiology, pharmaceutical, laboratory, and patient admission. The basic quality assurance terms (Donabedian, 2003) are:

- Efficacy: the ability of the science and technology of healthcare to bring about improvements in health when used under the most favorable circumstances.
- Effectiveness: the degree to which attainable improvements in health are in fact attained.
- Efficiency: the ability to lower the cost of care without diminishing attainable improvements in health.
- Optimality: the balancing of improvements in health against the costs of such improvements.
- Acceptability: conformity to wishes, desires, and expectations of patients and their families.
- Legitimacy: Conformity to social preferences as expressed in ethical principles, values, norms, mores, laws, and regulations.
- Equity: Conformity to a principle that determines what is just and fair in the distribution of healthcare and its benefits among the members of the population.

One can clearly see the benefit of applying quality assurance components in the development of a BSC strategy. A BSC framework that meets quality assurance in healthcare is most probable that will meet patient needs, practitioners' feelings, patient-practitioner relationship, amenities of care (e.g., confidentiality, privacy, comfort, cleanliness, convenience), as well as financial and organizational aspects required.

The most popular quality assurance model in healthcare is based, to the best of our knowledge, upon the Donadebian approach (Donabedian, 1980, 1982, 1985, 1993, 2003) where a healthcare organization (i.e., a hospital) is a system formed by the interaction of structures, processes, and outcomes. Structures are used to establish processes in order to create healthcare outcomes that have an effect on structures that need to change or adjust processes to meet the required outcomes. Strongly believing that healthcare outcomes are more important than financial outcomes in a healthcare system, we are confronted with a model where intangible assets are more important than tangible assets. This last statement makes a healthcare system very difficult to manage and a straightforward strategy hard to define.

The Need for a Specific Implementation Plan

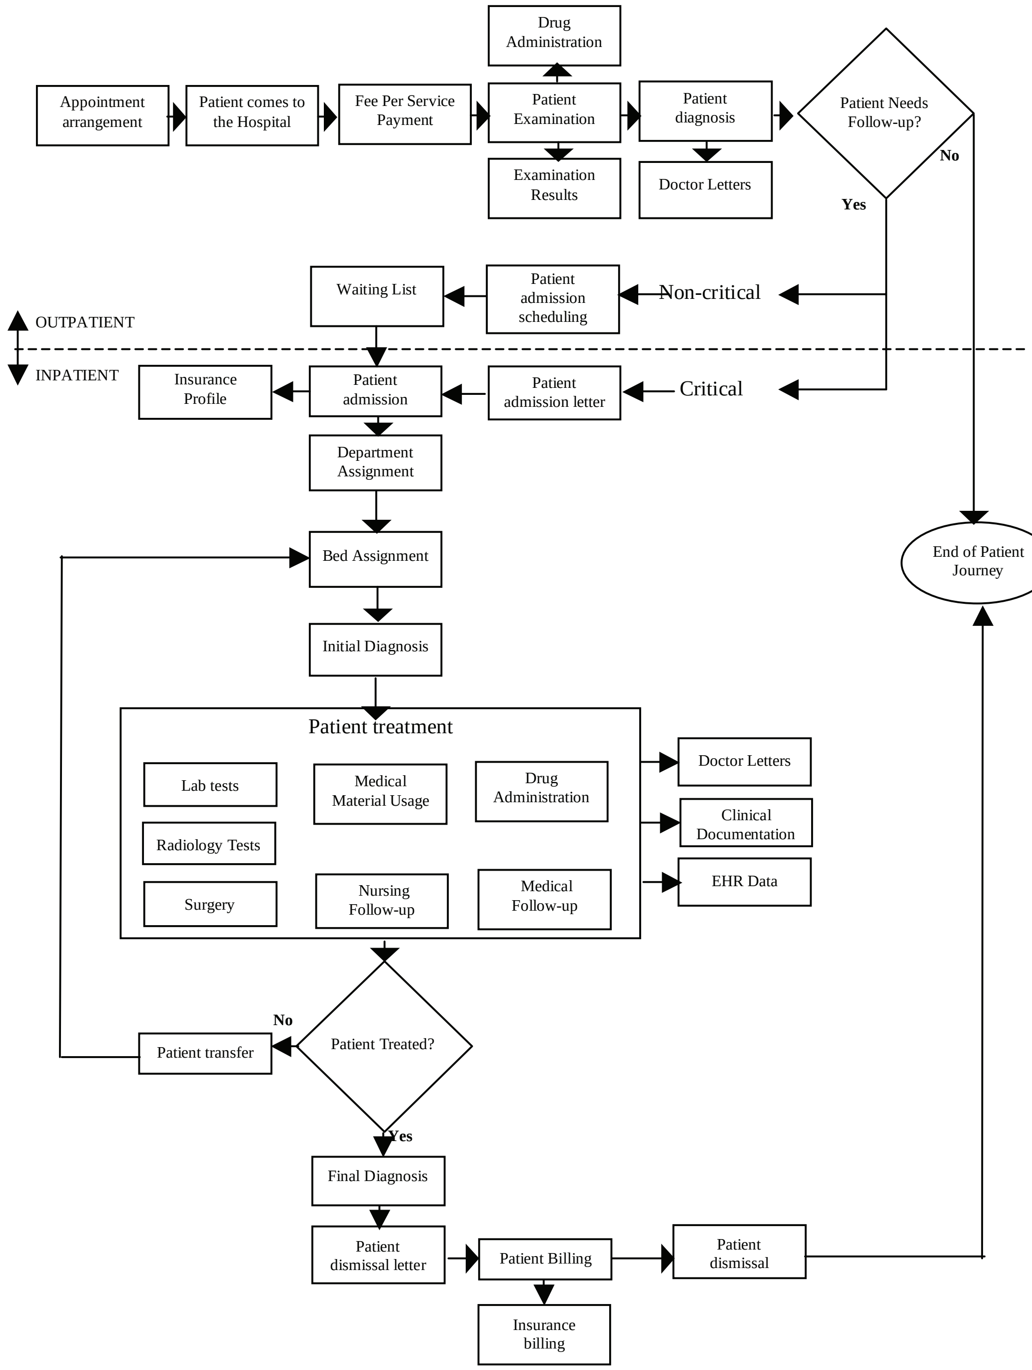
In order to implement a viable performance management strategy (i.e., a BSC framework) the steps one needs to take include:

- Determining what to monitor
- Determining priorities in monitoring
- Selecting an approach to assessing performance
- Formulating criteria and standards (i.e., Key Performance Indicators)
- Obtaining the necessary information
- Determining how and when to monitor
- Constructing a monitoring system
- Managing changes and improvements

Building a Patient-Centered Healthcare Model

Finally, the proposed KPIs are directly or indirectly driven from healthcare processes. As an example, we propose to analyze a standard patient journey of a citizen in a healthcare institution. Figure 2 shows how the patient journey for a hospital is

Figure 2. The patient journey centered model for a hospital institution



conceived (the patient journey in a primary care setting may be simpler). This workflow is the heart of the healthcare system and a prerequisite for any patient-centered information system to properly manage the information flow. This workflow is nowadays extended to include new processes such as emergency pre-hospital care and home care monitoring in order to create the hospital without walls of the 21st century.

Based on Figure 2 one can create a table where quality assurance and balanced scorecard features are confronted, analyzed, assessed and finally set. Table 1 is an example (non exhaustive) of the initial process.

From the above, it becomes apparent that the design and proposal of KPIs is not an easy task. KPI selection can vary upon specific measurement needs, upon goal set, and so on. In order to manage and validate the proposed KPIs by each BSC strategy, a set of KPI dashboards for each management entity, department or any other region of interest should be created.

USE CASE: REGIONAL HEALTHCARE AUTHORITIES IN GREECE

In 2001, a reform of the Greek National Healthcare System was introduced in order to enhance the performance and control of healthcare provision in Greece (Greek National Healthcare System Reform Act, 2001; Vagelatos & Sarivougioukas, 2003). One of the main changes was the division of the country in 17 autonomous healthcare regions where the Regional Healthcare Authority (RHA) is responsible for the regional healthcare strategy. This reform introduced the need to establish a three-level decision-making and performance management mechanism as described in Figure 3.

The proposed methodology was used to reach an initial set of KPIs by assessing existing knowledge and future needs (Decision No 1400/97/EC, 1997; McKee & Healy, 2002; Polyzos, 1999). Those KPIs were processed especially to serve the new strategy introduced in Greece.

As described in Figure 3, the regional healthcare system is comprised of a series of information systems covering the whole structures existing at any level, the processes required to meet the administrative and medical needs and finally, the outcomes that must come out from the implementation of such a complex interpolation of informatics infrastructure. The above information model was introduced to establish a community of networked healthcare organizations (hospitals, primary care) that are interoperating in order to support and implement the new healthcare strategy: to provide integrated and high quality healthcare services to the citizens based upon equal access to the resources (Information Society SA, 2003). In order to achieve this goal, two main issues were raised:

- How and when will information systems interoperate?
- What is the minimum required dataset to achieve the proposed strategy?

The first issue can be answered by using standards and protocols such as HL7 to meet with interoperability issues in healthcare (Spyrou, Berler & Bamidis, 2003). The second issue is partially addressed by the proposed initial set of KPIs presented below. The proposed KPIs are forming a complete set of metrics that enable the performance management of a regional healthcare system. In addition, the performance framework established is technically applied by the use of state-of-the art knowledge management tools such as data warehouses and business intelligence information systems.

The proposed KPIs are categorised into the four perspective stated by Norton & Kaplan, having also taken into account the raised quality

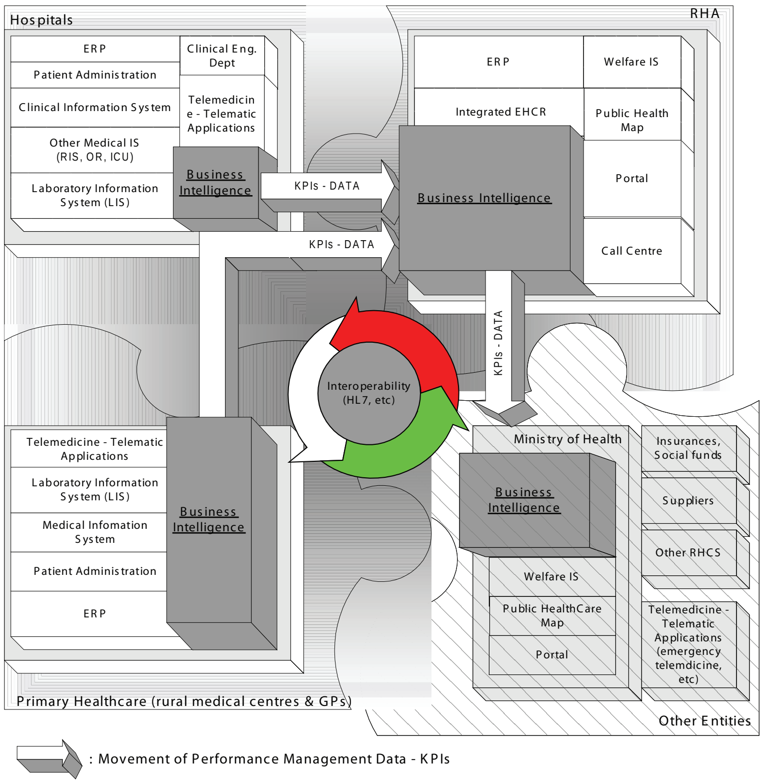
Table 1. Defining KPIs from processes, an example

Workflow process	BSC Perspective	KPI	QA approach	Source of information
Appointment arrangement	Patient	Appointments/day	Process	Hospital Information System (HIS), Scheduling S/W
Patient comes to the Hospital	Process	Number of outpatients	Process	Hospital Information System
Fee Per Service Payment	Financial	Mean cost per examination	Process	Billing, ERP S/W
Drug Administration	Process	Number of prescription/ drug	Outcome	Patient Order Entry S/W, HIS
Patient Examination	Patient	Patient satisfaction	Process	HIS, surveys
Examination Results	Growth	Number of patient with re-examination	Outcome	HIS, Electronic Healthcare Record (EHR)
Doctor Letters	Process	Number examinations/practitioner	Outcome	HIS, Electronic Healthcare Record (EHR)
Patient diagnosis	Growth	Visits/ICD codes	Outcome	HIS, Electronic Healthcare Record (EHR)
Patient Needs Follow-up?	Process	Number of inpatient from outpatient clinic	Process	HIS
Waiting List	Patient	Waiting time in days	Structure	Hospital Information System (HIS), Scheduling S/W
Patient admission scheduling	Patient	Equity of delivered care	Process	Hospital Information System (HIS), Scheduling S/W
Patient admission letter	Process	Number of emergency cases/day	Process	HIS
Patient admission	Process	Number of inpatients	Process	HIS
Insurance Profile	Financial	Net cash flow per insurance company	Process	HIS, ERP
Department Assignment	Financial	Mean operational cost per department	Structure	HIS
Bed Assignment	Process	Bed coverage rate	Structure	HIS
Initial Diagnosis	Process	Admission per case type (ICD 10)	Outcome	HIS, Electronic Healthcare Record (EHR)
Lab tests	Process	Mean value of lab test per doctor, per patient	Outcome	Laboratory Information System (LIS)
Radiology Tests	Process	Mean value of radiology test per doctor, per patient	Outcome	Radiology Information System (RIS)
Surgery	Financial	Mean cost of surgical procedure	Structure	HIS, Electronic Healthcare Record (EHR)
Medical Material Usage	Financial	Mean cost of medical material consumption	Outcome	HIS, ERP
Nursing Follow-up	Growth	Number of Nurses per bed	Process	HIS, Electronic Healthcare Record (EHR)
Medical Follow-up	Growth	Number of practitioners per bed	Process	HIS, Electronic Healthcare Record (EHR)
Clinical Documentation	Process	Number of medical procedures per day	Outcome	HIS, Electronic Healthcare Record (EHR)
EHR Data	Patient	Number of cases with EHR	Outcome	HIS, Electronic Healthcare Record (EHR)
Patient transfer	Process	Number of patient transfers/ patient or /day	Process	HIS
Patient Treated?	Growth	Number of patients treated under a specific critical pathway	Process	HIS, Electronic Healthcare Record (EHR)
Final Diagnosis	Growth	Cases per final diagnosis	Outcome	HIS, Electronic Healthcare Record (EHR)
Patient dismissal letter	Patient	Inpatient Satisfaction	Process	HIS, surveys
Patient Billing	Financial	Mean treatment cost per day	Process	Billing, ERP S/W
Patient dismissal	Process	Mean length of stay /per dept. per ICD code	Process	HIS
Insurance billing	Financial	Return of Capital Employed (ROCE)	Process	Billing, ERP S/W

assurance issues stated earlier. The performance indicators in a regional healthcare setting are depicted in Table 2.

Each of the above KPIs is the result of analysis based upon the needs of a standard regional healthcare authority. The proposition of a set of KPIs is nevertheless not the complete solution of the problem. Implementing KPIs is a constant process based upon specific metrics that each regional healthcare authority and each department or institution under its control must periodically assess and reengineer. Assessment should be based

Figure 3. Regional healthcare information systems framework and interoperability



upon specific goals met and reengineering is often required due to administrative, demographic or other important changes that must occur. Focusing for example in the KPI marked as "mean treatment cost per day" one should notice that the KPI does not mean much without a metric. In Greece, most of inpatient treatments are based upon fixed prices per day and do not follow the pay per service model which is financially more viable.

Healthcare financials are part of a national policy aiming at providing high quality healthcare services to all citizens regardless of their income, social status or other characteristic. As a consequence, the use of the fixed price model (per day quotas) in Greece serves that purpose albeit with its advantages and disadvantages. Current treatment cost per day (for an inpatient) has been fixed to about 135 Euros and this value could be used as an initial metric. If this value is exceeded this would mean that the RHA budget will cover the difference or transfer the cost to insurance companies and social welfare. In addition, a regional healthcare authority will then have credible proof that national standards are outdated and require revision in order to support the system. As a result, this KPI has now a specific meaning linked to regional strategy and budgetary needs. Following that example, all financial KPIs are therefore an important perspective of BSC since they are the measurement of the financial viability of the regional healthcare authority. In fact, all KPIs should be associated with adequate metrics in order to be assessed, thus driving the RHA towards the right strategic decisions.

In order to meet and populate the above-mentioned KPIs a regional healthcare authority has to implement a complex information technology system in order to gather up all needed informa-

Table 2. KPIs in a regional healthcare setting

No	Financial KPI description	No	Process KPI description
F1	Mean treatment cost per day	P1	Length of stay
F2	Mean cost of medical treatment per patient	P2	Patient admission rate per medical unit
F3	Mean cost of drugs consumption	P3	Percentage of bed coverage
F4	Mean cost of radiology testing	P4	Vaccination rate
F5	Mean cost of laboratory testing	P5	Mean value of performed test per patient, per doctor
F6	Mean cost of material consumption	P6	Number of inpatients
F7	Mean cost of surgical procedure	P7	Number of outpatients
F8	Mean operational cost per dept./clinic	P8	Number of drug prescription
F9	Mean cost of vaccination procedures	P9	Number of laboratory tests
F10	Mean cost per medical examination	P10	Number of surgery procedures
F11	Return of capital employed (ROCE)	P11	Number of radiology tests
F12	Net Cash flow	P12	Number of visit in outpatient clinics
F13	Income per employee	P13	Number of visits in primary care institutions
F14	Payroll rate versus operational costs.	P14	Number of dental care processes
		P15	Number of processed emergency cases
		P16	Number of unprocessed order entries on the same day
		P17	Number of preventive care visits
		P18	Number of home care monitored patients
		P19	Assessment of patient satisfaction

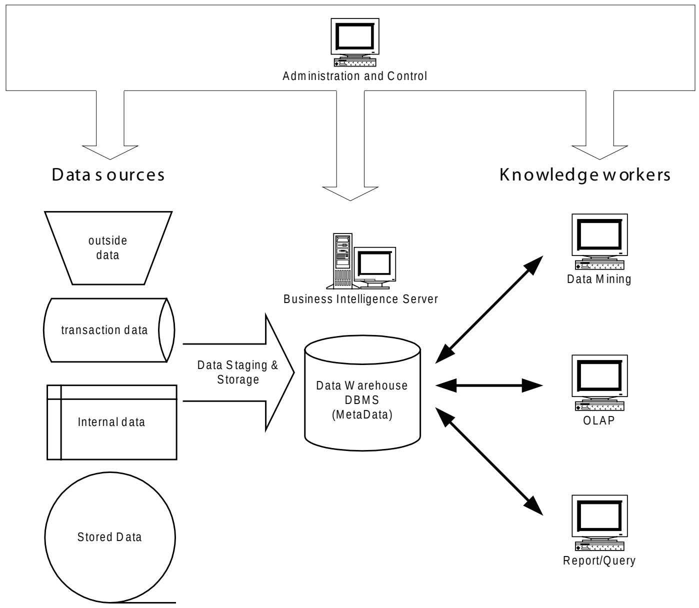
No	Customer (patient) KPI description	No	Learning and Growth KPI description
C1	Mortality rate	L1	Medical device usage growth
C2	Morbidity rate	L2	Healthcare professionals training rate
C3	Number of medical staff per 1000 inhabitants	L3	Employee Satisfaction rate
C4	Number of beds per 1000 inhabitants	L4	Number of doctors per bed
C5	Accessibility of patients to the medical units	L5	Number of nurses per bed
C6	Time in a waiting list	L6	Number of existing healthcare professionals versus expected job positions
C7	Equity of delivered care	L7	Personnel productivity rate
C8	Number of readmission per patient	L8	Number of medical interventions per doctor
C9	Mean length of stay	L9	Number of patient with re-examinations
C10	Patient Satisfaction rate	L10	Visits/ICD codes
		L11	Admissions per case type (ICD 10)
		L12	Dismissals per case type (ICD 10)

tion. Then the information collected through the use of enterprise resource planning software, hospital information systems, clinical information systems, radiology information system, and laboratory information systems has to be processed and interpolated to produce the final metadata set from which the KPIs are driven. In other words, the model is complemented by a business intelligence solution similar to the one depicted in Figure 4.

Figure 4 shows how data are collected from the various data sources, cleansed and homogenised, and finally redistributed to the knowledge workers and decision makers of the regional healthcare authority (Extraction, Transformation and Load—ETL).

The data collection process is extremely important since it is a basic feature of successfully populating the KPIs. In that sense both organizational and technological issues to achieve data quality should be considered. In the proposed setting, the regional healthcare authority has imposed on its healthcare units the use of specific classifications, codifications and taxonomies such as the 10th edition of the International Classification of diseases (ICD10). In addition, the proposed KPIs can be seen as attributes of structure, process or outcome (based upon the Donabedian approach) so that they can be used to draw an inference about quality. As such the KPIs are proposed, designed, tested and assessed by a panel of experts (executive officers of the RHA, practitioners). By implementing this organizational structure the quality level of the proposed KPIs is such that technological issues are greatly reduced.

Figure 4. Regional healthcare authority business intelligence framework



FUTURE TRENDS

Up to this point, this chapter has mostly dealt with organizational and strategic features of knowledge management in healthcare. In the proposed use case we have shown an ongoing implementation of a Balanced Scorecard Framework in a regional healthcare authority environment. This has been done intentionally wishing to state that the technological part on such an implementation is probably the less important issue. If one regards the future trends in knowledge management, one can see that a multitude of new tools are already proposed for use. This chapter will briefly set the focus on the trends that to our knowledge are the most promising and present more opportunities to healthcare organizations in creating effective performance management facilities.

Service Oriented Architecture and Patient-Centered Architecture (Based on the Electronic Health Record)

The term of patient-centered architecture has been already in the literature for some years. Many techniques have been used in the past such as Corbamed (Object Management Group, 2001) and Distributed Healthcare environment (DHE). The introduction of web technologies such as the Extensible Markup Language (XML), the Simple Object Access Protocol (SOAP), the Web Services Description Language (WDSL), and more precisely the concept of Web Services (Deitel, Deitel, DuWaldt, & Trees, 2003; W3C, 2003) are driving information technologies towards a Service Oriented Architecture (SOA).

A service is a software component that is suitable for cross-application access. A service is never a complete application or transaction. It is always a building block. SOA is the architecture of an application that uses services. Services define reusable business functions; SOA binds services into applications. Logically, services are defined by their interfaces. Technically, services are defined by their implementations (sometimes complex integrated flows, other times a single simple program). SOA is a logical concept, and its design is focused on the definition of service interfaces and interactions between service interfaces. Fundamental to SOA is the loose coupling between its components. At the logical level, this translates to the ability to add a new service for the end-user unobtrusively to the service provider. At the technical level, this translates to the ability of software developers to deploy a new application that calls a service without the need to redeploy or change the service. The use of SOA will allow the creation of process-based components of applications that will manipulate knowledge and information based upon the processes and the required or designed outcomes.

The Semantic Web

The Semantic Web goes beyond the World Wide Web by encoding knowledge using a structured, logically connected representation, and by providing sets of inference rules that can be used to conduct automated reasoning. Whilst the idea of knowledge representation languages is not new, existing languages generally use their own set of ontologies and inference rules to identify and eliminate logical contradictions and inconsistencies. The Resource Description Framework—RDF (W3C, 2003) and XML Topic Maps (TopicMaps.Org, 2001) are the most promising tools towards the implementation of the Semantic Web in practice. Nevertheless, a long way towards maturity has still to be covered since issues such as specific metadata frameworks and data quality are not yet solved. In any case, the Semantic Web should enhance the promotion of clinical practice guidelines and evidence based medicine. They can be seen as taxonomies of medical cases that could be both used for performance monitoring (in respect to commonly agreed levels of delivered care) and decision support for the healthcare practitioners.

Critical Pathways

Critical Pathways (Wall & Proyect, 1998) are mechanisms for transforming a reactive bureaucratic ritual to a dynamic, indispensable, clinical improvement process. A critical pathway when established is a mechanism for:

- Integrating continuous quality improvements with traditional patients' care review
- Managing and impacting of clinical and financial outcomes for a specific treatment procedure
- Proactively addressing economic and regulatory changes
- Improving clinical outcomes through reduction in variation
- Controlling unnecessary cost and resource usage without jeopardising quality of care
- Fostering multi-disciplinary approach to patient care
- Linking quality management to staff education
- Managing limited financial resources
- Making efficient use of scarce organizational resources
- Increasing readiness for anticipated changed in healthcare
- Applying and using clinical practice guidelines and other taxonomies set up by different professional societies

Critical Pathways can be seen as "specialized" performance management tools that would provide a BSC framework with very specific performance indicators for each treatment or clinical process.

CONCLUSIONS

Performance management is a key issue in the continuous process of delivering high quality healthcare services. The use of KPIs has proved that the design of a Balance Scorecard acts as the "cockpit" of a regional (or national) healthcare authority where all metrics are the flight instruments enabling the provision of healthcare based upon equity, financial control, continuous process and structure refinement, and outcome measurements. In that sense, the proposed infrastructure is, technologically speaking, an important knowledge management tool that enables knowledge sharing amongst various healthcare stakeholders and between different healthcare groups. The use of BSC is an enabling framework towards a knowledge management strategy in healthcare since KM is about discovering knowledge from existing information, about creating new knowledge and about implementing processes and taxonomies that enable the reuse and assessment of information as part and bits of knowledge.

Knowledge can be seen as a performance management tool both for administrative purposes and clinical improvements.

During the implementation process of deploying a technological platform for performance management or any other type of knowledge management infrastructure, one must have in mind that:

- The six issues described in the introduction section must being taken into strong consideration from day one.
- It is important to focus on people, processes and outcomes, and to set-up a straightforward strategy to plan, manage, assess, educate, disseminate, and maintain the developed BSC framework.
- Any type of knowledge management project bases its success on continuous improvement and assessment. Metrics and processes are meant to change in order to reflect improvements towards quality of healthcare.
- The knowledge and technology is there, but still very limited best practices have been successfully implemented.
- The implementation of BSC framework is a time consuming process that has to involve all stakeholders' representatives.

Chapter 1.23
Medical Decision Support Systems and Knowledge Sharing Standards

Srinivasa Raghavan
Krea Corporation, USA

ABSTRACT

This chapter discusses about the concept of medical decision support system and the knowledge sharing standards among medical decision support systems. The author discusses the evolution of decision support in the healthcare arena, the characteristics and components of a medical decision support system, the medical decision support problem domains, and the popular medical decision support systems. Furthermore, a unique challenge in the healthcare arena—sharing of knowledge among medical decision support systems is discussed. The author discusses about the need for knowledge sharing among medical decision support systems, the evolution of various knowledge sharing standards, and the application of the knowledge sharing standards by the medical decision support systems. Finally, interesting aspects about the future trends in the medical decision support systems, its awareness, its usage and its reach to various stakeholders are discussed.

INTRODUCTION

The healthcare industry has been a pioneer in the application of decision support or expert systems capabilities. Even though the area of medical informatics and decision support has been around for more than four decades, there is no formal definition for a medical decision support system. Wyatt & Spiegelhalter (1991) describes a medical decision support system as a computer-based system using gathered explicit knowledge to generate patient specific advice or interpretation. The healthcare industry has witnessed a phenomenal growth and advances both in the areas of practice and research. This rapid growth of medical science has made the practice of medicine both challenging and complex. To address these challenges, the recognized medical standards organizations developed medical practice guidelines to simplify the research findings to practical applications in order to improve the overall healthcare quality and delivery. Despite such initiatives, it has been difficult for the physicians to keep up with the guidelines and to tune it to their practice settings. A clear gap began to develop between developing of practice guidelines and the implementation of the same. Grimshaw and Russell (1993) identified that the knowledge dissemination and implementation strategies are critical to the impact the developed guidelines will have on the physician behavior.

The natural evolution was to develop paper-based decision support workflow or protocols. Paper-based decision support models were developed and are widely used at most physician practices to apply the guidelines into practice. Paper-based decision support models, while effective, are also error prone. For example, dose recommendation models could require tedious calculations and can be error prone when performed manually. Such errors could defeat the purpose of using a decision support model. Also, paper-based models require education and training to the personnel performing those calculation and require an additional layer to review the calculations. Most paper-based models are used by the medical personnel as a batch work flow process.

Thus computer-based decision support systems were developed to provide accurate guideline compliance and to enhance physician performance (Hunt, Haynes, Hanna, & Smith, 1998). Computerized decision support system can be extremely valuable for treatment or diagnosis support and compliance accuracy when used at the point of care (Lobach & Hammond, 1997). This feature of computerized medical decision support system is a key differentiator that makes the paper-based decision support models inferior. A well designed computerized medical decision support system can be used to provide patient specific support at the desired time and location with the adequate content and pace. When decision support systems are blended into the day-to-day practice workflow, these systems have the potential to function as a valuable assistant and also as an educational tool (Thomas, Dayton, & Peterson, 1999).

The computerized decision support systems make decisions based on the clinical practice guidelines. Clinical practice guidelines are the rule-based knowledge that guides the decision makers in a medical setting. These guidelines have been developed over the years to reduce the variations among medical practices with a common goal to provide cost effective and high quality healthcare services (Field & Lohr, 1992). The availability of several decision support systems and the use of common knowledge and rules triggered the need for a common method of sharing the knowledge. This technique can save the cost of developing the same medical practice guidelines for multiple decision support systems.

While it is common among organizations to share the data and information between computer systems, sharing the knowledge was a challenge. The medical arena rose to the occasion and various associations were involved in development of a standard way of sharing the medical knowledge and clinical practice guidelines among systems. After reading this chapter, the reader should be able to:

- Understand the complexity involved in medical decision making process
- Identify the commonly used decision support techniques in medical decision support systems
- Identify the characteristics of medical decision support systems
- Identify the various phases of the decision making process
- Identify the components involved in the development of a medical decision support system
- Analyze the various decision support functions addressed by medical decision support systems

- Know about the popular medical decision support systems in use around the world
- Understand the importance of knowledge sharing standards in the medical decision support arena
- Know about the popular medical knowledge sharing standards
- Understand the future trends in decision support in the field of medicine

BACKGROUND

The invention of computers resulted from the dream of creating an electronic brain. This quest to artificial intelligence has driven several technological advances in various industries. The potential of intelligence and decision support in the area of medicine was set forth more than four decades ago by Lusted and Ledley (1959). While several computer systems have been developed to improve the administrative efficiency and medical records access, the significant challenges have always been in the development of medical decision support systems. Knowledge-based decision support systems acquire, formalize, and store the expert knowledge in a computer system and infer the represented knowledge in a problem area by modeling the decision process of experts.

One of the first expert systems developed is in the field of medicine. This expert system called MYCIN, provides decision support to physicians on treatment related advices for bacterial infections of the blood and meningitis. The basic structure of the MYCIN expert system is to present a question and answer dialog to the physician. After collecting the basic information about the patient, it asks about the suspected bacterial organisms, suspected sites, presence of relevant symptoms, laboratory results and recommends the course of antibiotics (Buchanan & Shortliffe, 1984). Even though this was a primitive expert system, it brought out the power of such decision support tool in the area of medicine and the potential for more growth in the area of artificial intelligence in medicine. After the introduction of MYCIN in the field of medicine, various decision support systems were introduced and have been successfully used. The commonly used decision support techniques in medical decision support systems are intelligent agents, rule-based engines, heuristics, and decision algorithms.

The use of an intelligent agent or softbot (intelligent software robot) is a popular decision support technique that has the potential to become one of the most important in the next decade (Turban & Aronson, 2000). There are several definitions of an intelligent agent, but the general concept is that the agent carries out a set of operations with some degree of autonomy (Murch & Johnson, 1999). To perform these tasks, an intelligent agent should contain some knowledge. The key characteristics of an intelligent agent are that it should be autonomous, goal-oriented, collaborative, and flexible (Brenner, Zarnekow, & Wittig, 1998). For example, an appropriate task for an intelligent agent would be to use a patient's history and problem list to assist the physician with diagnostic coding during the order entry process.

A heuristic is a rule of thumb that is used primarily to arrive at a "good enough" solution to a complex problem. This technique is used primarily when input data are limited and incomplete. When the problem or the reality is extremely complex and optimization techniques are not available, a heuristic may be used. Heuristics do not yield definitive solutions, but assist decision makers in arriving at provisional solutions (Camms & Evans, 1996). For example, the determination of the choice of initial doses of both medication and dialysis treatment for a renal patient relies on population-based pharmacokinetic and solute kinetic heuristics, respectively. Subsequent dosing does not require heuristic reasoning, but may be calculated on the basis of measurements of the individual patient's response to the initial dose (Raghavan, Ladik, & Meyer, 2005).

Rule-based decision support systems primarily store knowledge in the form of rules and problem solving procedures. In expert systems, the knowledge base is clearly separated from processing. Inputs may come from the user, or may be collected from various other programs. Rules are applied on the data collected using an inference engine, decisions are suggested, and explanations supplied (Turban & Aronson, 2000). For example, DARWIN, a renal decision support system, uses rule-based reasoning to advise dialysis technical staff regarding the response to bacteriologic monitoring of fluids used during hemodialysis. Another example of a rule-based or expert system is the use of clinical protocols to generate suggestions regarding anemia treatment using erythropoietin and iron protocols. On the basis of knowledge of new and historical laboratory results and medications, the expert system can suggest the modification of drug doses or the discontinuation of a medication. The inference engine can also provide an explanation of the basis of the recommendation in the protocol.

A decision algorithm is a set of instructions that is repeated to solve a problem. Highly intelligent algorithms include the capability to learn and to perform several iterations of the algorithm or of parts of the algorithm until an optimal solution is reached (Turban & Aronson, 2000). A very simple decision algorithm may alert physicians on receipt of out-of-range laboratory results. If the decision algorithm verifies the patient's history and decides if the standard abnormal range is indeed abnormal for the patient, the algorithm can be classified as an intelligent decision algorithm.

In the next sections, we will discuss about the characteristics of a medical decision support systems, generic components, problem areas in which decision support systems are used and knowledge sharing standards.

CHARACTERISTICS OF MEDICAL DECISION SUPPORT SYSTEMS

To understand the characteristics of a medical decision support system, it is important to analyze the medical decision making process. A clear understanding of the medical decision making process is essential to appreciate the value and the characteristics of a medical decision support system. Decision making in medicine is not a single point event. It is an extremely complex sequence of inter related and differentiated activities that occur over a period of time. The vastness of the knowledge area presents itself infinite paths to reach a decision. Thus, the importance of finding an optimal path is extremely important in the decision making process. Any assistance in this critical step can be of immense value to the medical decision makers. Hastie (2001) identifies three components to a decision making process. The first component is the choice of options and courses of actions. The second is the beliefs and opinions about the objective states, and the processes including input and outcomes states. The third is the values and consequences attached to each outcome of the event-choice-action combination.

The decision support literature classifies problems into three major categories: structured, semi-structured, and unstructured (Gorry & Morton, 1971). Structured problems are routine and repetitive: solutions exist, are standard, and pre-defined. Unstructured problems are complex and fuzzy; they lack clear and straight-forward solutions. Semi-structured problems combine the features of the two previous categories; their solution requires human judgment as well as the application of standard procedures (Simon, 1971).

Thus the complexity involved in a decision making process can be grouped as a knowledge gathering process, knowledge storage, knowledge retrieval, and information processing. The literature categorizes the decision making process into four distinct phases: intelligence, design, choice, and review (Stohr & Konsynski, 1992).

During the intelligence phase of the decision making process, the need for a decision making (or the trigger) event is recognized and the clinical problem or opportunity is properly identified and defined. This is done by eliciting two different types of knowledge domains: public and private. Private knowledge generally is heuristic and experience-based knowledge that usually comes from the clinical practitioners. Public knowledge can be gathered from standards, guidelines, text books and journals. The office of technology assessment (1995) suggests usage of the following questions in identifying the problems and opportunities for medical decision support.

1. Can the solution to the problem/opportunity assist in diagnosing a patient's condition?
2. Can the solution to the problem/opportunity assist in determining what the proper drug dosage level should be?
3. Can the solution to the problem/opportunity remind the appropriate care giver about the preventative services to be administered to a patient or to patient care related function?
4. Can the solution to the problem/opportunity assist in carrying out diagnostic procedure by recommending specific treatments or tests?
5. Can the solution to the problem/opportunity assist in carrying out medical procedures by alerts regarding potential adverse events?
6. Can the solution to the problem/opportunity assist in providing cost effective medical care by reminding previous orders, results, frequency rule checks, and schedule of treatment or procedure?

During the design phase, the problems or opportunities identified during the intelligence phase are further analyzed to develop possible courses of actions to construct decision models. A thorough search for ready made solutions, customized off the shelf solution, or a decision to custom solution development is made. Modeling of a decision problem involves identification of variables, identification of the relationship between those variables, and developing an abstraction into quantitative or qualitative forms.

During the choice phase, the actual decision to follow a certain course of action is made. If a single option results from the design phase, the choice phase is a simple acceptance or rejection of the option. If multiple courses of actions are identified in the design phase, then the decision makers are challenged in choosing from multiple conflicting objectives. Some decision rules for multivariable problems have applied strategies like holistic evaluation methods, heuristic elimination, and holistic judgment.

During the review phase, the outcomes of the decision making process are reviewed for validity and applicability for the case in hand. Any deviation and changes to these outcomes could very well become an expert knowledge that can be fed back into the knowledgebase to help future decision making cases.

Several studies were performed to identify the characteristics and functions of a medical decision support system. Turban and Aronson (2000) and Beatty (1999) have performed extensive research in this area of medical decision support system. Turban and Aronson (2000) summarizes the characteristics into few categories as listed below.

1. Support decision makers in semi structured and unstructured situations by bringing medical expert judgment and computer knowledgebase together.
2. Support decision making when the problem area consists of various inter-dependent and/or sequential paths.
3. Should be adaptive and flexible in nature. This allows new learning, adjustments to current knowledge and knowledge pattern recognition.

4. User friendliness is a key for success. Even a great decision support system can be useless if the users are challenged by its interface. This is particularly true in the case of healthcare arena. The system should be easy, fast, and require few mouse clicks by physicians.
5. Allow decision makers to construct simple decision constructs.
6. Should provide both automated and interactive decision support depending on the nature of the problem/opportunity.
7. Should provide complete control to the medical decision maker and should not attempt to replace the clinician's judgment.

Beatty (1999) conducted an empirical study about the characteristics and functions of a medical decision support system. This study provided several interesting findings on what support do medical decision makers expect during a decision making process. Similar to Turban and Aronson (2000) study, Beatty's (1999) finding also indicates that the decision makers favored characteristics in a decision support system that advised or guided rather than controlled. Thus, medical decision makers prefer to be in total control during the decision making process and would use the computerized system as a support or assistance during the process.

Beatty's (1999) finding also differentiated between the expectations of a medical user from a non medical user in medical decision making. This is an important variation in a medical setting as several non medical people perform various routine functions in a medical setting and medical decision support systems could assist their functions as well. The interesting finding is that the non medical users prefer to give more control and trust to the decision support system while the medical users prefer to keep control.

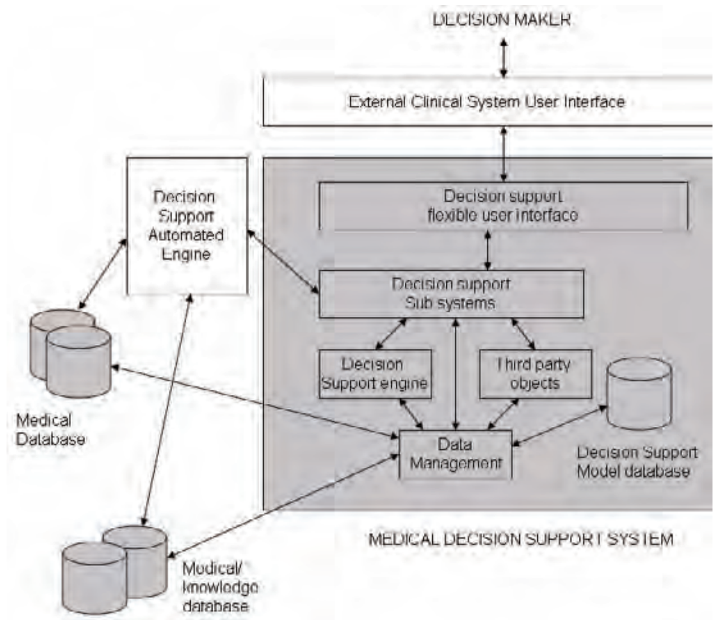
Medical decision support systems should be capable to operate in both an offline mode and a real time mode. This allows the system to be used as an educational tool during offline mode and as an advisor during the real time mode. Beatty (1999) indicates that the users prefer a detailed advice about a medical problem, treatment option, and so on, preferably through flow diagrams or case studies but a real time support should be clear, precise, alarms, and very sophisticated. The knowledge base for the decision support systems should be gathered from literature, case studies, and wide group of experts.

Turban & Aronson (2000) used a schematic view to describe the components of a decision support system. This view was used as a guideline to develop a schematic view to identify the components of a medical decision support system. As depicted in Figure 1, a typical medical decision support system consists of a medical decision support model database, a medical data management component, a medical decision support engine, third party objects including medical databases and rules, decision support sub systems, and a decision support user interface. The decision support model database contains all the tables and data needed to support the decision support models. The data needed for development of rules engine, prediction models, and protocols are stored in the model database.

The medical data management component is the critical part of the medical decision support system. This interfaces with the databases external to the decision support system to allow the decision support engine and third party interfaces to apply model database rule on the medical data to arrive at intelligent decisions.

The medical decision support engine is a set of programs that constitute the model for decision support. It was important to develop a flexible engine that could be data-driven. Several day-to-day decisions in patient care are based on changing regulations and practice guidelines. These guidelines are periodically reviewed and changed. In order to expedite such decision rule changes, it is important to maintain the rules themselves in databases, thus making the model database a meta-database.

Figure 1. Components of a medical decision support system



There are a few decision support processes that are available commercially. These third party objects may or may not include the model database bundled within the object. If they are bundled, it would become a direct interface with the decision support subsystem and the data management system. If they are not bundled, then the data is carefully placed either in the model database or in the medical database as appropriate.

Decision support subsystems are independent decision support systems that can interface with any external subsystem directly or through the decision support user interface. The medical decision support system generally consists of both automated and interactive subsystems. The automated decision support subsystems may use the automated engine to integrate the automated decision making capabilities with existing automated functions. For decision support functions that require user interaction, the decision support system flexible interface is called from the user interface layer and presented to the decision maker.

In the past four decades, numerous medical decision support systems were developed using a wide range of techniques such as automated reasoning, natural language processing, game playing, automatic programming, robotics, machine learning, and expert systems. These decision support systems generally address the medical decision support functions listed in Table 1 (Raghavan, Ladik, & Meyer, 2005). These functions are generic in nature, while the knowledge base of the decision support systems is generally specific to a medical domain area like oncology, nephrology, pediatrics, and so on.

The most common decision support function found in medical decision support systems is alerts and reminders. In a real time environment, these decision support functions are attached to the monitoring devices to provide immediate alerts as and when the trigger condition occurs. For example, the oxygen and blood pressure monitors in an acute setting can alert the nurses if the patient's condition goes beyond the set threshold value. In a chronic setting, a simple scan of laboratory results and an email or pager alert to the corresponding

Table 1. Decision support functions and clinical problems

Function	Sample Clinical Problems/Opportunities
Alert	Based on laboratory results with the range customizable at various levels
Diagnosis	Identify the possible diagnosis based on the history, physical, results, and evaluation inputs
Reminder	Reminding practitioners in order approvals, and schedules
Notification	Non conformance, risks, abnormal events, and episodes of care
Suggestion	Drug adjustments based on the recent lab values, trends, and current drug levels
Interpretation	Guidelines as applicable to the current situation – lab test schedule, protocol development
Prediction	Predicting results based on some independent variables
Assistance	Providing drug to drug interaction and drug-allergy interaction
Critique	The usage of diagnostic codes for medical procedure justification based on the applicable guidelines and the patient's medical history

decision maker are valuable decision support functions. A few medical decision support systems can provide image recognition and interpretation functions. These are extremely helpful in large hospitals where various radiology reports can be interpreted and alerts can be generated to gain the attention of the experts.

Diagnostic support is a key function that several medical decision support systems attempt to offer to help the physicians in detecting the problem based on symptoms and etiology. Such systems are commonly used to detect rare diseases and also as an aid for inexperienced practitioners. A few medical decision support systems offer care plan critiques by looking at data inconsistencies, errors, and omissions against practice guidelines.

In the next section, the problem domain, and the decision support functions provided by various popular medical decision support systems will be discussed. While there are close to hundred known medical decision support systems in use, the most popular medical decision support systems based on the existing literature and usage will be discussed in this chapter.

MEDICAL DECISION SUPPORT SYSTEMS

HELP (Health Evaluation through Logical Processes)

This is the most successful and popular medical decision support system in the United States. The HELP system of the Latter Day Saints Hospital in Salt Lake City is a hospital-based medical information system that gives practitioners a comprehensive patient record with decision support capabilities. HELP is a comprehensive medical information system with full fledged medical records, physician order entry, charges, radiology, pharmacy, ICU monitoring, laboratory, and robust decision support functions (MedExpert-HELP, 2004).

The success of HELP information system was due to the fact that the decision support functions were integrated with the hospital information system. The availability of required data and the knowledge base makes this a powerful system. The decision support capabilities made available to the decision makers at the point of care made this an effective product. This system has also been implemented at more than twenty hospitals.

The HELP information system supports the following decision support functions: alerts and reminders, decision critiquing, patient diagnosis, care suggestions, and protocols. The integrated laboratory information system allows automatic monitoring and alerts for abnormalities or out of range values. The critiquing feature is integrated within the transfusion ordering module to critique the reason provided against the strict guidelines. The system also includes modules such as automated surveillance system that uses various data elements to diagnose nosocomial infections. As an extension of this module, the antibiotic assistant recommends the antibiotics that can produce optimal benefit to the patient.

DXplain

Dxplain is a diagnostic decision support system that is owned by Massachusetts General Hospital and can be licensed and accessed over the internet as well. DXplain is a powerful diagnosis decision support system used in general medicine. The power of DXplain is its knowledge base that can diagnose close to 2000 diseases emphasizing the signs and symptoms, etiology, pathology and prognosis. This system was developed during the early 1990s by Massachusetts General Hospital and has been used by thousands of physicians and medical students.

DXplain uses a set of signs, symptoms, and laboratory results to produce a ranked list of diagnoses which might explain the clinical manifestations. DXplain uses Bayesian logic to derive the clinical diagnosis interpretation (MedExpert-DxPlain, 2004). It is important to note that the system only provides suggestion and not definitive conclusions. Since this system is in production and licensed as a product, the knowledge base should be continually updated.

DXplain is routinely used at medical schools for clinical education. DXplain diagnosis decision system has characteristics of an electronic medical textbook and a reference system. After receiving the inputs, the system develops a list of ranked diagnosis based on the input and provides the justification. This is one of the main reasons why this system is used widely for education purposes.

DXplain system provides about 10 appropriate references for each suggested diagnosis. The user interface for the DXplain system is very intuitive with graphical user interface requiring only clicks from the lists to drill down to the recommendations. This is one of the main reasons suggested for the success of this product.

RMRS

Regenstrief Medical Records System (RMRS) is one of the oldest, popular, and commonly cited decision support system in the United States. RMRS, developed at Indiana University, is a hospital-based medical information system with decision support capabilities like preventive care reminders and advice regarding cost- effectiveness details during physician order entry.

As early as 1974, RMRS began to deliver paper generated automatic reminders to the physicians the night before a patient's visit. This intelligent system reviewed the patient's medical record against the set of pre-defined protocols to generate reminders about the patient's condition and to suggest corrective actions. In 1984, this report-based decision support system was programmed into an interactive Gopher-based system to break the long list of reminders into logical groups, allowing physicians to step through the reminders during the physician order entry process. The success of RMRS system was due to the fact that the decision support functions were integrated with the hospital information system. The availability of required data and the knowledge base makes this a powerful system. The decision support capabilities made available to the decision makers at the point of care made this an effective product.

In the past decade, RMRS went through a lot of developments and has included various decision support techniques such as pattern recognition and intelligent agents to help physicians assess the patterns of care and identify patients with particular risk factors and adverse outcomes. This system is used at more than 40 inpatient and outpatient facilities and the commercial version is marketed internationally.

PRODIGY

PRODIGY (PROject prescribing rationally with Decision support In General practice study) is a prescribing decision support system that offers evidence-based, cost effective general practice prescribing. The Sowerby Center of Health Informatics at Newcastle University was approached by the English National Health Service Executive during 1995 to develop a medical decision support system to guide UK general practitioners on therapeutic actions covering prescribing. While developing PRODIGY, the research team realized the importance of integration with already existing general practice software used by the general practitioners. Hence integration with all the five major general practice software in the UK was performed to make PRODIGY a powerful medical decision support system.

While several medical decision support systems assist in diagnosing the problem, PRODIGY starts after the diagnosis is made by providing medical advice and therapeutic recommendations (MedExpert-Prodigy, 2004). The system also stores patient information leaflets containing information about the disease in simple terms. The trigger for decision support within PRODIGY is the input of diagnosis code. Once the physician enters the diagnosis code in their general practice system, it activates PRODIGY decision support to check if suitable medical recommendations are available. The decision maker at that point has the option to explore the recommendations or ignore it. When explored, the decision maker will be presented with therapy scenarios, evidence-based prescribing, and availability of patient information leaflets along with justification and references for the recommendations. PRODIGY medical decision support system has been successfully implemented nation wide at all general practitioners in the UK.

CADIAG – II (Computer Assisted DIAGnosis)

CADIAG – II is a hospital-based medical decision support system developed by the Department of Medical Computer Sciences at University of Vienna. CADIAG decision support system has been integrated with the medical information system of the Vienna General Hospital.

CADIAG decision support system focuses on the colon diseases, rheumatic diseases, gall bladder, pancreatic diseases, and bile duct diseases (MedExpert-Cadiag, 2004). This medical decision support system provides online consultation support for the physician to assist in diagnosis of the diseases given the signs, symptoms, etiology, and laboratory results. This system contains a very strong knowledge database in the specialty areas of colon diseases and rheumatic diseases.

NeoGanesh

NeoGanesh is a widely cited knowledge-based decision support system that is used primarily to manage the mechanical ventilation in Intensive Care Units. This decision support system is one of the very few automated and controlled system with very limited human intervention. This real time medical decision support system checks for the real time data and controls the mechanical assistance provided to the patients suffering from lung diseases in a pressure supported ventilation mode (Dojat, Pachet, Guessoum, Touchard, Harf, & Brochard, 1997). The other interesting feature of the system is to develop a therapeutic strategy to respond to the patients and evaluate the capacity to breathe. This system is used at Henri Mondor Hospital in France. This system is being planned to be released for commercial purpose as well.

MEDICAL DECISION SUPPORT KNOWLEDGE SHARING

Overview

The field of medicine has been a pioneer in the introduction of decision support systems. One of the first expert systems to be developed was in the field of medicine. The complexity of decision making in the field of medicine and the challenge of keeping up to date with the new findings and research has been a key motivator for the usage of medical decision support systems. As discussed in the previous sections, numerous medical decision support systems exist in the market. The knowledge for most of these medical decision support systems are acquired from the clinical practice guidelines issued by various government and medical associations. Clinical practice guidelines are the rule-based knowledge that guides the decision makers in a medical setting. These guidelines have been developed over the years to reduce the variations among medical practices with a common goal to provide cost effective and high quality healthcare services (Field & Lohr, 1992).

Healthcare organizations historically have focused more on the development of the clinical practice guidelines compared to the implementation of the guidelines (Grimshaw & Russell, 1993). Past research studies have proved that the computerized medical decision support systems when integrated with the clinical workflow can improve the practitioners' compliance with clinical practice guidelines and outcomes (Johnsons, Langton, Haynes & Mathieu, 1994). Thus, it was clear that the medical decision support systems are best vehicles to promote compliance. The availability of several decision support systems and the use of common knowledge and rules triggered the need for a common method of sharing the knowledge. This technique can save the cost of developing the same medical practice guidelines for multiple decision support systems.

While it is common among organizations to share the data and information between computer systems, sharing the knowledge was a challenge. While knowledge sharing could be considered as losing competitive advantage, the healthcare industry was one of the few industries where several guidelines are common as they are generally developed by government agencies or medical associations. The medical arena rose to the occasion and various associations were involved in development of a standard way of sharing the medical knowledge and clinical practice guidelines among systems. In the following sections, the various prominent clinical practice guideline models and knowledge sharing standards are discussed.

ARDEN Syntax

ARDEN Syntax is an ASTM (American Society for Testing and Materials) and ANSI (American National Standard Code for Information Interchange) standard a hybrid knowledge representation format that was created with the main aim to address the ability to share, reuse, and understand the medical knowledge base. It is first introduced in 1989 at the Columbia University's Arden homestead conference. The initial idea for the conference was to create a knowledge representation format that can facilitate the definition of knowledge bases and thus could result in an effective implementation of new knowledge consistently (Hripcsak, Pryor & Wigertz, 1995). The development of knowledge bases is the biggest challenge faced by the ever changing medical field and introducing a knowledge representation format was thought to be of significant help to allow various institutions to share their knowledge among medical decision support systems.

The ARDEN syntax was largely derived from the logical modules used by the HELP and RMRS medical decision support systems. The concept of the ARDEN syntax is to develop rule-based modular logical rules called medical logical modules (MLM). The medical decision support system that is based on Arden Syntax polls for the occurring events and executes the MLM's out of its knowledge base that has defined the occurring event as the triggering condition.

In ARDEN syntax, the MLM's are composed of slots that are grouped into three categories called maintenance, library, and knowledge. Each category has a set of predefined slots. The slots are broadly classified as textual slots, textual list slots, coded slots, and structured slots. The maintenance category contains the slots that specify general information about the MLM like title, mlmname, arden syntax version, mlm version, institution, author, specialist, date, and validation. The library category contains slots about the knowledge base maintenance that is related to the module's knowledge. This category contains the relevant literature, explanation, and links that were used in defining the MLM. The library category slots are purpose, explanation, keywords, citations and links. The knowledge category contains the slots that specify the real knowledge of the MLM. The knowledge category dictates the triggering event of the MLM and the logic of the MLM. The knowledge category slots are type, data, priority, evoke, logic, action, and urgency.

Example

Let us look at a simple anemia management protocol for a renal patient as an example. On receipt of new hemoglobin laboratory result, if the value is greater than 13.3, and if the patient is on Erythropoietin dose, then recommend discontinuation of the dosage. The MLM for this simple rule is given in Box 1.

ARDEN syntax-based decision support systems are widely in use. Since this syntax became an ANSI standard, it was embraced by several medical information system vendors to provide decision support capabilities. Vendors who have developed ARDEN compliant applications include: Cerner Corporation, Healthvision, McKesson, SMS, and Micromedex.

Asbru

Asbru is a knowledge representation language to capture the clinical guideline and protocols as time oriented skeletal plans. The development of Asbru was part of the Asgaard project developed by the Technical University of Vienna, Stanford Medical Informatics, University of Newcastle, and University of Vienna. The goal of the Asgaard project is to develop task specific problem solving methods that perform medical decision support and critiquing tasks (Seyfang, Miksch, & Marcos, 2002).

Asbru is a difficult language to be understood by a physician and hence a graphical knowledge acquisition tool is used to gather the knowledge or guideline and then output that into Asbru syntax behind the scenes for computer interpretation. The graphical tool used is called Protégé. The Asbru output created by Protégé can be shared with other medical decision support systems that are compliant with Asbru format.

Erythropoietin dosage. As per clinical guideline, it is recommended to discontinue the Erythropoietin dosage.";

        ;;

      urgency:  90;;

    end:
```

EON

EON is a clinical guideline modeling system developed by Stanford University for creating guideline-based decision modules. The EON guideline model system was developed to address the problem of modeling clinical guidelines and protocols to provide patient specific decision support. This modeling system allows creating a knowledge engineering environment for easy encoding of clinical guidelines and protocols. EON guideline model allows association of conditional goals with guidelines. It provides three criteria languages to allow the medical practitioners to use and express their decision making complexities: a simple object oriented language that medical practitioners can use to encode the decision criteria, a temporal query type language, and a predicate logic.

EON also uses Protégé as the medical knowledge acquisition tool to help medical practitioners provide medical decision criteria. The EON language is generated at the back end by the Protégé tool. This code is platform independent and can be shared between decision support systems that are EON compliant.

EON is widely used in European countries and one of the major decision support system that uses EON is PRODIGY. The decision support system ATHENA, which provides hypertension related advices, also uses the EON guideline model as its decision support architecture.

GEM (Guideline Elements Model)

GEM, an XML- (Extensible Markup Language) based guideline document model was introduced in 2000 by Yale center of medical informatics. This initiative is intended to facilitate the translation of medical guideline documents to a standard computer interpretable format. The key difference between the other techniques and GEM is that it uses the industry standard XML for knowledge transfer purposes. GEM's XML hierarchy is made up of 100 discrete tags and 9 major branches. These branches are identity, developer, intended audience, target population, method of development, testing, review plan, and knowledge components (Shiffman, Karras, Agrawal, Chen, Marenco, & Nath, 2000). Several of these branches appear identical to the slots of ARDEN syntax. While the goal of all of these knowledge transfer techniques is the same, they differ in their implementation strategies.

The strength of this model is that it encodes both the recommendations and adequate information about the guideline recommendations, including its reason and quality of evidence (Shiffman et al., 2000). GEM was accepted as an ASTM standard in 2002. Knowledge extraction in GEM is a simple document markup rather than a programming task. GEM uses a knowledge acquisition tool called GEM Cutter to interactively gather he knowledge data and store it in a XML format.

GLARE (Guide Line Acquisition Representation and Execution)

GLARE is a medical domain independent guideline model system for acquiring, representing, and executing clinical guidelines. GLARE was introduced in 1997 by the Dipartimento di Informatica, Universita del Piemonto Orientale , Alexandria, Italy. This system boasts a modular architecture with acquisition and execution modules. The GLARE Knowledge representation language is designed to satisfy both the complexity and expressive rules. The format is limited but focused set of primitives. It consists of plans and atomic actions that can be queries, decisions, work actions, and conclusions (Open Clinical-Glare, 2004).

GLARE knowledge acquisition system is an easy to use graphical user interface with syntactic and semantic verifications to check the formulated guidelines. Artificial intelligence temporal reasoning techniques are applied to weed out inconsistencies. The GLARE system goes one step ahead and also incorporates a decision support system for knowledge execution purposes. GLARE system has been tested for applicability in medical domains like bladder cancer, reflux esophagitis, and heart failure at the Laboratorio di Informatica Clinica, Torino, Italy. The commercial version of this product is still under development.

FUTURE TRENDS

While medical decision support systems have been around for the past four decades, its usage among clinicians is still questionable. Several variables play a role in a success of a medical decision support system and it is important to address these to move ahead from where we stand now. Issues like physician reluctance, intimidating systems, proprietary interests, local practice, technological factors, and outdated knowledgebase are all limiting factors for the growth and acceptance of computer-based decision support systems. In addition to these limitations, the decision making functions are no longer limited to the physicians. The patients, healthcare administrators, insurance carriers, healthcare professionals, policy makers, risk analysts, and the government at large are all stakeholders in this medical decision making process. It will be extremely limiting to tie down these requirements to local proprietary computer systems.

While the field of medicine pioneered the knowledge sharing techniques among decision support systems, the introduction of several sharing standards segmented market as a net result defeated the purpose of such standard. The growth, availability, and accessibility of the Internet opened the door for development of a new model for sharing medical knowledge and decision support systems across networks. Internet-based decision support systems with focus on a particular medical domain will be prevalent in the future.

The various knowledge sharing standards are naturally meeting a common merger. For example, several medical guideline modeling languages are using a common interface for knowledge acquisition purposes. Protégé is the most commonly used tool to acquire the knowledge and then formulate the output in various modeling languages. This converging trend will begin to happen at the knowledge representation and knowledge execution modules as well. This will give raise to a true acceptance of a common knowledge sharing technique.

The next key area of medical decision support systems is the unique characteristics of its users. Great medical decision support systems when seldom used solves no purpose. Most users get intimidated by the complexities and challenges posed by the user interface. While medical decision making is not a simple process, the decision support systems should help reducing the complexity and not increasing them. Past studies indicate that the complexity of customizing the knowledge or a simple rule forces the physicians to refrain form using the system. Training clinicians in usage of complex decision support process is a worthy investment. The benefits of the usage of medical decision support systems outweigh the costs incurred in development, implementation, and maintenance of such products.

CHAPTER SUMMARY

Medical decision support systems, when used along with the clinical information systems at the point of care can improve the quality of care provided. Despite evidence of the benefits of decision support, and despite endorsement by a national patient safety panel (Kohn, Corrigan & Donaldson, 2000), computerized clinical decision support has not achieved wide diffusion. A recent survey found that such systems were used in less than five percent of all healthcare facilities (Wong, Legnini, Whitmore, & Taylor, 2000). When the user interface, availability, and accessibility issues of the medical decision support systems are properly addressed, the usage of the systems will grow multi fold! When such medical decision support systems are blended into the day-to-day practice workflow, then these systems are destined to succeed!

Chapter 1.24
Kernel Methods in Genomics and Computational Biology

Jean-Philippe Vert
Ecole des Mines de Paris, France

ABSTRACT

Support vector machines and kernel methods are increasingly popular in genomics and computational biology due to their good performance in real-world applications and strong modularity that makes them suitable to a wide range of problems, from the classification of tumors to the automatic annotation of proteins. Their ability to work in a high dimension and process nonvectorial data, and the natural framework they provide to integrate heterogeneous data are particularly relevant to various problems arising in computational biology. In this chapter, we survey some of the most prominent applications published so far, highlighting the particular developments in kernel methods triggered by problems in biology, and mention a few promising research directions likely to expand in the future.

INTRODUCTION

Recent years have witnessed a dramatic evolution in many fields of life science with the apparition and rapid spread of so-called high-throughput technologies, which generate huge amounts of data to characterize various aspects of biological samples or phenomena. To name just a few, DNA sequencing technologies have already provided the whole genome of several hundreds of species, including the human genome (International Human Genome Sequencing Consortium, 2001; Venter, 2001). DNA microarrays (Schena, Shalon, Davis, & Brown, 1995), that allow the monitoring of the expression level of tens of thousands of transcripts simultaneously, opened the door to functional genomics, the elucidation of the functions of the genes found in the genomes (DeRisi, Iyer, & Brown, 1997). Recent advances in ionization technology have boosted large-scale capabilities in mass spectrometry and the rapidly growing field of proteomics, focusing on the systematic, large-scale analysis of proteins (Aebersold & Mann, 2003). As biology suddenly entered this new era characterized by the relatively cheap and easy generation of huge amounts of data, the urgent need for efficient methods to represent, store, process, analyze, and finally make sense out of these data triggered the parallel development of numerous data-analysis algorithms in computational biology. Among them, kernel methods in general and support vector machines (SVMs) in particular have quickly gained popularity for problems involving the classification and analysis of high-dimensional or complex data. Half a decade after the first pioneering papers (Haussler, 1999; T. S. Jaakkola, Diekhans, & Haussler, 1999; Mukherjee, Tamayo, Mesirov, Slonim, Verri, & Poggio, 1998), these methods have been applied to a variety of problems in computational biology, with more than 100 research papers published in 2004 alone. The main reasons behind this fast development involve, beyond the generally good performances of SVM on real-world problems and the ease of use provided by current implementations, (a) the particular capability of SVM to resist high-dimensional and noisy data, typically produced by various high-throughput technologies, (b) the possibility to model linear as well as nonlinear relationships between variables of interest, and (c) the possibility to process nonvectorial data, such as biological sequences, protein structures, or gene networks, and to easily fuse heterogeneous data thanks to the use of kernels. More than a mere application of well-established methods to new data sets, the use of kernel methods in computational biology has been accompanied by new developments to match the specificities and the needs of the field, such as methods for feature selection in combination with the classification of high-dimensional data, the invention of string kernels to process biological sequences, or the development of methods to learn from several kernels simultaneously. In order to illustrate some of the most prominent applications of kernel methods in computational biology and the specific developments they triggered, this chapter focuses on selected applications related to the manipulation of high-dimensional data, the classification of biological sequences, and a few less developed but promising applications. This chapter is therefore not intended to be an exhaustive survey, but rather to illustrate with some examples why and how kernel methods have invaded the field of computational biology so rapidly. The interested reader will find more references in the book by Schölkopf, Tsuda, and Vert (2004) dedicated to the topic. Several kernels for structured data, such as sequences or trees, widely developed and used in computational biology, are also presented in detail in the book by Shawe-Taylor and Cristianini (2004).

CLASSIFICATION OF HIGH-DIMENSIONAL DATA

Several recent technologies, such as DNA microarrays, mass spectrometry, or various miniaturized assays, provide thousands of quantitative parameters to characterize biological samples or phenomena. Mathematically speaking, the results of such experiments can be represented by high-dimensional vectors, and many applications involve the supervised classification of such data. Classifying data in high dimension with a limited number of training examples is a challenging task that most statistical procedures have difficulties in dealing with, due in particular to the risk of overfitting the training data. The theoretical foundations of SVM and related methods, however, suggest that their use of regularization allows them to better resist to the curse of dimension than other methods. SVMs were therefore naturally tested on a variety of data sets involving the classification of high-dimensional data, in particular, for the analysis of tumor samples from gene expression data, and novel algorithms were developed in the framework of kernel methods to select a few relevant features for a given high-dimensional classification problem.

Tumor Classification from Gene Expression Data

The early detection of cancer and prediction of cancer types from gene expression data have been among the first applications of kernel methods in computational biology (Furey, Cristianini, Duffy, Bednarski, Schummer, & Haussler, 2000; Mukherjee et al., 1998) and remain prominent. These applications indeed have potentially important impacts on the treatment of cancers, providing clinicians with objective and possibly highly accurate information to choose the most appropriate form of treatment. In this context, SVMs were widely applied and compared with other algorithms for the supervised classification of tumor samples from expression data of typically several thousands of genes for each tumor. Examples include the discrimination between acute myeloid and acute lymphoblastic leukemia (Mukherjee et al.); colon cancer and normal colon tissues (Moler, Chow, & Mian, 2000); normal ovarian, normal nonovarian, and ovarian cancer tissues (Furey et al.); melanoma; soft-tissue sarcoma and clear-cell sarcoma (Segal, Pavlidis, Noble, et al., 2003); different types of soft-tissue sarcomas (Segal, Pavlidis, Antonescu, et al., 2003); and normal and gastric tumor tissues (Meireles et al., 2003), to name just a few. Another typical application is the prediction of the future evolution of a tumor, such as the discrimination between relapsing and nonrelapsing Wilms tumors (Williams et al., 2004), the prediction of metastatic or nonmetastatic squamous cell carcinoma of the oral cavity (O'Donnell et al., 2005), or the discrimination between diffuse large B-cell lymphoma with positive or negative treatment outcome (Shipp et al., 2002).

The SVMs used in these studies are usually linear hard-margin SVMs, or linear soft-margin SVMs with a default C parameter value. Concerning the choice of the kernel, several studies observe that nonlinear kernels tend to decrease performance (Ben-Dor, Bruhn, Friedman, Nachman, Schummer, & Yakhini, 2000; Valentini, 2002) compared to the simplest linear kernel. In spite of contradictory opinions (Pochet, De Smet, Suykens, & De Moor, 2004), this is coherent with the intuition that the complexity of learning nonlinear functions in very high dimension does not play in their favor. On the other hand, the choice of hard-margin SVM, sometimes advocated as a default method when data are linearly separable, is certainly worth questioning in more detail. Indeed, the theoretical foundations of SVM suggest that in order to learn in high dimension, one should rather increase the importance of regularization as opposed to fitting the data, which corresponds to decreasing the C parameter of the soft-margin formulation. A few recent papers highlight indeed the fact that the choice of C has an important effect on the generalization performance of SVM for the classification of gene expression data (Huang & Kecman, 2005).

A general conclusion of these numerous studies is that SVMs generally provide good classification accuracy in spite of the large dimension of the data. For example, in a comparative study of several algorithms for multiclass supervised classification, including naive Bayes, *k*-nearest neighbors, and decision trees, Li, Zhang, and Ogihara (2004, p. 2434) note that "[SVMs] achieve better performance than any other classifiers on almost all the datasets." However, it is fair to mention that other studies conclude that most algorithms that take into account the problem of large dimension either through regularization or through feature selection reach roughly similar accuracy on most data sets (Ben-Dor et al.). From a practical point of view, the use of the simplest linear kernel and the soft-margin formulation of SVM seems to be a reasonable default strategy for this application.

Feature Selection

In the classification of microarray data, it is often important, for classification performance, biomarker identification, and the interpretation of results, to select only a few discriminative genes among the thousands of candidates available on a typical microarray. While the literature on feature selection is older and goes beyond the field of kernel methods, several interesting developments with kernel methods have been proposed in the recent years, explicitly motivated by the problem of gene selection from microarray data.

For example, Su, Murali, Pavlovic, Schaffer, and Kasif (2003) propose to evaluate the predictive power of each single gene for a given classification task by the value of the functional minimized by a one-dimensional SVM, trained to classify samples from the expression of only the single gene of interest. This criterion can then be used to rank genes and select only a few with important predictive power. This procedure therefore belongs to the so-called filter approach to feature selection, where a criterion (here using SVM) to measure the relevance of each feature is defined, and only relevant features according to this criterion are kept.

A second general strategy for feature selection is the so-called wrapper approach, where feature selection alternates with the training of a classifier. The now widely used recursive feature elimination (RFE) procedure of Guyon, Weston, Bamhill, and Vapnik (2002), which iteratively selects smaller and smaller sets of genes and trains SVMs, follows this strategy. RFE can only be applied with linear SVMs, which is nevertheless not a limitation as long as many features remain, and works as follows. Starting from the full set of genes, a linear SVM is trained and the genes with the smallest weights in the resulting linear discrimination function are eliminated. The procedure is then repeated iteratively starting from the set of remaining genes and stops when a desired number of genes is reached.

Finally, a third strategy for feature selection, called the embedded approach, combines the learning of a classifier and the selection of features in a single step. A kernel method following this strategy has been implemented in the joint classifier and feature optimization (JCFO) procedure of Krishnapuram, Carin, and Hartemink (2004). JCFO is, roughly speaking, a variant of SVM with a Bayesian formulation, in which sparseness is obtained both for the features and the classifier expansion in terms of a kernel by appropriate choices of prior probabilities. The precise description of the complete procedure to train this algorithm, involving an expectation-maximization (EM) iteration, would go beyond the scope of this chapter, and the interested reader is referred to the original publication for further practical details.

Generally speaking, and in spite of these efforts to develop clever algorithms, the effect of feature selection on the classification accuracy of SVM is still debated. Although very good results are sometimes reported, for example, for the JCFO procedure (Krishnapuram et al., 2004), several studies conclude that feature selection, for example, with procedures like RFE, do not actually improve the accuracy of SVM trained on all genes (Ambroise & McLachlan, 2002; Ramaswamy et al., 2001). The relevance of feature-selection algorithms for gene expression data is therefore currently still a research topic that practitioners should test and assess case by case.

Other High-Dimensional Data in Computational Biology

While early applications of kernel methods to high-dimensional data in genomics and bioinformatics mainly focused on gene expression data, a number of other applications have flourished more recently, some being likely to expand quickly as major applications of machine learning algorithms. For example, studies focusing on tissue classification from data obtained by other technologies, such as methylation assays to monitor the patterns of cytosine methylation in the upstream regions of genes (Model, Adorjan, Olek, & Piepenbrock, 2001), or array comparative genomic hybridization (CGH) to measure gene copy number changes in hundreds of genes simultaneously (Aliferis, Hardin, & Massion, 2002), are starting to accumulate. A huge field of application that barely caught the interest of the machine learning community is proteomics, that is, the quantitative study of the protein content of cells and tissues. Technologies such as tandem mass spectrometry to monitor the protein content (proteins or characteristic fragments of proteins) of a biological sample are now well developed, and the classification of tissues from these data is a future potential application of SVM (Wagner, Naik, & Pothen, 2003; Wu et al., 2003). Applications in toxicogenomics (Steiner et al., 2004), chemogenomics (Bao & Sun, 2002; Bock & Gough, 2002), and the analysis of single-nucleotide polymorphisms (Listgarten et al., 2004; Yoon, Song, Hong, & Kim, 2003) are also promising applications for which the capacity of SVM to classify high-dimensional data has only started to be exploited.

SEQUENCE CLASSIFICATION

The various genome sequencing projects have produced huge amounts of sequence data that need to be analyzed. In particular, the urgent need for methods to automatically process, segment, annotate, and classify various sequence data has triggered the fast development of numerous algorithms for strings. In this context, the possibility offered by kernel methods to process any type of data as soon as a kernel for the data to be processed is available has been quickly exploited to offer the power of state-of-the-art machine learning algorithms to sequence processing.

Problems that arise in computational biology consist of processing either sets of sequences of a fixed length, or sets of sequences with variable lengths. From a technical point of view, the two problems differ significantly: While there are natural ways to encode fixed-length sequences as fixed-length vectors, making them amenable to processing by most learning algorithms, manipulating variable-length sequences is less obvious. In both cases, many successful applications of SVM have been reported, combining ingenious developments of string kernels, sometimes specifically adapted to a given classification task, with the power of SVM.

Kernels for Fixed-Length Sequences

Problems involving the classification of fixed-length sequences appear typically when one wants to predict a property along a sequence, such as the local structure or solvent accessibility along a protein sequence. In that case, indeed, a common approach is to use a moving window, that is, to predict the property at each position independently from the others, and to base the prediction only on the nearby sequence contained in a small window around the site of interest. More formally, this requires the construction of predictive models that take a sequence of fixed length as input to predict the property of interest, the length of the sequences being exactly the width of the window.

To fix notations, let us denote by p the common length of the sequences, and by a typical sequence, where each x_i is a letter from the alphabet, for example, an amino acid. The most natural way to transform such a sequence into a vector of fixed length is to first encode each letter itself into a vector of fixed length , and then to concatenate the codes of the successive letters to obtain a vector of size $n = pl$ for the whole sequence. A simple code for letters is the following so-called sparse encoding: The size of the alphabet is denoted by α, and the i the letter of the alphabet is encoded as a vector of dimension α containing only zeros, except for the i the dimension that is set to l. For example, in the case of nucleotide sequences with alphabet (A,C,G,T), the codes for A, C, G, and T would respectively be (1,0,0,0), (0,1,0,0), (0,0,1,0), and (0,0,0,1), while the code for the sequence of length 3 AGT would be (1,0,0,0,0,0,1,0,0,0,0,1). Several more evolved codes for single letters have also been proposed. For example, if one has a prior matrix of pairwise similarities between letters, such as widely used similarity matrices between amino acids, it is possible to replace the 0/1 sparse encoding of a given letter by the vector of similarity with other letters; hence, the A in the previous example could, for instance, be represented by the vector (1,0,0.5,0) to emphasize one's belief that A and G share some similarity. This is particularly relevant for biological sequences where mutations of single letters to similar letters are very common. Alternatively, instead of using a prior matrix of similarity, one can automatically align the sequence of interest to similar sequences in a large sequence database, and encode each position by the frequency of each letter in the alignment. As a trivial example, if our previous sequence AGT was found to be aligned to the following sequences, AGA, AGC, CGT, and ATT, then it could be encoded by the vector (0.8,0.2,0,0,0,0,0.8,0.2,0.2,0.2,0,0.6), corresponding to the respective frequencies of each letter at each position.

In terms of a kernel, it is easy to see that the inner product between sparsely encoded sequences is the number of positions with identical letters. In this representation, any linear classifier, such as that learned by a linear SVM, associates a weight to each feature, that is, to each letter at each position, and the score of a sequence is the sum of the scores of its letters. Such a classifier is usually referred to as a position-specific score matrix in bioinformatics. Similar interpretations can be given for other letter encodings. An interesting extension of these linear kernels for sequences is to raise them to some small power d; in that case, the dimension of the feature space used by kernel methods increases, and the new features correspond to all products of d original features. This is particularly appealing for sparse encoding because a product of d binary factors is a binary variable equal to 1 if and only if all factors are 1, meaning that the features created by the sparse encoding to the power d exactly indicate the simultaneous presence of up to d particular letters at d particular positions. The trick to take a linear kernel to some power is therefore a convenient way to create a classifier for problems that involve the presence of several particular letters at particular positions.

A first limitation of these kernels is that they do not contain any information about the order of the letters: They are, for example, left unchanged if the letters in all sequences are shuffled according to any given permutation. Several attempts to include ordering information have been proposed. For example, Rätsch, Sonnenburg, and Schölkopf (2005) replace the local encoding of single letters by a local encoding of several consecutive letters; Zien, Rätsch, Mika, Schölkopf, Lengauer, and Müller (2000) propose an ingenious variant to the polynomial kernel in order to restrict the feature space to products of features at nearby positions only.

A second limitation of these kernels is that the comparison of two sequences only involves the comparison of features at identical positions. This can be problematic in the case of biological sequences where the insertion of deletions of letters is common, resulting in possible shifts within a window. This problem led Meinicke, Tech, Morgenstem, and Merkl (2004) to propose a kernel that incorporates a comparison of features at nearby positions using the following trick: If a feature f (e.g., binary or continuous) appears at position i in the first sequence, and a feature g appears at position j in the second sequence, then the kernel between the two sequences is increased by , where is a basic kernel between the features f and g such as the simple product, and σ is a parameter that controls the range at which features are compared. When σ is chosen very large, then one recovers the classical kernels obtained by comparing only identical positions($i = j$); the important point here is that for smaller values of σ, features can contribute positively even though they might be located at different positions on the sequences.

The applications of kernels for fixed-length sequences to solve problems in computational biology are already numerous. For example, they have been widely used to predict local properties along protein sequences using a moving window, such as secondary structure (Guermeur, Lifschitz, & Vert, 2004; Hua & Sun, 2001a), disulfide bridges involving cysteines (Chen, in, Lin, & Hwang, 2004; Passerini & Frasconi, 2004), phosphorylation sites (Kim, Lee, oh, Kimm, & Koh, 2004), interface residues (Res, Mihalek, & Lichtarge, 2005; Yan, Dobbs, & Honavar, 2004), and solvent accessibility (Yuan, Burrage, & Mattick, 2002). Another important field of application is the annotation of DNA using fixed-length windows centered on a candidate point of interest as an input to a classifier to detect translation initiation sites (Meinicke et al., 2004; Zien et al., 2000), splice sites (Degroeve, Saeys, De Baets, Rouze, & Van de Peer, 2005; Rätsch et al., 2005), or binding sites of transcription factors (O'Flanagan, Paillard, Lavery, & Sengupta, 2005; Sharan & Myers, 2005). The recent interest in short RNA such as antisense oligonucleotides or small interfering RNAs for the sequence-specific knockdown of messenger RNAs has also resulted in several works involving the classification of such sequences, which typically have a fixed length by nature (Camps-Valls, Chalk, Serrano-López, Martin-Guerrero, & Sonnhammer, 2004; Teramoto, Aoki, Kimura, & Kanaoka, 2005). Another important application field for these methods is immunoinformatics, including the prediction of peptides that can elicit an immune response (Bhasin & Raghava, 2004; Dönnes & Elofsson, 2002), or the classification of immunoglobulins collected from ill patients (Yu, Zavaljevski, Stevens, Yackovich, & Reifman, 2005; Zavaljevski, Stevens, & Reifman, 2002). In most of these applications, SVM lead to comparable if not better prediction accuracy than competing state-of-the-art methods such as neural networks.

Kernels for Variable-Length Sequences

Many problems in computational biology involve sequences of different lengths. For example, the automatic functional or structural annotation of genes found in sequenced genomes requires the processing of amino-acid sequences with no fixed length. Learning from variable-length sequences is a more challenging problem than learning from fixed-length sequences because there is no natural way to transform a variable-length string into a vector. For kernel methods, this issue boils down to the problem of defining kernels for variable-length strings, a topic that has deserved a lot of attention in the last few years and has given rise to a variety of ingenious solutions. As summarized in Table 1, three main approaches have been followed in the process of kernel design from strings: (a) computing an inner product in an explicitly defined feature space, (b) deriving a kernel from probabilistic models on strings, and (c) adapting widely used measures of similarity. These general strategies, surveyed in more detail in this section, are relevant beyond the specific problem of designing kernels for biological sequences. For example, we point out below strong similarities between some of these kernels and kernels developed for speech-recognition applications (surveyed in more detail in the chapters by Picone, Ganapathiraju, and Hamaker; and Wan).

The most common approach to make a kernel for strings, as for many other types of data, is to design explicitly a set of numerical features that can be extracted from strings, and then to form a kernel as a dot product between the resulting feature vectors. As an example, Leslie, Eskin, and Noble (2002) represent a sequence by the vector of counts of occurrences of all possible k-mers in the sequence for a given integer k, effectively

Table 1. A typology of kernels for variable-length biological sequences

Strategy	Example
Define a (possibly high-dimensional) feature space of interest	- Physico-chemical kernels (Wang et al., 2004 ; Zhang et al., 2003a) - Spectrum, mismatch kernels (Leslie et al., 2002, 2004) - Pairwise, motif kernels (Logan et al., 2001; Liao & Noble, 2003; Ben-Hur & Brutlag, 2003)
Derive a kernel from a generative model	- Fisher kernel (Jaakkola et al., 2000) - Pair HMM kernel (Watkins, 2000 ; Haussler, 1999) - Mutual information kernels (Cuturi & Vert, 2005) - Marginalized kernels (Tsuda et al., 2002; Kin et al., 2002; Kashima et al., 2004 ; Vert et al., 2006)
Derive a kernel from a measure of similarity	- Local alignment kernels (Saigo et al., 2004 ; Vert et al., 2004)

resulting in a vector of dimension a^k, where a is the size of the alphabet. As an example, the sequence AACGTCACGAA over the alphabet (A,C,G,T) is represented by the 16-dimensional vector (2,2,0,0,1,0,2,0,1,0,0,1,0,1,0,0) for $k = 2$; here, the features are the counts of occurrences of each 2-mer AA, AC, ..., TG, TT lexicographically ordered. The resulting spectrum kernel between this sequence and the sequence ACGAAA, defined as the linear product between the two 16-dimensional representation vectors, is equal to 9. It should be noted that although the number of possible k-mers easily reaches the order of several thousands as soon as k is equal to 3 or 4, the classification of sequences by SVM in this high-dimensional space results in fairly good results. A major advantage of the spectrum kernel is its fast computation; indeed, the set of k-mers appearing in a given sequence can be indexed in linear time in a tree structure, and the inner product between two vectors is linear with respect to the nonzero coordinates, that is, at most linear in the total lengths of the sequences. Several variants to the basic spectrum kernel have also been proposed, including, for example, kernels based on counts of k-mers appearing with up to a few mismatches in the sequences (Leslie, Eskin, Cohen, Weston, & Noble, 2004).

Another natural approach to represent variable-length strings by fixed-length numerical vectors is to replace each letter by one or several numerical features, such as physicochemical properties of amino acids, and then to extract features from the resulting variable-length numerical time series using classical signal processing techniques such as Fourier transforms (Wang, Yang, Liu, Xu, & Chou, 2004) or autocorrelation analysis (S.-W. Zhang, Pan, Zhang, Zhang, & Wang, 2003). For example, if denote P numerical features associated with the successive letters of a sequence of length P, then the autocorrelation function r_j for a given $j > 0$ is defined by:

$$r_j = \frac{1}{n-j}\sum_{i=1}^{n-j} f_i f_{i+j}.$$

One can then keep a fixed number of these coefficients, for example , and create an n-dimensional vector to represent each sequence.

Finally, another popular approach to design features and therefore kernels for biological sequences is to "project" them onto a fixed dictionary of sequences or motifs using classical similarity measures, and to use the resulting vector of similarities as a feature vector. For example, Logan, Moreno, Suzek, Weng, and Kasif (2001) represent each sequence by a 10,000-dimensional vector indicating the presence of 10,000 motifs of the BLOCKS database; similarly, Ben-Hur and Brutlag (2003) use a vector that indicates the presence or absence of about 500,000 motifs in the eMOTIF database, requiring the use of a tree structure to compute efficiently the kernel without explicitly storing the 500,000 features. Liao and Noble (2003) represent each sequence by a vector of sequence similarities with a fixed set of sequences.

A second general strategy that has been followed for kernel design is to derive kernel functions from probabilistic models. This strategy has been particularly motivated by the fact that, before the interest in string kernels grew, a number of ingenious probabilistic models had been defined to represent biological sequences or families of sequences, including, for example, Markov and hidden Markov models for protein sequences, and stochastic context-free grammars for RNA sequences (Durbin, Eddy, Krogh, & Mitchison, 1998). Several authors have therefore explored the possibility to use such models to make kernels, starting with the seminal work of T. Jaakkola, Diekhans, and Haussler (2000) that introduced the Fisher kernel. The Fisher kernel is a general method to extract a fixed number of features from any data **x** for which a parametric probabilistic model P_θ is defined. Here, θ represents a continuous n-dimensional vector of parameters for the probabilistic model, such as transition and emission probabilities for a hidden Markov model, and each P_θ is a probability distribution. Once a particular parameter θ_0 is chosen to fit a given set of objects, for example, by maximum likelihood, then an n-dimensional feature vector for each individual object **x** can be extracted by taking the gradient in the parameter space of the log likelihood of the point:

$$\phi(\mathbf{x}) = \nabla_\theta \log P_\theta(\mathbf{x}).$$

The intuitive interpretation of this feature vector, usually referred to as the Fisher score in statistics, is that it represents how changes in the n parameters affect the likelihood of the point **x**. In other words, one feature is extracted for each parameter of the model; the particularities of the data point are seen from the eyes of the parameters of the probabilistic model. The Fisher kernel is then obtained as the dot product of these n-dimensional vectors, eventually multiplied by the inverse of the Fisher information matrix to render it independent of the parametrization of the model.

A second line of thought to make a kernel out of a parametric probabilistic model is to use the concept of mutual information kernels (Seeger, 2002), that is, kernels of the form:

$$\kappa(\mathbf{x}, \mathbf{z}) = \int P_\theta(\mathbf{x}) P_\theta(\mathbf{z}) d\mu(\theta),$$

where $d\mu$ is a prior distribution on the parameter space. Here, the features correspond to the likelihood of the objects under all distributions of the probabilistic model; objects are considered similar when they have large likelihood under similar distributions. An important difference between the kernels seen so far is that here, no explicit extraction of finite-dimensional vectors can be performed. Hence, for practical applications, one must chose probabilistic models that allow the computation of the integral above. This was carried out by Cuturi and Vert (2005) who present a family of variable-length Markov models for strings and an algorithm to perform the exact integral over parameters and models in the same time, resulting in a string kernel with linear complexity in time and memory with respect to the total length of the sequences.

Alternatively, many probabilistic models for biological sequences, such as hidden Markov models, involve a hidden variable that is marginalized over to obtain the probability of a sequence, which be written as:

$$P(\mathbf{x}) = \sum_h P(\mathbf{x}, \mathbf{h}).$$

For such distributions, Tsuda, Kin, and Asai (2002) introduced the notion of a marginalized kernel, obtained by marginalizing a kernel for the complete variable over the hidden variable. More precisely, assuming that a kernel κ_0 for objects of the form (**x**,**h**) is defined, the marginalized kernel for observed objects *X* is given by:

$$\kappa(\mathbf{x}_1, \mathbf{x}_2) = \sum_{\mathbf{h}_1, \mathbf{h}_2} \kappa_0((\mathbf{x}_1, \mathbf{h}_1), (\mathbf{x}_2, \mathbf{h}_2)) P(\mathbf{h}_1 \mid \mathbf{x}_1) P(\mathbf{h}_2 \mid \mathbf{x}_2).$$

In order to motivate this definition with a simple example, let us consider a hidden Markov model with two possible hidden states to model sequences with two possible regimes, such as introns and exons in eukaryotic genes. In that case, the hidden variable corresponding to a sequence **x** of length *P* is a binary sequence **h** of length *P* describing the states along the sequence. For two sequences $\mathbf{x}_1$ and $\mathbf{x}_2$, if the correct hidden states $\mathbf{h}_1$ and $\mathbf{h}_2$ were known, such as the correct decomposition into introns and exons, then it would make sense to define a kernel taking into account the specific decomposition of the sequences into two regimes; for example, the kernel for complete data could be a spectrum kernel restricted to the exons, that is, to positions with a particular state. Because the actual hidden states are not known in practice, the marginalization over the hidden state of this kernel using an adequate probabilistic model can be interpreted as an attempt to apply the kernel for complete data by guessing the hidden variables. Similar to the mutual information kernel, marginalized kernels can often not be expressed as inner products between feature vectors, and they require computational tricks to be computed. Several beautiful examples of such kernels for various probabilistic models have been worked out, including hidden Markov models for sequences (Tsuda et al.; Vert, Thurman, & Noble, 2006), stochastic context-free grammars for RNA sequences (Kin, Tsuda, & Asai, 2002), and random walk models on graphs for molecular structures (Kashima, Tsuda, & Inokuchi, 2004).

Following a different line of thought, Haussler (1999) introduced the concept of convolution kernels for objects that can be decomposed into subparts, such as sequences or trees. For example, the concatenation of two strings $\mathbf{x}_1$ and $\mathbf{x}_2$ results in another string $\mathbf{x} = \mathbf{x}_1 \mathbf{x}_2$. If two initial string kernels $\kappa_1$and κ_2 are chosen, then a new string kernel is obtained by the convolution of the initial kernels following the equation:

$$\kappa(\mathbf{x}, \mathbf{z}) = \sum_{\mathbf{x}_1 \mathbf{x}_2 = \mathbf{x}} \sum_{\mathbf{z}_1 \mathbf{z}_2 = \mathbf{z}} \kappa_1(\mathbf{x}_1, \mathbf{z}_1) \kappa_2(\mathbf{x}_2, \mathbf{z}_2).$$

Here, the sum is over all possible decompositions of **x** and **z** into two concatenated subsequences. The rationale behind this approach is that it allows the combination of different kernels adapted to different parts of the sequences, such as introns and exons or gaps and aligned residues in alignment, without knowing the exact segmentation of the sequences. Besides proving that the convolution of two kernels is a valid kernel, Haussler (1999) gives several examples of convolution kernels relevant for biological sequences; for example, he shows that the joint probability *P*(**x**,**z**) of two sequences under a pair hidden Markov model (HMM) is a valid kernel under mild assumptions, a property that was also proved independently by Watkins (2000).

Finally, a third general strategy to design kernels for strings is to start from classical measures of similarity between strings and turn them into kernels. In the case of biological sequences, for example, a scheme known as Smith-Waterman local alignment score (Smith & Waterman, 1981) is widely used to compare sequences. Saigo, Vert, Ueda, and Akutsu (2004) show that a slight modification of this measure of similarity is a valid kernel, called the local alignment kernel. In fact, the proof of the positive definiteness of the new kernels builds on the study of convolution kernels presented above (Vert, Saigo, & Akutsu, 2004). Interestingly, the Smith-Waterman alignment score between biological sequences optimizes an alignment between sequences by dynamic programming, just like dynamic time warping (DTW) algorithms compare variable-length sequences in speech recognition. DTW kernels that violate the positive semidefiniteness assumption (surveyed in the chapter by Wan) have been proposed for speaker-recognition applications; adapting the local alignment kernel to this context, that is, replacing a Viterbi optimization with a forward summation in the dynamic programming algorithm, would result in a valid DTW kernel for speech applications. The local alignment kernel gives excellent results on the problem of detecting remote homologs of proteins, suggesting that combining domain knowledge (in the form of a relevant measure of similarity turned into a kernel) with kernel methods is a promising research direction.

These kernels for variable-length sequences have been widely applied, often in combination with SVM, to various classification tasks in computational biology. Examples include the prediction of protein structural or functional classes from their primary sequence (Cai, Wang, Sun, & Chen, 2003; Ding & Dubchak, 2001; T. Jaakkola et al., 2000; Karchin, Karplus, & Haussler, 2002; Vert et al., 2004), the prediction of the subcellular localization of proteins (Hua & Sun, 2001b; Matsuda, Vert, Saigo, Ueda, Toh, & Akutsu, 2005; Park & Kanehisa, 2003), the classification of transfer RNA (Kin et al., 2002) and noncoding RNA (Karklin, Meraz, & Holbrook, 2005), the prediction of pseudoexons and alternatively spliced exons (Dror, Sorek, & Shamir, 2005; X. H.-F. Zhang, Heller, Hefter, Leslie, & Chasin, 2003b), the separation of mixed plant-pathogen expressed sequence tag (EST) collections (Friedel, Jahn, Sommer, Rudd, Mewes, & Tetko, 2005), the classification of mammalian viral genomes (Rose, Turkett, Oroian, Laegreid, & Keele, 2005), and the prediction of ribosomal proteins (Lin, Kuang, Joseph, & Kolatkar, 2002).

This short review of kernels developed for the purpose of biological sequence classification, besides highlighting the dynamism of research in kernel methods resulting from practical needs in computational biology, naturally raises the practical question of which kernel to use for a given application. Although no clear answer has emerged yet, some lessons can be learned from early studies. First, there is certainly no kernel universally better than others, and the choice of kernel should depend on the targeted application. Intuitively, a kernel for a classification task is likely to work well if it is based on features relevant to the task; for example, a kernel based on sequence alignments, such as the local alignment kernel, gives excellent results on remote homology detection problems, while a kernel based on the global content of sequences in short subsequences, such as the spectrum kernel, works well for the prediction of subcellular localization. Although some methods for the systematic selection and combination of kernels are starting to emerge (see the next section), an empirical evaluation of different kernels on a given problem seems to be the most common way to chose a kernel. Another important point to notice, besides the classification accuracy obtained with a kernel, is its computational cost. Indeed, practical applications often involve data sets of thousands or tens of thousands of sequences, and the computational cost of a method can become a critical factor in this context, in particular in an online setting. The kernels presented above differ a lot in their computational cost, ranging from fast linear-time kernels like the spectrum kernel to slower kernels like the quadratic-time local alignment kernel. The final choice of kernel for a given application often results from a trade-off between classification performance and computational burden.

OTHER APPLICATIONS AND FUTURE TRENDS

Besides the important applications mentioned in the previous sections, several other attempts to import ideas of kernel methods in computational biology have emerged recently. In this section, we highlight three promising directions that are likely to develop quickly in the near future: the engineering of new kernels, the development of methods to handle multiple kernels, and the use of kernel methods for graphs in systems biology.

More Kernels

The power of kernel methods to process virtually any sort of data as soon as a valid kernel is defined has recently been exploited for a variety of data, besides high-dimensional data and sequences. For example, Vert (2002) derives a kernel for phylogenetic profiles, that is, a signature indicating the presence or absence of each gene in all sequenced genomes. Several recent works have investigated kernels for protein 3-D structures, a topic that is likely to expand quickly with the foreseeable availability of predicted or solved structures for whole genomes (Borgwardt, Ong, Schönauer, Vishwanathan, Smola, & Kreigel, 2005; Dobson & Doig, 2003). For smaller molecules, several kernels based on planar or 3-D structures have emerged, with many potential applications in computational chemistry (Kashima et al., 2004; Mahé, Ueda, Akutsu, Perret, & Vert, 2005; Swamidass, Chen, Bruand, Phung, Ralaivola, & Baldi, 2005). This trend to develop more and more kernels, often designed for specific data and applications, is likely to continue in the future because it has proved to be a good approach to obtain efficient algorithms for real-world applications. A nice by-product of these efforts, which is still barely exploited, is the fact that any kernel can be used by any kernel method, paving the way to a multitude of applications such as clustering (Qin, Lewis, & Noble, 2003; see also the chapter by Pochet, Ojeda, De Smet, De Bie, Suykens, & De Moor) or data visualization (Komura, Nakamura, Tsutsumi, Aburatani, & Ihara, 2005).

Integration of Heterogeneous Data

Operations on kernels provide simple and powerful tools to integrate heterogeneous data or multiple kernels; this is particularly relevant in computational biology, where biological objects can typically be described by heterogeneous representations, and the availability of a large number of possible kernels for even a single representation raises the question of choice or combination of kernels. Suppose, for instance, that one wants to perform a functional classification of genes based on their sequences, expression over a series of experiments, evolutionary conservation, and position in an interaction network. A natural approach with kernel methods is to start by defining one or several kernels for each sort of data, that is, string kernels for the gene sequences, vector kernels to process the expression profiles, and so forth. The apparent heterogeneity of data types then vanishes as one simply obtains a family of kernel functions . In order to learn from all data simultaneously, the simplest approach is to define an integrated kernel as the sum of the initial kernels:

$$\kappa = \sum_{i=1}^{p} \kappa_i .$$

The rationale behind this sum is that if each kernel is a simple dot product, then the sum of dot products is equal to the dot product of the concatenated vectors. In other words, taking a sum of kernels amounts to putting all features of each individual kernel together; if different features in different kernels are relevant for a given problem, then one expects the kernel method trained on the integrated kernel to pick those relevant features. This idea was pioneered by the authors of Pavlidis, Weston, Cai, and Noble (2002), in which gene expression profiles and gene phylogenetic profiles are integrated to predict the functional classes of genes, effectively integrating evolutionary and transcriptional information.

An interesting generalization of this approach is to form a convex combination of kernels of the form:

$$\kappa = \sum_{i=1}^{p} w_i \kappa_i ,$$

where the w_i are nonnegative weights. Lanckriet, De Bie, Cristianini, Jordan and Noble (2004) propose a general framework based on semidefinite programming to optimize the weights and learn a discrimination function for a given classification task simultaneously. Promising empirical results on gene functional classification show that by integrating several kernels, better results can be obtained than with each individual kernel.

Finally, other kernel methods can be used to compare and search for correlations between heterogeneous data. For example, Vert and Kanehisa (2003) propose to use a kernelized version of canonical correlation analysis (CCA) to compare gene expression data on the one hand with the position of genes in the metabolic network on the other hand. Each type of data is first converted into a kernel for genes, the information about gene positions in the metabolic network being encoded with the so-called diffusion kernel (Kondor & Vert, 2004). These two kernels define embeddings of the set of genes into two Euclidean spaces, in which correlated directions are detected by CCA. It is then shown that the directions detected in the feature space of the diffusion kernel can be interpreted as clusters in the metabolic network, resulting in a method to monitor the expression patterns of metabolic pathways.

Kernel Methods in Systems Biology

Another promising field of research where kernel methods can certainly contribute is systems biology, which roughly speaking focuses on the analysis of biological systems of interacting molecules, in particular, biological networks.

A first avenue of research is the reconstruction of biological networks from high-throughput data. For example, the prediction of interacting proteins to reconstruct the interaction network can be posed as a binary classification problem—given a pair of proteins, do they interact or not?—and can therefore be tackled with SVM as soon as a kernel between pairs of proteins is defined. However, the primary data available are about individual proteins. In order to use SVM in this context, it is therefore natural to try to derive kernels for pairs of proteins from kernels for single proteins. This has been carried out, for example, by Bock and Gough (2001) who characterize each protein by a vector and concatenate two such individual vectors to represent a protein pair. Observing that there is usually no order in a protein pair, Martin, Roe, and Faulon (2005) and Ben-Hur and Noble (2005) propose to define a kernel between pairs (*A*,*B*) and (*C*,*D*) by the equation:

$$\kappa((A,B),(C,D)) = \kappa_0(A,C)\kappa_0(B,D) + \kappa_0(A,D)\kappa_0(B,C),$$

where κ_0 denotes a kernel for an individual protein and κ is the resulting kernel for pairs of proteins. The rationale behind this definition is that in order to match the pair (*A*,*B*) with the pair (*C*,*D*), one can either try to match *A* with *C* and *B* with *D*, or to match *A* with *D* and *B* with *C*. Reported accuracies on the problem of protein-interaction prediction are very high, confirming the potential of kernel methods in this fast-moving field.

A parallel approach to network inference from genomic data has been investigated by Yamanishi, Vert, and Kanehisa (2004), who show that learning the edges of a network can be carried out by first mapping the vertices, for example, the genes, onto a Euclidean space, and then connecting the pairs of points that are close to each other in this embedding. The problem then becomes that of learning an optimal embedding of the vertices, a problem known as distance metric learning that recently caught the attention of the machine learning community and for which several kernel methods exist (Vert & Yamanishi, 2005).

Finally, several other emerging applications in systems biology, such as inference on networks (Tsuda & Noble, 2004) or the classification of networks (Middendorf et al., 2004), are likely to be subject to increasing attention in the future due to the growing interest and amount of data related to biological networks.

CONCLUSION

This brief survey, although far from being complete, highlights the impressive advances in the applications of kernel methods in computational biology in the last 5 years. More than just importing well-established algorithms to a new application domain, biology has triggered the development of new algorithms and methods, ranging from the engineering of various kernels to the development of new methods for learning from multiple kernels and for feature selection. The widespread diffusion of easy-to-use SVM software and the ongoing integration of various kernels and kernel methods in major computing environments for bioinformatics are likely to foster again the use of kernel methods in computational biology as long as they will provide state-of-the-art methods for practical problems. Many questions remain open regarding, for example, the automatic choice and integration of kernels, the possibility to incorporate prior knowledge in kernel methods, and the extension of kernel methods to more general kernels that are positive definite, suggesting that theoretical developments are also likely to progress quickly in the near future.

INTRODUCTION

Information extraction (IE) technology has been defined and developed through the US DARPA Message Understanding Conferences (MUCs). IE refers to the identification of instances of particular events and relationships from unstructured natural language text documents into a structured representation or relational table in databases. It has proved successful at extracting information from various domains, such as the Latin American terrorism, to identify patterns related to terrorist activities (MUC-4). Another domain, in the light of exploiting the wealth of natural language documents, is to extract the knowledge or information from these unstructured plain-text files into a structured or relational form. This form is suitable for sophisticated query processing, for integration with relational databases, and for data mining. Thus, IE is a crucial step for fully making text files more easily accessible.

BACKGROUND

The advent of large volumes of text databases and search engines have made them readily available to domain experts and have significantly accelerated research on bioinformatics. With the size of a digital library commonly exceeding millions of documents, rapidly increasing, and covering a wide range of topics, efficient and automatic extraction of meaningful data and relations has become a challenging issue. To tackle this issue, rigorous studies have been carried out recently to apply IE to biomedical data. Such research efforts began to be called biomedical literature mining or text mining in bioinformatics (de Bruijn & Martin, 2002; Hirschman et al., 2002; Shatkay & Feldman, 2003). In this article, we review recent advances in applying IE techniques to biomedical literature.

MAIN THRUST

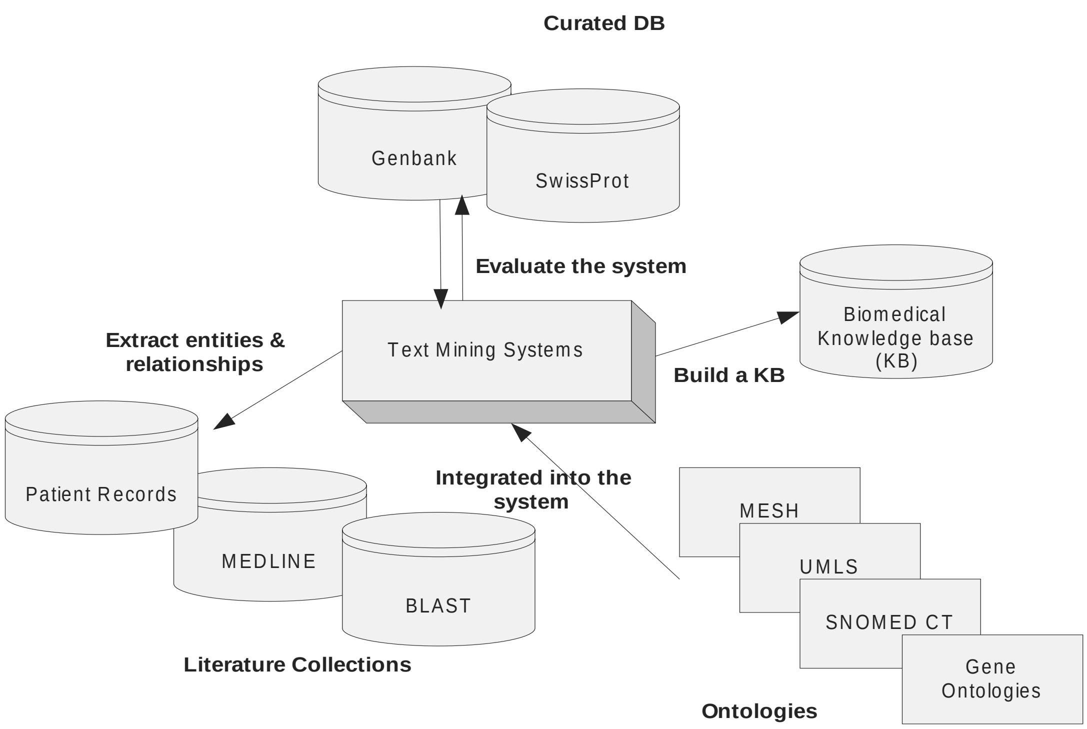
This article attempts to synthesize the works that have been done in the field. Taxonomy helps us understand the accomplishments and challenges in this emerging field. In this article, we use the following set of criteria to classify the biomedical literature mining related studies:

1. What are the target objects that are to be extracted?
2. What techniques are used to extract the target objects from the biomedical literature?
3. How are the techniques or systems evaluated?
4. From what data sources are the target objects extracted?

Target Objects

In terms of what is to be extracted by the systems, most studies can be broken into the following two major areas: (1) named entity extraction such as proteins or genes; and (2) relation extraction, such as relationships between proteins. Most of these studies adopt information extraction techniques using curated lexicon or natural language processing for identifying relevant tokens such as words or phrases in text (Shatkay & Feldman, 2003).

Figure 1. An overview of a biomedical literature mining system



In the area of named entity extraction, Proux et al. (2000) use single word names only with selected test set from 1,200 sentences coming from Flybase. Collier, et al. (2000) adopt Hidden Markov Models (HMMs) for 10 test classes with small training and test sets. Krauthammer et al. (2000) use BLAST database with letters encoded as 4-tuples of DNA. Demetriou and Gaizuaskas (2002) pipeline the mining processes, including hand-crafted components and machine learning components. For the study, they use large lexicon and morphology components. Narayanaswamy et al. (2003) use a part of speech (POS) tagger for tagging the parsed MEDLINE abstracts. Although Narayanaswamy and his colleagues (2003) implement an automatic protein name detection system, the number of words used is 302, and, thus, it is difficult to see the quality of their system, since the size of the test data is too small. Yamamoto, et al. (2003) use morphological analysis techniques for preprocessing protein name tagging and apply support vector machine (SVM) for extracting protein names. They found that increasing training data from 390 abstracts to 1,600 abstracts improved F-value performance from 70% to 75%. Lee et al. (2003) combined an SVM and dictionary lookup for named entity recognition. Their approach is based on two phases: the first phase is identification of each entity with an SVM classifier, and the second phase is post-processing to correct the errors by the SVM with a simple dictionary lookup. Bunescu, et al. (2004) studied protein name identification and protein-protein interaction. Among several approaches used in their study, the main two ways are one using POS tagging and the other using the generalized dictionary-based tagging. Their dictionary-based tagging presents higher F-value. Table 1 summarizes the works in the areas of named entity extraction in biomedical literature.

The second target object type of biomedical literature extraction is relation extraction. Leek (1997) applies HMM techniques to identify gene names and chromosomes through heuristics. Blaschke et al. (1999) extract protein-protein interactions based on co-occurrence of the form "… p1…I1… p2" within a sentence, where p1, p2 are proteins, and I1 is an interaction term. Protein names and interaction terms (e.g., activate, bind, inhibit) are provided as a dictionary. Proux (2000) extracts an interact relation for the gene

Table 1. A summary of works in biomedical entity extraction

Author	Named Entities	Database	No of Words	Learning Methods	F value
Collier et al. (2000)	Proteins and DNA	MEDLINE	30000	HMM	73
Krauthammer et al. (2000)	Gene and Protein	Review articles	5000	Character sequence mapping	75
Demetriou and Gaizauskas (2002)	Protein, Species, and 10 more	MEDLINE	30,000	PASTA template filing	83
Narayanaswamy (2003)	Protein	MEDLINE	302	Hand –crafted rules and co-occurrence	75.86
Yamamoto et al. (2003)	Protein	GENIA	1600 abstracts	BaseNP recognition	75
Lee et al. (2003)	Protein DNA RNA	GENIA	10,000	SVM	77
Bunescu (2004)	Protein	MEDLINE	5,206	RAPIER, BWI, TBL, k-NN , SVMs, MaxEnt	57.86

entity from Flybase database. Pustejovsky (2002) extracts an inhibit relation for the gene entity from MEDLINE. Jenssen, et al. (2001) extract a gene-gene relations based on co-occurrence of the form "… g1…g2…" within a MEDLINE abstracts, where g1 and g2 are gene names. Gene names are provided as a dictionary, harvested from HUGO, LocusLink, and other sources. Although their study uses 13,712 named human genes and millions of MEDLINE abstracts, no extensive quantitative results are reported and analyzed. Friedman, et al. (2001) extract a pathway relation for various biological entities from a variety of articles. In their work, the precision of the experiments is high (from 79-96%). However, the recalls are relatively low (from 21-72%). Bunescu et al. (2004) conducted protein/protein interaction identification with several learning methods, such as pattern matching rule induction (RAPIER), boosted wrapper induction (BWI), and extraction using longest common subsequences (ELCS). ELCS automatically learns rules for extracting protein interactions using a bottom-up approach. They conducted experiments in two ways: one with manually crafted protein names and the other with the extracted protein names by their name identification method. In both experiments, Bunescu, et al. compared their results with human-written rules and showed that machine learning methods provide higher precisions than human-written rules. Table 2 summarizes the works in the areas of relation extraction in biomedical literature.

Techniques Used

The most commonly used extraction technique is co-occurrence based. The basic idea of this technique is that entities are extracted based on frequency of co-occurrence of biomedical named entities such as proteins or genes within sentences. This technique was introduced by Blaschke, et al. (1999). Their goal was to extract information from scientific text about protein interactions among a predetermined set of related programs. Since Blaschke and his colleagues' study, numerous other co-occurrence-based systems have been proposed in the literature. All are associated with information extraction of biomedical entities from the unstructured text corpus. The common denominator of the co-occurrence-based systems is that they are based on co-occurrences of names or identifiers of entities, typically along with activation/dependency terms. These systems

Table 2. A summary of relation extraction for biomedical data

Authors	Relation	Entity	DB	Learning Methods	Precision	Recall
Leek (1997)	Location	Gene	OMIM	HMM	80%	36%
Blaschke (1999)	Interact	Protein	MEDLINE	Co-occurrence	n/a	n/a
Proux (2000)	Interact	Gene	Flybase	Co-occurrence	81%	44%
Puste-jovsky (2001)	Inhibit	Gene	MEDLINE	Co-occurrence	90%	57%
Jenssen (2001)	Location	Gene	MEDLINE	Co-occurrence	n/a	n/a
Friedman (2001)	Pathway	Many	Articles	Co-occurrence & thesauri	96%	63%
Bunescu (2004)	Interact	Protein	MEDLINE	RAPIER, BWI, ELCS	n/a	n/a

are differentiated one from another by integrating different machine learning techniques such as syntactical analysis or POS tagging, as well as ontologies and controlled vocabularies (Hahn et al., 2002; Pustejovsky et al., 2002; Yakushiji et al., 2001). Although these techniques are straightforward and easy to develop, from the performance standpoint, recall and precision are much lower than any other machine-learning techniques (Ray & Craven, 2001).

In parallel with co-occurrence-based systems, the researchers began to investigate other machine learning or NLP techniques. One of the earliest studies was done by Leek (1997), who utilized Hidden Markov Models (HMMs) to extract sentences discussing gene location of chromosomes. HMMs are applied to represent sentence structures for natural language processing, where states of an HMM correspond to candidate POS tags, and probabilistic transitions among states represent possible parses of the sentence, according to the matches of the terms occurring in it to the POSs. In the context of biomedical literature mining, HMM is also used to model families of biological sequences as a set of different utterances of the same word generated by an HMM technique (Baldi et al., 1994).

Ray and Craven (2001) have proposed a more sophisticated HMM-based technique to distinguish fact-bearing sentences from uninteresting sentences. The target biological entities and relations that they intend to extract are protein subcellular localizations and gene-disorder associations. With a predefined lexicon of locations and proteins and several hundreds of training sentences derived from Yeast database, they trained and tested the classifiers over a manually labeled corpus of about 3,000 MEDLINE abstracts. There have been several studies applying natural language tagging and parsing techniques to biomedical literature mining. Friedman, et al. (2001) propose methods parsing sentences and using thesauri to extract facts about genes and proteins from biomedical documents. They extract interactions among genes and proteins as part of regulatory pathways.

Evaluation

One of the pivotal issues yet to be explored further in biomedical literature mining is how to evaluate the techniques or systems. The focus of the evaluation conducted in the literature is on extraction accuracy. The accuracy measures used in IE are precision and recall ratio. For a set of N items, where N is either terms, sentences, or documents, and the system needs to label each of the terms as positive or negative, according to some criterion (positive, if a term belongs to a predefined document category or a term class). As discussed earlier, the extraction accuracy is measured by precision and recall ratio. Although these evaluation techniques are straightforward and are well accepted, recall ratios often are criticized in the field of information retrieval, when the total number of true positive terms is not clearly defined.

In IE, an evaluation forum similar to TREC in information retrieval (IR) is the Message Understanding Conference (MUC). Participants in MUC tested the ability of their systems to identify entities in text to resolve co-reference, extract and populate attributes of entities, and perform various other extraction tasks from written text. As identified by Shatkay and Feldman (2003), the important challenge in biomedical literature mining is the creation of gold-standards and critical evaluation methods for systems developed in this very active field. The framework of evaluating biomedical literature mining systems was recently proposed by Hirschman, et al. (2002). According to Hirschman, et al. (2002), the following elements are needed for a successful evaluation: (1) challenging problem; (2) task definition; (3) training data; (4) test data; (5) evaluation methodology and implementation; (6) evaluator; (7) participants; and (8) funding. In addition to these elements for evaluation, the existing biomedical literature mining systems encounter the issues of portability and scalability, and these issues need to be taken into consideration of the framework for evaluation.

Data Sources

In terms of data sources from which target biomedical objects are extracted, most of the biomedical data mining systems focus on mining MEDLINE abstracts of National Library of Medicine. The principal reason for relying on MEDLINE is related to complexity. Abstracts occasionally are easier to mine, since many papers contain less precise and less well supported sections in the text that are difficult to distinguish from more informative sections by machines (Andrade & Bork, 2000). The current version of MEDLINE contains nearly 12 million abstracts stored on approximately 43GB of disk space. A prominent example of methods that target entire papers is still restricted to a small number of journals (Friedman et al., 2000; Krauthammer et al., 2002). The task of unraveling information about function from MEDLINE abstracts can be approached from two different viewpoints. One approach is based on computational techniques for understanding texts written in natural language with lexical, syntactical, and semantic analysis. In addition to indexing terms in documents, natural language processing (NLP) methods extract and index higher-level semantic structures composed of terms and relationships between terms. However, this approach is confronted with the variability, fuzziness, and complexity of human language (Andrade & Bork, 2000). The Genies system (Friedman et al., 2000; Krauthammer et al., 2002), for automatically gathering and processing of knowledge about molecular pathways, and the Information Finding from Biological Papers (IFBP) transcription factor database are natural language processing based systems.

An alternative approach that may be more relevant in practice is based on the treatment of text with statistical methods. In this approach, the possible relevance of words in a text is deduced from the comparison of the frequency of different words in this text with the frequency of the same words in reference sets of text. Some of the major methods using the statistical approach are AbXtract and the automatic pathway discovery tool of Ng and Wong (1999). There are advantages to each of these approaches (i.e., grammar or pattern matching). Generally, the less syntax that is used, the more domain-specific the system is. This allows the construction of a robust system relatively quickly, but many subtleties may be lost in the interpretation of sentences. Recently, GENIA corpus has been used for extracting biomedical-named entities (Collier et al., 2000; Yamamoto et al., 2003). The reason for the recent surge of using GENIA corpus is because GENIA provides annotated corpus that can be used for all areas of NLP and IE applied to the biomedical domain that employs supervised learning. With the explosion of results in molecular biology, there is an increased need for IE to extract knowledge to build databases and to search intelligently for information in online journal collections.

FUTURE TRENDS

With the taxonomy proposed here, we now identify the research trends of applying IE to mine biomedical literature.

1. A variety of biomedical objects and relations are to be extracted.
2. Rigorous studies are conducted to apply advanced IE techniques, such as Random Common Field and Max Entropy based HMM to biomedical data.
3. Collaborative efforts to standardize the evaluation methods and the procedures for biomedical literature mining.
4. Continue to broaden the coverage of curated databases and extend the size of the biomedical databases.

CONCLUSION

The sheer size of biomedical literature triggers an intensive pursuit for effective information extraction tools. To cope with such demand, the biomedical literature mining emerges as an interdisciplinary field that information extraction and machine learning are applied to the biomedical text corpus.

In this article, we approached the biomedical literature mining from an IE perspective. We attempted to synthesize the research efforts made in this emerging field. In doing so, we showed how current information extraction can be used successfully to extract and organize information from the literature. We surveyed the prominent methods used for information extraction and demonstrated their applications in the context of biomedical literature mining

The following four aspects were used in classifying the current works done in the field: (1) what to extract; (2) what techniques are used; (3) how to evaluate; and (4) what data sources are used. The taxonomy proposed in this article should help identify the recent trends and issues pertinent to the biomedical literature mining.

KEY TERMS

F-Value: Combines recall and precision in a single efficiency measure (it is the harmonic mean of precision and recall): F = 2 * (recall * precision) / (recall + precision).

Hidden Markov Model (HMM): A statistical model where the system being modeled is assumed to be a Markov process with unknown parameters, and the challenge is to determine the hidden parameters from the observable parameters, based on this assumption.

Natural Language Processing (NLP): A subfield of artificial intelligence and linguistics. It studies the problems inherent in the processing and manipulation of natural language.

Part of Speech (POS): A classification of words according to how they are used in a sentence and the types of ideas they convey. Traditionally, the parts of speech are the noun, pronoun, verb, adjective, adverb, preposition, conjunction, and interjection.

Precision: The ratio of the number of correctly filled slots to the total number of slots the system filled.

Recall: Denotes the ratio of the number of slots the system found correctly to the number of slots in the answer key.

Support Vector Machine (SVM): A learning machine that can perform binary classification (pattern recognition) as well as multi-category classification and real valued function approximation (regression estimation) tasks.

Chapter 1.26
Realizing Knowledge Assets in the Medical Sciences with Data Mining:
An Overview

Adam Fadlalla
Cleveland State University, USA

Nilmini Wickramasinghe
Cleveland State University, USA

ABSTRACT

This chapter provides insight into various areas within the medical field that strive to take advantage of different data mining techniques in order to realize the full potential of their knowledge assets. Specifically, this is done by discussing many of the limitations associated with conventional methods of diagnosis and showing how data mining can be used to improve these methods. Comparative analyses of different techniques associated with various areas within the medical field are outlined in order to identify the right technique for particular medical specialties. Furthermore, suggestions are provided to appropriately utilize the various data mining techniques thereby leading to effective and efficient knowledge management and knowledge utilization. In this chapter we highlight the potential of data mining in improving the exploratory as well as the predictive capabilities of conventional diagnostic methods in medical science.

INTRODUCTION

Knowledge management is an emerging business approach aimed at solving current business challenges to increase efficiency and effectiveness of core business processes while simultaneously fostering continuous creativity and innovation. Specifically, knowledge management through the use of various tools, processes and techniques combines germane organizational data, information and knowledge to create business value and enable an organization to capitalize on its intangible (e.g., knowledge) and intellectual assets so that it can effectively achieve its primary business goals as well as maximize its core business competencies (Swan et al., 1999; Davenport & Prusak, 1998). The need for knowledge management is based on a paradigm shift in the business environment where knowledge is central to organizational performance (Drucker, 1993).

Knowledge management offers organizations many tools, techniques and strategies to apply to their existing business processes. In essence then, knowledge management not only involves the production of information but also the capture of data at the source, the transmission and analysis of this data as well as the communication of information based on or derived from the data to those who can act on it (Swan et al., 1999). Fundamental to knowledge management is effectively integrating people, processes and technologies.

A pivotal technique in knowledge management is data mining which is used to discover new knowledge from existing data and information and thus grow the extant knowledge asset of the organization. This is particularly relevant to health care because not only is health care a knowledge-based industry, but it is also currently experiencing exponential growth in the collection of data and information primarily due to new legislative initiatives such as Managed Care and HIPAA (Health Information Portability and Accountability Act) in the US. This then makes it imperative for medical science to incorporate the benefits of this technique. We address this imperative by first discussing basic concepts of data mining and how they relate to the medical sciences. Next we elaborate upon key data mining techniques as well as their advantages and disadvantages and how they contribute to the building of important knowledge assets within health care.

BACKGROUND TO DATA MINING

In the literature, data mining is generally described at two levels: a broad perspective and a narrow perspective. While the broader perspective equates data mining to the process of Knowledge Discovery in Databases (KDD), the narrow perspective sees data mining as a step within this KDD process. In either case data mining can be defined as, "*The nontrivial extraction of implicit, previously unknown, and potentially useful information from data*" (Frawley et al., 1992). Data mining uses machine learning, as well as statistical and visualization techniques to discover and present knowledge in a form that is easily comprehensible to humans. Data mining involves sifting through huge amounts of data and extracting the relevant pieces of data for the particular analysis of a problem. More than just conventional data analysis (such as basic statistical methods), the technique makes heavy use of artificial intelligence. Often the emphasis is not as much on the extracting of data but more on the generating of a hypothesis, as in the case of exploratory data mining. Data mining also uses sophisticated statistical analysis and modeling techniques, which allow users to find useful information such as trends and patterns hidden in their business data. Data mining is one of the latest technologies to assist users deal with the abundance of data that they have collected over time. For example, this technique will help optimize business decisions, increase the value of each customer, enhance communication, and improve customer satisfaction. The retail industry has been using data mining technology to understand customer buying patterns, product warranty management, detection of fraud, and identification of good credit risks. Data Mining has become more popular over time due to the following reasons:

1. The main reason for the popularity of various data mining techniques is due to the large amount of data already collected and newly appearing data that requires processing beyond traditional approaches. The amount of data collected by various businesses, scientific, medical and governmental organizations around the world is enormous. It is impossible for human analysts to cope with the ever-growing and overwhelming amounts of data.
2. When a person analyses the data, he/she is liable to make errors due to the inadequacy of the human brain (i.e., the bounded ratio-

nality problem) to solve complex multifactor dependencies in the data and sometimes a lack of objectiveness in such an analysis. A human always tries to derive results based upon previous experiments and experiences gained from investigating other systems, unlike data mining which simply reflects what the data is conveying without preconceived hypotheses.

3. One more advantage of data mining is that, particularly in the case of large amounts of data, this process involves a much lower cost than hiring a team of experts. Although this technique does not discard the human involvement, it significantly simplifies the job and allows an analyst who is not proficient in statistics or programming to manage the process of extracting knowledge from data (Mega Computer Intelligence).

DATA MINING IN MEDICAL SCIENCES

The medical sciences offer a unique opportunity to apply the many techniques of data mining. This is because health care generates mountains of administrative data about patients, hospitals, utilization, claims, etc. In addition, clinical trials, electronic patient records and computer supported disease management increasingly produce large amounts of clinical data. This data, both the administrative and clinical, is a strategic resource for health care institutions since it represents a raw form of their knowledge

Data mining discovers the patterns and correlations hidden within this raw knowledge, i.e., the data repository. Furthermore, it enables health care professionals to use these patterns to aid in decision making and the establishment of revised and improved treatment protocols, and thereby enhance organizational performance.

Previous studies (Maria-Luiza et al., 2001) in various areas of the medical sciences have revealed that conventional methods of detecting symptoms or other health-related problems have been very costly and error prone. Due to the complexities and inconsistencies in these detection methods, the diagnoses which are based on the information gained from these methods can lead to outcomes that are sometimes dangerous and even could lead to a person's death. For example, during the prognosis of breast cancer, the main detection method available is mammography. Due to the high volume and variation in the stage of potential malignancy of tumors from mammograms that need to be read by physicians, the accuracy rate tends to decrease, and methods that focus on automatic reading of digital mammograms become highly desirable. It has been proven that double reading (by two different experts) of mammograms increases the accuracy but also naturally increases the costs. Thus, making it even more imperative to incorporate computer-aided diagnosis systems to assist medical professionals in achieving cost efficiency and diagnostic effectiveness and thereby enabling more appropriate and timely treatment.

In more litigious environments, the increasing risk to health care organizations and providers due to error in detection and interpretations has become extremely costly. Therefore, it is becoming a necessity to adopt new methods to facilitate not only more accurate detection and then treatment but also better preventative measures. Health care organizations have already accumulated large raw knowledge assets in the form of administrative and clinical data. What is now important for them to do is to maximize the potential of this strategic asset, hence the need for embracing data mining.

DATA MINING TECHNIQUES AND THEIR ROLE IN HEALTHCARE

Data mining techniques are not only used in the detection of diseases but they also are beneficial in helping to compare the different procedures required for a prognosis. For example, a physician who has newly started in practice can learn from the association of different procedures to certain diagnoses, which is the result of exploratory data mining and thus can take advantage of these findings to more effectively treat their patients, rather than depending more on the prolonged "trial and error" diagnostic path which is both more time consuming and a lower quality of care approach. The following data mining techniques are recognized for being of great benefit to many areas in business, engineering, as well as other industries. Health care should not be an exception in the application of these techniques:

- Association Rules
- Clustering
- Neural Networks
- Decision Trees

While we acknowledge that there are numerous data mining techniques, we focus on these techniques since they are some of the major techniques that are most suitable in our opinion to the medical sciences. The first two techniques are used for exploratory data mining, the latter two techniques are used for predictive data mining. We will first outline the major steps involved in data mining in order to achieve the final goal of knowledge creation before we describe each of the above data mining techniques.

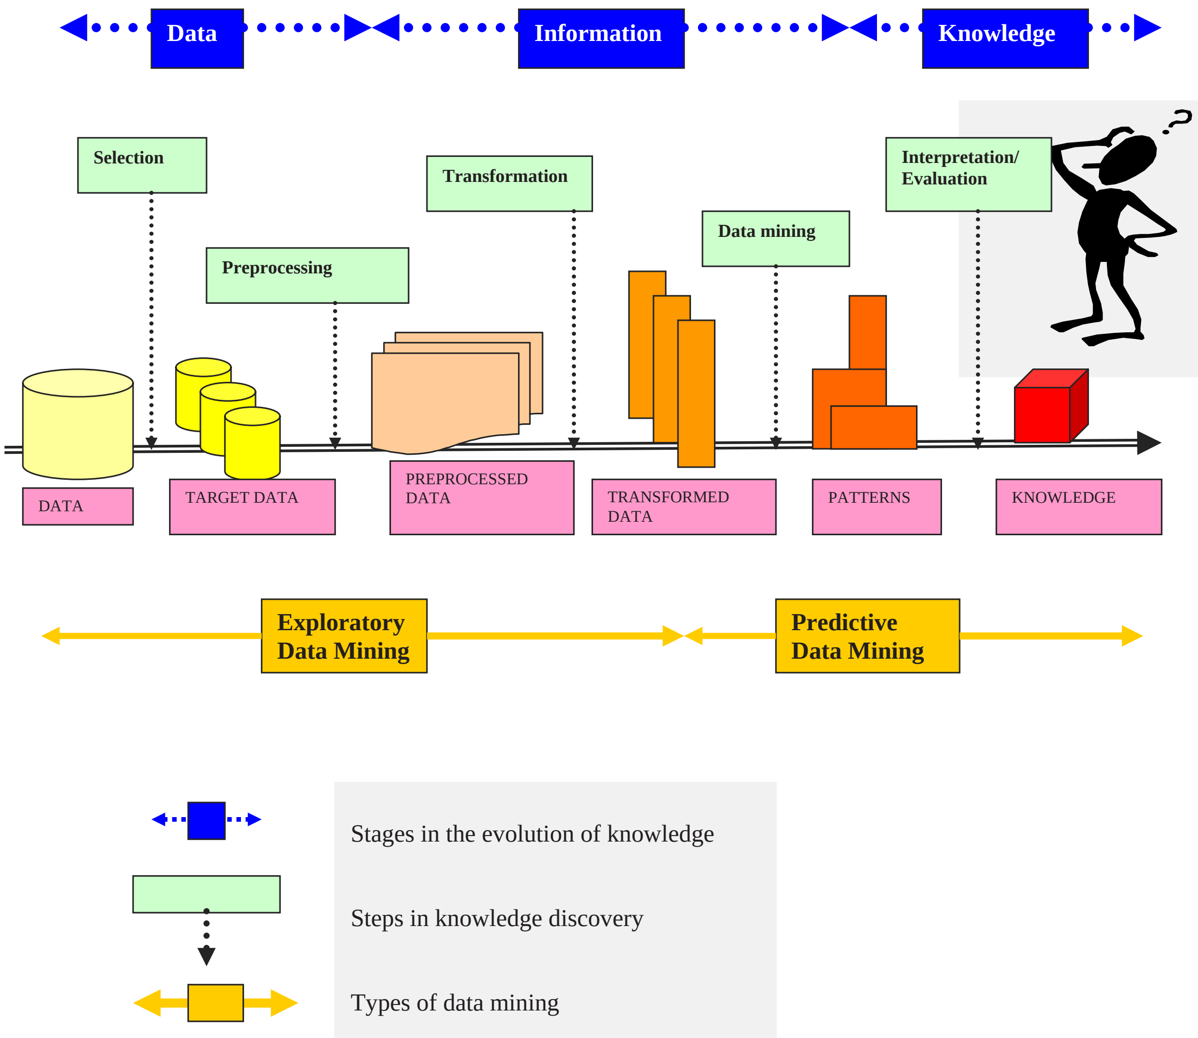
Knowledge Discovery Process

Figure 1 shows the knowledge discovery process, the evolution of knowledge from data through information to knowledge (Fayyad et al., 1996) and the types of data mining (exploratory and predictive) and their interrelationships. It is essential to emphasize here the importance of the interaction with the medical professionals and administrators who should always play a crucial and indispensable role in a knowledge discovery process, as depicted in *Figure 1* in the interpretation step. This is particularly true when we take into consideration features that are specific to the medical databases. For example, more and more medical procedures employ imaging as a preferred diagnosing tool. Thus, there is a need to develop methods for efficient mining in databases of images, which is inherently more difficult than mining in numerical databases. Other significant features include but are not limited to security and confidentiality concerns and the fact that the physician's interpretation of images, signals, or other clinical data, is written in unstructured English, which is also very difficult to mine (McGee, 1997). Some important data issues that data mining is most useful in helping organizations wrestle with include: huge volumes of data, dynamic data, incomplete data, imprecise data, noisy data, missing attribute values, redundant data, and inconsistent data.

Figure 1 also shows how data goes through the following process steps before being used for any decision-making:

- **Selection:** selecting the data according to some criteria, e.g., all those people who are suffering from or at risk of cardiac complications.
- **Preprocessing:** this is the data cleansing stage where certain unwanted information which may not be relevant or useful to the analysis is removed.
- **Transformation:** the data is not merely transferred but also changed using various mathematical manipulations (such as logarithmic transformations).
- **Data mining:** this stage is concerned with the extraction of patterns from the data. It includes choosing a data-mining algorithm, which is appropriate to discover a particular pattern in the data.
- **Interpretation and evaluation:** this is where human interaction and intervention is essential, specifically the patterns identified

Figure 1. Overview of the knowledge discovery process



by the system are interpreted into knowledge by humans and thereby redundant or irrelevant patterns are removed while patterns deemed useful are translated into potential treatment decisions.

Association Rule Mining

Association rules are used to discover relationships between attribute sets for a given input pattern. Such relationships do not necessarily imply causation, they are only associations. For example, an association rule that can be derived from medical data could be that 80% of the cases that display a given symptom are diagnosed with a similar condition and hence improves diagnostic capabilities. These patterns (associations) are not easily discovered using other data mining techniques. The support of an association rule is the percentage of cases which include the antecedent of the rule, while the confidence of the association rule is the percentage of cases where both the antecedent and the consequence of the rule are displayed. Only rules whose support and confidence exceed predetermined thresholds are considered useful. The classic algorithm used to generate these rules is the Apriori *algorithm* (Laura, 1990).

Advantages of Association Rule

- Association rules are readily understandable.
- Association rules are best suited for categorical data analysis
- It is widely used in hospitals to maintain patient's records.
- The outcomes are easy to interpret and explain and thus easy to use in the aiding of decision making.

Disadvantages of Association Rule Mining

- Generate too many rules and sometimes these are even trivial rules.
- The association rules are not expressions of cause and effect, rather they are descriptive relationships in particular databases, so there is no formal testing to increase the predictive power of these rules.
- Insight, analysis and explanation by health care professionals are usually required to identify the new and useful rules and thereby achieve the full benefits from such association rules.

Clustering

In clustering we are trying to develop groupings that are internally homogenous, mutually exclusive and collectively exhaustive. For example, in the study and treatment of chromosomal and DNA-related problems the clustering technique is important. This technique is an exploratory data mining technique. The outcome from the clustering process can then be used as input into a decision tree or neural network (Berkhin, 2002).

The most frequently used clustering method is k-means. This is a geometrical method, which uses the distance from the average location of all the members of a particular cluster to place a specific data point. The whole data field is divided into numbers and then these numbers are normalized. The value of each field is interpreted as the distance from the origin along corresponding axes. The initial clusters are randomly defined and computationally refined during the clustering process. The working of the clustering technique is dependent on two main criteria: (1) the members of a cluster should be most similar to each other, and (2) members of any two different clusters should be most dissimilar.

In most cases clusters are usually mutually exclusive but in some instances they may be overlapping, probabilistic or have hierarchical structures. In k-means a data point is assigned to the cluster which has the nearest centroid (i.e., the nearest mean). Clustering requires the data in numeric form since it works by assigning the cluster points accordingly. This process of assigning points to clusters continues until points stop changing positions (i.e., cluster hopping).

Advantages of Clustering

- The main strength of clustering is that it is an undirected knowledge discovery technique.
- The clustering can be used as a preparatory technique for other data mining techniques such as decision trees or neural networks.
- The outcome of clustering can be visually represented and hence easily understood.
- Creating clusters reduces the complexity of the problem by subdividing the problem space into more manageable partitions.
- The more separable the data points the more effective clustering is.

Disadvantages of Using Clustering

- Clustering represents a snap shot of the data at a certain point in time and thus may not be as useful in highly dynamic situations.
- Sometimes the clusters generated may not even have a practical meaning.
- Sometimes it is possible not to spot the cluster since you do not know what you are looking for.
- Clustering can be computationally expensive.

Neural Networks

The technique of neural networks is modeled after the human brain and normally consists of many input nodes, one or more hidden (middle) layer nodes and one or more output nodes. The input and output nodes relate to each other through the hidden layer. The input layer represents the raw information that is fed into the network. The hidden layer represents a computational layer that transforms the inputs coming from the input layer into inputs to the output layer. The behavior of the output layer depends on the activity of the hidden layer where the weights between the hidden and output layers are used as a reconciliation mechanism to help minimize the difference between the actual and desired outputs.

The outcome of a neural network is improved through the minimization of an error function, i.e., namely the difference between a desired output and an actual output value. The most widely used algorithm used to minimize this error function is known as backpropagation. Each input pattern is evaluated individually and if its value exceeds a predetermined threshold, then a pre-specified rule fires (i.e., is activated) whereby its outcome is fed forward to the next layer. The firing rule is an important concept in neural networks and accounts for their high flexibility since it determines how one calculates whether a subsequent neuron (node) should fire for any given input pattern.

The most important application of neural networks is pattern recognition. The network is trained to associate specific output patterns with input patterns. The power of neural networks comes into play in its predictive abilities, i.e., associating an input pattern that has not previously been classified with a specific output pattern. In such cases, the network will most likely give the output that corresponds to a pre-classified input pattern that is least different from the new input pattern.

Neural networks are mainly used in the medical sciences in recognizing disease types from various scans such as MRI or CT scans. The neural networks learn by example and therefore the more examples we feed into the neural network the more accurate its predictive capabilities become. Neural networks can process a large number of medical records, each of which includes information on symptoms, diagnoses, and treatments for a particular case. The use of neural network as a potential tool in medical science is exemplified by its use in the study of mammograms. In breast cancer detection the primary task is detection of a tumorous cell in the early stages. The best probability for a successful cure of this disease is in its early detection. Therefore, the power of neural networks lies in that they could be used to detect minute changes in tissue patterns (a key indicator of the existence of malignant cells) that are often difficult to detect with the human eye.

Advantages of Neural Networks

- Neural networks are good classification and prediction techniques when the results of the model are more important than the understanding of how the model works.
- Neural networks are very robust in that they can be used to model any type of relationship implied by the input patterns.
- Neural networks can easily be implemented to take advantage of the power of parallel computers with each processor simultaneously doing its own calculations.

- Neural networks are also very robust in situations where the data is noisy.

Disadvantages of Neural Networks

- The key problem with neural networks is the difficulty to explain its outcome. Unlike decision trees, neural networks use complex nonlinear modeling that does not produce rules and hence it is hard to justify one's decision.
- Significant preprocessing and preparation of the data is required.
- Neural networks will tend to over-fit the data unless implemented carefully. This is due to the fact that the neural networks have a large number of parameters which can fit any data set arbitrarily well.
- Neural networks require extensive training time unless the problem is small.

Decision Trees

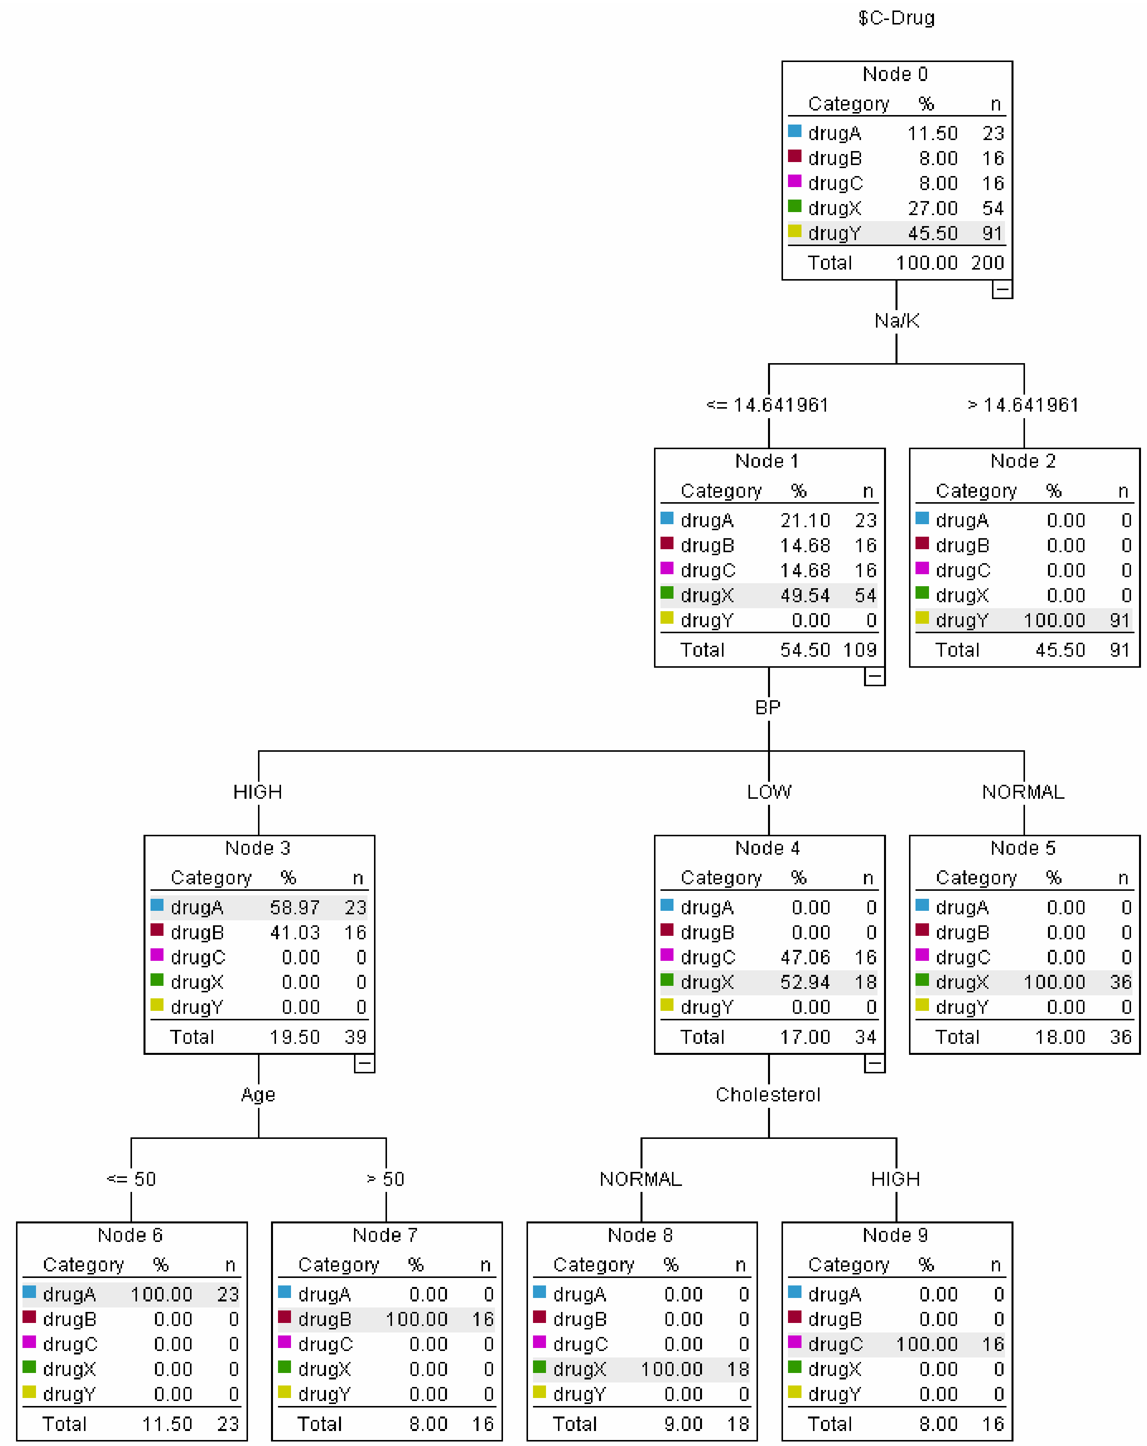
In critical decision situations, mistakes could be costly and have far reaching impacts. Thus data mining techniques are adopted in an attempt to minimize such mistakes. Decision trees split the available information in a treelike form and then arrive at a final decision by continuously refining the decision choices. The decision is usually made based on the choice between binary outcomes. For example, consider the binary decision of choosing between two methods—surgery and radiation—in the case of cancer treatments.

Decision making permeates health care but is of particular significance in the treatment of life-threatening diseases such as cancer. The decision tree then becomes a particularly powerful tool in such circumstances. Particularly in the case of cancer, early detection is critical since the disease grows rapidly and secondaries are more likely to develop in the meantime. A principal decision-making aspect is to decide quickly upon the specific treatment technique and then administer it and proceed with the delivery of care. For example, in *Figure 2* we can see a simple decision tree that tries to model the underlying decision problem of which drug to administer under which circumstances/conditions. At the root (the top node), the data is split into two partitions with respect to this decision problem, where one partition reflects cases where the Na/K ratio is less than or equal to 14.6 and it is not clear which drug should be administered, while the other partition represents the cases where the Na/K ratio is greater than 14.6 and it is clear that Drug Y is the drug of choice. Partition 1 therefore needs to be further subdivided into three sub-partitions; namely high (partition 1.1), low (partition 1.2) or normal (partition 1.3) blood pressure cases. In the case of partition 1.1 we can see that the choice is narrowed to Drug A or Drug B, so further sub-partitioning is required (namely, partition 1.1.1 and partition 1.1.2) and is performed on age in order to get clear decisions. It then becomes clear that age is a deciding factor between administering Drug A or Drug B—something that could not be seen from partition 1.1 or even less obvious from partition 1.

Advantages Of Decision Tree

- The graphical representation of a decision tree makes it a convenient and user-friendly modeling technique since it becomes very easy to visually follow the appropriate decision path and thereby facilitate accurate decision making.
- The decision tree algorithms are not only very fast and efficient to implement but the results are also unambiguous and thus easy to interpret. This feature of easy interpretability becomes of even greater significance in the medical sciences because often times doctors must justify their treatment decisions, such as in litigation instances.
- Decision trees can handle categorical (non-numeric) decision variables which are

Figure 2. Data mining resulting in the decision tree – each path from the tree root down represents a rule (i.e. a type of pattern)
Knowledge stage: Knowledge
Type of data mining: Predictive



common in the medical sciences such as in *Figure 2* where the decision variable is the drug to be administered.

- Decision trees can handle modeling situations where there is missing data, a situation that better mirrors practice.
- Decision trees prioritize the variables, using those with the most predictive power early in the partitioning process, hence using the most informative data first.

Disadvantages of Decision Trees

- When a decision variable is continuous, a categorization scheme needs to be developed first before applying the decision tree. Any weaknesses in this categorization scheme will be reflected in the outcome of the decision tree technique.
- There are dependencies between generations of splits (i.e., partition 1 impacts partitions 1.1, 1.2, etc.).
- The way in which decision trees handle numeric variables sometimes leads to loss of information due to loss of detail.

CONTRIBUTION TO KNOWLEDGE ASSETS

Irrespective of the specific data mining technique adopted, the significant common outcome of the application of all of these techniques is the generation of new knowledge. This newly created knowledge grows the extant knowledge base of the organization and thus not only adds value to its intangible assets but also increases its overall organizational value as new management techniques, such as the balanced scorecard, have demonstrated (Kaplan & Norton, 1996). In today's knowledge-based economy sustainable strategic advantages are gained more from an organization's knowledge assets than from its more traditional types of assets. Therefore, processes, tools and techniques that serve to grow the knowledge assets of an organization and thereby increase their value are strategic necessities to effectively compete in today's economy.

Healthcare is noted for using leading edge medical technologies and embracing new scientific discoveries to enable better cures for diseases and better means to enable early detection of most life threatening diseases. However, the healthcare industry globally, and in the US specifically, has been extremely slow to adopt key business processes (such as knowledge management) and techniques (such as data mining) (Wickramasinghe et al., 2003; Wickramasinghe & Mills, 2001). "Despite its information-intensive nature, the healthcare industry invests only 2% of gross revenues in information technology, compared with 10% for other information-intensive industries" (Bates et al., 2003). Furthermore, "[e]ven though US medical care is the world's most costly, its outcomes are mediocre compared with other industrial nations" (Bates et al., 2003). Therefore, making more of an investment in key business processes and techniques is a strategic imperative for the US healthcare industry if it is to achieve a premier standing with respect to high value, high quality and high accessibility of its healthcare delivery system.

In the final report compiled by the Committee on the Quality of Healthcare in America (Crossing the Quality Chasm, 2001), it was noted that improving patient care is integrally linked to providing high quality healthcare. Furthermore, in order to achieve a high quality of healthcare the committee identified six key aims — namely that healthcare should be: (1) safe: avoiding injuries to patients from the care that is intended to help them, (2) effective: providing services based on scientific knowledge to all who could benefit and refraining from providing services to those who will not benefit (i.e., avoiding under-use and overuse), (3) patient-centered: providing care that is respectful of and responsive to individual patient preferences, needs, and values and ensuring that patient values guide all clinical decisions, (4) timely: reducing waiting and sometimes harmful delays for both those receiving care and those who give care, (5) efficient: avoiding waste and (6) equitable: providing care that does not vary in quality based on personal characteristics.

Most of the poor quality connected with healthcare is related to a highly fragmented delivery system that lacks even rudimentary clinical information capabilities resulting in poorly designed care processes characterized by unnecessary duplication of services and long waiting times and delays (ibid). The development and application of sophisticated information systems is essential to address these quality issues and improve efficiency, yet healthcare delivery has been relatively untouched by the revolution of information technology, new business management processes such as knowledge management or new techniques such as data mining that are transforming so many areas of business today (Wickramasinghe et al., 2003; Wickramasinghe & Mills, 2001; Bates et al., 2003; Crossing the Quality Chasm, 2001; Wickramasinghe, 2000; Stegwee & Spil, 2001; Wickramasinghe & Silvers, 2002).

CONCLUSIONS

This chapter attempted to provide a survey of the four major data mining techniques and their application to the medical science field in order to realize the full potential of the knowledge assets in healthcare. We also presented an enhanced framework of the knowledge discovery process to highlight the interrelationships between data, information and knowledge as well as between knowledge creation and the key steps in data mining. There is no single data mining technique that will be best under all circumstances in healthcare as well as other industries. However, a comparative analysis of the various techniques as they are used in medical science suggests the following:

1. Neural networks are general and flexible thus can model situations with either numeric or non-numeric data. Further, they can handle noisy data effectively. However, their major limitation is that it is difficult to understand the reasoning behind their outcomes.
2. Decision trees on the other hand are very intuitive to understand but are not as flexible, nor as tolerant with noisy data.
3. Clustering provides a powerful exploratory data mining technique, however it can also be very computationally expensive. Further, it could sometimes generate clusters that are difficult to justify in practice. Clustering can be used as a first step for either decision trees or neural networks.
4. Association rules are very general in nature and their outcomes are very easy to understand, since these outcomes are made up of nested if-then rules. However, they require human insights to identify which rules are significant and useful and which are trivial.

Finally, we discussed the importance of data mining to the growing of the organizational knowledge assets and argued why this is of such significance in today's knowledge-based economy for healthcare. Clearly, as much as there is a need for such techniques in creating knowledge-based organizations in healthcare, there is still much to be done before knowledge management enabled through the adoption of these data mining techniques is diffused en mass throughout healthcare organizations and thereby enabling these organizations to realize the full benefits of their knowledge assets. This chapter then has served as an overview of how to realize the full potential of knowledge assets in the medical sciences using various key data mining techniques. There is naturally scope for future research to take a more detailed view of these techniques within the medical sciences.

Chapter 1.27
Data Mining Medical Digital Libraries

Colleen Cunningham
Drexel University, USA

Xiaohua Hu
Drexel University, USA

INTRODUCTION

Given the exponential growth rate of medical data and the accompanying biomedical literature, more than 10,000 documents per week (Leroy et al., 2003), it has become increasingly necessary to apply data mining techniques to medical digital libraries in order to assess a more complete view of genes, their biological functions and diseases. Data mining techniques, as applied to digital libraries, are also known as text mining.

BACKGROUND

Text mining is the process of analyzing unstructured text in order to discover information and knowledge that are typically difficult to retrieve. In general, text mining involves three broad areas: Information Retrieval (IR), Natural Language Processing (NLP) and Information Extraction (IE). Each of these areas are defined as follows:

- **Natural Language Processing:** a discipline that deals with various aspects of automatically processing written and spoken language.
- **Information Retrieval:** a discipline that deals with finding documents that meet a set of specific requirements.
- **Information Extraction:** a sub-field of NLP that addresses finding specific entities and facts in unstructured text.

MAIN THRUST

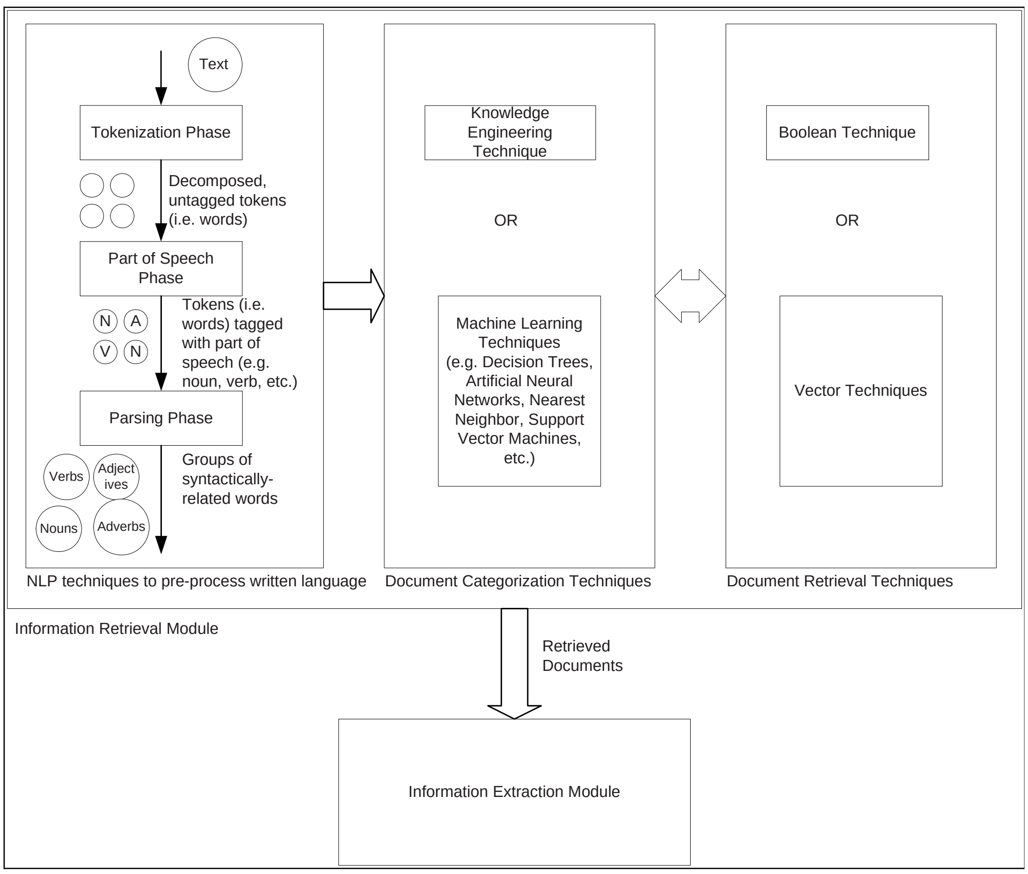
The current state of text mining in digital libraries is provided in order to facilitate continued research, which subsequently can be used to develop large-scale text mining systems. Specifically, an overview of the process, recent research efforts and practical uses of mining digital libraries, future trends and conclusions are presented.

Text Mining Process

Text mining can be viewed as a modular process that involves two modules: an information retrieval module and an information extraction module. presents the relationship between the modules and the relationships between the phases within the information retrieval module. The former module involves using NLP techniques to pre-process the written language and using techniques for document categorization in order to find relevant documents. The latter module involves finding specific and relevant facts within text. NLP consists of three distinct phases: (1) tokenization, (2) parts of speech (PoS) tagging and (3) parsing. In the tokenization step, the text is decomposed into its subparts, which are subsequently tagged during the second phase with the part of speech that each token represents (e.g., noun, verb, adjective, etc.). It should be noted that generating the rules for PoS tagging is a very manual and labor-intensive task. Typically, the parsing phase utilizes shallow parsing in order to group syntactically related words together because full parsing is both less efficient (i.e., very slow) and less accurate (Shatkay & Feldman, 2003). Once the documents have been pre-processed, then they can be categorized.

There are two approaches to document categorization: Knowledge Engineering (KE) and Machine Learning (ML). Knowledge Engineering requires the user to manually define rules, which can consequently be used to categorize documents into specific pre-defined categories. Clearly, one of the drawbacks of KE is the time that it would take a person (or group of people) to manually construct and maintain the rules. ML, on the other hand, uses a set of training documents to learn the rules for classifying documents.

Figure 1. Overview of text mining process



Specific ML techniques that have successfully been used to categorize text documents include, but are not limited to, Decision Trees, Artificial Neural Networks, Nearest Neighbor and Support Vector Machines (SVM) (Stapley et al., 2002). Once the documents have been categorized, then documents that satisfy specific search criteria can be retrieved.

There are several techniques for retrieving documents that satisfy specific search criteria. The Boolean approach returns documents that contain the terms (or phrases) contained in the search criteria; whereas, the vector approach returns documents based upon the term frequency-inverse document frequency (TF x IDF) for the term vectors that represent the documents. Variations of clustering and clustering ensemble algorithms (Iliopoulous et al., 2001; Hu, 2004), classification algorithms (Marcotte et al., 2001) and co-occurrence vectors (Stephens et al., 2001) have been successfully used to retrieve related documents. An important point to mention is that the terms that are used to represent the search criteria as well as the terms used to represent the documents are critical to successfully and accurately returning related documents. However, terms often have multiple meanings (i.e., polysemy) and multiple terms can have the same meaning (i.e., synonyms). This represents one of the current issues in text mining, which will be discussed in the next section.

The last part of the text mining process is information extraction, of which the most popular technique is co-occurrence (Blaschke & Valencia, 2002; Jenssen et al., 2001). There are two disadvantages to this approach, each of which creates opportunities for further research. First, this approach depends upon assumptions regarding sentence structure, entity names, and etcetera that do not always hold true (Pearson, 2001). Furthermore, this approach relies heavily on completeness of the list of gene names and synonyms and summarizes the modular process of text mining.

Research to Address Issues in Mining Digital Libraries

The issues in mining digital libraries, specifically medical digital libraries, include scalability, ambiguous English and biomedical terms, non-standard terms and structure and inconsistencies between medical repositories (Shatkay & Feldman, 2003). Most of the current text mining research focuses on automating information extraction (Shatkay & Feldman, 2003). The scalability of the text mining approaches is of concern because of the rapid rate of growth of the literature. As such, while most of the existing methods have been applied to relatively small sample sets, there has been an increase in the number of studies that have been focused on scaling techniques

Table 1. General text mining process

General Step	General Purpose	General Issues	General Solutions
IR	Identify and retrieve relevant docs	aliases, synonyms & homonyms	
IE	Find specific and relevant facts within text [e.g., find specific gene entities (entity extraction) & relationships between specific genes (relationship extraction)]	aliases, synonyms & homonyms	Controlled vocabularies (ontologies) [e.g., gene terms and synonyms: LocusLink (Pruitt & Maglott, 2001), SwissProt (Boeckmann et al., 2003), HUGO (HUGO, 2003), National Library of Medicine's MeSH (NLM, 2003)]

to apply to large collections (Pustejovsky et al., 2002; Jenssen et al., 2002). One exception to this is the study by Jenssen et al. (2001) in which the authors used a predefined list of genes to retrieve all related abstracts from PubMed that contained the genes on the predefined list.

Since mining digital libraries relies heavily on the ability to accurately identify terms, the issues of ambiguous terms, special jargon and the lack of naming conventions are not trivial. This is particularly true in the case of digital libraries where the issue is further compounded by non-standard terms. In fact, a lot of effort has been dedicated to building ontologies to be used in conjunction with text mining techniques (Boeckmann et al., 2003; HUGO, 2003; Liu et al., 2001; NLM, 2003; Oliver et al., 2002; Pruitt & Maglott, 2001; Pustejovsky et al., 2002). Manually building and maintaining ontologies, however, is a time consuming effort. In light of that, there have been several efforts to find ways of automatically extracting terms to incorporate into and build ontologies (Nenadic et al., 2002; Ono et al., 2001). The ontologies are subsequently used to match terms. For instance, Nenadic et al. (2002) developed the Tagged Information Management System (TIMS), which is an XML-based Knowledge Acquisition system that uses ontology for information extraction over large collections.

Uses of Text Mining in Medical Digital Libraries

There are many uses for mining medical digital libraries that range from generating hypotheses (Srinivasan, 2004) to discovering protein associations (Fu et al., 2003). For instance, Srinivasan (2004) developed MeSH-based text mining methods that generate hypotheses by identifying potentially interesting terms related to specific input. Further examples include, but are not limited to: uncovering uses for thalidomide (Weeber et al., 2003), discovering functional connections between genes (Chaussabel & Sher, 2002) and identifying viruses that could be used as biological weapons (Swanson et al., 2001). He summarizes some of the recent uses of text mining in medical digital libraries.

FUTURE TRENDS

The large volume of genomic data resulting and the accompanying literature from the Human Ge-

Table 2. Some uses of text mining medical digital libraries

Application	Technique	Supporting Literature
Building gene networks	Co-occurrence	Jenssen et al., 2001; Stapley & Benoit, 2000; Adamic et al., 2002
Discovering protein association	Unsupervised cluster learning and vector classification	Fu et al., 2003
Discovering gene interactions	Co-occurrence	Stephens et al., 2001; Chaussabel & Sher, 2002
Discovering uses for thalidomide	Mapping phrases to UMLS concepts	Weeber et al., 2001
Extracting and combining relations	Rule-based parser and co-occurrence	Leroy et al., 2003
Generating hypotheses	Incorporating ontologies (e.g., mapping terms to MeSH)	Srinivasan, 2004; Weeber et al., 2003
Identifying biological virus weapons		Swanson et al., 2001

nomic project is expected to continue to grow. As such, there will be a continued need for research to develop scalable and effective data mining techniques that can be used to analyze the growing wealth of biomedical data. Additionally, given the importance of gene names in the context of mining biomedical literature and the fact that there are a number of medical sources that use different naming conventions and structures, research to further develop ontology will play an important part in mining medical digital libraries. Finally, it is worth mentioning that there has been some effort to link the unstructured text documents within medical digital libraries with their related structured data in data repositories.

CONCLUSION

Given the practical applications of mining digital libraries and the continued growth of available data, mining digital libraries will continue to be an important area that will help researchers and practitioners gain invaluable and undiscovered insights into genes, their relationships, biological functions, diseases and possible therapeutic treatments.

KEY TERMS

Bibliomining: Data mining applied to digital libraries to discover patterns in large collections.

Bioinformatics: Data mining applied to medical digital libraries.

Clustering: An algorithm that takes a dataset and groups the objects such that objects within the same cluster have a high similarity to each other, but are dissimilar to objects in other clusters.

Information Extraction: A sub-field of NLP that addresses finding specific entities and facts in unstructured text.

Information Retrieval: A discipline that deals with finding documents that meet a set of specific requirements.

Machine Learning: Artificial intelligence methods that use a dataset to allow the computer to learn models that fit the data.

Natural Language Processing: A discipline that deals with various aspects of automatically processing written and spoken language.

Supervised Learning: A machine learning technique that requires a set of training data, which consists of known inputs and a priori desired outputs (e.g., classification labels) that can subsequently be used for either prediction or classification tasks.

Unsupervised Learning: A machine learning technique, which is used to create a model based upon a dataset; however, unlike supervised learning, the desired output is not known a priori.

Section II
Development and Design Methodologies

This section provides in-depth coverage of conceptual architectures, frameworks and methodologies related to the design and implementation of medical information systems and technologies. Throughout these contributions, research fundamentals in the discipline are presented and discussed. From broad examinations to specific discussions on particular frameworks and infrastructures, the research found within this section spans the discipline while also offering detailed, specific discussions. Basic designs, as well as abstract developments, are explained within these chapters, and frameworks for designing successful e-health applications, mobile healthcare systems, and clinical decision support systems are discussed.

Chapter 2.1
Building Better E-Health Through a Personal Health Informatics Pedagogy

E. Vance Wilson
University of Wisconsin–Milwaukee, USA

ABSTRACT

E-health use is increasing worldwide, but no current e-health paradigm fulfills the complete range of user needs for online health services. This dilemma clouds a number of issues surrounding e-health, as promoters of e-commerce, personal health records, and consumer health informatics paradigms attempt to create encompassing e-health within the constraints of each unique perspective. In the long term, the most important of these issues may be the need to develop an e-health pedagogy that offers conceptual grounding and course curricula in order to effectively represent all facets of e-health. To address that issue, this article introduces a personal health informatics (PHI) paradigm that incorporates the best features of preceding paradigms by integrating informatics, personal, and healthcare perspectives. Drawing from PHI, a pedagogical framework is proposed to guide instruction in the design and development of encompassing e-health.

INTRODUCTION

Use of e-health continues to expand worldwide. Harris Interactive reports that the number of Americans who have searched for health information online has increased to 117 million, and 85% of the these individuals searched within the month prior to being surveyed (Krane, 2005). Outside the U.S. and Europe, e-health use has grown more slowly (Holliday & Tam, 2004). However, further expansion seems likely as the World Health Organization and similar groups undertake efforts to increase availability of e-health in developing nations (Kwankam, 2004; WHO, 2005).

While some aspects of successful e-health are well-established, such as the need to provide encyclopedic health content, other aspects are less obvious. For example:

- Which services should be deployed online, and how should users interface with these services?
- If communication is offered, what is the best way to coordinate this to balance the needs of the public with those of healthcare

representatives (e.g., physicians and clinic staff)?
- How should personal health records (PHR) be incorporated into e-health, who owns the data in these records, and what (if any) data should PHR share with records of the healthcare provider, insurer(s), and payer(s), such as an employer or a government agency?

These are not idle questions to the health informatics and IT professionals who must design and deploy e-health applications. However, the area of e-health currently is underserved (or not served at all) in health informatics and IT curricula. This is a situation that should be remedied as soon as possible, given the large number of healthcare providers who currently are investing in e-health as an important part of organizational strategy (Lazarus, 2001; Martin, Yen & Tan, 2002).

In developing effective curricula for designers and developers of e-health, I propose that it will be helpful to view e-health from a user-centered perspective that can incorporate best practices of current e-health paradigms without being limited by their constraints. This article presents the foundational concepts that underlie this perspective and proposes a new pedagogy.

PARADIGMS OF E-HEALTH

E-health is a broad domain with numerous published definitions that primarily address the convergence of healthcare and Internet technology (Oh, Rizo, Enkin, & Jadad, 2005). A frequently cited definition by Eysenbach (2001) highlights e-health's interdisciplinary underpinnings.

E-health is an emerging field in the intersection of medical informatics, public health and business, referring to health services and information delivered or enhanced through the Internet and related technologies. In a broader sense, the term characterizes not only a technical development, but also a state-of-mind, a way of thinking, an attitude, and a commitment for networked, global thinking, to improve health care locally, regionally, and worldwide by using information and communication technology. (Eysenbach, 2001, p. e20)

Historically, each of the paradigms discussed in the following sections has played an important role in developing e-health to its current state. Yet, I will argue that none of these paradigms fulfills the complete range of user needs for online health services, and for this reason, none presents a suitable basis for pedagogy in design and development of encompassing e-health.

E-Commerce Paradigm

Prominent early developers of e-health services operated within an e-commerce paradigm in which vendors expected to profit from users paying directly for products and services acquired through the site or from advertisers paying for exposure to users. Typically, vendors were not affiliated with healthcare providers, so they could not provide services that link individuals with their own physician, clinic, or pharmacy. Although numerous vendors developed e-health within the e-commerce paradigm, few survived the ensuing shakeout due to failure to provide value to customers or to adequately control costs, lack of effective revenue models, or simple inability to ensure sustainable competitive advantage (Itagaki, Berlin, & Schatz, 2002; Rovenpor, 2003). Among the prominent e-health ventures representing the e-commerce paradigm, such as DrKoop.com, MediConsult.com, and PlanetRx.com, only a handful remains. The best-known of these is WebMD, which provides an exceptionally wide range of health services but continues to struggle toward profitability.

Personal Health Record Paradigm

A second approach to e-health that initially was based on profit motives is the personal health record (PHR) paradigm. The PHR is defined as follows:

An electronic, universally available, lifelong resource of health information needed by individuals to make health decisions. Individuals own and manage the information in the PHR, which comes from healthcare providers and the individual. The PHR is maintained in a secure and private environment, with the individual determining rights of access. The PHR is separate from and does not replace the legal record of any provider. (AHIMA, 2005, p. 64A)

The idea of computerizing personal health information is not new. A number of vendors introduced PHR products during the 1990s, both as stand-alone software and as online services. To date, demand for commercial PHR products has been low—only 2% of individuals who maintain health records use purchased PHR software (Taylor, 2004)—and none of these products has gained financial success (Holt, 2005). However, several factors may prompt increased use of PHRs in the near term. First, the U.S. public gained increased awareness of the value of portable health records as a result of the massive human displacement and damage to healthcare facilities sustained from hurricanes during 2005. This awareness is likely to affect public sentiment and governmental policies for some time to come (Kloss, 2005). Second, PHR software is continuing to improve. Current offerings have become easier to use and are more fully capable of integrating health resources beyond the individual's immediate data, such as linking to relevant medical journals and FDA drug information (Campbell, 2005). Finally, researchers are beginning to study how individuals go about maintaining health records in non-computerized settings, and this research is clarifying the opportunities and constraints that PHR developers face. For example, two recent studies in this area assess the importance of privacy and security in health records (Taylor, 2004) and shed light on the diverse strategies that individuals prefer to employ in storing health records (Moen & Brennan, 2005).

Consumer Health Informatics Paradigm

Although healthcare providers did not participate strongly in early stages of e-health development (Lazarus, 2001), these organizations have been instrumental in developing an increasing amount of e-health within a consumer health informatics (CHI) paradigm. CHI is "a branch of medical informatics that analyzes consumers' needs for information; studies and implements methods for making information accessible to consumers; and models and integrates consumers' preferences into medical information systems" (Eysenbach, 2000, p. 1713). Where e-commerce vendors hoped to achieve competitive advantage, healthcare provider organizations appear to be driven more by concerns of achieving competitive equity, both with competing providers and commercial e-health sites. Because CHI is produced by healthcare provider organizations, e-health produced within this paradigm has been oriented toward providing added customer service, increasing healthcare delivery quality, and containing costs rather than selling products, services, or advertising access. Although the CHI paradigm is designed to address needs of the individual user, it inherently takes an organizational perspective that imposes a passive view of users as consumers rather than suppliers of information. Thus, providing PHRs and integrating external patient data typically have not been high priorities for e-health created within the CHI paradigm.

A New Paradigm: Personal Health Informatics

Each of the three historical paradigms identifies an area of need in the population of e-health users. However, none addresses the total range of needs that e-health users identify. These include communicating with physicians and clinic staff, arranging services (e.g., scheduling appointments and renewing prescriptions), checking bills and making payments, viewing lab results, accessing records of procedures/tests/immunizations, receiving online alerts, monitoring chronic conditions, and interacting with online support communities (e.g., patient chat groups), in addition to accessing encyclopedic health information (Fox, 2005; Harris, 2000; Taylor & Leitman, 2002). Furthermore, individuals want the ability to control their personal data, to ensure that recordkeeping aspects of e-health are interoperable and portable, and to be assured of privacy and security (Holt, 2005; Taylor, 2004). In order to capture the complete set of knowledge and skills that will be necessary to encompass e-health services, I propose that it is essential to consider a new paradigm that can integrate best practices of the three paradigms discussed previously. Because of its user-centered focus, which views e-health from the perspective of individual users in the role of information provider as well as information consumer, I term this paradigm *personal health informatics* (PHI). PHI is defined as the knowledge, skills, practices, and research perspectives necessary to develop e-health that is effective, efficient, encompassing, and user-centered.

FOUNDATIONS OF A PHI PEDAGOGY

A conceptual model of PHI is presented in Figure 1. Four structural components define the content of PHI within three focal areas. Web e-service infrastructure is the hardware, software, and networking capabilities that support all e-health functions. Because e-health is primarily service-oriented, the informatics focus in PHI centers on infrastructure that is specialized for e-service presentation and delivery. Personal health management and user-centered development comprise the personal focus that PHI presents to individual users. User-centered development methods provide tools for eliciting user needs, designing solutions, and evaluating the utility of these solutions in meeting user needs. Personal health management addresses individual practices as well as psychological, social, and cultural aspects of the management, storage, and retrieval of personal health information. Personal health management and the health informatics domain combine in the healthcare focus of PHI. Content within the health informatics domain addresses the skills, knowledge, and surrounding use of IT within the subject health area(s).

In order for students to enter the health informatics and IT workforce with sufficient preparation to develop e-health that can fully support individual users' needs, training will be needed in each of the structural areas of PHI, which are presented in Figure 1. None of these areas is beyond the grasp of graduate or advanced undergraduate students; however, the combination of content areas represents a set of specializations that rarely are combined in current curricula. Thus, for the time being, PHI training necessarily will have to be pieced together from existing textbooks, research reports, and industry cases. I address each curricular area in the following sections.

E-Service Web Infrastructure Curriculum

E-health in the PHI paradigm is essentially a form of e-service, defined as services provided over electronic networks such as the Internet (Rust & Lemon, 2001) Thus, most texts that focus on development and administration of Web infrastructure for e-services will be applicable to PHI. Texts that address the general topic of e-commerce typically are less applicable, as large portions of these dwell on factors that are not central to e-health, such as general business models, marketing and consumer behavior issues, and methods for increasing online sales. Web infrastructure changes rapidly, so texts in this area must not be allowed to become stale. New texts should be chosen, based upon inclusion of emerging technologies such as mobile devices, speech recognition, and natural language parsers, as well as effective coverage of more mature technologies such as XHTML, database connectivity, and network communications.

User-Centered Development Curriculum

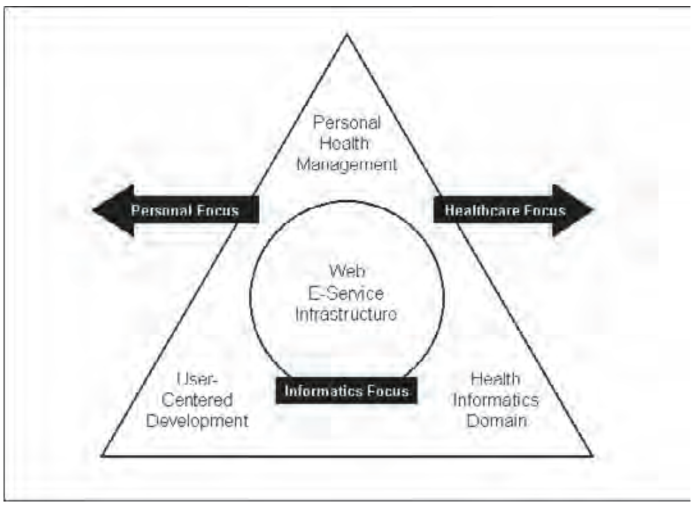
User-centered development refers to a software development process that incorporates the user viewpoint, assesses user needs, and validates that user needs are met. There are two complementary approaches to this process that will be valuable to students of PHI. The first of these is the design guide approach. Design guides emphasize generic or context-specific design principles, such as the following example for use of color on Web sites:

In the physical world, color has embedded meaning, usually culturally based. In the American culture, at a simplistic level, red means stop and green means go, red means hot and blue means cold, black means death and white means birth, and green represents money and greed. These embedded meanings of color differ from culture to culture; for instance, the color white is symbolic not of birth, but of a funeral in Japan or India. (Lazar, 2001, p. 158)

Design guides are valuable in establishing general guidelines in conventional use of design features and in broadening students' appreciation of ways that others' perspectives may differ from their own.

The second approach emphasizes the design process by establishing an algorithmic approach or how-to guidance for developing functionality and user interface features. For example, the

Figure 1. Conceptual model of key PHI structural components



SALVO method (Wilson & Connolly, 2000) guides students through five development stages. The first three of these are planning stages in which designers specify user needs, adopt a technology-specific design guide, and leverage appropriate matches between technology and user needs in order to enhance user abilities and to support user disabilities. Once planning stages are initially completed, developers perform visualization techniques, including mockups to elicit user feedback early in the development cycle. Visualization is followed by an observation stage, in which designers observe and evaluate attempts by users to perform representative tasks using the mockup or completed software. SALVO takes an iterative approach to development, and it is accepted throughout the development cycle that prior stages and sequences of stages can be repeated, as necessary. The design process approach provides PHI students with a methodology and specific tools for customizing e-health in order to meet the needs of a specific user audience, which may differ substantially, for example, between a macular degeneration support group and the general public.

Personal Health Management Curriculum

Personal health management is an emerging area of research, and new findings likely will emerge that add appreciably to current knowledge in this field. Although it may be too early to look for texts that focus on personal health management and good empirical studies, and cases are available that would be highly applicable to PHI. One exemplar is a study by Moen and Brennan (2005) that investigates strategies for health information management (HIM) that are applied by individuals in their own homes. Their research identifies four HIM strategies:

- **Just in Time.** Information is kept with the person at most times in anticipation of immediate need.
- **Just at Hand.** Information is stored in familiar, highly accessible locations, often serving as a reminder.
- **Just in Case.** Information is stored in order to be accessible in case of need, but out of view.
- **Just Because.** Information is retained in interim storage pending a decision to file or to discard it.

This study presents several important implications for developers of HIM software that would be highly relevant for PHI students to consider and discuss. These include effects of tradeoffs between information accessibility and visibility on the success of individuals' efforts to coordinate HIM, implications of the high degree of reliance that individuals place on paper-based records, and design decisions that would be necessary in order to align electronic records to support the differentiated storage strategies that individuals are found to prefer.

Health Informatics Domain Curriculum

The health informatics domain encompasses use of IT to support the delivery of healthcare services (including communication, coordination, logistics, and other business processes) as well as applicable practices and procedures that surround the use of IT in the healthcare setting. It is important to recognize that while the health informatics domain is a key component of PHI, it is not the central element of e-health from the user's perspective. In order to preserve a user-centered focus, it is essential that distinctive components of PHI pedagogy should not be replaced by health informatics courses that focus on IT from a perspective that is internal to the organization (i.e., managerial or technical). Where PHI is taught within an existing health informatics program, a range of courses already will be in place in order to effectively cover topics in the domain. Where PHI is taught in technology programs, topics in the health informatics domain may be covered effectively by traditional health informatics or by medical informatics texts.

Suggested Modes of Curriculum Organization

As discussed previously, PHI can be integrated into the undergraduate or graduate curricula of existing health informatics programs or used to augment offerings in technology programs, such as information systems, computer science, or information science. As a specialization within a health informatics program that already incorporates domain coverage, in-depth PHI training can be achieved by a curriculum that offers one course-equivalent each in user-centered development and personal health management and up to two courses in Web e-service infrastructure. If two courses are offered, the first should focus on basic development methods, including XHTML, XML, and simple database connectivity, and the second on administration issues and advanced development methods including Web services, mobile applications, and emerging technologies.

As an augmentation to a technology program that already incorporates Web e-service infrastructure coverage, substantial depth of PHI training can be achieved by offering a specialization with one course equivalent in each of user-centered development, personal health management, and health informatics. A final alternative is to offer a basic introduction to each of these subjects within a single course equivalent. Although not ideal for career preparation, this alternative could be an effective way to direct technology-area undergraduates toward careers and further educational opportunities in the field of health informatics and IT.

CONCLUSION

Although not always profitable for commercial vendors, e-health has been a success for individual users. Major healthcare provider organizations have adopted e-health as a means of attaining competitive equity in the marketplace, thus providing greater opportunities for individuals to use e-health and creating a demand for trained health informatics and IT professionals to work in e-health. PHI presents a conceptual perspective that incorporates the best features of preceding paradigms and provides a framework for improving instruction in e-health design, development, and administration.

Chapter 2.2
Web Service Design Concepts and Structures for Support of Highly Interconnected E-Health Infrastructures:
A Bottom-Up Approach

Adamantios Koumpis
ALTEC S.A., Greece

ABSTRACT

In this chapter we present organizational aspects that appear when considering the case of interconnecting and integrating different compartments of a modern hospital. While the information and communication technologies provide advanced and powerful means for the creation of coherent information supply services, such as the Web service and ontology technologies, there is a lack of appropriate organizational metaphors that will enable the successful assimilation of these technologies, helping to aid in the improvement of critical cost parameters that concentrate a large part of the hospital's management resources, while also helping to improve the knowledge capital and the intangible and immaterial assets of any particular hospital, which are considered as the most essential and scarce resource. In this paper we presents a technology-based approach for solving interoperability problems at the service level, and we deliberately adopt a problem-solving approach that has successfully been adopted by the European IST Project ARTEMIS.

INTRODUCTION

What we more intensively experience is that the Web is moving from being a collection of pages toward a collection of services that interoperates through the Internet (Paolucci, Kawamura, Payne, & Sycara, 2002). According to the same source:

Web services provide a new model of the web in which sites exchange dynamic information on demand. This change is especially important for the e-business community, because it provides an opportunity to conduct business faster and more efficiently. Indeed, the opportunity to manage supply chains dynamically to achieve the greatest advantage on the market is expected to create great value added and increase productivity. On the other hand, automatic management of supply chain opens new challenges: first, web services should be able to locate automatically other services that provide a solution to their problems, second, services should be able to interoperate to compose automatically complex services. In this paper we concentrate on the first problem: the location of web services on the basis of the capabilities that they provide.

In this chapter our concern is the application of some Web service design concepts and structures in order to support highly interconnected e-health infrastructures; though health for sure constitutes a special application domain with several idiosyncrasies and singular characteristics, there is a great extent of paradigms and analogies that can be drawn from the area of e-business and supply chain management.

We believe that our contribution by means of the work conducted under the European IST project ARTEMIS (ARTEMIS, 2004), which was lead by professor Asuman Dogac of the Middle East Technical University, constitutes a success story that can be followed to form the basis of several VE ventures in the area of e-health as well as in other business domains.

Currently, the majority of the interoperability problems of medical information systems are two-fold (Bicer, Banu Laleci, Dogac, & Kabak 2005a; Bicer, Kilic, Dogac, & Banu Laleci, 2005b):

1. First there are multiple, incompatible, proprietary approaches to connecting disparate applications to clinical networks and information systems. As a result, for example it is not possible to integrate electronically the clinical patient records with critical emergency control information.
2. Secondly, when there are standards to achieve interoperability, there are more than one standard to represent the same information, which in turn creates an interoperability problem. For example, GEHR, CEN 13606 and openEHR are all standards for patient electronic health records.

The proposed model provides the most important entity of the healthcare industry, namely the hospital, with an ideal platform to achieve difficult organizational and technology integration problems. The proposed services as developed in our project ARTEMIS allow for seamless integration of disparate applications representing different and, at times, competing standards, thus allowing for a service to be invoked *on demand* pervasively by business processes, applications or people to fulfil a particular function. The latter forms the most important innovation of the presented work and a tangible contribution towards smarter hospitals that are capable to build dynamic information exchange and sharing infrastructures that might have the form of virtual enterprises. Though from a legal point of view there are many problems and difficulties, it is however important that such a goal will guide the investments in the health industry in Europe.

As will be further described, the innovation of our approach comes to the fact that our approach for design and management of services is implemented in a distributed service infrastructure according to a *preplanned usage of a multiple service actors' scheme*. The term distributed service infrastructure is used for description of an environment with the following characteristics:

1. It consists of a number of service flows that are executed using resources of several sites simultaneously.
2. That service flows communicate with each other by exchanging messages over a commonly agreed network of participants (in our case it is the network of the hospitals

or hospital units involved in the provision of a service).

Our efforts may be viewed from within the perspective of building the service flow execution kernel for mobile agent applications that may regarded as the high-end of the foreseen application service providers (ASP) market in terms of *aggregating* functionality requested by the particular differentiated users of the distributed service environment. In this respect, the approach we employ address the following two needs:

1. From an *operational* viewpoint, it focuses on the intersite aspects (timing and security) for remote interoperability of the participating hospital services. Intrasite, it will focus on the dynamic adaptation of the application to changes in the environment of a single hospital (unit).
2. From a *methodological* viewpoint, it focuses on the way to capture and validate dependability requirements and validates these requirements, on the way to derive from requirements the structure of the modeling approach, and on the use of modeling to drive the development and the assessment of the proposed solutions.

The building of the proposed services is based on:

- **Service elements:** Regarded from the service designer's perspective as these concern reusable elements that may be used for developing new services or enhancing/changing the functionality of existing (operational) ones
- **Service pages:** Entities upon which the hospital user (i.e., a doctor, a nurse or an administration employee) may regard services either for carrying out customization activities such as personalization of the access-to-service interface for example, for different user categories and different types of usage (data entry, retrieval of data, sophisticated query formulation and processing, etc.)

The approach taken helps in the creation of a significant competitive advantage and market knowledge and creates first-mover advantage in the addressed transition towards *service-oriented architectures.* This know-how is faster transferable from within the operational environment to those key divisions that will be acting as uptakers and adopters. Of course, a key objective has been how to get improved ideas to those who can effectively apply them. The main focus is to gain the technological capabilities and the necessary means (i.e., methods, practices and software components) so that any new services will be affordably priced for a segment of the hospital market that has been *largely unable to afford such services—namely small and medium sized hospitals with fewer than 200 employees such as the case of regional or prefecture-level hospital and / or health centers.*

The access-to-service environment under implementation enables the users of the service platform to:

- Establish an overall service flow direction, by means of providing linkage to a set of pre-programmed resources that are executed in the distributed (Internet) environment, such as ERP, patient recording applications, and so forth.
- Acquire resources for a particular service property which may be it a service flow, a service element, or a service "page".
- Provide "capabilities" to a service flow by means of integrates both structural and behavioral aspects from within a single perspective, which will be utilized to instantiate the actual service delivery at the end user's point.
- Execute the service flow by means of utilizing resources to accomplish the particularly

assigned service scenario.

The last may also be regarded also the "bottom-line" for the actual service delivery by a particular service flow to support the purpose of the latter's establishment (i.e., the reason for existence of that particular service flow in the overall hospital value chain).

The Artemis Project

Medicine is one of the few domains to have some domain knowledge in a computable form which can be exploited in defining the semantics of Web services. This semantic knowledge exists in "controlled vocabularies", or "terminologies". Some vocabularies are rich semantic nets, such as SNOMED-CT while others such as ICPC and ICD are little more than lexicons of terms. Although such vocabularies do not express all the possible semantics of basic concepts—they are generally limited to terms, definitions and some semantic relationships—they offer significant value in terms of expressing the semantic of Web services.

ARTEMIS is a project that runs under the 6th Framework Programme of the European Commission, and aims to develop a semantic Web services based interoperability framework for the health care domain. The interoperability problems of medical information systems are two fold:

- First there are multiple, incompatible, proprietary approaches to connecting disparate applications to clinical networks and information systems. As a result, for example it is not possible to integrate electronically the clinical patient records with billing information.
- Secondly, when there are standards to achieve interoperability, there are more than one standard to represent the same information, which in turn creates an interoperability problem. For example, GEHR, CEN 13606 and openEHR are all standards for patient electronic health records. The CEN 13606 model, for instance, describes a hierarchical representation for all data using the cluster and data_item classes. The GEHR model does the same thing, with its hierarchical_value and hierarchical_group classes.

Figure 1 gives an overview of the ARTEMIS architecture to enable the peer-to-peer networks as a platform for publishing, discovering and invoking semantically enriched Web services that wrap Medical Information System Applications based on the semantic Web initiative. To achieve this objective the following basic components will be provided by the ARTEMIS project:

- Semantically enriched and secure P2P Web service environment for medical information systems
- Semantic wrapper for Web service creation and composition that adapts the medical information system applications
- Service-based access layer for electronic health records
- User friendly interfaces for the healthcare organizations, such as for publishing, discovering and composing Web services

These components are presented in more detail in Figure 2.

Furthermore, in our approach we provide a P2P platform that with enhanced capabilities for publishing, discovering and invoking *semantically enriched medical Web services in a highly secure framework*.

This component will be a base for the medical informatics Web services to operate on. The objective of this component is to facilitate the discovery of medical Web services both from the individual peers in a network and also from the public service registries.

However neither existing P2P architectures nor the Web service registries provide facilities

Figure 1. An overview of the service-oriented architecture in the ARTEMIS project

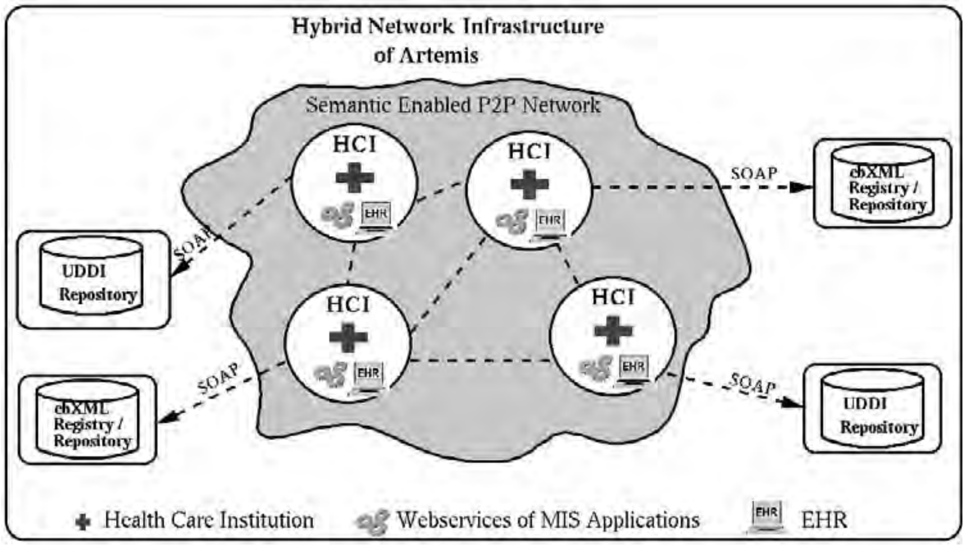

Figure 2. ARTEMIS components overview

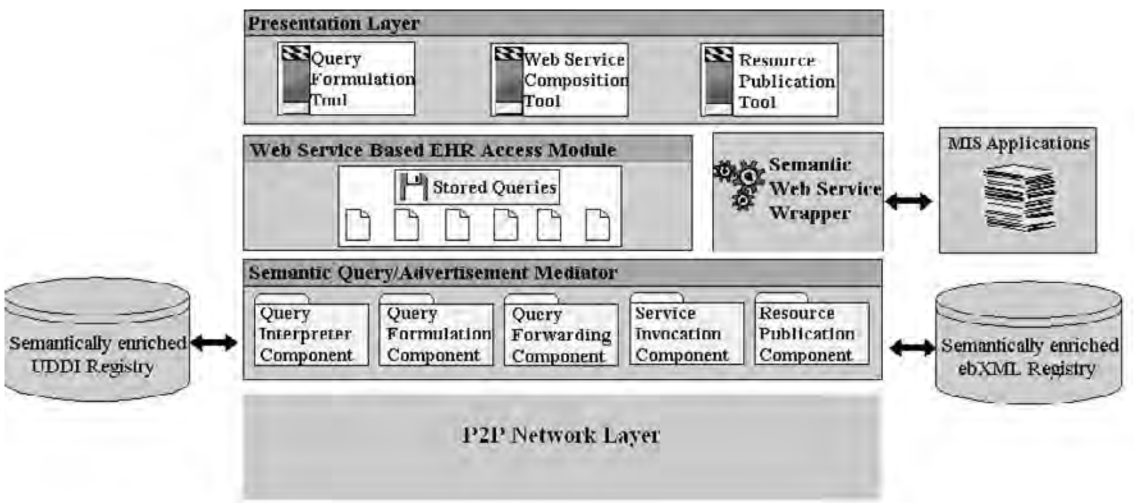


for exploiting the semantics of the services, and P2P security models are still emerging mainly in the context of the WS-Security standardization roadmap (Dogac, Bicer, Banu Laleci, Kabak, Gurcan, & Eichelberg, 2006).

In order to achieve an integrated hybrid semantic based infrastructure, this component will be developed in three main steps. In the first step existing Web service registries will be enhanced to store domain specific ontologies, and services based on these ontologies; the second step will be incorporating service semantics in to P2P networks, particularly developing semantic based advertisement and discovery mechanisms for P2P networks. In the final step, semantically enriched service registries will be integrated to the P2P architecture.

POSITIONING OF THE SYSTEM AND THE APPROACH

Having in mind that some of the most essential problems that users, administrators, developers and vendors of information supply services in the health discipline, as well as in every application and service field, face today may be viewed under the common denominator of "interoperability" problems, the presented approach illustrates possible ways to address these problems. A design goal of the project is to provide a cohesive technological infrastructure independent of any specific implementation pathway and to contain features that are effective and easy to use in a broad range of representative networked service environments which may be subject to variable configurations. For this reason we recognize the following types and broad categories of users:

1. Platform and service vendors (may concern IT companies, content providers or—in case they exhibit competencies in any of them—as a specialization of the broker category)
2. Professional health service providers (as a specialization of the broker category)
3. Service developers (as a specialization of the broker category)
4. Service administrators (as a specialization of the broker category)
5. Service end users (i.e., hospitals—either public or private owned ones)
6. Information technology managers (as a specialization of the previous end user category)

These users participate in one or more of the following four stages in the development and usage of the health-based service infrastructures:

- **Establishment:** Implementing and deploying the presented service approach across the health information "supply chain."
- **Build:** Exercising the service elements to define a baseline service flow configuration (establishing the exchange paths between known service sources and targets as well as the various filtering mechanisms involved).
- **Operation:** Operating the service flow infrastructures.
- **Maintenance:** Exercising the introduced concepts to define changes in the distributed service configuration (e.g., to cover changes as "small" as the addition of new service elements in the overall service configuration and as "large" as merger with or replacement by another configuration such as in the case of replacing a service flow with a group of supplying service flows loosely linked and using a new distributed management scheme); this is a quite complex issue for which description may be regarded as outside the scope of the project. It concerns the "reverse" engineering of a service into a set of constituent services that should be chosen for support of an, for example, localization exercise (a global service gets localized

Table 1. Shows the forseen added values to the users

		Foreseen Added Value to the Users		
User category	**Stage**	**Problem or need**	**Tools and repositories**	**How the system promotes better service utilization**
Platform and Service vendors	Build	Must subscribe to standards for intervendor interconnect	– Web service infrastructure – Common Repository Facility – Tools for modeling, development, deployment and service management	– System provides a common "backplane" for pluggable subsystems. – It may be exploited as a globally usable notation for metaservice exchange protocols which enables flexible distribution of distributed services over a heterogeneous collection of information systems.
Professional Service Providers	Build	Must accumulate and reuse elements from service engagement	Third party and in-house tools that apply metaservices to concrete service-base catalogs and vice versa	Reusable, editable, and extensible metaservice should provide a first-level "asset base" that builds (new) value. This base of reusable elements starts a self-reinforcing feedback loop with continually increasing returns improved by engagement productivity for the users.
Professional Service Providers	Maintenance	Must modify Service process configuration: knowing what and where to modify; knowing dependency closure	Third party or in-house tools to manage reconfiguration editing of a service flow	System exposes the information required to modify a service flow model. Service context definition and self-describing features for the service flows are used to isolate dependency relationships.
Professional Service Providers, Dielemma Service Administrators	Maintenance	Must integrate existing tools and data which adhere to standards other than service flow model into a distributed service configuration environment.	Tools based on ability to incorporate metamodels of services and alternate service definition practices and standards.	System does or can subsume non-service representations. For example, may be elaborated in the future to contain any XML-based service model with a focus to domain-specific characteristics.
Service Administrators	Build	Must establish and manage expressions, relationships, and lineage over multiple service-based schemata.	Tools that use built-in facilities to define schema content, relationships, and lineage.	System design is based on need to manage such information at multiple levels. The basic Web services will have to be designed to allow navigation of metaservices correlated to schemata.
Service Administrators	Maintenance	Must add, subtract, re-partition, reallocate, or merge service resources in deployment configuration.	Service management tools.	System consists of models of metaservices that assist in making such changes and allow impact of these changes to be assessed.

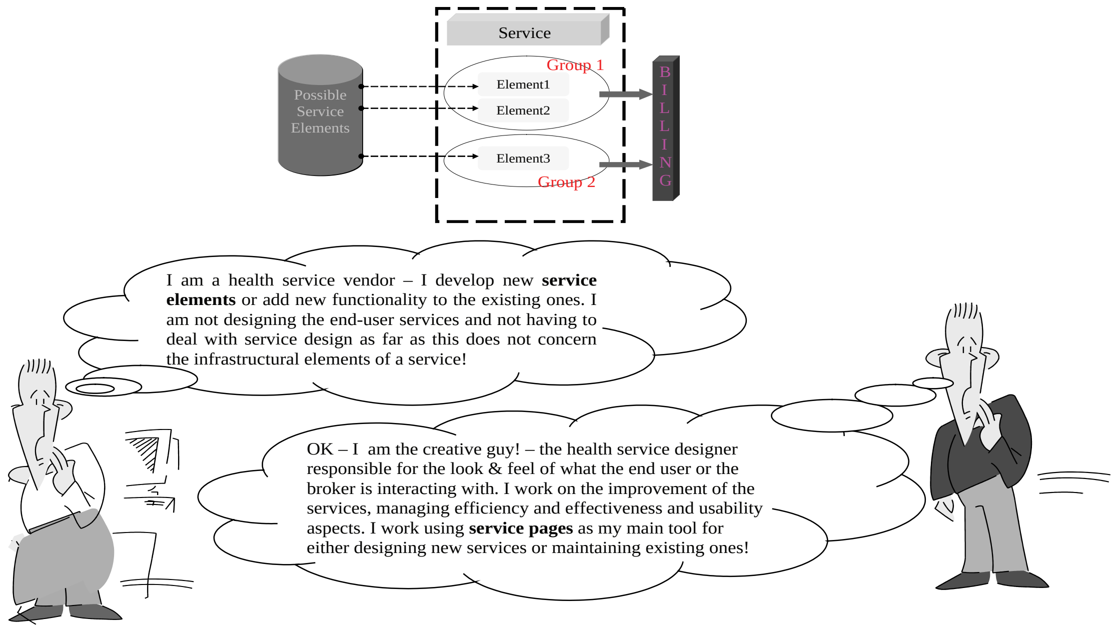
and a set of local service points are now assigned the responsibility for running the service). In the following we present some usage scenarios that illustrate activities in the *build* and *maintenance* steps that clearly demonstrate the value addedness of the approach.

In regard to positioning the added value of the project in terms of linkage with the business opportunity for the project and its real applicability and potential for adoption in the health sector within a supportive uptake environment that would favorably sustain business development in that specific area, we note that there is certain potential in coupling the project work with developments in the application service provider (ASP) market segment. In our context we adopt the usual definition for an application service provider as a 3rd-party service firm which deploys, manages, and remotely hosts a both the various application and service portfolios through centrally-located servers in a "rental" or lease agreement as well as the related business model for operating them. Our work in the project helps a revisit to the topic of ASPs for two main reasons:

- We now see that there is a strong future for ASP related businesses.
- A great deal has changed on the ASP competitive landscape.

Over the past months multiple variations on the basic ASP model have emerged which warrant review and analysis. In addition, the ASP business model is beginning to face serious challenges regarding its viability and broader market acceptance, linking those models to the potential of providing through ASPs the means for operating into a networked enterprise environment.

Figure 3. Distinction of roles in the operation of the system



In its "purest" sense, the ASP model invokes the delivery of software as a service. In exchange for accessing the application, the client renders rental-like payments; in this respect, an ASP facilitates a remote, centrally-managed "rent-an-application" service for the client. The emphasis is placed on the *use and not on the ownership* of the application. The client no longer owns the application or the responsibilities associated with initial and ongoing maintenance. The client, through an Internet browser, accesses remote, centralized computer servers hosting the application. Only the results from the application are managed locally by the client.

Currently the ability of an ASP to sell "mission-critical" solutions to early ASP adopters hinges to a large degree on whether the application being hosted was designed specifically for delivery over the Internet. In point of fact, many of the "mission-critical" packages sold by highly respected vendors were *not* developed for a hosted / services delivery methodology.

Where the added value of our approach comes to the stage relates to the fact that our approach for design and management of services is implemented in a distributed service infrastructure according to planned (actually: envisaged) usage of a multiple actors scheme. The term distributed service infrastructure is used for description of an environment with the following characteristics:

1. It consists of a number of service flows that are executed using resources of several sites simultaneously.
2. The service flows communicate with each other by exchanging messages over a commonly agreed network of participants (in our case it is the network of the health organizations i.e., hospitals and regional health centers involved).

In this respect our efforts in the project may be viewed from within the perspective of building the service flow execution kernel for mobile agent applications that may regarded as the high-end of the foreseen ASP market in terms of *aggregating* functionality requested by the particular differentiated users of the distributed service environment.

SETTING THE STAGE FOR THE VE BUSINESS DESCRIPTION

According to "The Emerging European Health Telematics Industry" market analysis report (2000), developed by Deloitte (2000) on assignment by the European Commission-Directorate General Information Society, "the healthcare sector represents 6% of the overall current European IT market" and the "consolidation on the supply side" constitutes on the most important "vital conditions" for the market growth.

The ARTEMIS platform can have a significant role in e-health, as it may form the basis for realizing most of the e-services that all health institutions will be providing to their beneficiaries.

The ARTEMIS platform aims at delivering a *semantic Web services based interoperability support* and an associated software engineering methodology specific to the issue of e-health data, systems and service interoperability. The approach of the ARTEMIS project to the addressed problem is holistic. It targets in satisfying the needs of all stakeholders in the provision of such e-services, namely health sector IT staff (administrators), health sector domain experts (medical experts and doctors), managers of health sector authorities (managers) and patients, businesses that do business with health authorities (e.g., in terms of hospital procurements, etc.) or any other health sector employees (end users). The approach of ARTEMIS also covers all steps and processes involved in the e-health services provision, as it will be demonstrated further on in the project, and shall cover other related parties, such as insurance companies.

In this chapter, the opportunities and drivers for the project are analyzed, the ARTEMIS platform is positioned amongst other relative products and technologies, the available services are outlined, and lastly, the Unique Selling Proposition of the ARTEMIS project is presented.

Business Opportunity: Business Drivers

According to the above mentioned survey the drivers for the provision of e-services as those we are developing in ARTEMIS (2004) include:

- As the market is made up of hardware, software and services, the role played by services in 1998 was an estimated 26 % while the projection for 2002 was for this to raise to 37 %, becoming the largest component in terms of revenue ahead of the other two, and with an incremental pattern
- "The main trend which can be observed in European hospitals, which presents a challenge in the coming years, consists of integrating the different areas of the HIS (medical, nursing, technical or administrative) into a common architecture.
- However, when looking more closely at hospital information systems, the picture is more fragmented. The analysis confirmed that currently there is no architecture which can integrate all modules of the HIS, but they are often run alongside each other in the forms of the clinical patient record, the laboratory information system, the patient administration system, etc." (p. 188).
- "Apart from internal integration of HIS, hospitals are also heading towards external integration on a regional, national and even an international level. Here, the emergence of care networks, involving many different healthcare actors, hopes to optimise patient management" (p. 192).

In the light of the above the main opportunity concerns an apparent need for common service platforms. Furthermore, it was identified that the main need that ARTEMIS aims to fulfill is to enable *otherwise disconnected systems* to communicate *over different standards*. This will result in services of one health institution being available to another, which will carry all users of the ARTEMIS platform to become members of the same domain.

Since ARTEMIS works over standards and enables to map and convert them to each other, it lowers the negotiation cost, when one system is integrated to or with another. As a result, some services which may require huge costs in terms of investment to hardware/staff may be presented to other institutions, resulting in much better *price discrimination* for suppliers, and new service opportunities for consumers of such services.

This service-oriented business model enables implementers of products to have a much larger market by selling / renting them as services over the ARTEMIS "network".

The basic business opportunity for the ARTEMIS project lies in that the health sector spends on integration forms—including cost of designing, management and handling—is massive. Bureaucracy is the inevitable consequence of the traditional method of handling the extreme volume of information and knowledge derived from them, while the low quality of service is another collateral outcome of this situation.

ARTEMIS aims at capitalizing on this opportunity by offering the means to the health authorities and institutions to reduce involved costs by the implementation of e-services (note: we refer to e-services for simplicity reasons; the correct terms for the ARTEMIS services is "semantically enriched Web services") and associated service management infrastructures. The appropriate design of e-services, according to ARTEMIS approach, will increase cost-efficiency and effectiveness. Moreover, the interaction between the health sector and businesses will be improved when the ARTEMIS tools are combined with best practices. Additionally, the platform is open to enhancements with facilities such as open source development paradigm and self-regulated communities of practice.

Identification of the ARTEMIS Platform

Taking into consideration the various software solutions available to health authorities, it is evident that the market is quite chaotic in the sense that there are no well-established products on the market for healthcare-specific enterprise application integration (EAI), but the rather inflationary estimates we mention previously (have) attract(ed) many vendors. This means that there are many projects, many announcements, but very few results so far. This is where ARTEMIS comes and fills the gap.

Only for Germany, where one of the partners of the ARTEMIS project came from, are two indicative projects to take into consideration, namely:

- The Bit4Health project, a big national initiative to establish a smartcard based PKI for the healthcare sector which would be used for electronic prescriptions, digital signatures (e.g., patient consent) and, at some point in the future) as an "access key" to a national electronic healthcare record, which is, however, totally unspecified at the moment. (http://www.dimdi.de/de/ehealth/karte/bit4health/index.htm)
- The "doctor 2 doctor" (D2D) and "VCS" communication standards, which aim at integration of private practices. While D2D is promoted by an organization representing medical doctors, VCS is promoted by healthcare IT industry. (http://www.kvno.de/mitglieder/d2d/; http://www.vdap.de/html/vcs/vcs.html)

Both projects have at most a few hundred installations so far, which is a very limited success given there are about 130,000 private practices in Germany.

ARTEMIS as a stand-alone product is characterized as a user-friendly service development tool, which can be complementary to the above software solutions. But more importantly, it can be offered as a solution, and furthermore it features a service platform which interacts with the various legacy systems and assists deployment parties in the generation and manipulation of online (transaction-based) services. Using ARTEMIS as a stand-alone product will simplify the development and maintenance of these e-services. On the other hand, using ARTEMIS with another installed IT system will not create any technical or process problems in the integration stage, due to the platform's open architecture.

The ARTEMIS platform constitutes an environment that enables health sector professionals in different levels (administrators, experts / doctors and managers) to develop and maintain services for both their own institution and for other authorities as end users. In this environment an employee with the necessary skills and domain knowledge will be able to use a predefined form template or create a new service in order to implement a new functionality or to edit an existing service.

The employee will be assisted by the ARTEMIS development environment (i.e., the ARTEMIS platform), which will automate parts of the development process. At the end of the development procedure the employee will be able to activate the service even if the connection to the back-end has not been implemented yet. The platform will retain all collected data and once the IT staff implements the connection to the back-end the data will be processed.

The types of the envisaged users of the system can be listed as follows:

- Users should know the backend legacy system.
- Users should know the input output structures of the applications from which the Web services will be created.

Additionally, we can open ARTEMIS certificate programs such as:

- ARTEMIS healthcare ontology engineer
- ARTEMIS healthcare service engineer
- ARTEMIS P2P engineer

Unique Selling Proposition of the ARTEMIS Services

A holistic approach in the management of services in the health sector reveals the Unique selling proposition of the ARTEMIS system. The system's approach to the introduction of semantically enriched Web services in the health sector very much takes into account, that the addressed area is a process and person related issue. It has to involve individual participants from different organizations and with different backgrounds, cultural elements and adopted practices, where continuous and situated elaboration and maintenance of the required knowledge through the involved parties is necessary (actually: a precondition if not a sine qua non). This means a shift from a technology oriented paradigm to an activity oriented paradigm, where involved human beings, administrative processes and technical resources represent the equally eligible units of analysis and where system design follows the concept of socio-technical systems as holistic and dynamic structures.

The ARTEMIS project suggests that by adopting the above *holistic approach* for the introduction of semantically enriched Web services in the health sector, most of the following problems, that health sector stakeholders face can be reduced or even eliminated:

- Complexity in creating e-services and most importantly difficulty in encapsulating domain expertise in them
- Difficulty in interoperability with existing IT systems within the organization and with external IT systems of other organizations
- Lack of user-friendliness for the end-user in the service creation phase
- Lack of mechanisms to encapsulate the knowledge as a whole also by transforming implicit knowledge into an explicit form. ARTEMIS shall provide tools for creating and mapping ontologies; of course, ARTEMIS aim is not proposing ontologies to the healthcare community, but providing all the necessary technology means so that if ontologies are available, then be also exploited to facilitate semantic interoperability.
- Lack of coherent process models for exploiting the use of "public" e-services within the health sector
- Organizational and cultural barriers, such as health sector employees' fear of new technology and new methods of work.

Target Market: A Dynamic Health Service Market

ARTEMIS supports the concept and the implementation of decentralization in European health care systems thus setting the stage for multiple different types of synergies and ventures to emerge and foster a culture of joining efforts and resources. Though such an exercise may face impediments from the legal environments on the one hand and from the tendency of private organizations to operate on short term profitability plans, it is yet an open challenge for all actors in Europe and internationally.

The concept of decentralization has become a cornerstone of health policymaking in an increasing number of Western European countries. Once confined only to the Nordic region and Switzerland, intergovernmental decentralization has now become a central principle of health policy in Spain and Italy, in a different context in the United Kingdom (to Scotland, Wales and Northern Ireland), and to a lesser degree in France, Portugal and more recently in Greece.

In certain respects, decentralization has become a synonym for a strengthening process of regionalization not just in the health sector, but in broader social as well as political arenas, serving as something of a cultural corrective in a Europe where more and more aspects of national sovereignty are being exercised at the supranational European Union level.

The best-known public administration effort to define decentralization is that of (Rondinelli, 1983), with a four-part, structurally oriented framework of:

- Devolution
- De-concentration
- Delegation
- Privatization

The economic argument in favor of decentralization typically has as its common denominator the belief that decentralization will create competition between different local actors, thus opening the door for local/regional-based small or medium-sized enterprises to innovate and provide cost-efficient services to the health care institutions for both sides (i.e., themselves and the particular health organizations). Not unlike economic assumptions about commodity markets generally, the economic argument here is that decentralization will enable different SMEs to provide different levels of *e*-health-related services, which will generate three economically-"prized" advantages:

- Greater efficiency in the service provision process (same is the case for the service conception, design and delivery processes)
- Greater choice for the health institutions of different alternative services
- Smaller complexity (bureaucracy) reduced times and improved responsiveness in the identification of a need and its fulfillment

Moreover, the complex intergovernmental relations created by the EU single market are seen as an extremely suitable opening to adopt such an economically-driven mechanism.

Of course, the basic and strongest from an economical standpoint argument regarding the disadvantages of decentralization focuses on the inefficiency and duplication of having multiple small service providers.

At this point it is interesting to carry out some type of sensitivity analysis regarding how many customers should an SME afford to have for ARTEMIS customers so that it can operate its business with different levels of profitability and amortization period. (Independently to this, there is also the concern (worry, rather) that such smaller operating units will be managerially weaker than larger ones.)

CONCLUSION

With the approach developed as part of the IST Project ARTEMIS, we provide the healthcare industry with an ideal platform to achieve difficult integration problems while also utilising the VE concept as the underlying basis for all different types of ventures and business partnerships. Our Web service model encapsulates already existing applications and access to documents in a standard way and incorporates service providers, service consumers and service registries.

It should be noted that currently most prominent Web service registries are universal description, discovery, integration (UDDI) and electronic business XML (ebXML). There are also very recent efforts to use peer-to-peer networks based on Web services. However both service registries and P2P architectures available do not provide semantically enriched search capabilities.

Furthermore, in ARTEMIS we provide extensions to these architectures to enable discovery of the Web services based on their semantic descriptions. As mentioned above, medicine is one of the few domains to have some domain knowledge in a computable form, which we exploit in defining the semantics of medical Web services.

The nature of business model research is extremely demanding as an exercise (Afuah, 2003; Alt & Zimmermann, 2001) and in many scientific research projects is not given adequate importance – however the reasoning behind a business model is not the understanding of a phenomenon, rather it is a problem-solution finding approach. In this respect, a particular technology may or may not facilitate the success of a business model; and similar to this, a particular market may or may not support the uptake of a particular solution as result of a more or less appropriate business model.

As a result of the approach taken, virtual enterprises (VEs) may emerge taking the form of joint ventures which will aim to provide operative and highly specialized value added services in all necessary e-health application fronts related to individuals, private companies and public health organizations, such as in the following application fields:

- Single point access to health services using technologies and methodologies developed within the project and which base on the ARTEMIS conceptual architecture and service modeling approach
- Heterogeneous hospital platform integration for support of online one-stop-shop services in various situations
- Design and lifecycle management of integrated hospital or other health care organization services from different back-offices, based on advanced interoperability frameworks and standards for the health sector

ACKNOWLEDGMENT

Work reported was partially funded by the European Commission under the contract IST-1-002103-STP, and under the e-Health priority. The authors would like to thank the European Commission for the generous support provided. Chapter 2.3
The PsyGrid Experience:
Using Web Services in the Study of Schizophrenia

John Ainsworth
The University of Manchester, UK

Robert Harper
The University of Manchester, UK

ABSTRACT

The key aim of the PsyGrid project was the creation of an information system to ascertain and characterise a large, representative cohort of schizophrenics, beginning from their first episode of psychosis. The cohort was to be drawn from eight geographically dispersed regions of England, covering in total one-sixth of the entire population. In order to meet the current and future requirements we needed to build a secure distributed system, which not only could support remote data collection, but could also be integrated with other data sets, applications, and workflows for statistical analysis. We concluded that a service-oriented architecture was required and that the implementation technology should be Web services. In this article we present the design, deployment and operation of the PsyGrid data collection system as a case study in applying Web services to health informatics. The major problems we faced were related to the deployment of Web services into an existing network infrastructure, but overall found Web services to be the most suitable middleware technology.

INTRODUCTION

In the 1970's Archie Cochrane (Cochrane, 1972) and colleagues alerted the medical profession to the need to weed out subjectivity and anecdote from clinical practice. At the same time there was a move to improve the safety of medicines. Since then the evidence-based care movement has grown and is now accepted by most healthcare professionals to be best practice. However, there are serious problems with the evidence on which we base healthcare: it is expensive to produce; it takes a long time to produce; it takes a long time to influence clinical practice; it is based on clinicians' more often than patients' perceptions of important outcomes, which might not match; and it is crude—relating to the average participant and simple treatment definitions under ideal/trial conditions, often long ago—in other words, it gives a low-resolution picture of how your patient might respond to treatment. Most of the health informatics literature on electronic health records and "evidence into practice" is about weaving the existing evidence-base into healthcare decision-making. The role of clinical information systems in improving the evidence-base, however, has been neglected. This situation is changing: PsyGrid, which is funded under the UK Medical Research Council's E-Science programme, is focused on providing informatics employing e-Science principles for improving clinical trials and longitudinal studies in mental health research (Ainsworth et al., 2006).

PsyGrid employs service-oriented architecture computing techniques and technologies in the implementation of a system that will remove the barriers to epidemiological research. The process of epidemiological research has three phases—the establishment and characterisation of a large, representative cohort from a geographically distributed population; the integration of the cohort data with other data sources to provide additional characterisation; and the formulation of a hypothesis and generation of the corresponding predictions. For the establishment and characterisation of a cohort, many epidemiological studies use paper based data collection systems. A computer-based data collection system which enables geographically distributed data collection would alleviate much of the labour, tedium, and error that are inherent in paper-based data collection. Such a system is required to store personal, confidential medical data, and this data must be sent across a network from remote data entry clients to a data repository server. The immediate goals in developing the system were to ensure high quality data; ensure privacy and confidentiality of sensitive patient data; enable data collection to be performed at any location; ensure that the system was scaleable to cover larger populations and that it was highly available. In the long term the system needs to be enhanced and extended to provide a platform for the epidemiological study of schizophrenia and intervention research for predicting and preventing adverse outcomes.

We selected Web services as the underlying middleware because they offer firewall traversal, interoperability, modularity, and loose coupling which provides the ability to incrementally extend the capabilities of the system as it grows.

The health informatics findings from PsyGrid will be generalisable well beyond its disease focus. By treating every new patient as a participant in a longitudinal study, it will start to test a new model of care and research combined. We believe that this combination is essential to providing a timely and more flexible evidence base for future healthcare. This future could be called "high resolution healthcare"; it would encompass "personalised medicine", self-care decision-support, efficient and opportunistic clinical trials, complex (including genomic) epidemiology, and tactical development of local services based on local environmental factors and outcomes at the population level. High-resolution care and research requires information systems to link relevant data, methods and people in a clear and timely fashion.

In the following section we examine the clinical need for PsyGrid, and in then we analyse the requirements that flow from this. Afterwards, we provide a description of the NHS Information Technology infrastructure into which PsyGrid will be deployed. The rationale for using Web services is then presented, followed by an overview of the PsyGrid system architecture and the interactions between the Web services. We report our experience of implementing Web services, and provide a detailed description of the systems functionality and implementation. Thereafter, we capture our experiences of deploying and operating the system, and finally, we cover related work, future work, and a discussion of our findings.

CLINICAL OVERVIEW OF PSYGRID

Mental disorders are a large public health burden, whose treatment accounts for about 22% of the UK National Health Service (NHS) budget (Davies & Drummond, 1994). The major disorders are schizophrenia and bipolar disorder, each with a lifetime prevalence of about 0.5%. Both are major public health challenges, with costs of health and social care in the UK of over £2 billion annually, a similar order of magnitude to cancer or ischaemic heart disease. Schizophrenia usually starts in early adult life and leads to persistent disability in most cases. It arises out of a complex interaction of genetic and environmental risk factors.

The evidence base for the treatment of psychotic disorders is underdeveloped (NICE, 2003). Interventions can be divided into drug treatments, psychological treatments, and service-level interventions. Historically, randomised, controlled trials have been few in number and uneven in quality (Thornley & Adams, 1998). Rational service planning is constrained by the lack of knowledge currently about the comparative incidence rates and course of psychotic disorders in different regions of the UK. Models purporting to predict local service usage on the basis of demographic indicators are not well developed (Glover et al., 1998). For example, the extent to which an urban environment contributes to the risk of psychosis has only recently been understood and quantified (Pederson & Mortensen, 2001).

The focus of first episode psychosis (FEP) in PsyGrid arises out of a convergence of key questions in clinical science that require large, well characterised, representative cohorts to address them, along with recent developments in the NHS and NHS R&D to facilitate such research. Delayed detection and treatment is a widespread problem and predicts poor clinical outcome (Marshall et al.,2005).

Schizophrenia typically first occurs in one to two people in every 10,000 of a population each year. However, about two-thirds of episodes of schizophrenia start before 35; this proportion is higher in men, who more commonly suffer from the disorder anyway. PsyGrid subjects are drawn from eight different geographic regions of England that together cover one-sixth of the population. This coverage could be expected to yield up to 1,000 patients per year who would meet the eligibility criteria for the project.

REQUIREMENTS

In this section we discuss the key requirements of the system that shaped the system architecture.

- **Privacy and Confidentiality:** The PsyGrid data repository stores sensitive clinical data describing a patient's mental illness. Ensuring a patient's privacy and the confidentiality of their data was of prime importance. A fine-grained access control system was required which would only permit users with the necessary privileges to access and operate on the data in the repository. The ethical approval granted to PsyGrid further restricted the data we could store, mandating that the data stored be anonymous. However, removing certain identifying data items completely, such as post code and date of birth, restricts the hypotheses that can be tested and so these data items needed to be transformed such that they are still useful, but are not identifying.
- **Remote Data Entry:** The goal of the project is to study the occurrence and outcome of schizophrenia, beginning from a patient's first episode, over the course of the next 12 months. Subjects were to be drawn initially from eight geographically dispersed locales

covering in total one-sixth of the population of England, thus providing a highly representative sample. Consequently, a client-server architecture was required, where data collection clients provide the user interface for data entry, and the server hosts a centralised data repository, which persists the assessment data. In line with the privacy and confidentiality requirements, all communications between client and server had to be secure against interception attacks.

- **Paperless Data Collection:** PsyGrid was required to be a paperless data collection system, where the data is entered directly into the system at the time of collection. The implication of this requirement was that the system must be as natural and easy to use during a client interview as a pen and paper form. Since data capture is happening in real time it also implies that the system is *always* available for data entry. Due to the nature of the illness, if a schizophrenic is willing and able to be interviewed, then the opportunity should not be lost. The absence of a paper record from which the data could be recovered if necessary necessitates a back up system that can recover data up to the last committed transaction.
- **Off-line Data Entry:** The clinical researchers needed the capability to interview clients in any location, such as the hospital for the initial assessment or the client's home for any of the follow-up assessments. Consequently, a connection to the network cannot be guaranteed to be present and so the data entry system must be capable of working off-line on a portable computer. When a connection to the network becomes available, then the data entered whilst off-line will be uploaded. This requirement places a lot of complexity into the data entry client, and so a rich client application was preferable to Web-browser based solution.
- **High availability:** This requirement was implied by paperless data collection. The central data repository must be hosted on a high availability hardware platform, with data storage redundancy, to ensure continuous operation. The high availability architecture also must have the capability of performing a live upgrade to the system software and to modify a data set definition.
- **Scaleable:** The initial sizing of the system was for eight remote locations with 25 users using a single data set, which it was anticipated would contain approximately 1,500 subjects. However, we worked on the assumption that the initial deployed system would be require to support 32 remote locations with 100 users and four different data sets.
- **Data Quality:** Data quality (or the lack of it) is a major problem for all evidence based medical research. Electronic data entry systems can restrict the range of valid values and enforce them in a way that is not possible with pen and paper. Wherever possible we needed to restrict the ranges of data elements and provide an intuitive user interface for our end users.
- **Extension:** The data collection system is the first phase of the PsyGrid system. One vision for PsyGrid is to provide an epidemiology work-bench which will provide the capability to integrate the PsyGrid data set with other data sets, such as socio-economic data, which will enable the aetiology of schizophrenia to be studied in the population at large, which can be directly used in service planning for the treatment of the disease. The myGrid (Goble et al., 2003) toolkit provides this capability for the bioinformatics domain and could easily be adapted to epidemiology. This improved understanding of the lifestyle and environmental causes of schizophrenia, when combined with genetic information,

could be used to predict an individual's risk of developing schizophrenia, and so early intervention treatment could be effectively targeted.

- **Remote Management:** The PsyGrid system was required to support a geographically dispersed user base, with minimal technical support available on site. Therefore the goal was to build a system that could be managed remotely with no ongoing on site support required. All software upgrades needed to be performed remotely and ideally automatically. This requirement suggested to us that a browser-based Web application, which could be managed centrally, would be the easiest solution, but this solution would not support off-line data collection.
- **User Defined and User Managed:** PsyGrid was required to be simple to use and simple to extend. PsyGrid needed to support multiple independent data collection projects that could be designed and managed by their users. To simplify the creation of a new data set, the user interface for entering data should not need to be defined as well, as the data collection client application must be able to render this solely from the data set definition. The user interfaces for the management tools needed to be intuitive and easy to use.
- **Security Credential Management:** Based on our end user community we ruled out the possibility of using file system based Public Key Infrastructure (PKI). It is unrealistic to expect clinical users to deal with the complexity of managing certificates and keys themselves, and it would be a deterrent to the use of the system, which was not our aim. However, we did not want to preclude the use of a hardware token-based PKI approach in the future, and so the system needed to be designed with a PKI security infrastructure that would enable this to happen in the future. Consequently, the system needed to provide the ability to translate a user name and password credential into a PKI credential.
- **Federation of Systems:** Over time we envisage that multiple PsyGrid data repositories could be deployed. By supporting federation of these systems, much larger data sets could be used in analysis. In this federated scenario, there would be multiple instances of PsyGrid, where each one is operated by a different autonomous organisation and has its own user directory and security policy, which can be used collaboratively, such that a user from one PsyGrid in the federation can access another system without repeated authentication.

THE OPERATING ENVIRONMENT

The National Health Service (NHS) in England and Wales provides publicly available healthcare for the whole population. The NHS comprises of largely autonomous Trusts, which are responsible for procuring, deploying and operating their own IT infrastructure and applications. Consequently, no two Trusts are the same, and a large variety of infrastructure exists. To address the problems inherent in the NHS IT infrastructure, and to enable the deployment of NHS wide applications, such as the Electronic Care Record, the UK government embarked on the £6 billion "Connecting for Health" IT infrastructure project (formally the National Programme for IT). The aim of Connecting for Health is to modernise the NHS IT infrastructure and provide a set of global applications that will enable mobility of patients and their clinical data between Trusts. The first phase of the project was to deploy a new NHS-wide network infrastructure, which would provide high-speed links (>100Mb/s) between all Trusts via the backbone network. This infrastructure is commonly known as N3. The backbone would then be able to host applications global to the

NHS, which are known as spine services. These services include the National Care Record, the Secondary Usage Service and Picture Archiving and Communication Services, and will be rolled out in subsequent phases. The current state of the NHS IT infrastructure can best be described as transitional.

During the design of the PsyGrid data collection system we made the following assumptions about the NHS network infrastructure. Firstly, we assumed that the N3 high bandwidth infrastructure would be ubiquitous; secondly that each Trust would allow direct HTTP/HTTPS outbound connections to be made to any public NHS server in any trust on any port; and thirdly that inbound HTTP and HTTPS connections would be possible on ports 80, 443, and 8443 from any source address on the NHS network.

Motivation for Using Web Services

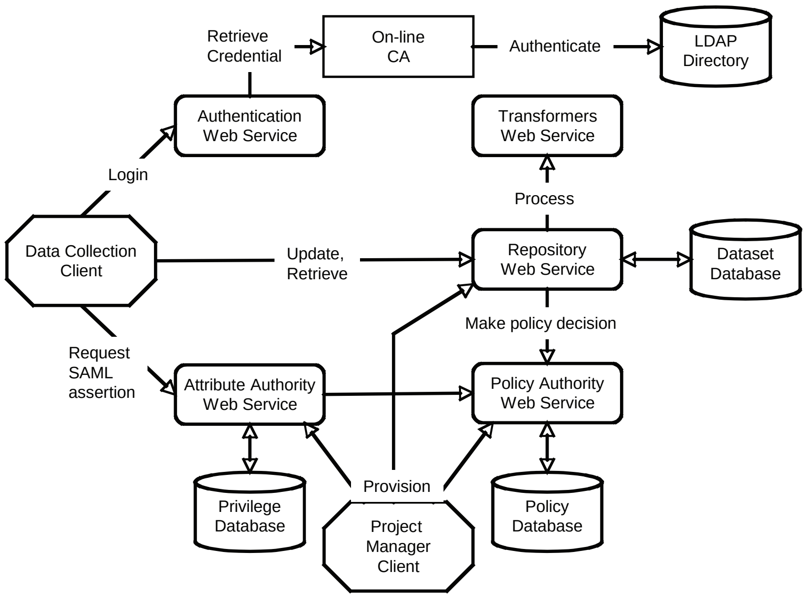
Service-oriented architectures have been successfully applied in the bioinformatics domain as typified by the myGrid (Goble et al., 2003) project. One of the motivations for the PsyGrid project was to provide the same ability to integrate and analyse multiple data sources using the same workflow approach based on Web services (Oinn et al., 2004). This was the primary factor in our decision to pursue a service-oriented architecture. By exposing our data repository this way, it enables the data to be analysed as part of a workflow that tests an epidemiological hypothesis. The need for a service-oriented architecture leads directly to Web services as the implementation technology. Perhaps the most compelling advantage Web services have over other technologies is the ability to pass through firewalls, which the analysis of the operating environment (presented previously) identified as particularly important. The availability of open-source implementations of Web service containers and protocol stacks also played a role, as PsyGrid was to be made freely available to the community, and it should be possible for other groups to deploy a PsyGrid system without purchasing any software. The existence of open Web service standards was also a factor in the decision, which would enable the PsyGrid system to be used from disparate implementations and operating systems, removing some of the barriers that are commonly found in heterogeneous environments such as the NHS. This is critical to fostering adoption of PsyGrid, as we do not have to mandate one particular platform or implementation. Finally, Web services bring with them the benefits of loose coupling. The system would be deployed and operational for data collection early in the project, long before much of the functionality for data integration and workflow-based statistical analysis could be completed. As additional functionality became available we needed the capability to add this into the operating system incrementally with no disruption to the deployed system.

However, we did have concerns about using Web services in the PsyGrid project. We were not aware of the use of Web services in the NHS and so we would not be able to benefit from the experience of others. Also, many of the Web services standards are new and potentially immature. This would be true of the open source implementation of these standards. Finally Web services have a reputation for being very slow in comparison to other technologies offering similar functionality. There was concern that a system based on Web services would not scale.

SYSTEM ARCHITECTURE

The data collection system has four main architectural components. The data repository stores the datasets, the data collection client provides the user interface for data entry, the security system provides authentication and authorization capability, and the project manager client provides the tools to setup and manage data collection projects. The data repository has been implemented as two

Figure 1. PsyGrid system architecture showing principal interactions between clients, Web services and databases.



Web services, and the security system is composed of three Web services. The data collection client and the project manager are clients of the Web services. The project manager client application is still under development and we do not describe it further. Figure 1 shows the architecture of the system and the principal interactions between the components.

Data Repository

The two Web services, which together form the data repository, are the Repository service and the Transformers service. The Repository service provides a Web service interface to the backend database, which stores the data set definitions and the collected patient data. The operations on the Web service can be grouped into two. The first set of operations enables the remote management of data set definitions such that they can be installed and updated. These operations are used by the Project Manager client application. The other set are used by the Data Collection client application and allow patient data to be added, updated, and retrieved. The implementations of these operations allow for client applications that must operate off-line. For instance, a client is not required to download an existing record when new documents are to be completed; the repository manages appending the new document instances to the existing record during the save process. The Repository service enforces access control on its exposed operations to ensure data privacy and confidentiality. The Transformers service provides a set of operations that enable data to be anonymised. For example, a SHA-1 operation is provided to return the hash value of the input. For any data value contained within a data set, a transformer can be specified. The input data type and the output data type are specified along with the URL of the Transformer Web service and the operation to be invoked. The Transformers Web service effectively provides a configurable data pre-processor, which is primarily used for de-identification of identifiable data between it being entered by a user and stored in the database.

Security System

The three services implemented for the security system are the Authentication service, the Attribute Authority and the Policy Authority. Together they provide a Role Based Access Control (RBAC) (Sandhu et al., 1996) system for PsyGrid. In RBAC, users are assigned privileges, and authorisation decisions are based upon the possession of the required privilege. There are three components in RBAC. The first is a privilege manager, which maps a user to their privileges. The second is a policy decision point (PDP) that is used to control access to a resource. The third component is a Policy Decision Function (PDF), which is used to make a decision on whether a user has sufficient privileges to access a resource.

The Authentication service provides a port type for the user to login to the system. It is essentially a Web service wrapper around an on-line certificate authority, which itself authenticates users against an LDAP directory. If authentication is successful, then the on-line certificate authority will issue an X.509 PKI credential, bound to the user's identity. This credential is then used to authenticate with the other Web services in the system which require mutual authentication over SSL.

In PsyGrid, the Attribute Authority (AA) provides the privilege management function. It stores the list of projects that are active on the system. For each project it records its name, a unique identifier, a list of the sub-groups of the project, and the roles that users can take on in this project. It also maintains a registry of users and their privileges. The user's privileges are maintained on a per project basis. For each project the user is a member of, the privileges granted to the user (role or group membership) are listed. The AA issues Security Assertion Mark-up Language (SAML) tokens that bind a user's identity to their privileges in a project. The AA digitally signs these statements, which guarantees their authenticity. Any entity that trusts the AA can accept its assertion about a user's privileges.

The Policy Authority (PA) maintains the security policy. It stores multiple policies, such that each data collection project can have a unique policy. A policy consists of statements, and each statement has an *action*, *target*, and a *rule*. The rule is a Boolean logic expression composed of operators (AND, OR, NOT) and privileges. A rule may be composed of many sub-expressions. The *action* is the operation the user wishes to perform, and the *target* is the resource on which they want to perform it. In the following example, in order to invoke the "getRecordSummary" method (the "action") on the data repository to retrieve the records owned by the North West hub (the "target"), then you must either be a Clinical Researcher belonging to the North West hub or be the Clinical Project Manager (the "rule"):

```
ACTION="ACTION_DR_GET_RECORD_SUMMARY", TARGET="NORTH_WEST_HUB",
RULE={{ROLE=CLINICAL_RESEARCHER AND GROUP=NORTH_WEST_HUB} OR
{ROLE=CLINICAL_PROJECT_MANAGER}}
```

The current policy for the First Episode Psychosis study has approximately 600 statements, covering some 30 actions and 10 targets.

The access enforcement function (AEF) provides the policy decision function. It is a client side API for the PA, which can be invoked from any Web service that protects a resource. The AEF requires the caller to supply the target and action, and either the users identity, or a signed SAML assertion that can be verified. The PA, AA and Repository all use the AEF to protect the operations that are exposed as Web services.

The on-line certificate authority is used to issue short-lived user credentials. However, an alternative source of authority, the off-line PsyGrid Infrastructure Certificate Authority (CA), is used to issue long-lived credentials. This gives us two levels of trust, determined by the certificate authority that issued the end entity's credentials. Those in possession of a credential from the PsyGrid Infrastructure CA, typically servers, are able to invoke services on behalf of other users. In this case, the identity presented during authentication and the identity of the subject in the SAML assertion need not be the same. This is known as delegation.

By using signed SAML assertions to identify a user's roles, and using a role-based access control system, then to federate multiple data collection systems only requires the policy decision function to accept SAML assertions signed by the other attribute authorities participating in the federation. In the current implementation, the PA is configured with a list of AA's that it trusts. This federated model is similar in design to the Shibboleth (Shibboleth, 2006) system but has been implemented for Web services, where as Shibboleth is used to protect Web pages.

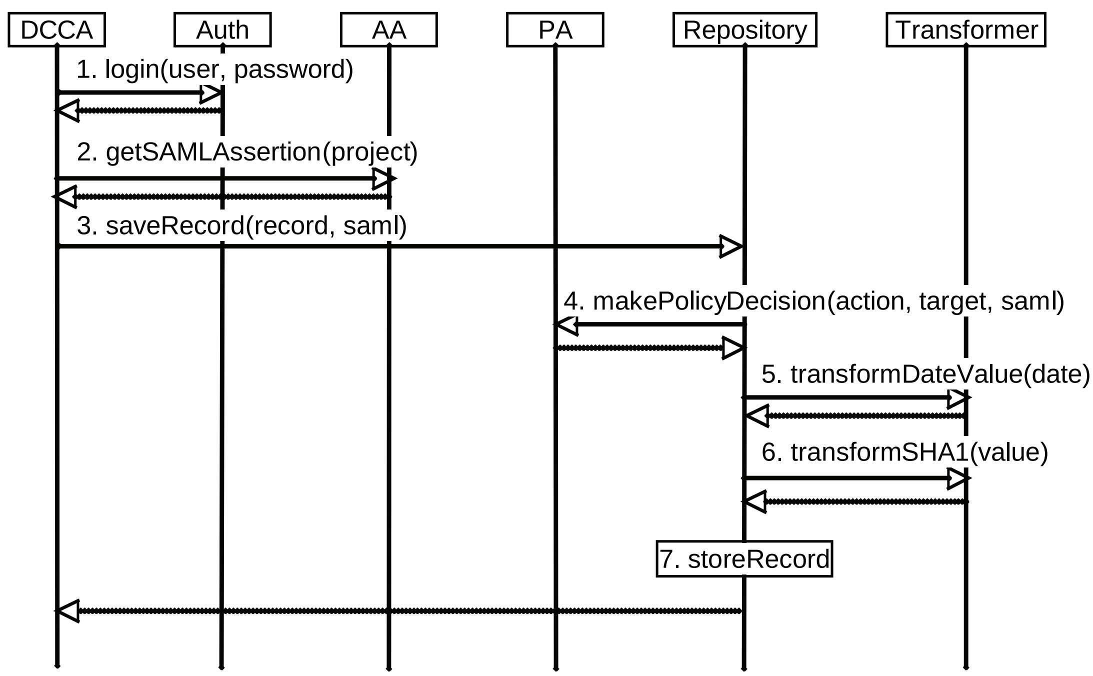
Data Collection Client Application (DCCA)

The PsyGrid data collection client application provides the functionality required for the entry, secure storage and secure transmission of data collected from longitudinal studies. To achieve this, it interacts with the data repository and the security subsystem. A Web-services interface is used by the data client to communicate with the other systems, including the data repository, attribute authority, policy authority, and certificate authority. All communication is encrypted through the use of SSL.

Inter Service Communication

To ensure confidentiality and privacy, all components in the PsyGrid system communicate over secure, encrypted communications links.

Figure 2. Interaction between services when the user logs in and saves a document



We selected transport layer security (TLS) in conjunction with HTTP as the transport for our SOAP-based Web services. We use TLS in mutual authentication mode to ensure both server and client can be sure of the identity of the other party. TLS was chosen over message level security (MLS), as specified in WS-Security, because it is widely available and implementations are mature.

The basic interaction between the client, the data repository and the security system can be illustrated by the example of a user logging into the system and saving a document, as shown in the interaction sequence in Figure 2. Prior to this the user has been working off-line and completed a patient assessment form, which they now wish to save.

1. The user launches the data collection client application and logs in with their user name and password. The DCCA passes the login information to the Authentication service, which attempts to authenticate with the credential repository. The credential repository in turn attempts to authenticate the user with the directory; if successful, it uses its on-line certificate authority to generate a temporary PKI credential for the user, which contains the user's Distinguished Name as the principal.
2. The DCCA next contacts the attribute authority, which issues a signed SAML assertion for the user, based on the Distinguished Name in the credential supplied during mutual authentication between DCCA and the AA, containing their privileges for the requested data collection project.
3. The DCCA then invokes the `saveRecord()`operation on the repository passing the Record which contains the document(s) to be saved and the signed SAML assertion.
4. The Web service uses the AEF to invoke the Policy Authority's `makePolicyDecision()` operation, including the *action* (saveRecord), *target* (determined from the owning group of the record) and SAML assertion. Based on the users privileges listed in the SAML assertion and the stored policy, the Policy Authority will either grant or deny access.
5. The document to be saved has a date entry marked as requiring date transformation. The date is to be converted from day-month-year to a month-year, and the appropriate transformer is invoked.
6. The document has another entry that is marked as requiring encryption. The SHA-1 encryption transformer is invoked.
7. The document is store in the Repository's database, and the unique identifier of the persisted object is returned as an indication of success.

Once the user has logged into the system then temporary credentials can be used until they expire. The DCCA will automatically refresh the end user's temporary credential before it becomes invalid by accessing the `login()` operation of the authentication service, using user name and password which were cached by the client when the user logged in. This is done without further interaction from the user. Thus the infrastructure is secured by PKI, and yet there is no burden on the user of managing any more than a user name and password. It would not require any changes to the backend system to integrate a hardware token approach; only the DCCA would be affected.

Interface Description

Each of the Web service exposes a number of operations, and the parameters required range in complexity from simple integers or strings, to complex documents that describe an entire data set. For the Repository, Authentication and Transformer Web services, the interface description in WSDL is generated from the Java implementation of the interface. For the PA and

Table 1. Examples of operations exposed by the PsyGrid Web services

Web Service	Operation	Input Parameters	Output	Description
Transformer	encrypt	Value:string	String	Returns a SHA-1 hash of the input string
Authentication	login	userId:String password:char[]	String	Authenticates the user and returns a PKI credential store in a Java KeyStore that is base-64 encoded and returned as a string.
Repository	getRecordsByGroups	project:String groups:String[] saml:String	Record[]	Returns an array of Java Record objects (as defined by the Repository data model), which exists in the specified project and groups within the project.
Policy Authority	makePolicyDecision	project:ProjectType action:ActionType target:TargetType saml:String	boolean	Determines whether the user's privileges are sufficient to perform the requested action on the specified target. The input is an XML document containing the project, action, target and SAML assertion.

AA services, the Java stubs are generated from the WSDL definition, and the messages are documents defined by an XML schema. The number and range of operations is too great to describe each one in detail, but selected examples are presented in Table 1.

WEB SERVICE IMPLEMENTATION EXPERIENCES

In this section we discuss three detailed aspects of implementing our Web services together with the lessons learned.

Using WS-Security

Our original intention was to use the WSS4J implementation of the WS-Security standard for retrieving, transporting and verifying the signed SAML assertions used in the access control system. Whilst the transport and verification functionality met our needs, retrieval from the Attribute Authority required that the data collection project identifier be included in the request. There was no easy way to communicate this from the client application through the Axis Web service stack to the WSS4J handler that implemented the SAML retrieval function. The only way we found to do this was to set the information on the Axis `Call` object, but this required that the Web service client API stubs were extended to pass this information through to Axis, which in turn meant that they could not be generated automatically from the WSDL definition of the service. Consequently, we moved the SAML functionality into the application layer and added the SAML assertion as a parameter to each operation of the repository Web service that required access control.

Document vs. RPC Encoding

Within PsyGrid we have used both styles of encoding for our services. The Authentication and the Repository services use RPC encoding, and are generated using Java2WSDL, directly from the Java class definitions. Conversely the Policy Authority and the Attribute Authority use document-literal encoding. An XML schema defines the content of the documents, which is used in the WSDL definitions of the services. WSDL2Java was then used to generate the Java classes for the implementation. The Repository object model was implemented making full use of Java's complex types for managing collections. Java2WSDL was unable to map these complex types into the corresponding XML representation and so a Data Transfer Object layer was implemented which mapped the complex collections types into simple arrays. We then used the DTO classes to generate the WSDL for the Repository. In a similar way we also implemented a DTO layer for the Policy Authority and Attribute Authority. The WSDL2Java implementation was unable to handle abstract types in the XSD definition, however they were required for the natural implementation of the object models of these two services. Consequently the XSD was restructured to eliminate the use of abstract types and the DTO layer was implemented to restore this in the Policy Authority and Attribute Authority services.

SSL Implementation

By default Axis provides a default SSL socket factory for the management of SSL connections, but allows a custom socket factory to be configured. The default factory was unsuitable for our needs as the DCCA had to refresh the PKI credential each time it expires and so we implemented a PsyGrid specific socket factory. The PsyGridClientSocketFactory Java class provides a specialised key manager and a certificate manager that is capable of updating the Java SSL subsystem with the new PKI credentials.

Logging

All Web services implement logging of each attempt to access the operations they provide. This provides a full audit trail of the usage of the system. Each log entry records the entity invoking the operation (from the X.509 certificate), the user requesting access (from the SAML assertion), the source IP address from which the request originated, a time stamp, and the name of the operation being invoked. If a request to access a Web service is denied, this is also logged. A common logging API was implemented for use by all Web services, which uses the Apache Log4J framework.

IMPLEMENTATION DETAILS

We describe the implementation of three of the four core components of the data collection system architecture. The project manager client application has not been implemented at the time of writing.

Data Repository

The PsyGrid data repository has two principal objectives; to store the definition and structure of the data to be stored in the repository, and to store the data itself. It also performs a number of ancillary functions, which will be described below.

To define the definition of the data to be collected a three-level hierarchy has been created. At the top-level of the hierarchy a single data repository may define a number of datasets, each dataset being equivalent to a single data collection project. At the next level of the hierarchy, within each dataset may be defined a number of documents, each document being equivalent to a single paper-based assessment form. The repository also caters for documents that are to be completed multiple times within a single study (for instance for longitudinal studies), and allows documents to be grouped into those that are intended to be completed together.

The final level of the hierarchy allows each document to contain a number of entries, with each entry being equivalent to a single item of data to be collected. Provision has been made for collecting a variety of different types of data, including, but not restricted to, numeric data, textual data, and selection from a list of options. The entries in a document may be logically grouped into sections, and it is possible to define sections that are to be completed multiple times, but with a different context each time. This simplifies the definition of documents with repetitive entries.

More advanced behaviour for entries is also supported. Each entry may have one or more validation rules defined for it to prevent illegal data from being entered. Also, an entry type is provided for which data is not entered directly, but the value is calculated by performing a calculation involving the values entered for other entries in the document; this can be used to calculate the overall value of an assessment scale involving multiple questions for example. Finally, for entries where the value is selected from a list of options it is possible to define the users flow through a document in response to the option they select, by enabling or disabling subsequent entries in the document.

For storing the data collected a similar three-level hierarchy is used, to match the hierarchy of the data definition. At the top level of the hierarchy a record represents a single instance of a dataset. At the bottom level of the hierarchy is a response to a single entry; each response maintains a collection of values which represent an add-only store of all entered data for the response, with accompanying provenance metadata.

The PsyGrid data repository is implemented as a set of persistable Java classes, mapped to a relational database using the open-source Hibernate object-relational mapping package. As well as reducing development time by eliminating the need to hand-craft SQL this approach also allows the PsyGrid data repository to be deployed using any of the back-end databases supported by Hibernate, which includes MySQL (used during development), IBM DB2 (used for the production deployment) and the majority of other RDBMS providers. The data repository also provides scheduling functionality whereby for a dataset representing a longitudinal study it can be configured to send e-mail reminders to the responsible persons when the next set of documents are ready to be completed for each record.

Data Collection Client

The PsyGrid data client is a rich-client application that automatically generates a visual representation of a data set from a definition provided by the data repository. It represents the data set by using a combination of simple user interface elements such as radio buttons, combo boxes and text fields, as well as more complex ones such as tables. The data client also has a specialised date widget that allows the user to select a date from a calendar-like interface. Finally, support for grouping is available in the form of sections.

The application presents a clean and simple interface using a wizard-like approach providing the user with a unique path to follow in order to complete an assessment. This approach was taken considering that users of the system are unlikely to have a technical background. In addition, context-sensitive help is available throughout the application. The data set definition is the source of the information used by the context-sensitive help, providing maximum flexibility. In keeping with making the usage of the application as intuitive as possible, the application is able to fully restore its state after being terminated. So, if for some reason an assessment had to be interrupted, the user could simply close the application without having to worry about losing data.

The accuracy of the data entered is of great importance, and humans entering data are likely to occasionally make mistakes. The data client attempts to mitigate this problem by providing instant ("as you type") feedback on the validity of the data inserted. If the data entered is not valid, an icon is displayed next to the entry to indicate it. An explanation is also available and it is shown as a tool tip when the mouse cursor hovers over the icon. Validation rules to govern this process can be defined per data set and can be applied to individual entries. A common source of errors is the incorrect usage of measurement units. In order to solve this issue, the client application displays the units defined for an entry in a combo box, allowing the user to choose from one of them. Finally, entries whose values are calculated from values in other entries do not require human intervention at all. The calculated score is updated in real-time as the values are entered in the relevant entries. Additional features provided by the client are a "review mode", and specific support for unanswered questions. The former allows a user to examine a completed assessment in order to correct any mistakes. Any correction requires an annotation describing the reason for the change. An audit trail is retained making it possible for a change to be reverted if necessary. Unanswered questions are common when collecting data, so special support is present to allow the user to select the reason for not answering the question. The set of options available is defined per repository. This information can be useful in the analysis stage and when revising the contents of an assessment.

The client has two modes of operation, "off-line" and "on-line". The former provides a subset of the functionality available in the latter mode. The ability to save records, retrieve data sets, and to review already submitted data are only available in the on-line mode. While in the off-line mode, the information collected is stored in an encrypted form and as soon as the application enters the on-line mode, the data is uploaded to the data repository and deleted from local storage.

Security

The Authentication service provides a Web service interface to the myProxy credential repository (Basney et al., 2005) that has been configured to act as an on-line certificate authority (CA). The Attribute Authority is implemented as a set of persistable Java classes, mapped to a relational database. The definition of a project includes the project name, a list of sub-groups which exist for this project, and a list of the valid roles which a user can be assigned. The AA knows each user by their Distinguished Name, and the AA stores the list of projects and privileges for the user. The AA provides a Web service interface, which exposes operations to query project information and user privileges. The other major function of the AA is the issuing of signed SAML assertions, which binds a users identity to their privileges. We have used the OpenSAML implementation for this. The Policy Authority makes access control decisions, based on the stored policy and the user privileges supplied in the SAML assertion. Policies are implemented as sets of persistable Java objects, and any number of policies may be stored; typically there will be one policy for each data collection project. The PA verifies the validity and integrity of a SAML assertion and confirms it comes from a trusted AA. It then checks the policy to determine if the supplied privileges are sufficient for the request target and action. In this context a target corresponds to an object or object group in the data repository and the action is the operation to be performed.

Client side APIs have been developed for both the PA and AA to hide the details of accessing the Web service. This means the services using the access control functionality need only call the makePolicyDecision() function provide by the API

DEPLOYMENT AND OPERATION

Third Party Software Components

All software components developed as part of PsyGrid are open source licensed under the GPL. We rely on a number of 3rd party software components, and to ensure that anyone can deploy their own PsyGrid, we have used only free, open source components. Most notably we have used Apache Tomcat (version 5.5.12) as our Web service container and Apache Axis (version 1.3) as our Web service stack. OpenLDAP was used for the directory, which provides user authentication, combined with myProxy on-line credential repository. Our backend database in the production system is IBM DB2, although in our development environment we use mySQL. Hibernate (version 3.1) provides an object relation mapping service (ORM) which enables any database supported by Hibernate to be used.

Hardware Architecture

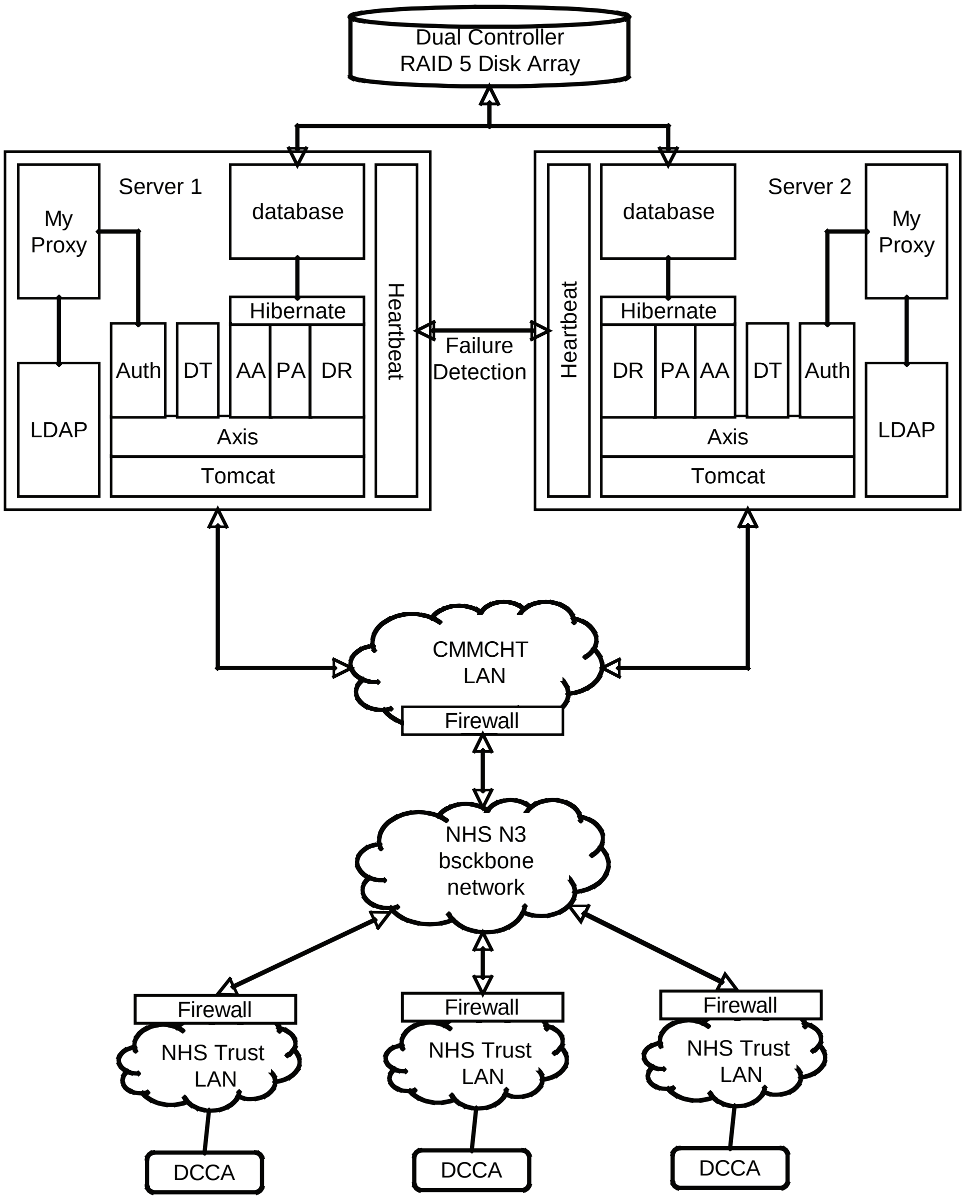
PsyGrid is a production system and so it was designed to be continuously available. The deployment configuration is shown in Figure 3. High availability was achieved by using a pair of servers to host the Web services and database. These two servers are deployed with an identical software stack, which consists of the Web service container (Apache Tomcat), the LDAP directory (OpenLDAP), the database, which is IBM DB2 in the production system, and the myProxy on line certificate authority. The disk used for storage of the data is a RAID 5 array. The servers are identical in every respect, and use the Linux Heartbeat application to manage high availability, using a shared "virtual" IP address. At any one time one server is active and the other is in standby. The active server is assigned the virtual IP address by Heartbeat. The URL of the Web services, that the client used to access the system, resolves in the NHS network DNS to this virtual IP address. The active server has the RAID 5 disk mounted, which stores the database. Heartbeat manages failure detection, and can switch activity for the active server to the standby under a number of conditions. Heartbeat will determine that the active server has failed if the active server does not respond to the heartbeat message sent by the standby server via both IP and a direct serial cable connection. It will also determine the active server to have failed if the Web services do not respond to a getVersion() request, which would indicate a Tomcat failure. The active server continually monitors the health of the DB2 and Tomcat processes. A switch of activity proceeds as follows:

1. The standby node forces the other node to shutdown, releasing the virtual IP address and unmounting the database disk.
2. The standby node mounts the database disk.
3. Tomcat is started and the Web services initialised. myProxy and the LDAP server are always running.
4. The virtual IP address is taken over by the standby server, which is now the active server.

Since all persistent data for the AA, PA and Repository services is stored on the shared disk, there is no need for replication of their data. The LDAP directory uses the openLDAP replication service to keep the two directories synchronised, and myProxy maintains no state data. A switch of activity has been measured to take 12 seconds on the production system, which causes minimal interruption to service.

There was no opportunity to perform scaling tests on the system before it had to be placed

Figure 3. PsyGrid Data Collection System deployed for FEP data collection (DCCA = Data Collection Client Application, AA=Atribute Authority, PA=Policy Authority, DT=Data Transformer, DR=Data Repository, Auth=Authentication Service)



into production due to time constraints, though for the initial deployment we were confident that our hardware platform would be more than powerful enough. We have long since passed the initial sizing requirements and we now support three independent data collection projects, with a combined user base of fifty distributed across 16 sites, and there is no degradation in performance. As and when performance becomes an issue, the use of Web services will enable us to seamlessly add new hardware and redistribute the services among the available hardware.

Software Upgrade

Our requirement was that a software upgrade should not cause an interruption to service. There are two different types of modification that need to be made to the running system.

The first of these is an upgrade to the Web services that occurs when bugs are fixed or new functionality has been added. The redundant hardware architecture employed enables the upgrade to be completed with minimal service interruption. The process we used is as follow:

1. Suspend the heartbeat application so that fail-over cannot occur.
2. On the standby machine remove the currently deployed Web services that are to be upgraded
3. Deploy the new versions of the Web services.
4. Restart heartbeat and manually switch activity. The upgraded Web services now become active.
5. Repeat steps 1, 2, and 3 so that the other server is upgraded.
6. Repeat step 4 to ensure that the deployment to the second server has been successful.

Changes to the interface of Web services require the data collection client to also be upgraded. The client is distributed using Java WebStart, and a new version is checked for each time it is launched by the user. If a newer version exists it is automatically updated. If the user is running the client during the upgrade, then any change to an existing Web service port type will cause problems. Consequently we maintain backwards compatibility between consecutive releases of a Web service. The addition of new port types to a Web service can be safely deployed without affecting running clients. To assist in debugging and user support, all Web services implement a `getVersion()` port type which return the version information set at compile time. We do not use Tomcat's Web service "hot deploy" capability as it proved to be unreliable, producing runtime errors. Instead the Web archive file and the deployment directory of the service are completely deleted.

The second type of modification we need to make to a running system is modification of the data sets. This is required when either a bug is found or a change request from the project clinicians is made. The repository Web service enables a live update to the data set to be made using a "patching" port type. This enables the complete object graph to be downloaded, modified by the patching client and then saved in the repository. Each data set records its own patch level.

The combination of Web services and the high availability hardware architecture enable us to upgrade and patch the system remotely and in a way that is largely transparent to our users.

Remote Connectivity

Deploying PsyGrid across the eight NHS Trusts proved to be very difficult. The NHS code of connection requires that only computers owned and managed by an NHS Trust may connect to the NHS network. Consequently, the purchase of hardware for the PsyGrid project and the configuration of those computers had to be devolved to the local NHS Trusts. We also required information from the Trusts about the source IP addresses the remote client computers would present to the firewall protecting the Central Manchester and Manchester Children's Hospital Trust (CMMCHT), which was the host for the central PsyGrid servers, so that this could be configured accordingly. The CMMCHT policy is to treat the NHS network link as hostile, and so connection was denied by default. The IP addresses were needed so that they could be added to the "white list" of trusted remote computers. Acquiring this information proved to be very difficult. The first hurdle that had to be overcome was to find the person who was able to release this information, and then to explain to them we were a legitimate research project, providing our supporting documentation. The response we often received to our first approach was one of suspicion, and that we were attempting to obtain restricted security information using social engineering techniques. The situation was further compounded by the fact the NHS IT departments are often overloaded with the work of keeping the IT systems used for the provision of clinical care running. Whilst we encountered no refusals to help support PsyGrid, research projects such as ours have a low priority and so help was provided on a best effort basis. We concluded that we needed to minimise as much as possible our dependence on NHS Trust IT staff as each dependency could turn into a project delay. We were fortunate in that we were able to negotiate with CMMCHT a relaxation in their firewall policy such that access to our servers would be possible from any computer on the NHS network. Without this relaxation it would be impossible to scale the deployment of PsyGrid across the NHS in the future.

Once the central system was deployed the next step was to test connectivity from the remote NHS Trusts. The initial assumptions we made about the NHS network infrastructure (in a previous section) were very quickly shown to be wrong. We discovered that there were three different classes of NHS Trusts differentiated by the way they allowed connections to be made to the NHS network. The first type of Trust caused no problems as they permitted direct connection to the NHS network with no restrictions on the ports that could be used. The second type of Trust employs HTTP proxy servers between the Trust's network and the NHS network. These proxy servers only permit HTTP traffic on port 80 and HTTPS traffic on port 443. The third type of Trust also employs proxy servers, but additionally requires the user to authenticate to the proxy server. All of the Trusts that require proxy authentication were not using the standard HTTP proxy server authentication method, but were using the proprietary Microsoft NTLM authentication protocol, which requires the user to supply their Windows domain credentials.

Whilst it may have been possible to negotiate with the individual Trust's to remove these restrictions so that a direct connection could be made in line with our initial assumptions, we had already concluded that relying on NHS Trusts for this was not viable or scaleable. Even if we could negotiate direct connection, there would be no guarantees that this would not be withdrawn in the future without out knowledge. Therefore we had to extend and refactor the system to take into account the reality of the different types of Trusts. The first task was to use only the standard ports for HTTP(S). We were using two ports for HTTPS traffic, 443 and 8443, with Tomcat configured to perform server side authentication and mutual authentication respectively. The data collection application Web start Web service and the authentication service were hosted on the server-authenticated connector and the other Web services required mutual authentication. We now only had one port we could use for HTTPS and one port for HTTP. The data collection application Web start Web service was moved to the HTTP connector on port 80. The authentication service could not be moved to an unecryptyed connection however, since the user name and password would be sent in the clear to the authentication service. However, the available HTTPS port had to employ mutual authentication, for the other Web services that use the distinguished name for the client certificate to make access control decisions (for Policy Authority and Attribute Authority) and log service invocation. We therefore had to place the authentication service on this connector and distribute with the data collection client a default certificate that would enable authentication to the server, so that login may proceed. The consequence of this is that the client application is distributed with a certificate with a long lifetime, which could be used to mutually authenticate with the PsyGrid servers. However, the actual access-control decision on all services requires either a valid signed SAML Assertion or a certificate issued by the PsyGrid Infrastructure CA. This default certificate has the distinguished name of "CN=nobody, O=user, O=psygrid, C=uk", and is issued by the PsyGrid Online CA and so can not be used to do anything more than complete the SSL mutual authentication. It cannot be used to retrieve a SAML Assertion (as there is no user with this Distinguished Name), nor are certificates from this CA accepted as valid for access without a SAML assertion.

The next task was to provide the ability to tunnel SSL through proxy servers. By default the version of Apache Axis (version 1.3) we were using did not provide support for SSL tunnelling through proxy servers. The existing PsyGridClientSocketFactory was extended to provide this behaviour and a configuration dialog was added to set the proxy server address and port number to the client application. If a proxy server were configured, then the PsyGridClientSocketFactory would setup an SSL tunnel through the proxy, using the HTTP Connect method. One negative consequence of this is that it requires the end user to perform this configuration, which often requires a call to PsyGrid technical support to guide then through this process. Finally we had to deal with authenticating proxies. Basic and digest authentication is a standard extension of the HTTP protocol, but the NTLM protocol is Microsoft proprietary, and the specification is not published. However, the protocol has been reverse engineered and the Apache Commons HTTP Client provides an implementation. It also implements basic and digest authentication methods. Axis 1.3 does not use the HTTP Client and so we had to again integrate this into the PsyGridClientSocketFactory, so that it would perform authentication if this was configured. We had to further extend the configuration dialog so that the authentication type could be selected, and a further user name and password dialog is displayed during login if proxy authentication is configured.

DISCUSSION

The operating environment in the NHS has undoubtedly provided the biggest challenge to PsyGrid. The high degree of heterogeneity between NHS Trusts, the use of propriety protocols and the firewall restrictions, which we only really began to understand when we tried to make the system operational, all caused the system to be reworked to overcome these restrictions. This is the single most important lesson learnt—a thorough understanding of the operating environment is required when the system is being design. However, these obstacles were not insurmountable and this shows that Web service implementations have reached a level of maturity that is able to cope with such a hostile environment. There is no doubt that a Web application based around off the shelf products would not have encountered these problems, but this would not have met our current or future requirements. We identified restrictions in the Web service tooling which defined a lowest common dominator as to the way we structured our data types whether the starting point was Java or XML. We anticipate our decision to use Web services will be fully justified in subsequent phases of the project as we begin to extend the system to include Web service orchestration and workflow techniques. Performance of the Web services, which we thought might cause problems, has not proved to be an issue to date, and we currently support three data collection projects encompassing 16 locations and 50 users.

The adoption of the PsyGrid system for mental health research in the UK has resulted in modification to the business processes of data collection in three ways. Firstly, data collection is now paperless, and data no longer needs to be transcribed from paper into an electronic format for analysis. This requires fewer resources, and the risk of introducing errors in the transcription is eliminated. Secondly, because PsyGrid can operate off-line, clinical researchers are able to enter data at any time in any location, including patient's homes, and consequently they have more flexibility in their working patterns. Thirdly, we believe that the system is easier to use, and the restrictions on data input imposed in the user interface will lead to higher data quality. An informal analysis indicates that this is likely to be true, and we will report on a thorough evaluation in the future.

Grid computing techniques and technology are spreading rapidly through the health informatics community. Web services underpin the majority of current Grid middleware and consequently the use of Web services is becoming wide spread. The caCORE project (Phillips et al., 2006) and the closely allied caBIG from the National Cancer Institute Centre for Bioinformatics, have developed a set of tools and applications that provide much of the functionality of PsyGrid for the cancer domain. We are evaluating whether the caCORE SDK can be used to implement the data set designer function in the Project Manager application. PsyGrid is closely allied with three sister projects, namely CancerGrid (Brenton et al., 2005), NeuroGrid (Geddes et al., 2006) and VOTES (Virtual Organisations for Trials and Epidemiological Studies) (Stell et al., 2006). All these projects have a common theme, which is to develop middleware that will enable distributed collaboration and resource in their specific domain. CancerGrid is focused on supporting clinical trials in cancer research. NeuroGrid is developing a medical imaging Grid, which provides a searchable, distributed file system for the curation brain images, and workflow tools for analysis. Finally VOTES is focused on the security aspects of dynamic virtual organisations in a clinical context, and their application to the integration and query of clinical data sets arising from routine care, which can be used to identify eligible clinical trial participants.

We have described the PsyGrid data collection system, which is being used to record the patient assessments in the longitudinal FEP cohort study. The next phase of the project will see the development of tools for epidemiology, which will enable the testing of hypotheses about the causes of schizophrenia, and identify environmental risk factors. This will require the core PsyGrid data set to be integrated with existing data sets such as census data from the Office of National Statistics and mental health service data from the Mental Health Minimum Data Set. We plan to expose these data sets using grid-computing techniques. The OGSA-DAI protocol (Chervenak et al., 2003) provides a uniform method of accessing data sources and OGSA-DQP (Alpdemir et al., 2004) provides the capability to perform distributed queries over multiple data sets. A range of Web services will be created to provide functionality for data cleaning and statistical analysis. To orchestrate the Web services developed for epidemiology we will use the myGrid e-science workbench that provides a creation and execution environment.

We will add a clinical trial manager component to the data collection system. This will be implemented as an additional Web service and will provided the ability to randomise treatments according to a user configurable algorithm.

In the long term we plan to further develop PsyGrid so that it can be used for predicting patients most at risk, and given their early symptoms from brain imaging and psychiatric assessments combined with genetic data, can be used to target the most effective treatments to prevent adverse outcomes. This will require integration with further data sources collected as part of clinical care and the development of a decision support system for clinicians. The longitudinal data collected during the FEP cohort study will provide the evidence base for making these predictions.

ACKNOWLEDGMENT

The PsyGrid project was funded by the UK Medical Research Council and the Department of Health under the core e-science program, grant number G0300610. We would like to thank Ismael Juma for implementing the Data Collection Client Application.

ABSTRACT

In this article we report upon our experiences of developing Web-services based infrastructures within two e-health projects. The first—a small demonstrator project funded by the UK's National Cancer Research Institute (NCRI)—is concerned with facilitating the aggregation of different types of data (specifically, MRI scans and histopathology slides) to aid the treatment of colorectal cancer; the second—a rather larger project funded by the UK's Medical Research Council (MRC)—is concerned with the development of a virtual research environment to support neuro-imaging research. In both cases, the underlying infrastructures are being developed by a team that is based in Oxford; it is the experiences of this team that we report upon in this article. We also report upon how we have considered the future potential for our systems interoperating with other systems which are deployed within the UK's National Health Service (NHS).

INTRODUCTION

The potential for distributed, service-oriented architectures to support healthcare delivery, training and research has been acknowledged widely. In this article we report upon our experiences of developing Web-services based infrastructures within two projects. In both cases, the architectures have been influenced by our earlier experiences within the e-DiaMoND project (Brady, Gavaghan, Simpson, Parada, & Highnam, 2003), which explored the development of distributed architectures to support a number of breast-cancer related applications. Although the e-DiaMoND infrastructure was based on grid services—rather than Web services—we have used many of the lessons learnt and adapted many of our designs from that project.

The two projects that we report upon are rather different in nature, but the same broad principles underpin both. The first project—a small demonstrator project funded by the UK's National Cancer Research Institute (NCRI)—is concerned with facilitating the aggregation of different types of data to aid the treatment of colo-rectal cancer. The second project is concerned with the development of a virtual research environment to support neuro-imaging research. In both cases, the projects involve multi-disciplinary teams from a number of institutions, with the underlying infrastructures being developed by a team within Oxford. It is the experiences of this team that we report upon here.

In Power, Politou, Slaymaker, and Simpson (2005), the authors considered the information security requirements incumbent upon health grid architectures deployed within the United Kingdom, and presented an architecture for an idealised health grid that was informed by those requirements; in Power, Politou, Slaymaker, and Simpson (2006), the authors described requirements for, and an approach to, the facilitation of fine-grained access control within systems in which third party Web services are deployed. In this article, we describe how some of the ideas from those articles have been combined to produce designs for, and implementations of, secure infrastructures, which underpin the two aforementioned e-health projects. We also comment our future intentions—which involve building on the work undertaken thus far and considering the potential for inter-operating with systems deployed within the UK's National Health Service (NHS).

The structure of the remainder of the article is as follows. In the next section we describe the background and motivation for our work. Then we reprise the contributions of Power et al. (2005) and Power et al. (2006), which, together, provide a blueprint for our work. Next we report upon our experiences within two projects: an NCRI-funded demonstrator project and the MRC-funded NeuroGrid project. We first introduce the projects, and then present an overview of the technologies used within our solutions. We also briefly consider some of the challenges that we have faced. Finally, we summarise the contribution of this article and outline some areas for future work, much of which is being undertaken with the GIMI (Generic Infrastructure for Medical Informatics) project (Simpson, Power, Slaymaker, & Politou, 2005).

CONTEXT

A number of *e-health* projects have been undertaken in recent years, with the term *grid computing* (see, for example, Foster & Kesselman [1999] and Berman, Fox, & Hey [2003]) often being used within this context. Some interpretations of the term grid computing characterise it as the utilisation of a specific collection of services and toolkits to build a distributed architecture; other interpretations are rather looser and characterise it as the bringing together and sharing of compute and data resources from different administrative domains—in the form of a *virtual organisa-*

tion—to perform tasks that would otherwise be very difficult, if not impossible. In this respect, *compute grids* offer the opportunity to provide unparallelled processing power to facilitate, for example, analysis of 3D images, and *data grids* offer the opportunity to share information between sites to allow distributed data analysis.

The UK's national e-Science Programme (Hey & Trefethen, 2002)—the main aims of which were to build a computational infrastructure to support large-scale research and to identify potential applications for such an infrastructure—funded a number of *e-health* projects. Such projects, including the aforementioned e-DiaMoND, have sought to develop distributed infrastructures to facilitate healthcare research, training, and delivery. Other initiatives have been seen in other countries, with examples including Singapore and Australia.

The EU HealthGrid initiative, aims (amongst other things) to promote the concept of grid computing within the biomedical community, are being undertaken to ensure that relevant technological advances developed by the grid computing community benefit healthcare research and delivery.

Simultaneously, the UK government has invested significant amounts (the initial estimate was approximately six billion pounds; the latest is approximately 12 billion pounds) in a National Programme for Information Technology (NPfIT) (since renamed Connecting for Health) in the NHS, which promises to deliver electronic records, electronic prescription of drugs and electronic booking of appointments, all of which will be underpinned by an NHS Information Technology (IT) infrastructure (Humber, 2004). Similar schemes are being developed throughout Europe and in Australia, Canada, and the United States to provide "cradle-to-grave" views of patients via the linking of electronic information (Cornwall, 2002).

While the potential benefits of the system are significant in terms of increased quality of healthcare delivery, there are potential drawbacks, with many authors (see, for example, Collins [2004], Leyden [2004], Carvel [2005], Keighley [2005], and Mulholland [2005]) being critical. Critics have tended to focus on potential breaches of security and confidentiality. (The interested reader is referred to Anderson [1996] and Anderson [1999] for overviews of the relevant issues.)

It seems almost inevitable that the two paths of e-health research and systems such as Connecting for Health will converge in the near future: with real patient data stored in electronic patient records being used to support medical research. In this respect, it should be noted that research has been characterised as a "secondary use" for Connecting for Health. The following quote from the editors of the Journal of Medical Internet Research supports this view:

One aspect of electronic care records which has received little attention is the potential benefit to clinical research. Electronic records could facilitate new interfaces between care and research environments, leading to great improvements in the scope and efficiency of research. Benefits range from systematically generating hypotheses for research to undertaking entire studies based only on electronic record data ... Clinicians and patients must have confidence in the consent, confidentiality and security arrangements for the uses of secondary data. Provided that such initiatives establish adequate information governance arrangements, within a clear ethical framework, innovative clinical research should flourish. Major benefits to patient care could ensue given sufficient development of the care-research interface via electronic records. (Powell & Buchan, 2005)

Of course, it will first be necessary to consider the confidentiality and security of patient records, and, in particular, appropriate anonymisation and pseudonymisation of data before new interfaces between healthcare delivery and clinical research environments can be facilitated. Other issues include determining appropriate consent arrangements (whether "opt-in" or "opt-out"), ensuring that trust between practitioners and patients isn't compromised, and establishing workable governance arrangements.

Our work over the past three years has been concerned with the design, implementation, and deployment of distributed security solutions (or health grids) to facilitate medical research. Early work—such as that within e-DiaMoND—utilised Globus Toolkit 3 and enterprise-level commercial products. More recent work—for reasons of interoperability and extensibility—has been based on Web services and freely available software.

In Power et al. (2005), the authors considered the information security requirements incumbent upon health grid architectures deployed within the United Kingdom, and presented an architecture for an idealised health grid that was informed by those requirements. In Power et al. (2006), the authors described an approach to the facilitation of system-wide security that enables fine-grained access control within systems in which third party Web services are deployed. We provide a brief overview of the work of these articles in the next section before considering how the theory has been realised in practice.

TOWARDS SECURE HEALTH GRIDS

In this section, we provide brief overviews of the work of Power et al. (2005), which presented an architecture for a secure health grid, and Power et al. (2006), which described an approach to the securing of Web services.

A Secure Health Grid Architecture

Our discussion is necessarily focused on the situation within the United Kingdom: other countries will have their own concerns to address. Within the United States, for example, the Health Insurance Portability and Accountability Act of 1996 (HIPAA) is of concern: the privacy rule "sets forth what uses and disclosures are authorized or required and what rights patients have with respect to their health information" (Verhanneman, Jaco, & De Win, 2003); the security rule "specifies what implementation is obligatory for enforcement of this policy or what reasonable efforts should be [undertaken]'' (Verhanneman et al., 2003).

UK-based e-health projects must adhere to the principles of the Data Protection Act of 1998, which can be stated as follows.

- Personal data shall be processed fairly and lawfully (and in accordance with certain conditions).
- Personal data shall be obtained for one or more specified and lawful purposes, and shall not be further processed in any manner incompatible with that purpose or those purposes.
- Personal data shall be adequate, relevant, and not excessive in relation to the purpose or purposes for which they are processed.
- Personal data shall be accurate and, where necessary, kept up to date.
- Personal data processed for any purpose or purposes shall not be kept for longer than is necessary for that purpose or those purposes.
- Personal data shall be processed in accordance with the rights of data subjects under the Data Protection Act.
- Appropriate technical and organisational measures shall be taken against unauthorised or unlawful processing of personal data and against accidental loss or destruction of, or damage to, personal data.
- Personal data shall not be transferred to a country or territory outside the European Economic Area unless that country or territory ensures an adequate level of protection for the rights and freedoms of data subjects in relation to the processing of personal data.

The DPA is augmented by the Council of Europe's Recommendation on the Protection of Medical Data.

If any UK-based health grid were to be deployed to facilitate healthcare delivery, or if it were to receive data from systems deployed within the NHS, then it would have to consider additional requirements. The NHS comprises a number of independent legal entities—known as *hospital trusts*—with each hospital trust is being responsible for the data held at its sites. This data is released only with respect to the principles of the Caldicott Guardian, which can be stated thus.

- Justify the purpose(s): every proposed use or transfer of patient-identifiable information within or from an organisation should be clearly defined and scrutinised, with continuing uses regularly reviewed by an appropriate guardian.
- Don't use patient-identifiable information unless it is absolutely necessary.
- Use the minimum necessary patient-identifiable information.
- Access to patient-identifiable information should be on a strict need-to-know basis.
- Everyone should be aware of their responsibilities.
- Understand and comply with the law: every use of patient-identifiable information must be lawful.

It should be noted that each trust retains the ownership of all data located at its sites and each trust determines who can access its data (and under what circumstances): this is a model that we have adhered to when developing infrastructures to facilitate research. A goal of our work, then, is to design and deploy systems that allow data to be shared as ensuring that the data owner retains absolute control over who can access which data, when it can be accessed, and even where it can be accessed from.

To this end, a number of use cases—pertaining to information security requirements—were presented in Power et al. (2005). We provide an overview of these below.

- **Distributed queries of patient data.** "A user wishes to query the data held on a subset of the hospitals that form the health grid. Each hospital is allowed to decide its own policy for data access. The user should receive the combined results containing only data that they are permitted to access."
- **Working at a remote site.** "A doctor is working at a remote hospital, which is part of the health grid. The doctor should be able to access data from their home hospital, though their request may be subject to a policy that differs from the one used when they are at their home institution.''
- **Delegation of access permissions.** "A senior health professional would like to grant access to data to a colleague. This access should be temporary, and could be granted to either a named individual or a group of people.''
- **External access.** "Either a health professional working from home or an individual patient wishing to see their own records should be able to access data in accordance with the local hospital's access control policy. The hospital would use a different policy for such external access than would be used for requests from a remote hospital. This use case differs from the others as the request comes from outside of the current virtual organisation.''
- **Modification of data.** "Having made a clinical decision about a case, a doctor wishes to modify the data stored in the health grid. A doctor will only be able to modify data if a hospital's policy allows it. Each hospital is responsible for the data it stores and as such it should keep a record of all modifications made. This use case is similar to the

delegation of access permissions described above, with the only difference being that the data—rather than the policy—is being changed.''

- **Transferring patient records.** "In this use case a patient has moved and is now being treated at a new hospital. As the patient is likely to stay at the new hospital for some time, it would make sense to move their data. To be able to move the data it will first need to be read: this may involve a distributed query as data may already be present at other hospitals. The data will then need to be deleted from one hospital and copied to another—as the responsibility for it has transferred. This will involve the modification of data. Finally the access policies at both of the hospitals may need to be changed to reflect the change of ownership of the data.''

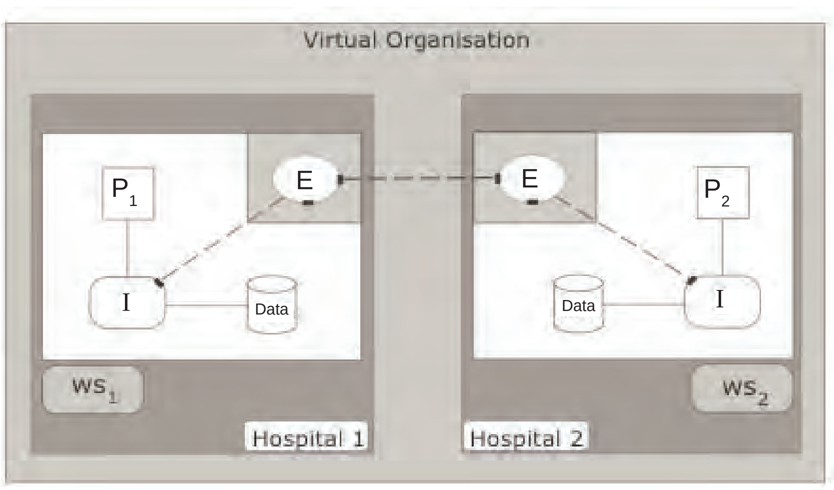
In the architecture of Power et al. (2005), each node contains a data store, externally facing services, internally facing services, access control policies, and workstations (see Figure 1). (This situation is visualised in terms of a health grid with two nodes above.) It is the externally facing services that allow different sites to communicate with each other. Importantly, this architecture allows each site to retain control of its data and access control policies. All access requests within this system are governed by the policies accessible to the internal service, with the policies governing who can access the data, when they can access it, where it can be accessed from, and what rights they have to delegate that access.

In this architecture, a local user can make a request to its local externally facing service, which would then direct that request to: the local internal service; another external service (or set of external services) at a remote site; or both the local internal service and other sites' external services.

Securing Web Services

In Power et al. (2006) an approach to the facilitation of system-wide security that enables fine-grained access control within systems in which third party Web services are deployed was described; in particular, a characterisation of security features required to enable existing Web services to be secured to fit in with a secure infrastructure was presented. We provide an overview of some of these requirements here.

Figure 1.



- **Authenticating clients.** Our assumption is that the system of interest already has an established authentication mechanism. The existing Web service, however, may utilise a different authentication mechanism. When writing a wrapper service, it is possible to authenticate clients using the system-wide authentication mechanism and then translate the system-wide client identifier into one that is understood by the existing Web service via the utilisation of a client mapping function. Once the mapping has been performed, the original SOAP message can be passed to the existing service using whatever authentication mechanism it supports.
- **Secure messaging.** If the content of the message is encrypted, then the message will need to be decrypted and possibly encrypted again. Furthermore, the keys used between the client and the wrapper will differ from those used between the wrapper and the Web service.
- **Access control.** The resource which we are trying to provide access to will typically have its own access control mechanism. Ideally, to be consistent with the requirements of Section 3.1, all access control for the resources at a single node should be determined by a single set of coordinated policies, with all requests for access to the existing Web service having to comply with these policies.

A PLATFORM FOR DATA AGGREGATION TO SUPPORT COLORECTAL CANCER APPLICATIONS

The National Cancer Research Institute (NCRI) Informatics Initiative has facilitated funding for a nine-month demonstrator project to bring together researchers from various disciplines to demonstrate the utility of a multi-scale, multi-disciplinary approach to enhancing the information that can be derived from data collected within a clinical trial. The intention is to develop a prototype system to relate MRI images to the consequence macro images, and to demonstrate the application of medical image analysis (developed for radiological scale images) to macro slides.

The development of a secure computing infrastructure to link disparate sites is being undertaken at Oxford University Computing Laboratory; the development of a prototype viewing application is the responsibility of the Department of Engineering Science at Oxford; the development of appropriate ontologies and meta-models is being undertaking by the Department of Computer Science at University College, London; and data collection is being undertaken by the Pathology Department at Leeds University and the Royal Marsden Hospital. Finally, the task of coordinating all of this activity is the responsibility of the NCRI Informatics Coordination Unit.

In Slaymaker et al., 2006), the development of the underlying computing infrastructure was reported. In this section, we characterise this development in terms of the requirements of a previous section.

Colorectal cancer is first diagnosed using endoscopy and confirmed by histopathology. It is then staged radiologically in order to determine the extent of local and distant disease—with this being best done using MRI. The primary tumour site is assessed to determine if the tumour has extended into the adjacent fat and involved the adjacent tissue planes, including the mesorectum; the detection of lymph nodes and their possible infiltration by the tumour is also crucial, with distant metastases being assessed separately using Computed Tomography (CT) or (if appropriate) Positron Emission Tomography (PET).

Typically, an oncologist sends a patient who is suspected of suffering from colorectal cancer to a radiologist for a CT scan: suspicious dense areas that could be cancer may be revealed; the scans may also give early evidence that, in the case of colorectal cancer, there is already strong evidence of metastasis. A number of options are available on the basis of the CT examination: "palliative care"; sending the patient for MRI scans for further information; providing a course of chemo- or radiotherapy; or surgery. The project is concerned with the last of these options.

During surgery, the surgeon cuts out the tumour. The extracted tumour, together with some flesh, is photographed from the front and the back. The tumour is divided into slices of three-mm thickness, with each slice being captured in slides with two different resolutions: a low-resolution image is taken at about x20 zoom (macroscopic resolution), and a high resolution is taken at about x140 zoom (microscopic resolution). The microscopic slides are analysed by histopathologists to assess type and stage of a cancer, with this analysis consisting of considering the distribution, shape variation, and staining of cells visible at the higher resolution.

The Royal Marsden Hospital has collected (anonymised) MRI volumes of colorectal tumours, with all MRI volumes being taken prior to chemotherapy/radiotherapy and prior to surgery. These volumes are also accompanied with descriptive metadata such as the MRI position, the extent of the tumour, the surgical plan, etc. The other data resource that the project draws upon is a collection of macroscopic and microscopic slides in digital form supplied by Leeds University, with each micro image being stored in a custom file format.

NEUROGRID

Currently, neuro-imaging research typically consists of small studies being carried out in single centres. The sharing of data between centres is limited and even when data is shared, it is common for researchers to be very guarded with their data and algorithms—which leads to much duplication of effort.

The NeuroGrid project (Geddes et al., 2005, Geddes et al., 2006), which is funded by the UK's Medical Research Council, is concerned with tackling problems that are currently holding back widespread data sharing, with the principal aim of the three-year project being to develop a distributed collaborative research environment to support the work of neuroscientists. The potential benefits of the NeuroGrid platform include the streamlining of data acquisition, the aiding of data analysis, and providing improvements to the power and applicability of studies. The project involves collaborators from the University of Oxford, University and Imperial Colleges, London, Nottingham University, Edinburgh University, Cambridge University, and Newcastle University.

As a means of ensuring that the technological solutions being developed within NeuroGrid are of clinical relevance, the project is focusing on a number of exemplars, which pertain to Dementia, Stroke, and Psychosis. The Dementia exemplar requires real-time transfer and processing of images with a view to assuring image quality prior to the patient leaving the examination. The Stroke exemplar is establishing and testing mechanisms for interpretation and curation of image data which are essential to the infrastructure of many multi-centre trials in common brain disorders. The Psychosis exemplar is testing the capabilities of NeuroGrid to: deal with retrospective data, assimilate material into databases, and facilitate data analysis.

SOLUTIONS

In this section we describe the solutions deployed within the projects described previously. Although the approaches taken in both cases are broadly similar we consider different aspects in our discussions of both projects to reflect the different natures of the two projects: first we concentrate on database aspects; and then we concentrate more on Web services.

An Infrastructure for Data Aggregation to Support Colorectal Cancer Applications

It is essential that it is verified that both MRI and pathology images come from the same patient cases, and that these two sets of data can be related (both technically and ethically). If this is the case, we can then relate and integrate pathology and radiology images of a case in two ways. The first means of relating these different types of data is via the integration of the full images as entities—which means having available the pathology image one can retrieve together with its associated MRI image/report. The second method is via the association of their corresponding region of interests (ROI)—which means if one has a ROI in an MRI volume, then one should be able to retrieve its associated area in the 3D pathology images.

Typically, each MRI volume can have more than one ROI, because individual lymph nodes could also be annotated as well as the main tumour (although only one of these annotations would apply to a lesion). Thus, a flexible database schema that can effectively describe all of the above data is necessary. The database underpinning the project is based on the work described in Power, Politou, Slaymaker, Harris, and Simpson (2004), in which a relational structure for images stored in the standard Digital Imaging and Communications in Medicine (DICOM) format is presented.

As the pathology images are not in DICOM format, a different method of dealing with them is required. The two formats that need to be handled are JPG for the macroscopic images and a custom file format for the microscopic images. We have chosen to employ a method that effectively automatically generates suitable DICOM wrappers for each image file. This has the benefit of allowing maximum flexibility while requiring minimal changes to the existing underlying schema.

Another advantage of using DICOM-style wrapping is that it handles collections of images well. A single set of macro images would form a DICOM series and hence be addressed together. This is also the case with the micro images. Furthermore, the two series—macro and micro—can be collected together as a single study. This provides a great deal of flexibility when processing queries.

All data is stored in a federated database that is distributed over several sites, with all of the data servers being exposed via Web service interfaces. The patient and image data are stored at the site at which they originated, with the data from each location reflecting the specialisation of that site. The selection of MRI and pathology data pertaining to a single case is achieved by federating data between multiple sites. The architecture is based on that of a prior section and utilises open source Web services technologies and standards.

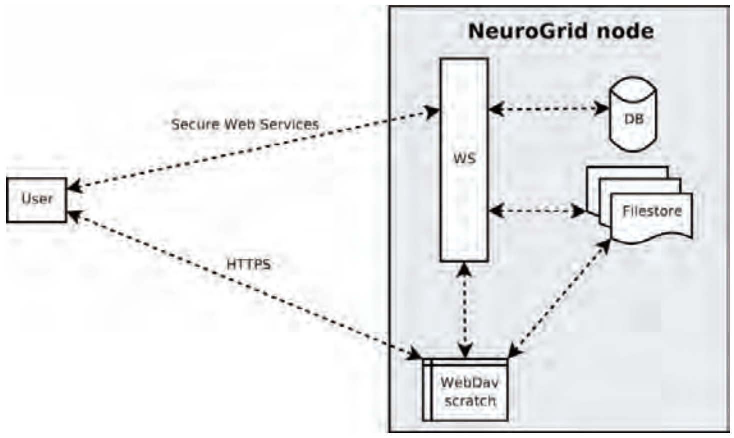
The NeuroGrid Infrastructure

While our developments within NeuroGrid have followed the sentiments of the architecture of Power et al. (2005), the system is by no means a direct implementation. For example, there has been no need to distinguish between internal and external services as both kinds of service have been written and deployed by the NeuroGrid core technology team. Should there be any need in the future to decouple the internal and external services (if, for example, a third party internal service were to be used), then this could be achieved via the existing services calling through to the internal services.

The configuration of a NeuroGrid server node is illustrated in Figure 2.

Ensuring secure messaging was our first challenge, and we use secure Web services to this end. In addition, we utilise WebDAV (Web-based Distributed Authoring and Versioning) (Whitehead, 1998) folders to provide scratch space for operations. The Web services and WebDAV folders are accessible only by using PKI mutual authentication using X.509 certificates. The Web

Figure 2.



services use an insecure channel to carry secure messages signed by the originator and encrypted for the recipient, ensuring both the identity of the sender and secrecy. The users communicate with the WebDAV server over HTTPS with mutual authentication enabled—which establishes a secure channel over which insecure messages can be passed.

WebDAV plays a key role in the NeuroGrid architecture. First, there is no standard high-speed and secure way of transferring binary data using SOAP messages; WebDAV allows us to both get files from and put files to Web servers in a secure way efficiently. Second, WebDAV allows the user to browse, upload and download files directly to their scratch space using a variety of third party WebDAV clients—this is especially useful when wrapping the Web services with a portal. The WebDAV folders also provide an ideal location for any intermediate results that might be generated by algorithms which do not belong in the file-store but may be of interest to the user.

A file-store and a database of meta-data provide part of the back-end of the system: this is where data is stored, with all interactions occurring through Web service calls. We separate image data from patient and meta-data (with appropriate references between the two to guarantee referential integrity). The use of the Apache Derby database—which is written entirely in Java, is easy to install, and has a minimal system footprint—was chosen as it enhances the interoperability and portability of the underlying infrastructure.

We are also using Sun's JWSDP (Java Web Services Development Pack) Web service implementation in the Sun customised version of the Apache Tomcat container. The intention behind using Java-based technologies is that it should allow us to deploy to any platform with a Java Virtual Machine; using Web services allows maximum interoperability with client implementations in a variety of languages. We are also using the Apache Web server which is available for most platforms.

The technologies we have used to create the NeuroGrid infrastructure were chosen to ensure that it would be as portable and interoperable as possible: we have attempted to choose solutions with excellent cross-platform support and which is at freely available—if not open source.

We now consider how the use cases of the third section are being realised.

- **Distributed queries of patient data.** This use case requires the ability to perform federated queries—an ability that the NeuroGrid infrastructure provides. To enable federated queries the system must support onward Web service calls—a situation in which one Web service makes a call to another Web service, which can be local or on a remote node. A request to a federated query Web service at one site will query local resources and, in addition, make Web service query calls to other known sites. On receipt of the results of its Web service queries the federated Web service assembles all the data into a single set of results and returns this to the caller of the federated Web service.

In order to identify the originator of the request, a *ticketing* system is being used. The ticketing system iteratively propagates information pertaining to authentication: each Web service call has a ticket associated with it and each Web service examines the tickets it receives. When a Web service creates a new ticket, the calling Web service's ticket (or a ticket issued to the calling user in the initial case) is embedded in the new ticket. Tickets are always signed by the sender ensuring the validity of the ticket can be verified by all subsequent receivers. The tickets constitute a verifiable audit trail which can be used to restrict access control when combined with a relevant access control policy.

- **Working at a remote hospital.** This simple use case again relies on the ticket system. At the points when access control policies are evaluated, the audit trail of the ticket can be consulted and that shows exactly the route the user has taken to make the request. Access can then be restricted by combining a policy which restricts access based on origin and/or route.

NeuroGrid already has the ability to onwardly call Web services (one Web service making a call to another Web service). Using this capability a user can make calls to a node at the hospital where they are currently located and that node will make appropriate requests to the user's home hospital on their behalf.

In a hospital situation it would be appropriate to have nodes which could only be communicated with locally—apart from node-to-node communication which is essential to the system's operation. This could be achieved by several means, such as IP address restrictions or the utilisation of a Virtual Private Network.

In the currently deployed NeuroGrid system, nodes are all public facing, which means that a user could bypass the step of calling the Web services on a local node and instead call directly to a remote node.

- **Delegation of access permissions.** In the original presentation of the use case of Power et al. (2005), the delegation of access permissions was similar to that pertaining to the modification of data; within NeuroGrid we are also looking at a model of delegation based on the aforementioned ticket system.

Using the ticket system a user can delegate their permissions to access data to another user. Using the ticket system, the originator of the request is known—and thus their identity can be used in making access control decisions. This information can also be used to delegate authority from one user to another.

- **External access.** In Power et al. (2005), external access referred to any access that was not initiated from within a site of the virtual organisation, such as a doctor accessing some medical records from home. From the perspective of the NeuroGrid infrastructure, all access is considered external: in the current system, physical location does not affect access rights.

There are two ways to access the NeuroGrid system: talking directly to a server using an application that utilises an API or through a Web portal (which itself is just an application using the API).

It is trivial to establish external access as any location not in a restricted list. This could then be used to deny direct access to NeuroGrid to any location not on the list. Locations not on the list could access the NeuroGrid through the Web portal—with more restricted rights than permitted to an internal user.

It is well understood that it is difficult to establish a definite location of a client on a network. As such, it could be argued that this "all or nothing" (without going through the portal) model represents a sensible approach: the users' rights would simply be restricted when accessing the system though a portal. Additionally, there is no reason why externally-facing NeuroGrid nodes could not be configured to give the same reduced rights to users directly through Web services.

The access control policies can take advantage of the tickets to accomplish this restricted access as they contain the audit trail of the request: any requests which have passed through a specific node can be given restricted access rights.

- **Modification of data.** Within the current implementation, it is perfectly possible to modify the data held in the system; all modifications are recorded as part of an audit system, so changes to the data can be tracked back to the responsible party if necessary. Again, the implementation of this use case is benefiting from the ticket system (combined with access control policies) to allow and disallow rights to modify data as necessary.
- **Transferring patient records.** It is entirely possible within NeuroGrid to copy some data (in this case, a patient record) to another node. Ideally, this process would take place within the scope of an atomic transaction ensuring that the patient record is neither duplicated, nor, more seriously, lost. Support for atomic transactions is part of the WS-Transaction specification, and support for this specification is under development as part of a future version of JWSDP. Once this becomes available we plan to add transactional support to the NeuroGrid system.

As any deployment of the NeuroGrid infrastructure evolves, modifications of access control policies—to reflect the change in location of data—will occur. For a standard record, this will typically mean that it is added to a list of records associated with a standard access control policy at the hospital it was transferred to—with any relevant specific policies for that patient also being transferred.

Challenges

Our goal is to develop secure distributed systems that will support a wide range of platforms: by using open standards we aim to support interaction with third party systems that may be developed in the future. By using a platform-independent programming language (Java) and open standards for communication (HTTP, SOAP) and security (TLS, WS-Security) we should—in theory—be able to meet these objectives. We also aim for our systems to be free to deploy and use—which prohibits the use of most commercially produced software.

Although large vendors provide free versions of commercially available software, they (typically) provide limited support for its use. In spite of this, we have chosen to use several software packages that fall into this category alongside some open source components. We discuss two of the challenges that we have faced in this regard in the following.

The distributed systems we have developed consist of multiple components, which communicate using a combination of WebDAV and Web services. The WebDAV services are provided using an Apache Httpd server with DAV and SSL extensions—which allows us to provide a mutually authenticated WebDAV service. The URLs used tend to be long—for technical and security reasons (and user convenience). This had led to several problems on the client-side, where ideally we would like to use the default WebDAV clients provided as part of the operating system.

Microsoft provides a WebDAV client built into Internet Explorer and also support the opening of WebDAV folders as a Network Connection. We have had two problems with these clients. The first is the lack of support for long URLs in Internet Explorer—a series of support calls over a period of several months led to a suggestion that we shorten the URLs. We also have had problems with Microsoft clients trying to write to the root of the server's file system as this would be normal behaviour on a Microsoft server. Apple also provides a WebDAV client which is used primarily for their Mac services. This client has the problem that it does not support mutual authentication.

As a means of providing Web services, we use the Sun Java Web Services Development Pack (JWSDP) running on top of a Sun provided version of Tomcat 5.0 (Sun do not currently support a version of Tomcat 5.5 although the reason for this is unclear). Part of our reason for choosing the Sun provided software instead of the open source Axis was because of its support for a large number of the Web service standards. Unfortunately, the WS-security libraries require extensions to the Java security libraries—which are shipped with all Sun-provided JVMs, but not IBM-provided JVMs. This has led to problems running our Web services on IBM servers.

There are a number of lessons to be learnt from this. First, the use of Web services to develop *real, interoperable* systems to support genuine virtual organisations still has some way to go. Second, it is arguable that the use of extensible standards to facilitate interoperability is doomed to failure as long as vendors are able to release product versions underpinned by their own closed-source extensions to these open standards.

DISCUSSION

In this article we have described how some of the requirements and approaches described in Power et al. (2005) and Power et al. (2006)—pertaining to the design of health grid architectures and the securing of Web services, respectively—have been realised in two e-health projects.

Developing robust distributed solutions using current technologies is a challenging task. One of the major issues that we have faced is that current toolkits for Web services are very much focused on a single server being contacted by multiple clients; as such, are merely a substitute for a traditional HTML-based solution. We would argue that inadequate thought has been given to building multiple-server applications. For example, we have encountered several problems when making onward calls from one Web service to another. Other challenges include "standard" extensions not being standard and a lack of a mechanism for transferring large binary objects that is both secure and efficient *simultaneously*.

Future work is being taken in a number of directions, much of which is being undertaken within the GIMI (Generic Infrastructure for Medical Informatics) project (Simpson et al., 2005). The main aim of GIMI is to develop a generic, dependable middleware layer capable of: (in the medium-term) supporting secure and ethical data sharing across disparate sources to facilitate healthcare research, delivery, and training; and (in the longer-term) interfacing with technological solutions deployed within the NHS.

The key to ensuring legal and ethical access to such data is that the mechanism should offer *fine-grained* and *dynamic* access control to resources: this is the key driver behind GIMI. The infrastructure will be developed so that it is sympathetic to the needs of clinical researchers, commercial organisations involved in the medical domain, healthcare providers, and those concerned with providing training facilities—all of which will be concerned with sharing confidential data. Our plan is to extend our existing designs and implementations to facilitate such means of authorisation.

First, we have made significant strides towards realising the architecture of Power et al. (2005). There is some way to go, however: the addressing of the "transferring of patient records" use case, for example, has yet to be addressed. Continuing to realise these use cases within the context of the NeuroGrid project shall continue to be a priority.

Second, our architectures have been designed with the opportunity for fine-grained and flexible access control policies in mind. Our medium-term goal is to realise this opportunity by utilising XACML to secure nodes in such a fashion. This—together with the long-term interoperability view—is our focus within GIMI.

Finally, to date, our techniques have been deployed exclusively within the healthcare domain; we intend, in the near future, to determine other relevant application domains in which our approaches may be validated.

Chapter 2.5
Decision Support With BPEL and Web Services

Iain Morrison
The University of Melbourne & Bond University, Australia

Sony Nugrahanto
The University of Melbourne, Australia

ABSTRACT

A review of difficulties experienced with proprietary guidelines languages and in clinical decision support has led us to the development of a decision support system (DSS) based on a service oriented architecture (SOA) using Business Process Execution Language (BPEL) and Web services. BPEL allows simple branching conditions and tests to be set based on the information artifacts in the workflow. For more complex tests, we preferred to place decision support in an external DSS Web service. An advantage of this approach is that the DSS could evolve independently of the clinical workflow. We have implemented an exemplar of the above using the Java expert system shell (JESS). The domain objects are sent by the BPEL engine into the DSS which consults external rules, reasons on the domain objects and rules, and transmits recommendations back. The article will discuss issues involved in implementation using as an example drug-drug adverse reactions.

INTRODUCTION

In an earlier article (Liaw, Deveny, Morris, Lewis, & Nugrahanto, 2004), we developed an approach to Clinical Decision Support (CDS) based on the BPEL and Web services. The process flow associated with the treatment (diagnosis, referrals, consolidation, and action), was expressed, following expert group analysis, in a series of blocked activities which could then be drilled down into specific actions. The expert analysis led to (i) a set of activities (tasks or services or actions) and decision points; (ii) a set of information requirements at each stage of the process flow, to be mapped onto information sources and sinks; and (iii) a "best-practice" sequence of activities and actions. The sources and sinks and activities could be resolved into local process variables, or a Clinical Information System (CIS) or a set of external service providers described through Web Service Description Language (WSDL) (W3C, 2001).

In a follow-up article (Morrison, Lewis, & Nugrahanto, 2006), we explored issues in interoperability between the workflow engine executing the decision support guideline and the endpoints supporting the external service providers (including manual intervention). We showed the pros and cons of using either SOAP-encoded RPC-style information transfer or document-style transfer and how these approaches were reflected in the design of Web services endpoints and the types of Information Models able to be used to transfer application data.

The examples we provided at that time performed decision support within the workflow engine, utilizing BPEL decision constructs. However, this approach is not suitable when the decision is complex or if flexibility is required in environment/language bindings as in rule-based approaches commonly used in clinical decision making.

In this article, we present and discuss implementation of an evolved architecture, focussing attention on the separation of concerns amongst clinical workflow, reasoning engines, and rules bases in drug-drug adverse reactions as an application scenario. We place complex decision support in an external DSS Web Service accessible to the workflow engine in the same way as the EHR and other service providers Thus, the detail of the DSS implementation is abstracted from the workflow description and its mechanisms hidden behind an interface façade. Different reasoning engines can be made available depending on the application context and rules bases can be updated following expert review independent of the CDS processes. The rules bases could be maintained centrally and the most current version loaded on-demand.

SERVICE ORIENTED ARCHITECTURE AND CLINICAL DECISION SUPPORT

Service Oriented Architecture

The basic principles of SOA consist in modularizing functions and exposing them as services. This idea of a software application as a service was recognized in the past (Sun's RPC, Microsoft's COM/DCOM), but it can now be fully realized using the Web services for systems interoperability.

A Web service is a software application available on the Web whose capabilities are described in XML and is able to communicate through XML messages over an Internet transport protocol. Basic elements of Web services are the standards for interoperability: XML for information representation), SOAP (W3C, 2000) for invoking, WSDL (W3C, 2001) for describing, and UDDI (http://www.uddi.org) for discovering.

On top of this basic interoperability protocol stack, new languages and specifications for defining the composition of Web services to form business processes have emerged, such as Business Process Execution Language (BPEL) (IBM, 2002). Characteristics of BPEL include a service orientation model that emphasizes standards compliance and XML encoding. As well as a formal basis to the language, services are loose coupled and can support synchronous and asynchronous activation.

When compared to related standards (such as XPDL and WSCI), it appears that BPEL is relatively expressive (Wohed, van der Aalst, Dumas, & ter Hofstede, 2003) and currently BPEL is the only standard that comes with execution engines such as Oracle BPEL Manager (Oracle, 2006), IBM's BPWS4J (IBM, 2004a) and ActiveBPEL (ActiveBPEL, 2006)

SOA and CDS

Benefits from CDS include improved patient safety, improved quality of care, and improved efficiency in health care delivery (Sinchenko, Westbrook, Tipper, Mathie, & Coiera, 2003). However, these goals are yet to be fully realized largely due to poor integration with clinical workflow and practice and poor integration with EHR and/or other clinical systems (Eccless et al., 2003).

In recent years, we have seen development in SOA-related standards and technologies that could potentially to provide answers to some of the technical challenges around integration and interoperability in the clinical and health care context. Research in this areas are quite fluid at the moment but initial indications are positive (Peleg, 2005; Kawamoto, 2005; Anzböck & Dustdar, 2004; Anzböck & Dustdar, 2005).

Recognizing the need to develop service interface specification standards to support clinical decision support in SOA, the Health Level 7 (HL7, http://www.hl7.org) and Object Management Group (OMG, http://www.omg.org) have agreed to collaborate in the Healthcare Services Specification Project (HSSP, http://hssp.wikispaces.com). The project has identified some of the services that may be useful for the implementation of a CDS system. These services concern with, for example, managing patient identity, locating records, verifying terminology, and drawing conclusion based on patients' data.

In Australia, NEHTA (The National E-Health Transition Authority) has recently recommended the use of SOA for the design of health applications and has produced an Interoperability Framework (NEHTA, 2005) and a Web Services Standards Profile (NEHTA, 2006) lending further weight to the adoption of these standards and approaches.

CDS with Web Services and BPEL

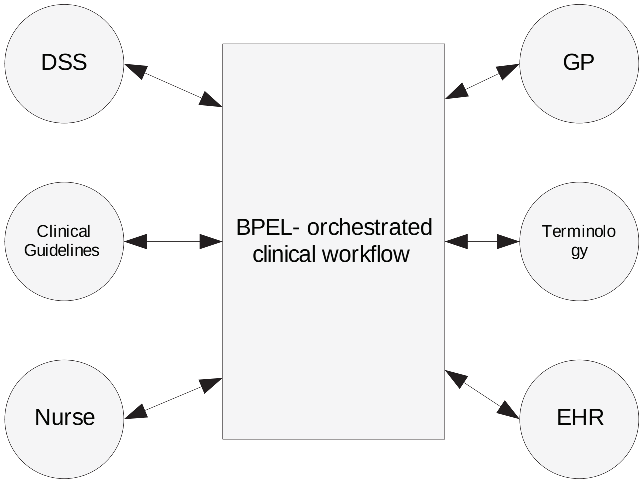
As clinical decision support requires a robust distributed architecture (Nealon & Moreno, 2003), Web services are a strong candidate as a delivery mechanism. BPEL has been developed in tandem with the development of Web services, firstly as a process description and execution language, and then, due to availability of Java-platform Application Programming Interface (API) and execution engines, as a means of automating (orchestrating) the coordination of Web services.

In using SOA (BPEL and Web services) as an architectural design, we noted (Morrison et al., 2006):

- Web services may not completely solve interoperability problems between clinical systems, however, they show great promise of reducing the complexity of interconnecting heterogeneous software systems distributed over the Internet partially by providing a level of service and information flow abstraction.
- The expressiveness of BPEL as a process description language to model business processes (Wohed et al., 2003) as well as providing execution engines supportive of web-services-based tasks/activities makes it a strong candidate for modelling coordination required in a clinical setting to assist decision making.
- BPEL cleanly separates transport, process definitions and information flows. Information flows can be defined by schemas (document-style) or mappings to classes/objects which are defined by SOAP-encoded RPC.

Coordination of decision-making process in BPEL can be done in a way that reinforces the centrality of the roles enacted (see Figure 1),

Figure 1. Representation of roles assignments using BPEL



whether they be by the General Practitioner (GP), EHR, or another entity, and specifies the interfaces to be implemented in a technology-neutral way. Although BPEL does not directly support a "role" at a language level, these can be affected through environmental bindings. BPEL then makes these roles and services explicit and transparent while hiding details of service implementations—in our earlier examples, we had a GP, practice nurse, and external service providers.

In the SOA architecture (with BPEL and WS), for example, roles can be assigned to a healthcare–provider, a patient (and patient health record), the DSS/Workflow engine and associated services, such as terminology or medicines information.

Decision Making Strategies with BPEL

BPEL allows simple workflow branching conditions and tests to be set based on the information artefacts provided by the services or held in the process execution context. For example, in the case of asthma (Liaw et al., 2004), we could check the patient's age and X-Ray consolidation (extracted from CIS or Provider reports as external services) before deciding on the next course of action.

For more complex tests, we could embed snippets of Java code into BPEL as proposed by IBM and BEA (IBM, 2004b). The BPELJ extension will allow BPEL to not only to orchestrate web services but will also allow orchestration of local resources which is more efficiently accessed with local means. However, this approach as noted earlier would be at a cost to the portability, language and platform neutrality of BPEL as the extension deals only with Java 2 Platform Enterprise Edition (J2EE) (Sun, 2001) resources.

Therefore, we will investigate placing complex decision support in an external DSS Web service accessible to the workflow/process engine in the same way as the EHR and other service providers.

An advantage of this approach is that the clinical workflow, reasoning engine, and rules bases are all separated. Furthermore:

- The approach places all services on an equal conceptual footing. In particular, the DSS as a service could itself call on other services independently and as required.

- In the Web Services context, the DSS could itself then be comprised of other complex flows and be independent of the workflow provided it met the required interface contract-for-service.
- The approach decouples the clinical workflow and timing from the decision tests. In the case of the introduction of new drugs or the publishing of an update or an alert on an existing medication, the clinical workflow would not be affected however the DSS would draw on the new information.

THE TEST APPLICATION SCENARIO

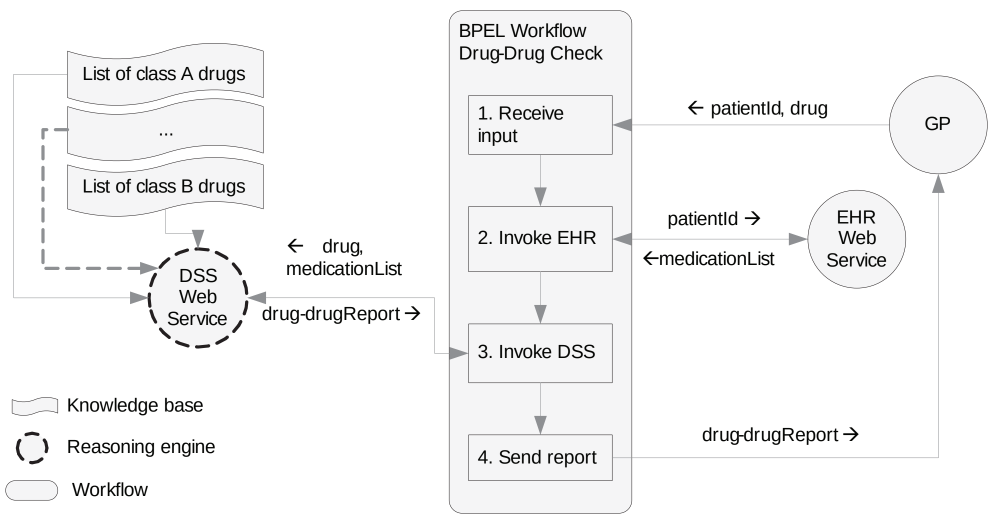
We will look at the example of drug-drug adverse reactions. Drug-drug interactions occur when two or more drugs react with each other with potentially adverse consequences to the patient to whom they are being administered. For example, mixing a sedative and an antihistamine can slow reactions and make driving a car dangerous.

We model a GP interacting with a patient and deciding on a course of medication (see Figure 2).

The proposed medication, determined by the GP after consultation with the Patient, is sent with the patient external ID to an external (to the workflow engine) EHR service which then calls the EHR (practice-based or externally-based) and extracts the current medication list (expressed in this case as a drug list modelled as extracted from a Medical Director (http://www.hcn.com.au/) application (Practice CIS).

The current medication list and the proposed medication goes to the DSS which has loaded (i) drug concepts and drug classes and (ii) decision support rules in terms of these classes. The current implementation (there could be many rule sets per supported CIS) maps the proposed medication into a drug class and checks for known adverse

Figure 2. BPEL scenario for drug-drug collisions checking



reactions with other drug classes. That is we did not map specific medicine preparations but more types of drug (e.g. determined as per active ingredient, not preparation). This, of course, could be easily generalised. The examples we used in testing were drawn from the Therapeutics Goods Administration (TGA) Adverse Drugs Reaction Bulletin (http://www.tga.gov.au).

The decision-making process implemented was choreographed in a synchronous BPEL process and all services were implemented as Web Services (EHR, DSS, and GP) that exchanged activity and information via the SOAP protocol over HTTP. Although we focus in this article on rule-based decision support, and implemented the test scenario in a simple Web Services Profile (equivalent to the NEHTA Basic v1.0 Profile), the addition of other services (e.g. WS-Reliable Messaging, WS-Security) and alternate communication models and transports is quite straightforward as shown in an earlier analysis of practice workflow and interoperability framework (Morrison, Lewis, Liaw, 2005).

Rule Engine

For the reasoning engine behind the DSS service facade we used Jess (Friedman-Hill, 2006), a rule engine developed at Sandia National Laboratories in the late 1990s and written in Java. Creating and invoking Java objects from Jess (or vice versa) is fairly transparent if the objects have JavaBeans (Sun, 1997) properties and reflect domain constructs able to be represented in XML schemas. As a result, domain-level attributes can be easily mapped into specific rules and facts and reasoned on.

The current Jess implementation does not support, however, automatic conversion of collection objects other than Java arrays but this restriction parallels those involved in the choice of Document-based rather than SOAP-encoded RPC-based content model transfer in Web services and is more an application-level design issue. It does not have practical limitations for the types of information models currently used in CIS Extracts and on Drug-Drug and Drug-Condition tests.

Architecturally, Jess is well suited to Web services DSS use as it complies with the JSR94 specification (JSR94, 1994) for “plug-and-play” rules engines for Java-based Decision Support and is the first engine to be endorsed under this community standard. This allows the DSS façade to be backed by an API that can select specific engines at run-time based on application requirements—facilitating multi-facetted DSS services. The concept is very similar to having multiple messaging providers and directory service providers behind a standardised service interface. Applications see the standard interface and providers can be switched.

One of interesting features of Jess is the notion of shadow facts. A shadow fact is an unordered fact whose slots/properties correspond to the properties of a JavaBeans. Therefore shadow facts serve as a connection between facts in Jess working memory and Java objects representing the facts.

Workflow Engine

For the workflow engine we used ActiveBPEL BPEL engine (ActiveBPEL, 2006), an open source and free-to-use implementation of BPEL engine with a strong community support. It has a visual tool to design workflows and thus minimizing the need to script them at textual level.

We should mention that as this engine is BPEL-compliant, we had no difficulty importing our examples in the treatment process for asthma (Liaw et al., 2004), previously developed in Oracle BPEL Process Manager (Oracle, 2006). However, we noted that one must develop in this case a library to accommodate the omission of user task management (a given, straight-out-of-the-box feature in Oracle PM). Also, there is no persistence mechanism by default but we could use any standard or public domain database as the linking mechanism has been provided as part of the suite.

EHR

For implementation of the EHR service we have extracted data from the Medical Director Practice CIS and organized them into a Clinical Document Architecture (CDA) (HL7, 2004) structure appropriate for Summary Clinical Data Extracts. Using the associated XML schema, we populated our EHR using XMLBeans (Apache, 2006). As noted, our approach is schema-driven throughout. The patient summary schema is not only useful for populating the EHR, but can easily be used to import the information models into our BPEL workflow. Using this approach, we are able to easily change patient record structures (and other required information structures associated with support services) as these are agreed to extend our prototype. In this way, clinical summaries and external services report content is made available to both the BPEL Process and the DSS. The approach and architecture are quite flexible and allow the data to be sent directly (encrypted, de-identified, and through choice of multiple communication channel—mail, http, Message Oriented Middleware [MOM], etc.) or by reference/delegation and extracted as required by the workflow engine or DSS services.

RESULTS AND SUMMARY

We applied the above architecture and test scenario to a number of drug-drug adverse reaction alerts published by the TGA. In the cases considered the Process Engine and DSS operated within specification in detecting specific collisions between drug classes. The drug codes (by preparation) as prescribed and listed in the CIS were mapped to drug classes and the Jess rules scripted (i) to encode class definitions and (ii) define adverse reaction rules. The latter were drawn from the expert reference and the former from application (CIS) mapping tables. Once the class concepts were defined (schema, Java, or facts), the rules for each adverse reaction alert were trivial (a few lines of text each). The application mappings from a given CIS to drug classes needs done only once per CIS, however we note that a move to standardize medication descriptions (especially in schema form) would largely eliminate this last step. The rules base itself transparently factors into three elements (i) the adverse reaction alerts in standardized form, (ii) the concept definitions (drug class etc.), and (iii) per-CIS drug-class mappings. This leads to easier maintenance.

The tests show, in extension to our earlier work, that an SOA, Web services and BPEL approach to complex DSS in clinical care is feasible and architecturally exhibits useful features in (i) support for service and DSS abstraction; (ii) separation of concerns of clinical workflow, information models and flow, services, and transports; (iii) factoring of DSS concerns (concepts, rules, and application mappings); and (iv) concurrent support for multiple DSS mechanisms behind a common service façade. Although this article focused only on one specific application, the approaches support scalability and generalization at several levels, including drug-condition and related condition/co-morbidity checks.

The HSSP project has identified several services required to support clinical decision support in SOA. With regard to the DSS service, the project seeks to identify a common service interface for how DSS services make their knowledge available to the decision support applications (CDSs). As more functional and technical details become available, we could incorporate work on this area into our propotype.

Chapter 2.6
A Framework for the Design of Web Service Based Clinical Management Systems to Support Inter and Intra Organizational Patient Journeys

Carolyn McGregor
University of Western Sydney, Australia

ABSTRACT

The clinical management of premature and ill term babies is challenged by the necessity of several inter and intra organizational patient journeys. Premature and ill-term babies born in regional Australia and Canada must be moved to another hospital with Neonatal Intensive Care Unit (NICU) facilities. NICU babies requiring surgery must be moved to a Level IV NICU for surgery. Current clinical management supports the transfer of limited patient data via paper or telephone exchange. In this article a framework for the design of Web-service-based clinical management systems to support inter and intra organizational patient journeys is presented. A series of Web services are described and integrated and coordinated through BPEL processes enabling greater support for inter- and intra-organizational transfer of patient data. This framework is demonstrated through a NICU case study. A key benefit of this framework is that it enables the establishment of "on demand" patient journeys eliminating the need to establish permanent point-to-point connections.

INTRODUCTION AND MOTIVATION

Healthcare and specifically the allocation of funds towards improved provision of healthcare via improved patient journeys represents a significant portion of the Australian, USA, United Kingdom, and Canadian National Budgets (Curry, McGregor, & Tracy, 2006).

Patient Journeys document a pathway of Clinical Management guidelines that represent the patient's journey through treatment and care.

Clinical Management systems are designed to assist care providers in diagnosis and treatment using existing already established methods of diagnosis and accepted treatments (Gross-Portney & Watkins, 2000).

Health care redesign and in particular patient journey redesign (also sometimes referred to as patient pathway or flow) involves analyzing the overall processes involved with the intra- and inter- organizational movement of a patient and then identifying how this journey can be improved via the removal of wasted and excessive activities, process duplication and improved communications between the patient, their carers and the clinicians involved with the journey itself. Process redesign techniques have been used extensively in the business, manufacturing, and computing domains for many years but it is only recently that process improvements in healthcare have been achieved through similar reengineering approaches (Curry, McGregor, & Tracy, 2006).

In general, the research, development and adoption of new information technologies (IT) and information systems (IS) within the healthcare domain is currently lagging behind other industries (McGregor, 2006; Wu, Wang, & Lin, 2005).

Web services enable standardized information exchange through XML messaging. Business Process Execution Language for Web services (BPEL) (Andrews et al., 2003) provides a mechanism to integrate and coordinate the invocation of several Web services within the structure of a business process. Web-service-enabled Patient Journeys have the potential to significantly impact the effective expenditure of these funds by enabling paradigm shifts in Clinical Management.

This article presents case study based research supporting the development of a framework for the design of Web-service-based Clinical Management systems to support intra- and inter-organizational patient journey workflows. The framework enables the modeling of existing patient journeys and supports the reengineering of these patient journeys to improve communication between clinicians and remove duplication, wasted, and excessive activities. Web services are designed that enable greater support for inter- and intra- organizational transfer of patient data. This research builds on existing model-driven Web services integration and development research (Bordbar & Staikopoulos, 2004) by further applying these concepts researched within the business context to the domain of clinical management activities within a patient journey. To facilitate the coordination of the complete inter and intra organizational patient journeys, Business Process Execution Language for Web services (BPEL) is used as BPEL enables the generation of executable workflows built using Web services. A key benefit of this framework is that it enables the establishment of "on demand" patient journeys eliminating the need to establish permanent point to point connections.

The case study used for this research is the patient journey of neonatal and ill-term babies between (1) special care nurseries in urban, rural, or remote hospitals to tertiary or children's hospital Neonatal Intensive Care Units (NICUs) and (2) tertiary NICUs and children's hospital NICUs, when a baby is transferred for surgery.

The article is organized as follows. First a discussion is presented on related recent research in the areas of health informatics to support ICUs together with recent Web services and BPEL research. The next section presents an overview of the framework for the design of Web service based clinical management patient journeys. The following section introduces the Neonatal Intensive Care Unit (NICU) case study environment. Afterwards, the application of the framework to generate BPEL process to support neonatal patient journeys is presented. The article is concluded where future work is presented.

RELATED WORK

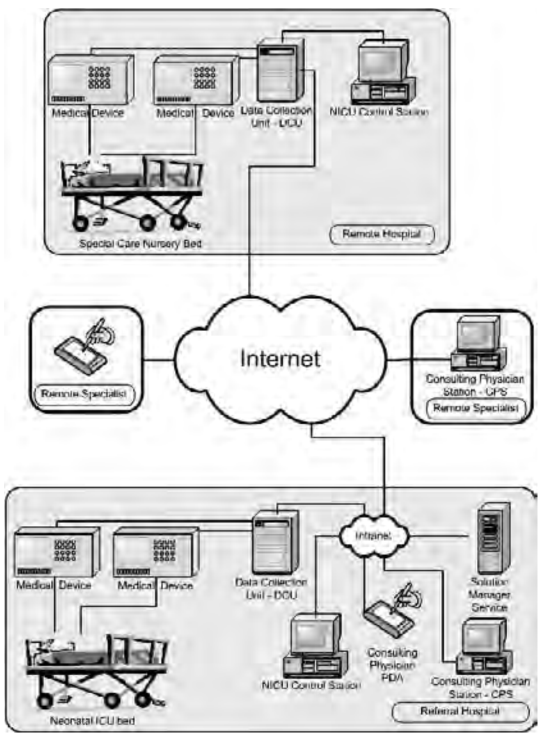
Much of the recent computing and IT related research to support intensive care units (ICUs) has focused on clinical alerts (Catley & Frize, 2003; Catley et al., 2003; Shabot, LoBue, & Chen, 2000; Sukuvaara, Makivirta, Kari, & Koski, 1989; van der Kouwe & Burgess, 2003). The information made available to these systems is limited to a small set of physiological data and/or clinical data from patients located within their ICUs. Clinician access to these systems is limited to the receipt of alerts with minimal content via email and in some cases pagers.

An integrated XML-based health care framework for a neonatal intensive care unit is described by Catley and Frize (2003) and Catley, Frize, Walker, and StGermain (2003). That research enables the capture of local real-time patient device data within a data repository located within a data collection unit (DCU). It utilises XML as a means to transfer data from a NICU data repository to clinical decision support system (CDSS). The transmission of the data from the medical devices to the DCU is not in XML.

Kregar (2001) defines a Web service as *an* interface that describes a collection of operations that are network-accessible through standardised XML messaging. Web Service Definition Language (WSDL) supports the implementation of Web services by providing a standard XML format for describing network services as a set of endpoints operating on messages containing either document-oriented or procedure-oriented information (Christensen, Curbera, Meredith, & Weerawarana, 2001).

Business Process Execution Language for Web Services (BPEL) defines a notation for specifying business process behaviour based on Web services (Andrews et al., 2003). There has been recent focus on linking process modeling with Web services development resulting in model driven Web services integration and development (Bordbar & Staikopoulos, 2004).

Figure 1. e-Baby architecture (McGregor, Heath et al., 2005)



This research is part of the larger "e-Baby" research project (Foster & McGregor, 2006; McGregor, 2005; McGregor, Bryan, Curry, & Tracy, 2002; McGregor, Heath, & Wei, 2005; McGregor, Kneale, & Tracy, 2005, 2006). The broad aims of the e-Baby project are to develop:

- Generic computer interface technologies to allow the integration of data emanating from several disparate medical monitoring systems and a clinical information database.
- Data management technologies to allow for the detection of trends and patterns in clinical and real-time physiological data.
- An Internet-based data distribution mechanism which is capable of integrating data from a number of cooperating data sources while supporting access security controls down to a specific item within a specific individual's medical record.

The e-Baby architecture defines architectural components located at Referral Hospitals containing NICUs, Remote Hospitals with Special Care Nurseries and supports remote and Referral Hospital access by Neonatologists.

The Solution Manager Service (SMS) architecture within the context of its use for business performance measurement is introduced in (McGregor & Schiefer, 2003, 2004; McGregor, Schiefer, & zur Muehlen, 2006; Schiefer & McGregor, 2004). The SMS is an agent-based intelligent decision support system that allows organizations to collect information about their business processes in a centralized repository, and share them among authorized parties, such as supply chain partners, clients, or government agencies. A key contribution of that research is that the interaction with this IDSS is via a set of Web services. In addition, the infrastructure boasts several innovative agent-based modules that support different components, providing the intelligence within this IDSS (McGregor, Schiefer et al., 2006). Within that research business process audit stream data is transmitted to the SMS via the use of a *log Web service*. The e-Baby research reapplies the principles of the SMS within the context of receiving and processing physiological stream data via a *physiological log Web service*.

This article focuses on the framework that enables the coupling of various previously defined e-Baby components (Foster & McGregor, 2006; McGregor, 2005; McGregor et al., 2002; McGregor, Heath et al., 2005; McGregor, Kneale et al., 2005, 2006) using Web-services-based Clinical Management systems to support intra and inter organizational patient journey workflows.

FRAMEWORK FOR THE DESIGN OF WEB SERVICE BASED CLINICAL MANAGEMENT PATIENT JOURNEYS

In this section the framework to enable the establishment of Web-service-based clinical management patient journeys is introduced. The framework builds on previous model driven Web service integration and development research (Bordbar & Staikopoulos, 2004) and proposes the following phases:

1. Model the existing patient journey
2. Reengineer the patient journey
3. Determine inter and intra information flows
4. Web Services Design
5. BPEL Design
6. Development/Testing/Implementation Phase
7. Post Implementation Evaluation

Each phase within the framework is briefly described in the following subsections. An NICU case study is used to demonstrate this framework in the following section.

Existing Patient Journey Model

During this phase information is gathered to enable the construction of patient journey model. Participants may include management, IT support staff, healthcare workers, patients, and their carers. This framework enables the patient journey to be modelled within a chosen patient journey/business process modelling tool. In this article, cross-functional flowcharts have been used to diagrammatically represent the existing patient journey. Further research has commenced on a patient journey modelling and communication tool for use during this phase that better supports the domain of healthcare (Curry, McGregor, & Tracy, 2006). Output from this phase is the documented existing patient journey model.

Reengineer the Patient Journey

The patient journey is then reengineered during this phase. To enable this reengineering focus sessions are run by an experienced facilitator whose role it is to encourage discussion and involvement amongst the participants and translate what is said into a resulting diagrammatic.

Output from this phase is the documented reengineered patient journey model.

Determine Inter and Intra Information Flows

Once the reengineered patient journey has been established, information flows are defined for each communication between the participating organization units. XML schemas are then constructed to represent information flows. The outputs from this phase are the associated XML Schemas.

Web Services Design

For each information flow between organization units that has been defined by an XML schema, Web services are designed to support the intra- and inter-organizational transfer of information. Output from this phase is the design of the Web services.

BPEL Design

During this phase the patient journey model is utilized to provide the information to enable the translation of the patient journey into a Business Process Execution Language for Web Services (BPEL) design. Organizational participants in the patient journey become partners in the BPEL definition. Web Services are invoked at the appropriate place in the patient journey. The output from this phase is the BPEL representation of the patient journey.

Development/Testing/Implementation Phase

The Web services and controlling BPEL are developed, tested, and implemented using the chosen development lifecycle during this phase. The BPEL representation of the BPEL journey and the associated Web services are implemented during this phase.

Post Implementation Evaluation

Once implemented, the patient journey is evaluated. Evaluation within this context is performed via clinical trial to evaluate performance based on the clinical management requirements. In addition, further performance evaluation is performed based on system performance measurement to assess system performance. Output from this evaluation will drive future iterations of this framework.

Figure 2. Neonate or ill-term baby patient journey—remote and referral hospital

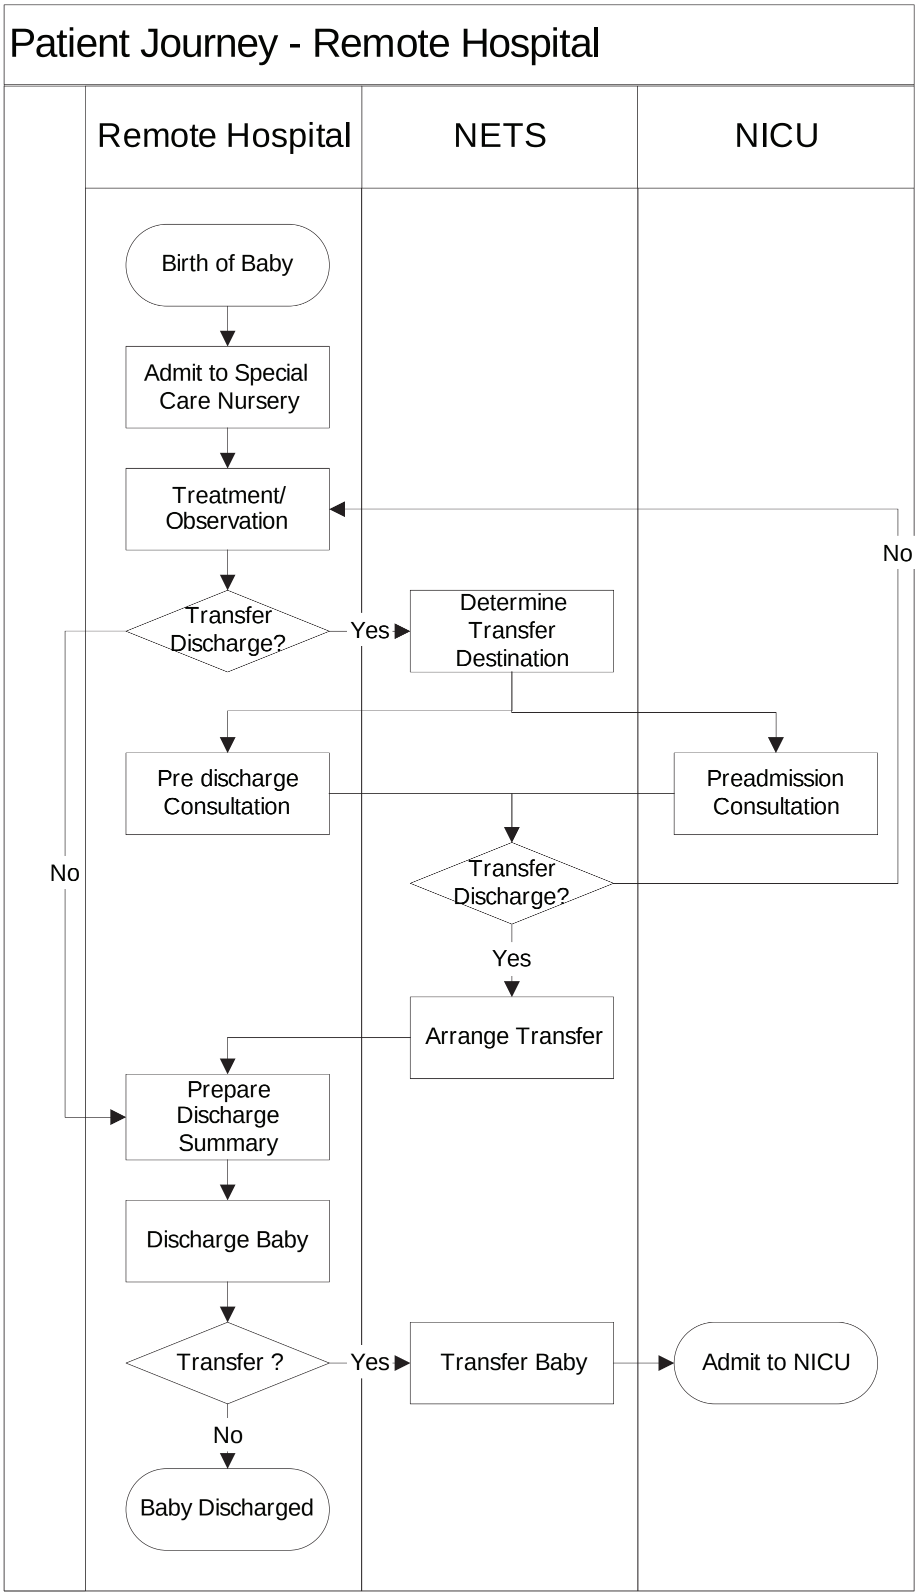


Figure 3. Neonate or ill term baby patient journey—referral and Children's Hospital

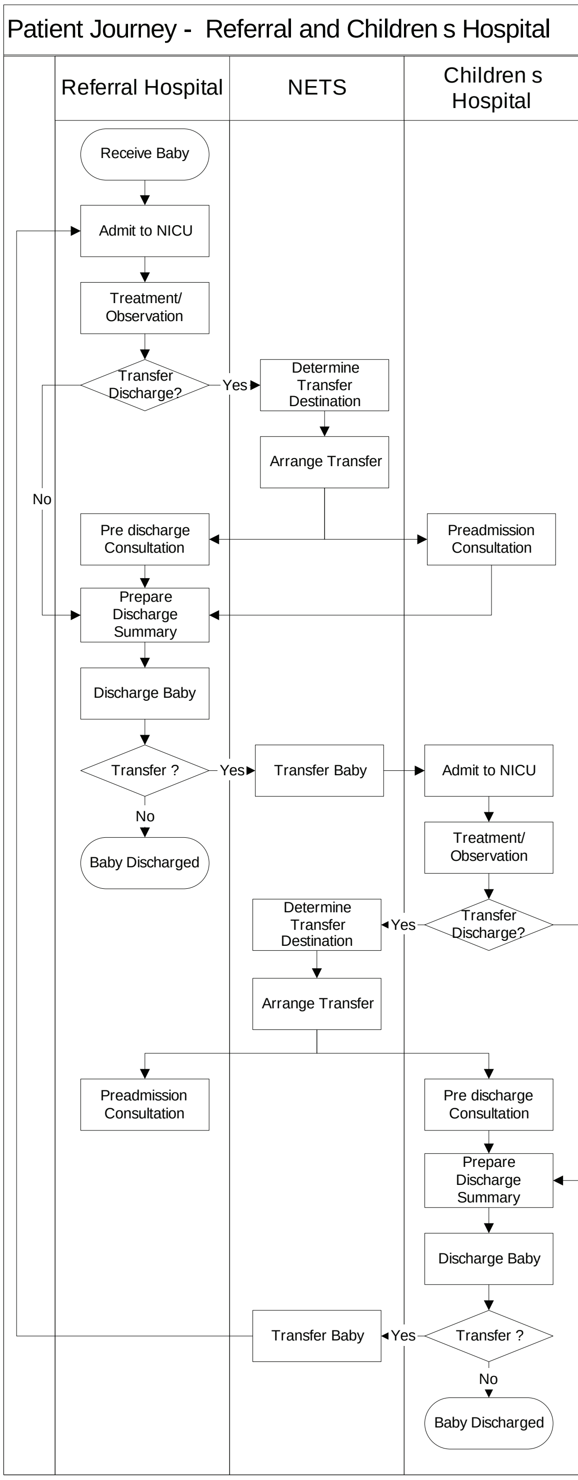


NEONATAL INTER AND INTRA ORGANIZATIONAL PATIENT JOURNEYS

The framework to enable the establishment of Web service based clinical management patient journeys is now demonstrated using neonatal inter- and intra-organization patient journeys.

Intensive care units (ICUs) worldwide offer support for patients in need of critical care. They boast a range of state of the art medical monitoring devices to monitor a patient's physiological parameters such as blood oxygen, blood pressure, and heart rate. Other devices such as ventilators offer mechanical life support.

Broadly, there are three types of intensive care namely, adult, pediatric, and neonatal. While the age of the patient is the differentiator between adult and pediatric ICUs, the clinical management differs greatly from these ICUs to the neonatal ICUs (NICUs)—where gestational age greatly impacts clinical management.

From a total of 86,414 babies born in New South Wales (NSW), Australia during 2003, 15 percent (12,296) required admission to a special care ward and 2.6 percent (2,277) were admitted to neonatal intensive care units (NICUs). These figures are similar to previous years (NSW Midwives, 2004). Premature babies can be up to 17 weeks early and may only weigh 450gms; they can spend three or four months in intensive care and have dozens of specific diseases before discharge. Ten percent of severely ill babies will die and 15 percent of survivors will have significant life-long disability. Premature babies, by the time they are discharged, can increase in body mass by as much as six times, and have had dozens of medical diagnoses and treatments. Many of these may have long-term implications for the future health of the individual. In addition, 15 percent of neonatal intensive care admissions are transferred after delivery from smaller regional or remote hospitals without intensive care facilities to larger tertiary referral or children's hospitals with Neonatal Intensive Care Units (NICUs). Similar conditions apply within Australia, New Zealand, Canada, and the USA where small non-tertiary units are spread throughout the country (McGregor, Kneale et al., 2006).

The NSW newborn and paediatric Emergency Transport Service (NETS) is the state wide clinical service for medical retrieval of critically ill newborns, infants, and children in NSW, Australia. Since 1995 NETS neonatal retrievals from regional hospitals to tertiary referral or children's hospitals has averaged 70 per month. There are only three children's hospitals in NSW, (two children's hospitals in Sydney and the John Hunter Children's Hospital in Newcastle). Children's Hospitals contain NICUs and in addition, are able to perform surgery on Neonates. Another seven hospitals are tertiary referral hospitals providing NICUs onsite for newborn babies. All of these hospitals are in major metropolitan areas on the eastern coast of NSW. There are approximately 200 other hospitals in NSW without specialist NICU care that must refer to Neonatologists within the NICUs at either the children's or tertiary referral hospitals for the care of critically ill newborns and infants.

Current treatment practices for premature babies and ill-term babies born in geographically rural and remote hospitals are impacted by the lack of NICU support onsite. Regional hospitals have equipment to provide limited NICU support, but without the ability for a Neonatologist to receive information from this equipment, the baby must be moved to another hospital with Neonatologist support. Given the critical requirement to maintain a consistent environment, moving a baby at this time can be life threatening. Transferred pre-term and critically-ill-term babies have higher mortality rates and much higher rates of long-term disability than similar babies born in hospitals with NICU facilities (McGregor et al., 2002). A major limitation is that the attending physician must contact a Neonatologist via telephone, who may or may not be located at the NICU at that time, to describe the baby's condition and, where possible, relay any physiological information verbally. The consulting Neonatologist must then make decisions based on this verbal exchange.

It is very common for critically ill babies to have significantly abnormal variation in the measured parameters minute by minute and not all of these variations are made available to the consulting Neonatologist. Frequent transient falls in blood pressure and blood oxygen content, often with swings into the high range, may be of critical importance in survival and quality of survival free of significant disability (Lister, Bryan, & Tracy, 2000).

Adding to the complexity of this neonatal support function, the NICUs located at the children's hospitals and tertiary referral hospitals each have a limited number of humidicribs. As a result, the remote hospital attending physician must contact NETS who utilise their referral database to determine which children's or tertiary referral hospital NICUs the remote hospital should contact for support and/or transfer, based on humidicrib availability. Thus the NICU patient journey support that the approximate 200 regional and tertiary referral metropolitan hospitals require is an adhoc connection to any of the Children's or Tertiary Referral hospital NICUs (10) for which they are referred to by NETS, on a needs basis, at a total rate of 70 per month (McGregor, Kneale et al., 2006).

Typical medical records for the most premature babies consist of manually prepared paper notes that detail enormous data collection and can weigh up to three to four kilograms. The preparation of these notes is dependent on the hand-annotated records of nursing staff, usually at 60-minute intervals, and 30-minute intervals at best. Also, within the NICUs, the collection of the information contained within the baby's notes to form a discharge letter represents a manually intensive analysis of physiological statistics, together with the replication of clinical data that can take the Neonatologist many hours to produce.

The following subsections present and describe the use of the framework proposed within this research on two high-level patient journeys namely: neonate or ill-term baby patient journey—remote hospital; and neonate or ill-term baby patient journey—referral hospital. The example commences with the second phase where the improved patient journey model has been developed and concludes at the BPEL Design.

Reengineer the Patient Journey

Neonate or Ill Term Baby Patient Journey—Remote Hospital

The neonatal or ill-term baby patient journey where the baby is born in a remote hospital is summarised in Figure 2. A neonate or ill-term baby born within a *Remote Hospital* firstly goes through the activity of *Admit to Special Care Nursery* (ie. placed within a humidicrib in the Special Care Nursery). They then begin to undergo *Treatment/Observation*. During the *Treatment/Observation,* the attending paediatrician will constantly access the baby's condition. While the care of neonates on a daily basis is quite complex and requires in simple terms nutrition planning, observation, and treatment, of relevance to this research is the point in the treatment/observation activity determining whether the baby can be discharged, or whether a discharge via transfer to a NICU may be required. If a transfer may be required, they will contact NETS to determine the transfer destination. Once NETS has allocated a humidicrib within a receiving NICU, the pediatrician at the remote hospital will contact the receiving on-call neonatologist from the NICU (who may or may not be located within the NICU at that time) for a predischarge/preadmission consultation and to determine whether a transfer discharge is required. If they decide not to transfer the baby the paediatrician continues the treatment/observation activity. If they decide a transfer discharge is required, NETS is contacted again to arrange the transfer. The pediatrician will then prepare the discharge summary. If the discharge is a transfer, NETS perform the activity of transferring the baby.

Neonate or Ill Term Baby Patient Journey—Referral Hospital

The neonatal or ill-term baby patient journey for a baby admitted into a tertiary hospital's NICU is summarised in Figure 3. Once admitted to the *NICU*, they then, similarly to that defined earlier, begin to undergo the complex Treatment/Observation activity. Of relevance to this research is the point(s) during the treatment/observation activity that the attending neonatologist will assess whether the baby can be discharged, or whether surgery may be required. If surgery may be required, then a transfer will be required. They will contact NETS to determine the transfer destination to confirm which children's hospital the baby will be transferred to. Once NETS has allocated a humidicrib within a receiving NICU, the Neonatologist at the tertiary hospital will contact the receiving on-call neonatologist from the children's hospital NICU (who may or may not be located within the NICU at that time) for a predischarge/preadmission consultation prior to surgery and to arrange the transfer. The neonatologist will then prepare the discharge summary. If the discharge is a transfer, NETS perform the activity of transferring the baby. Within the children's hospital, the baby undergoes the same patient journey as that of the referral hospital. The surgery is performed during the treatment/observation. Once the baby is stable post surgery, NETS are contacted to arrange the return of the baby to the tertiary hospital NICU and a similar transfer process proceeds.

Determine Inter and Intra Information Flows

As can be seen from Figure 2 and Figure 3, interorganization information flows are required to support the following activities:

1. *Determine Transfer Destination*
2. *Predischarge/Preadmission Consultation*
3. *Transfer Baby*

Determine Transfer Destination

The pediatriciation/neonatologist require the ability to contact NETS to determine where a humidicrib is available to receive the transferred baby.

Predischarge/Preadmission Consultation

The neonatologists located at both the children's hospitals and tertiary referral hospitals require the ability to obtain information from the monitors attached to babies that are not physically located at that specific hospital, but perhaps at another regional hospital where only limited support for premature babies exists. Similarly, a Neonatologist need not be located within the hospital to view patient data, but should be free to view this information through any secure Internet/Intranet connection.

Transfer Baby

Remote hospitals require the ability to send discharge information through to the receiving NICU in a standardised format to enable the receiving NICU to integrate the information directly within the receiving hospitals database.

In addition, there is a need to extract information from NICU databases to automate the preparation of discharge information to be sent to the receiving NICU.

Finally, the pediatriciation/neonatologist requires the ability to contact NETS to confirm the execution of the transfer.

Web Services Design

To support the information flows required as detailed in the previous section, five Web services are required to satisfy each of the listed information flow functions namely the:

1. Availability Web Service established by NETS
2. Physiological Log Web Service established by each NICU
3. Allocation Web Service established by NETS
4. Clinical Web Service established by each NICU
5. Analyse Web Service established by each NICU

Each Web service is detailed briefly below.

Availability Web Service

A database of all receiving neonatologists, together with their hospital's details are contained within the Referral Database. This information provides details based on humidicrib availability. The Referral Database is located within NETS and accessible via a set of Web services. The *Availability Web Service* forwards details of the receiving Neonatologist together with the details for the receiving Neonatologist's *Physiological Web Service*. Further details on Web services by NETS are contained in (McGregor, Kneale et al., 2005, 2006).

Physiological Web Service

To address the need for standardising physiological data transmission, a Web service based framework for the transmission, display, and storage of physiological data for local and remote neonatal intensive care has been established known as the *physiological Web service*. The Web service enables transmission of time interval packets of physiological data through the *physiological Web service* by sending *Physiological Log Packets* and receiving *Acknowledgements*. Further details on the *physiological Web service* are contained in (McGregor, Heath et al., 2005; McGregor, Purdy, & Kneale, 2005).

Allocation Web Service

This Web service enables NETS to be advised of the execution of the transfer.

Clinical Web Service

This Web service enables the receiving NICU to advertise the standardised format to receive discharge information from other hospitals

Analyse Web Service

This Web service enables NICUs to extract discharge summary information from their systems to send to receiving NICUs via their Clinical Web Service.

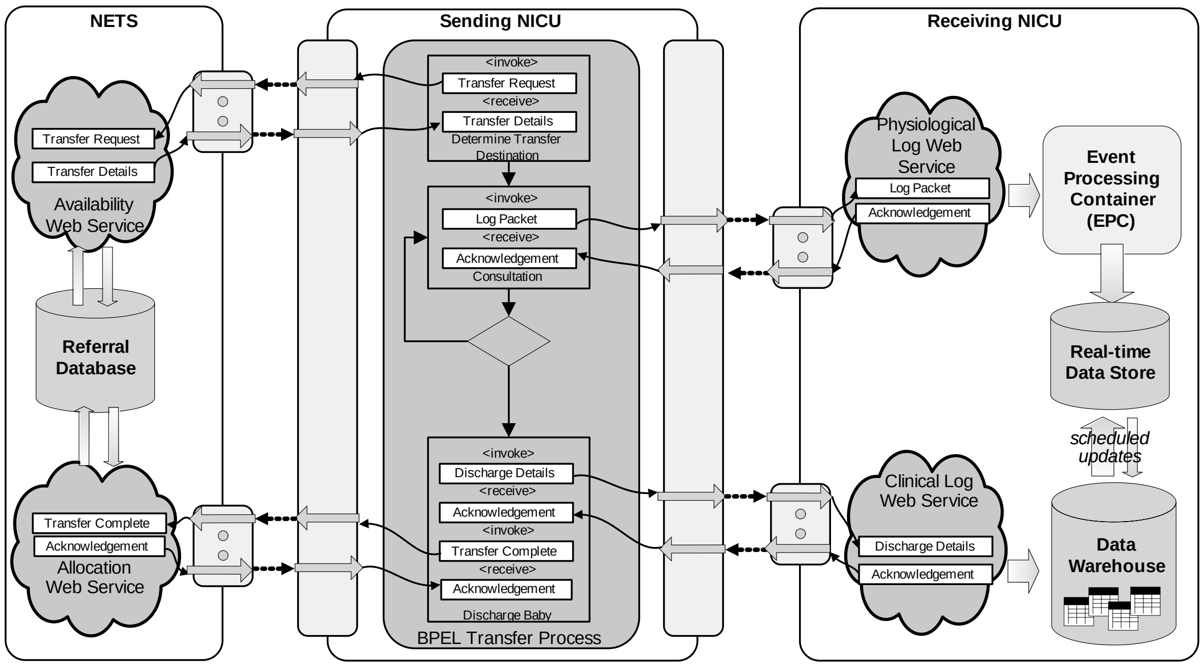
BPEL Design

The BPEL design of the patient journey as detailed previously are now presented in the following two subsections. The Web services introduced in the previous section are invoked at the appropriate place in the patient journey.

BPEL Transfer Patient Journey—Remote Hospital

The BPEL Transfer Patient Journey from a remote hospital is summarized in Figure 4 highlighting calls to the *Availability Web Service*, *Physiological Web Service*, *Clinical Web Service* and finally the *Allocation Web Service*.

Figure 4. BPEL Transfer Process—Remote to NICU



BPEL Transfer Patient Journey—NICU to NICU

The BPEL Transfer Patient Journey between NICUs is summarized in Figures 4 and 5, highlighting calls to the *Availability Web Service*, *Physiological Web Service*, *Clinical Web Service,* and finally the *Allocation Web Service*. In addition during the Discharge Baby activity a local call to the local *Analyse Web Service* is made to gather the information to be forwarded via the *Clinical Log Web Service*.

PATIENT JOURNEY PROTOTYPES

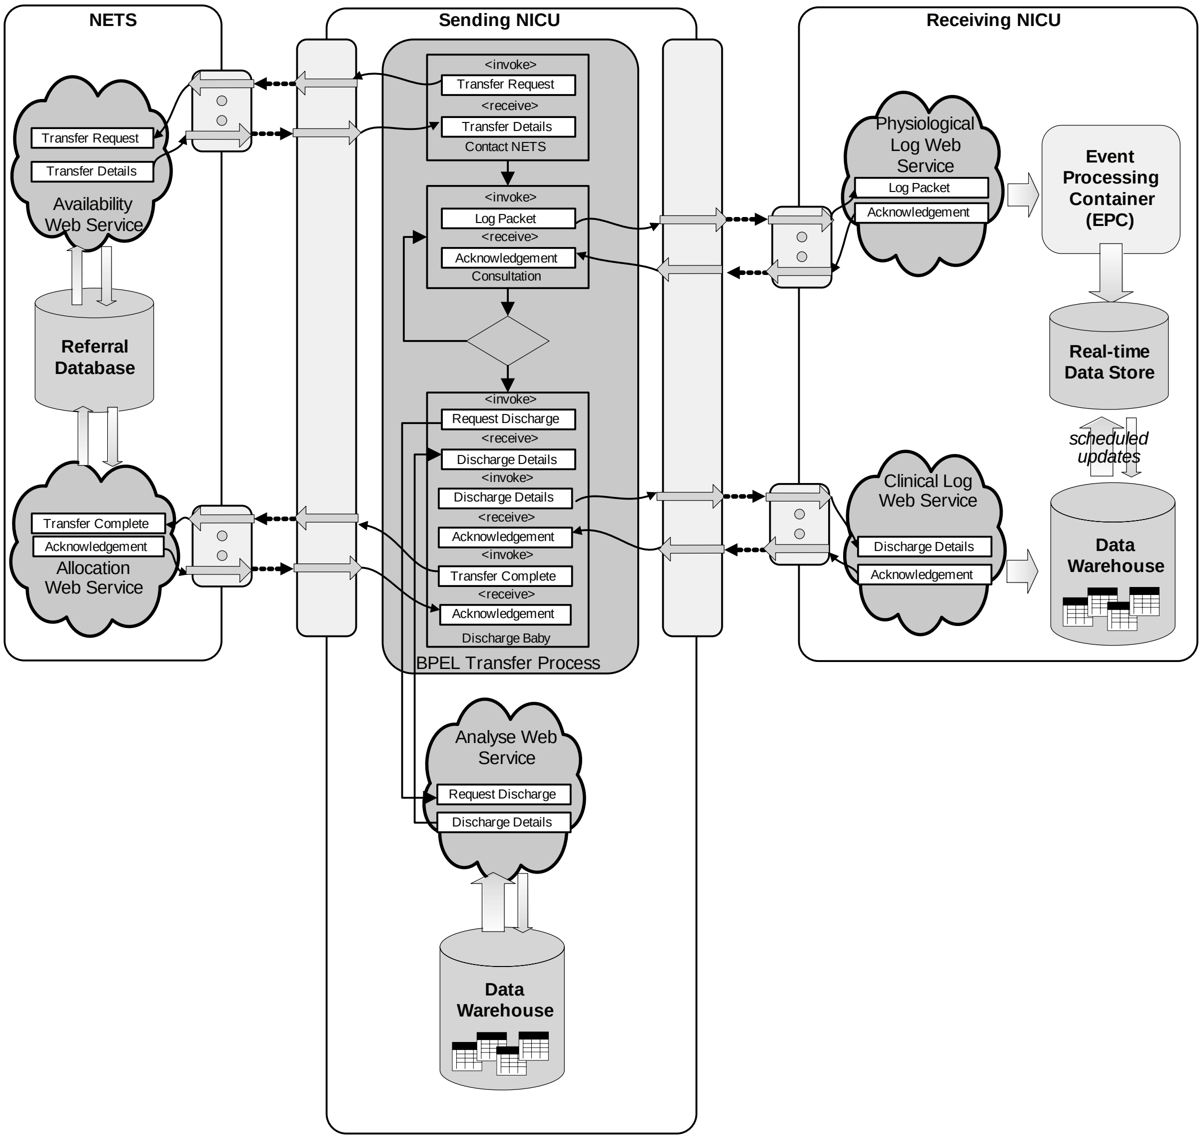
Several of the Web service components within this research have been or are currently being prototyped within or in association with the Nepean Hospital NICU.

The *physiological log Web service* and Data Warehouse components of the Solution Manager Service have been demonstrated via a pilot development using physiological data supplied by a Dragar Ventilator and the Phillips Component Monitoring System (CMS) monitor (McGregor, Heath et al., 2005). Initial testing of compression of XML encoded physiological data streams to improve Web service performance is detailed in (McGregor, Purdy et al., 2005).

The NETS *availability Web service* and *Referral Database* has been developed and are currently being prototyped as part of the Bush Babies on Broadband component of the e-Baby collaboration (McGregor, Kneale et al., 2005, 2006).

XML encoding of the discharge summary has been completed and further testing of the generation of this XML coded discharge summary will form part of our future research.

Figure 5. BPEL transfer process—NICU to NICU



CONCLUSION AND FUTURE WORK

This article has presented case study based research supporting the development of a framework for the design of Web-service-based Clinical Management systems to support intra- and inter-organizational patient journey workflows. The framework enables the modeling of existing patient journeys and supports the reengineering of these patient journeys to improve communication between clinicians and remove duplication, wasted and excessive activities. Web Services are designed that enable greater support for inter- and intra-organizational transfer of patient data. To facilitate the coordination of the complete inter and intra organizational patient journeys, Business Process Execution Language for Web services (BPEL) is used. A key benefit of this framework is that it enables the establishment of "on demand" patient journeys eliminating the need to establish permanent point to point connections.

This article further describes the application of that architecture to a specific pilot in association with the NICU at Nepean Hospital, Penrith Australia where several of the Web services have been or are currently being tested and trialed. The set of Web services described here have been found to enable mobility, interoperability, alert delivery, and to improve data capture for later research and analysis. While the paradigm shift to using Web services within BPEL processes to support NICUs offers the potential to significantly improve the speed, efficiency, and effectiveness of critical care within NICUs, there are currently several factors impacting its mainstream adoption. These include issues relating to the use of wireless networks in addition to security, privacy, cost, and a lack of standards for physiological data capture and exchange and user interface design. In addition, management issues associated with inter-organization collaboration impact embracing such approaches.

While this research has used cross-functional flowcharts to model the patient journey, research has commenced on an alternate patient journey modeling/communication tool to more richly describe patient journeys (Curry, McGregor, & Tracy, 2006).

Data security and privacy are significant issues within the healthcare domain. Future research has commenced to incorporate privacy policy information and security models during all phases of this framework.

ACKNOWLEDGMENTS

This research is supported by an Australian Research Council (ARC) Linkage Project Grant (LP0561518). In addition, the researchers wish to thank the staff of the Neonatal Intensive Care Unit, Nepean Hospital, Sydney West Area Health Services, NSW, for their continued support and collaboration in this research.

Chapter 2.7
Conceptual Framework for Mobile-Based Application in Healthcare

Matthew W. Guah
Erasmus University Rotterdam, The Netherlands

ABSTRACT

The significance of aligning IT with corporate strategy is widely recognised, but the lack of an appropriate framework often prevents practitioners from integrating emerging Internet technologies (like Web services and mobile technologies) within organisations' strategies effectively. This chapter introduces a framework that addresses the issue of deploying Web services strategically within a mobile-based healthcare setting. A framework is developed to match potential benefits of Web services with corporate strategy in four business dimensions: innovation, internal healthcare process, patients' pathway, and management of the healthcare institution. The author argues that the strategic benefits of implementing Web services in a healthcare organisation can only be realized if the Web-services initiatives are planned and implemented within the framework of an IT strategy that is designed to support the business strategy of that healthcare organisation.The chapter will use case studies to answer several questions relating to wireless and mobile technologies and how they offer vast opportunity to enhance Web services. It also investigates what challenges are faced if this solution is to be delivered successfully in healthcare. The healthcare industry globally, with specific emphasis on the USA and United Kingdom, has been extremely slow in adopting emerging technologies that focus on better practice management and administrative needs. The chapter elaborates on certain emerging information technologies that are currently available to aid the smooth process of implementing mobile-based technologies into healthcare industry.

INTRODUCTION

This chapter is based on research—using a longitudinal case study—into the National Programme for Information Technology (NPfIT). NPfIT is an initiative that has been budgeted to cost the UK government £6.3 billion for the purpose of improving the information systems in the National Health Service (NHS), with emphasis on IT infrastructure and the creation of a nationwide patient database.

The significance of aligning IT with corporate strategy in healthcare organisations is widely recognised, but the lack of an appropriate framework often prevents medical practitioners from integrating emerging Internet technologies (like Web services and mobile technologies) within healthcare organisations' strategies effectively. This chapter introduces a framework that addresses the issue of deploying Web services strategically within a mobile-based healthcare setting. A framework is developed to match potential benefits of Web services with corporate strategy in four business dimensions: innovation, internal healthcare process, patients' pathway, and the management of healthcare institution. The author argues that the strategic benefits of implementing Web services in a healthcare organisation can only be realized if the Web-services initiatives are planned and implemented within the framework of an IT strategy that is designed to support the business strategy of that healthcare organisation.

The chapter will also consider certain essential issues regarding the deployment of any mobile data solution (i.e., reliability, efficiency, and security) in the healthcare industry and how such deployment can support healthcare professionals in saving patients' lives. Using case studies, the chapter will answer the following questions:

- Wireless and mobile technologies offer vast opportunities to enhance services, but what challenges are faced if this solution is to be delivered successfully in healthcare?
- Why has the global healthcare industry, with specific emphasis on the USA and United Kingdom, been extremely slow in adopting technologies that focus on better practice management and administrative needs?
- How complacent can IS strategists be to the productivity paradox in the wake of HIPAA (Health Insurance Portability and Accountability Act in USA) and NPfIT (in UK)?
- What emerging information technologies are there to aid the smooth process of implementing mobile-based technologies into the healthcare industry?

The existing economics and IS literature on information-technology adoption often considers network externalities as one of the main factors that affect adoption decisions (Brown & Venkatesh, 2003). It is generally assumed that potential adopters achieve a certain level of expectations about network externalities when they have to decide whether to adopt a particular technology. However, there has been little discussion on how the potential adopters reach their expectations. This chapter attempts to fill a gap in the literature on the adoption of mobile healthcare technology by offering an optimal control perspective motivated by the rational expectations hypothesis and exploring the process dynamics associated with the actions of decision makers in the healthcare industry. They must adjust their expectations about the benefits of a mobile healthcare technology over time due to bounded rationality. The model posed in this chapter addresses mobile healthcare technologies that exhibit strong network externalities. It stresses adaptive learning to show why different healthcare organisations that initially have heterogeneous expectations about the potential value of a mobile healthcare technology eventually are able to arrive at contemporaneous decisions to adopt the same technology, creating the desired network externalities. This further allows these organisations to become catalysts to facilitate processes that lead to healthcare industry-wide adoption.

BACKGROUND

The NHS has been responsible for the provision of healthcare and services in the United Kingdom for the past 56 years on the basis of being free for all at the point of delivery. The traditional perception of the NHS is one of a healthcare system organised as a professional guild, with unlimited finance from the government. This type of NHS is experiencing an irrevocable change as taxpayers are no longer complaisant and paternalistic employers are reacting against inflating costs and escalating complaints from the patients. The employer is reacting to the continuous massive flow of subsidies for inefficient physician practices, fragmented delivery systems, and cost-unconscious consumer demand. The patients are increasingly assertive as to their preferences and few have expressed their willingness to make additional contributions for particular health benefits and medical interventions.

Web services are technologies with roots in the Application Service Provision (ASP) business model that are used mostly to automate linkages among applications (Hagel, 2002). They are generally anticipated to make critical system connections not only possible but also easy and cheap (Kreger, 2003; Sleeper & Robins, 2001). One of the perceived benefits of Web services is that organisations would be able to concentrate on their core competencies (Perseid Software Limited, 2003). Service providers argued that the remote delivery of software applications would release managers from the perennial problems of running in-house IT departments, allowing more time to develop IT and e-business strategy rather than the day-to-day operations (Currie, Desai, & Kahn, 2004). This justification has been used in traditional forms of outsourcing over many years (Willcocks & Lacity, 1998).

The NHS is experiencing massive changes in the structure of information systems provision markets and organisations. The local service provision (LSP) and national service provision (NSP) models in use by the NPfIT are in a state of ferment. The payment methods borrow from both capitation and fee for service, and methods of utilisation management are compromised between arm's-length review and full delegation (Guah & Currie, 2006). LSP and NSP consist of large and more complex entities. These are the result of merger, acquisition, and product diversification. The service providers involved have had to take on a visible feature of ceaseless acquisition and divestiture, integration and outsourcing, and combination and recombination. Providers of medical systems, hospital administration systems, and health plans are coming together and then coming apart. They are substituting contracts for joint ownership, creating diversified conglomerates and refocused facilities, and experimenting with ever-new structures of ownership, finance, governance, and management (Robinson, 2000). These would give the NHSIA (National Health Service Information Authority) the benefits not only of a middle ground between the extremes of vertical integration and spot contracting, but also a balance of coordinated and autonomous adaptation in the face of its ever-new challenges.

The general assumption is that expenditures in the nation's health will outpace the overall growth in the economy (Collins, 2003; Pencheon, 1998). This is reflected in the percentage of the GDP (gross domestic product) of USA (13%), Germany (10.7%), France (9.6%), and the United Kingdom (7.6%) being devoted to the total cost of healthcare resources (Brown, 2002). Unlike the United Kingdom, however, some of these countries are faced with limitations in social willingness to pay. It has been documented that millions of U.S. residents currently lack the most basic insurance coverage (Institute of Medicine, 2002).

Response to Emerging Technologies in the NHS

Over the years, nontechnologists in the NHS have managed to muddle through one powerful new system after another. Generational strategy is one continuously being used to deal with some of the pressures induced by IS. Adopting such innovations as PCs (personal computers) and the Internet requires the personal and organisational costs of unfreezing deeply ingrained old habits. Many workforces ignore, deny, or deal awkwardly with such technologies.

Srinivasan, Lilien, and Rangaswamy (2004) found several reasons why an organisation should respond to new technology development. Two major reasons are listed below:

- Technological change is a principal driver of competition. This is principally because it destroys monopolies, creates new industries, and renders products and markets obsolete.
- Additional sources—both within and outside the organisation or industry—are increasingly complementing in-house technology development efforts.

A common response to new systems is the "not invented here" (NIH) syndrome (Collins, 2003; Guah & Currie, 2004; Haines, 2002). This often leads to certain organisations rejecting a perfectly useful system based on an implicit assumption that the system does not fully recognise or accommodate their own needs and idiosyncrasies (Brown & Venkatesh, 2003; Davis, 1989). Davis sees this as a likely result of a decline in communication with external sources. NIH syndrome could also result from competences that can be proven to be outdated and inefficient in comparison to an existing technology. One Trust, which places a central role in the direction of regional IS strategy, had to reject a system promoted by the Department of Health because the system was not as familiar as another bespoke system (Haines).

The common characteristics of new systems in the NHS are uniformity in products and prices in the face of great variability in consumer preferences and the actual costs of providing service (Collins, 2003). This one-size-fits-all approach usually leads to services that are of excessive costs for some users and insufficient quality for others, impeding the use of price flexibility to enhance capacity utilisation (Robinson, 2000). Also of concern is a combination of overcapacity and low load factors in some regional trusts with undercapacity and shortages elsewhere. Concerns are growing in the NHS that this may generate cross-subsidies from trusts for which the cost of service will be low to trusts for which the cost of service will be high (McGauran, 2002). Additionally, deregulation of healthcare costs has spurred an outpouring of new services. Consequently, several of these services are the following (Collins; Pencheon, 1998):

- A different cost structure.
- An impact on IS budgets.
- A better match between supply and demand.

Incomplete information has been a fascinating attribute of the NHS's unusual system's organisational and normative characteristics. The asymmetry of NHS information between patients and medical practitioners has changed in an exogenous fashion over its 56 years. The amount of healthcare information available to patients is usually the result rather than the cause of changes in the economic and political environment (Robinson, 2000).

PROJECT DESCRIPTION: NATIONAL PROGRAMME FOR INFORMATION TECHNOLOGY

The NPfIT is an initiative by the National Health Service Information Authority, born as a result of several plans to devise a workable IS strategy for the NHS (NHSIA, 2003; Wanless, 2002). The NPfIT was designed to connect the capabilities of modern IT to the delivery of the NHS plan devised in 1998. The core of this strategy is to take greater control of the specification, procurement, resource management, performance management, and delivery of the information and IT agenda (NHSIA).

The NPfIT is an essential element in delivering the NHS plan. It has created £6 billion information infrastructure, which could improve patient care by increasing the efficiency and effectiveness of clinicians and other NHS staff. The intention of the plan is to address the following (http://www.npfit.nhs.uk):

- Create an NHS Care Records Service to improve the sharing of consenting patients' records across the NHS.
- Make it easier and faster for GPs (general practitioners) and other primary care staff to book hospital appointments for patients.
- Provide a system for electronic transmission of prescriptions.
- Ensure that the IT infrastructure can meet NHS needs now and in the future.

The decision to implement a national programme for IT into the NHS system complexity is only the first step in the IS modernisation journey for a multifaceted organisation. There are many examples of new technologies disrupting organisational routines and relationships in the NHS (Atkinson & Peel, 1998; Majeed, 2003; Metters, Abrams, Greenfield, Parmar, & Venn, 1997). These usually require both medical professionals and NHS regional trusts managers to relearn how to work together. Orlikowski (1993) and Edmondson (2003) suggest that one technology can be seen differently by two groups of people in an organisation. Findings from Barney and Griffin (1992) and Orlikowski have showed how this could result in the elicitation of different responses for members of that organisation.

Scope of Project Work

The chapter takes a more in-depth look at the role of the NHSIA (seen as the project leader for the NPfIT), currently the most visible spokesperson and translator for the potential implications of the resulting new technologies. Research has shown NHS IS staff to pay particular attention to what the NHSIA says and does in regard to information systems (Collins, 2003; Ferlie & Shortell, 2001). This research builds on a framework that identifies the key dimensions of the NHSIA tactic that is situation specific for NPfIT assumptions. The work looks at the NHSIA goal and roles for the NPfIT, as well as the role of the private-sector service providers in the implementation of NPfIT.

Here are a few objectives the NPfIT hopes to accomplish:

- To have a series of tightly specified and priced framework contracts on a short list (of about five) primary service providers (PSPs) who can work at the regional and local Strategic Health Authority (StHA) level. This should enforce the integration and implementation partnership—at a national level—during all aspects of the NPfIT project. Each PSP will have an aligned consortium of service providers and vendors for the integrated care resource service element of the NPfIT, and will be mandated to work with the domain PSP for electronic booking, the infrastructure providers, and healthcare providers. StHA PSPs may not make their products exclusive or mandatory to their StHA.
- To create priced packages of national services and applications that the PSPs and StHAs can together implement locally. This activity will include managing the creation of a single Human Resource Information Systems (HRIS) and other national services to access and move health-record information as required.
- To create service-level agreements for the national services and other services out of the scope of the PSP consortium that the PSPs can work toward in providing an integrated service to the StHA
- To develop and maintain the national standards and specifications that all vendors must use. It is also anticipated to create the national business cases required for the

Department of Health governance (required by the National Treasury), and to support the local decision-making business cases required at the StHA level.

- To procure, under national contracts, a backbone network infrastructure

Such an arrangement provides the greatest clarity in respect to the appropriate allocation of responsibilities and should be well understood in the public and private sectors (see Table 1). Services will be procured on a long-term basis so the combination of local and central funding will be required for at least 5, and preferably 10, years at guaranteed levels.

THE RESEARCH STUDY

This study intended to address the gap in the existing literature with regard to the complex issues surrounding the adoption of mobile technology in healthcare. I define mobile healthcare as the use of all kinds of wireless devices (cell phones, personal digital assistants, mobile e-mail devices, handheld computers, etc.) to provide health information and patient-care records to healthcare practitioners, patients, and their caregivers, employers, and employees of health service providers and public regulars of healthcare and services.

Table 1. PSP implementation timetable (as of July 2002)

Activity/Output	***Target Date***
Agree on procurement strategy (Department of Health (DoH) & local health authorities)	End Jul 2002
Service requirement finalized and approved	End Sep 2002
Outline business case developed and approved	End Sep 2002
Official Journal of European Communities (OJEC) advert	Oct 2002
Procurement of systems and implementation services for electronic booking begins	Oct 2002
National long list of PSPs created	Dec 2002
Invitation to negotiate issued	Jan 2003
National short list of PSPs created	Apr 2003
First local health authorities begin detailed planning with PSPs	Aug 2003
PSP framework contract finalized	Oct 2003
Infrastructure provider(s) contract agreed	Oct 2003
First local health authorities begin implementation	Nov 2003
Infrastructure migration begins	Mar 2004

The findings reported in this chapter are part of a larger 5-year research study that was developed to investigate the deployment, hosting, and integration of the ASP and Web-services technologies from both a supply-side and demand-side perspective. The overall research was in two phases. The first phase, comprising of a pilot study, was conducted in the USA and United Kingdom (Currie et al., 2004). An exploratory-descriptive case-study methodology (Yin, 1994) was used to investigate 28 ASP vendors and seven customer sites in the United Kingdom. The dual focus upon supply side and demand side was critical for obtaining a balanced view between vendor aspirations about the value of their business models and customer experiences, which may suggest a less optimistic picture. The unit of analysis was the business model (Amit & Zott, 2001), not the firm or industry level, so a case-study methodology was anticipated to provide a rich data set for analysing firm activities and behaviour (Currie et al.).

The result from the pilot study led to the funding of two additional research studies by the Engineering and Physical Sciences Research Council (EPSRC) and Economic and Social Research Council (ESRC) respectively. Industrial collaborators were selected for the roles of technology partners, service providers, and potential or existing customers. These studies were concerned with identifying sources of value creation from the ASP business model and Web-service technologies in different vertical sectors (including health).

Research Methodology

The research followed a number of stages involving the use of both qualitative and quantitative data-collection techniques and approaches (Walsham, 1993). A questionnaire survey was distributed by e-mail to businesses and healthcare organisations all over the United Kingdom. These organisations were listed on a national database maintained by the NHSIA, plus those maintained by the university. To ensure relevant managers and practitioners responded, the covering note clearly stated the purpose of the questionnaire and requested that it be passed on to the person(s) with responsibility for managing healthcare e-business strategy. Scales to address the research questions were not available from the literature, so the questionnaire was developed based on the theory of strategic value (Banker & Kauffman, 1988). It included a checklist, open-ended questions, and a section seeking organisational data. Research questions under Part 1 required respondents to answer yes or no if the application of Internet technologies in healthcare were bringing value to patients. Data in Part 2 of the questionnaire were collected by open-ended questions seeking respondents' views on the best approach to healthcare performance improvement and Web-service value creation. This line of questioning was used to increase the reliability of data since all respondents were asked the same questions, but some added additional information. The purpose was to impose uniformity across the sample of representation rather than to replicate the data obtained from each participant (Yin, 1994).

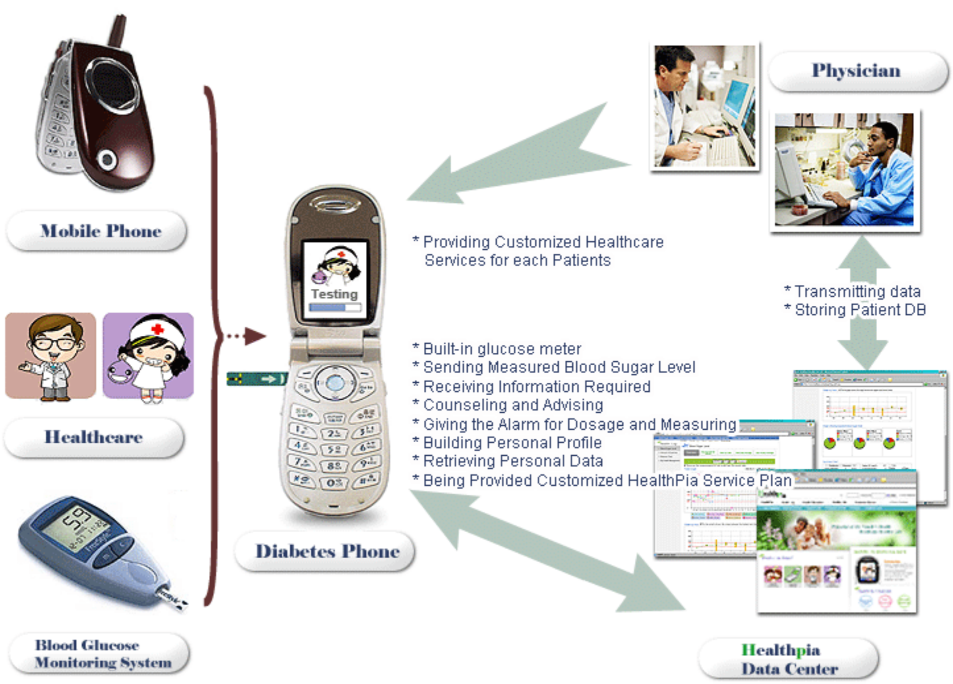
PATIENT-INFORMATION MANAGEMENT

Healthcare organisations are showing a clear interest in accelerating the transformation of clinical care through the routine use of appropriate emerging technologies by clinicians when diagnosing problems and subsequently planning and administering patient care. To support such noble efforts toward delivering better healthcare to the public, President George Bush and other national leaders have publicly called for the development of a national health information infrastructure. The U.S. government (in 2005) has over the past 2 years published plans for all Americans to have an electronic health record by 2014. Similar to the NPfIT in the United Kingdom, the plans call for a hierarchical set of local, regional, state, and national networks that facilitate peer-to-peer sharing of patient records.

When considering the deployment of any mobile data solution, reliability, efficiency, and security are essential, none more so than in the emergency services if lives are to be saved. To support such communication of critical and personal information, there has been an increased demand for the creation of electronic methods for storing and tracking clinical information (see Figure 1). This requires the solution for some fundamental architectural problems within the healthcare environment: scalability, reliability, recoverability, interchangeable vocabularies, and integration:

- Most service providers can support several thousands of simultaneous log-ons. Many are finding it difficult to demonstrate scalability in thin-client, rules-based order entry or structured clinical information.
- Service providers need to show evidence that they have appropriate schedules for downtime because healthcare organisations require reliability of 99.999% due to the critical nature of the information in the healthcare industry.
- There has to be a recognisable solution for a very quick data-recoverable plan in the event that downtime or a system failure occurs. Healthcare organisations have to ensure there are fault-proof backup plans to provide medical practitioners with information that is only available in an electronic form in the event that systems become suddenly unavailable. Certain work processes in the healthcare industry (including emergency care, scheduling, registration, order entry, and clinical procedure recording) would need to continue seamlessly, even with a primary-system interruption (see Figure 1). After there has been an interruption, recovery must be complete with no loss of

Figure 1. Flexible and independent patient care (http://www.healthpia.us/services.asp)



information. Backup, therefore, must prevent any IT failure from making care to the patient impossible. Where mobile healthcare technology is involved, adequate hardware, infrastructure, and tested processes should exist as part of a complete implementation to guarantee this recoverability.

Due to a previous lack of harmonized acquisition, healthcare organisations in both the United Kingdom and USA are frequently challenged by a variety of code sets and files that have proliferated across various healthcare institutions. HIPAA attachment transactions (in the United States) and the NPfIT (in the United Kingdom) are beginning to dictate that the future exchange of patient information be carried out electronically between healthcare organisations. To facilitate this portable and interoperable mobile healthcare technology, certain local vocabularies need to be replaced and the use of government-specified code sets should be synchronized. The way forward is to maintain current systems and historic data through mapping infrastructures that manage the correct translation, giving semantic meaning to patient data with the hope that one day soon there will be a complete migration to common vocabularies.

Many applications currently in the NHS have been designed with the assumption that that the approach and architecture does not need to co-exist and interoperate. While some of these may support integration with other applications that also have significantly different philosophical stances, they do not fully recognise that the need for a healthcare organisation to implement a total solution involves the practicalities of many different dimensions of time, scope, economics, and service providers' organisational politics. Toward this goal, all interoperability for a mobile healthcare technology should require that all features and functions work across all applications. The NPfIT project is proving that all service providers have to significantly alter their current approach to internal and external integration, security, and nomenclatures during the life of the project.

Case 1: MotoHealth

Motorola, along with its partners, initiated a telemedicine service at Harvard Teaching Hospital called MotoHealth (http://www.motorola.com/mediacenter/news/detial) late 2004. The Motorola solution uses mobile phones to help healthcare professionals to monitor chronically ill patients during their normal daily routines. This product was designed to meet the customer's convenience, and as a discreet way of monitoring patients in the mobile environment, can replace in-home hospital and home monitoring devices. As a result, it gives the patient more independence to continue daily activities virtually anywhere they like. This method to providing healthcare pushes healthcare and services out of high-cost health institutions. It enables the patient's body to become the point of care and the mobile healthcare technology becomes the bridge to the patient's body, thus, enabling the delivery of care, educational advice, and support remotely and transparently.

This case has proven that when a mobile healthcare technology is implemented as part of a comprehensive healthcare program, it can give healthcare providers useful daily updates on a patient's physiological levels such as blood pressure, glucose level, and weight control. Such a method of healthcare facilitates proactive treatment action, resulting in fewer hospitalizations and visits to emergency rooms, potentially lowering the increasing demand on the costs of providing healthcare and services to the public.

Policy Issues

Arguably, the most viable techniques for successful mobile healthcare technology implementation are practical guidelines and good management practices. Policies established by a healthcare organisation are the first steps toward this goal.

There are, however, few steps for establishing a policy for mobile healthcare technology:

Guidelines must be developed for the acquisition of mobile healthcare technologies. This would balance the need to encourage innovative applications against wasteful spending, which can be seen by certain members of the staff as duplication of effort. This in turn makes it the responsibility of every medical practitioner who may need a particular type of application to strictly adhere to this policy.

There must be regular inventory taken. This helps to identify and evaluate all installed hardware and software before setting or changing the standards. These would certainly affect policy decisions and future acquisitions. While standards can sometimes be looked upon as restrictive in the IT industry, medical practitioners actually see these to offer benefits for the care providers and the patients alike. Nearly all healthcare organisations have standards that cover many aspects of their operations within the healthcare process. Generally, standards in the NHS are recorded in formal standards and procedures manuals, but in certain cases, we came across informal handwritten notes (i.e., "this is the way we do things here") that are also considered to be standards.

Ruyter, Wetzels, and Kleijnen (2001) show how organisations implementing e-commerce first learn to exploit the Internet for information transfer before supporting transactions, and then finally use it for commercial trading and collaboration among various actors. Considering mobile healthcare is still in its infancy, borrowing from the e-commerce experience will mean that healthcare organisations will probably adopt wireless e-business methodologies first to support their existing healthcare processes and improve efficiency before they come up with new business models to transform the competitive landscape in the healthcare industry.

In the case of the NHS, wireless enterprise implementation issues frequently extend well beyond the technology domain and into areas of medical practices and organisational culture (see Figure 2). Nearly all the regional healthcare trusts that are actively pursuing wireless enterprise strategies at the moment are handcrafting solutions around their own local IT infrastructures and their own homegrown healthcare processes partly because there are very few packaged mobile healthcare solutions on the market.

The focus, currently, is on accessing information via wireless mobile healthcare messaging. However, the future should hold more applications like mobile access, telemedicine, and alerts for facilitating better disease management and controls. Given the emerging state of mobile

Figure 2. Home visits and general-practice consultation (http://www.bmj.com, 2004)

technology and its potential impact on healthcare, mobile healthcare can be seen as truly radical. Mobile healthcare has the potential to remake this entire industry and obsolete established strategies. Most healthcare organisations in Western Europe and North America feel they must participate in this emerging healthcare technology in order to survive the increasing demand to service a continuously evolving patient environment.

The research found two reasons why healthcare organisations are beginning to pay keen attention to mobile healthcare:

- These organisations are being defensive. There is a general belief that newcomers in the healthcare-provision market may be plotting to use new functionalities available through the use of mobile healthcare to attack the incumbents' core providers.
- Converse to the previous reason is the understanding that mobile healthcare could realize its potential. If this happens successfully, mobile healthcare would be too attractive a proposition to ignore, and joining in at a later date may prove too expensive.

The author poses a conceptual framework for the research upon which this chapter is based, showing the different stages of the technology-adoption process for healthcare organisations as well as the main factors operating at each stage (see Figure 3). In the preadoption stage, healthcare organisations take an internal perspective and analyse the fitness of the mobile healthcare technology for the contemplated task as well as the value of this technology. These should be the drivers of the adoption decision. The phase after that shows the healthcare organisation analysing whether organisational and environmental factors are favourable for continuing with this novel technology. This may uncover inhibitors that could slow down the adoption process. In situations where the healthcare organisation decides to implement the mobile healthcare technology in the next stage, it should find adoption facilitators that can help in the diffusion of mobile technology within the healthcare environment. Readers should note that implementation is beyond the scope of this framework.

This framework borrows from the technology-organisation-environment framework put forward by Tornatzky and Fleischer (1990) as well as the deinstitutionalisation framework by Tolbert and Zucker (1994). Tornatzky and Fleischer's framework identifies three aspects of an organisation's context that influence the process by which it adopts and implements innovation: technological context, organisational context, and environmental context. The omission of environmental context here is due to the fact that this chapter is about a single industry in which the environment is held constant.

The author considers innovation in healthcare as an idea, medical practice, or any material artefact in the healthcare process that is perceived to be new by the relevant unit of adoption in medical

Figure 3. Conceptual framework of mobile healthcare technology adoption

treatment. The relative advantage, compatibility, complexity, trial, and observation of such innovation can usually be used to determine the tendency for its adoption in the healthcare environment.

By relative advantage, the author means the degree to which an innovation within the health industry is perceived as better than the idea it supersedes. Compatibility, on the other hand, is seen as the degree to which an innovation within the health industry is perceived as being consistent with the existing values given by a particular healthcare community, or with past experiences and needs of potential adopters within the healthcare process. Compatibility of mobile healthcare technology can also be explained in terms of a combination of what healthcare practitioners feel or think about a particular innovation. This would also involve a critical look at the practical and operational compatibility with what healthcare practitioners are doing in the ongoing healthcare process. This interpretation of compatible innovation is in conjunction with perceived usefulness, the degree to which an end user believes a certain system can help perform a certain medical task. Complexity is the degree to which an innovation within the health industry is seen to be difficult to understand and use within the healthcare industry.

The trial of an innovation within the healthcare industry is an important part of evaluating new technologies within this critical industry. It is the degree to which an innovation within the health industry is experimented with on a limited basis. Given an opportunity to experiment with a new mobile healthcare technology before decisions are made about the adoption is an important benefit, especially for emerging technologies. This is an industry where practitioners take very highly the availability of information, while learning from experiences with previously disappointing IT projects.

Observation is a reliable means by which the healthcare industry evaluates innovations. This process identifies the degree to which the performance of a mobile healthcare technology and related benefits to the patients are visible to the medical practitioners and not only the service providers.

The determinants of mobile healthcare technology adoption are the benefits to the patients vs. the cost of such adoption. Most often, the NHS measures this in terms of the difference in costs for the shift from a previous technology to a mobile healthcare technology. Also worth considering are several factors that are important to the health service, such as the improvements made to the healthcare process as a result of a mobile healthcare technology after its introduction. There might even be a discovery of new uses for the mobile healthcare technology and the development of certain complementary inputs.

Hartmann and Sifonis (2000) relates to some of these features of mobile healthcare technology application by the identification of four dimensions within an organisation: leadership, governance, technology, and operational competencies. By leadership, they referred to the process of managing the initiatives and how the host organisation should stay motivated throughout the adoption process. By governance, they referred to the process of organising the innovation as regards the structure and operating procedures. Technology is where Hartmann and Sifonis looked at the organisation's ability to rapidly develop and implement new applications. They finally explained operational competencies as the way the host organisation manages the coordination of the relationship between leadership, governance, and technology as well as exploiting the available resources.

Levy and Powell (2005), on the other hand, presented evidence—from their study of small and medium-sized businesses in the United Kingdom—that the adoption of emerging technologies posits a similar framework as adoption related to the readiness of organisations taking into consideration the perceived ease of use and perceived usefulness. The readiness of the NHS to adopt mobile healthcare technology can be determined by reviewing the financial and technological resources available as well as various other factors dealing with the compatibility and consistency of emerging technologies with organisational culture and values.

Case 2: Pervasive Monitoring System

Oracle, along with its London partners, piloted a wireless sensor interface technology platform in mid-2005 (http://www.toumaz.com/news.php?act). It used advanced transactional database capabilities and offered the potential to transform the treatment and management of chronic diseases for millions of patients. This project was meant to bring the economies of scale of semiconductors into the healthcare industry with its advantages of real-time, personalised care and the delivery of some form of breakthrough. The system was based on a low-cost, disposable, integrated sensor interface chip.

Due to the chip's ultra low power and very small battery size, it could be worn on the body with complete freedom of movement, or it could be implanted. Such a mobile healthcare technology is compatible with a wide range of sensors (see Figure 4) and can therefore be configured to detect vital signs such as ECG (electrocardiogram), blood oxygen and glucose, body temperature, and mobility. The device can also dynamically process and filter event data (including irregularities in heartbeat or blood pressure) and send the details to a mobile phone or PC via an ultra low-power, short-range radio telemetry link.

Further improvements to this kind of mobile healthcare technology could enhance the quality and efficiency of the healthcare patients of the NHS receive in the future. It could permit the following in future healthcare:

- Provide more timely and personalised care.
- Deliver unprecedented freedom, flexibility, and control for patients.
- Include exciting possibilities for medical practitioners to ultimately offer consumer items for which selection is based on quality and efficiency.

Figure 4. Mobile healthcare technology with built-in sensor (http://www.healthpia.us)

CONCLUSION

This chapter has provided examples of mobile healthcare technologies (case studies) for which the successful delivery of mobile solutions can help with certain kinds of emergency services. When considering the deployment of any mobile data solution, reliability, efficiency, and security are essential, none more so than in the emergency services if lives are to be saved. Wireless and mobile technology offers the opportunity to vastly enhance services, but there are still challenges to be faced if a cost-efficient solution is to be delivered.

Although some of these initiatives described as e-health can deliver certain benefits (including increased productivity and effectiveness of healthcare personnel and improved delivery of information and services), they will be faced with a number of challenges. Service providers in the private sector are looking to government for more leadership on identification issues and, as such, mobile healthcare technology should be a welcomed measure.

IT is seen as a key driver in the delivery of an efficient public sector, but how can departments justify further expenditure and eventually provide a clear road map to return on investment whilst delivering what has been promised? Also, what are the key short-term issues and, more importantly, the solutions that government departments can focus on? This panel will examine the savings that ICT investment is expected to deliver in the public sector, and how to serve more people by making things more efficient.

The United Kingdom has certainly increased its uptake on open-source software since the Office of Government Commerce's (OGC's) announcement that open source is a viable desktop alternative for the majority of users. However, many government organisations have chosen to remain with their existing proprietary software. This panel will examine the advantages and the drawbacks of both software solutions.

While this chapter is not intended to give specific guidelines for using mobile healthcare technologies, the author finds it useful to mention the following two points:

- Have clear objectives. Mobile healthcare technology is only a means to an end. It is advisable for managers of healthcare organisations to not be dazzled by the technology.
- Mobile healthcare technology is a unique medium, requiring management to capitalize on its uniqueness. The information being transmitted by mobile healthcare technology is the same, but is just delivered in a different way.

A conceptual framework has been posed from the research upon which this chapter is based, showing the different stages of the mobile healthcare technology-adoption process for healthcare organisations as well as the main factors operating at each stage.

In conclusion, the author has argued that Web services can aid the strategic planning of a healthcare organisation and can be used for competitive advantage. Web services can also contribute to improving our understanding and management of the critical issues surrounding mobile-based healthcare. Such understanding not only avoids disastrous consequences during the adoption of information systems, but also proves essential in supporting healthcare professionals to effectively manage the current trend of rapid increase in healthcare costs.

ABSTRACT

An enhanced mobile healthcare multi-collaborative system operating over Third Generation (3G) mobile networks is presented. This chapter describes the design and use of this system in different medical and critical emergency scenarios provided with universal mobile telecommunications system (UMTS) accesses. In these environments, it is designed to communicate healthcare personnel with medical specialists in a remote hospital. The system architecture is based on advanced signalling protocols that allow multimedia multi-collaborative conferences in IPv4/IPv6 3G scenarios. The system offers real-time transmission of medical data and videoconference, together with other non real-time services. It has been optimized specifically to operate over 3G mobile networks using the most appropriate codecs. Evaluation results show a reliable performance over IPv4 UMTS accesses (64 Kbps in the uplink). In the future, advances in m-Health systems will make easier for mobile patients to interactively get the medical attention and advice they need.

INTRODUCTION

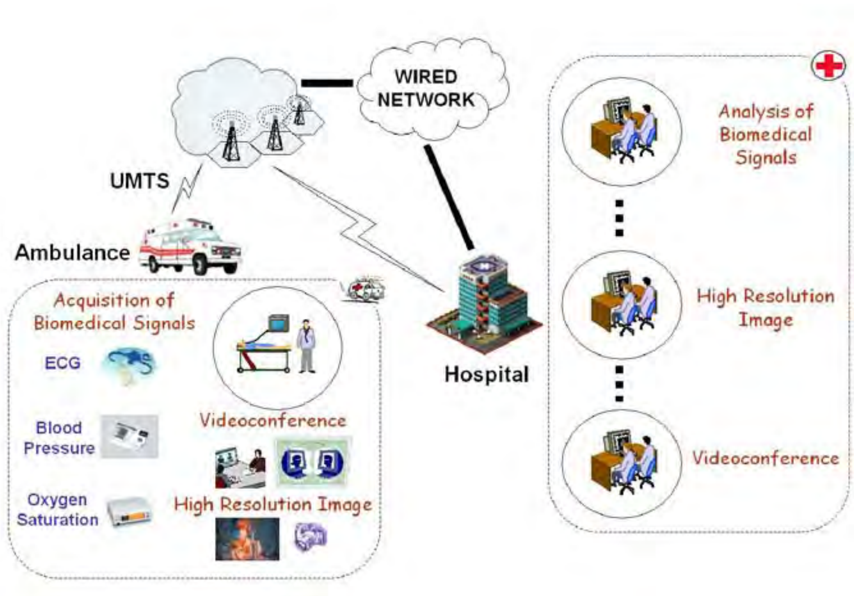
Mobile health (m-health) is an emerging area of telemedicine in which the recent development in mobile networks and telemedicine applications converge. m-health involves the exploitation of mobile telecommunication and multimedia technologies and their integration into new mobile healthcare delivery systems (Istepanian & Lacal, 2003). Wireless and mobile networks have brought about new possibilities in the field of telemedicine thanks to the wide coverage provided by cellular networks and the possibility of serving moving vehicles. One of the first wireless telemedical systems that utilized second-generation (2G) global system for mobile communications (GSM) networks addressed the electrocardiogram (ECG) transmission issues (Istepanian, 2001a). In recent years, several m-health and wireless telemedical systems based on GSM were reported (Istepanian, 2001b), allowing the accomplishment of remote diagnosis in mobile environments, as well as communication to geographic zones inaccessible by wired networks. The recent developments in digital mobile telephonic technologies (and their impact on mobility issues in different telemedical and telecare applications) are clearly reflected in the fast growing commercial domain of mobile telemedical services. A comprehensive review of wireless telemedicine applications and more recent advances on m-health systems is presented in Istepanian, Laxminarayan, and Pattichis (2005).

However, 2G-based systems lack the necessary bandwidth to transmit bandwidth-demanding medical data. The third-generation (3G) universal mobile telecommunications system (UMTS) overcomes limitations of first and second mobile network generations supporting a large variety of services with different quality of service (QoS) requirements. However, this fact makes network design and management much more complex. New applications require networks to be able to handle services with variable traffic conditions keeping the efficiency in the network resources utilization. The UMTS air interface is able to cope with variable and asymmetric bit rates, up to 2 Mbps and 384 kbps in indoor and outdoor environments, respectively, with different QoS requirements such as multimedia services with bandwidth on demand (Laiho, Wacker, & Novosad, 2000). In this kind of scenario, the emergence of 3G mobile wireless networks will permit to extend the use of m-health applications thanks to the provided higher transmission rates and flexibility over previous mobile technologies.

UMTS introduces the IP multimedia core network subsystem (IMS) (3GPP, 2005a), an IPv6 network domain designed to provide appropriate support for real-time multimedia services, independence from the access technologies and flexibility via a separation of access, transport and control. The fundamental reason for using IPv6 is the exhaustion of IPv4 addresses. Support for IPv4 is optional, but since network components require backward compatibility, it is clear that a dual stack configuration (IPv4 and IPv6) must be provided. The IMS uses the session initiation protocol (SIP) as signalling and session control protocol (Rosenberg et al., 2002). SIP allows operators to integrate real-time multimedia services over multiple access technologies such as general packet radio service (GPRS), UMTS or, ultimately, other wireless or even fixed network technologies (interworking multimedia domains). This chapter presents a 3G-based m-health system designed for different critical and emergency medical scenarios, as shown in Figure 1. Several medical specialists in the hospital take part in a multipoint conference with the ambulance personnel, receiving compressed and coded biomedical information from the patient, making it possible for them to assist in the diagnosis prior to its reception.

The 3G system software architecture includes intelligent modules such as information compression and coding, and QoS control to significantly improve transmission efficiency, thus optimizing the use of the scarce and variable wireless channel bandwidth compared to previous systems (Chu & Ganz, 2004; Curry & Harrop, 1998). Finally, unlike Chu and Ganz (2004), this m-health system follows a multi-collaborative design which supports IPv6/IPv4 interworking, uses SIP as

Figure 1. Typical medical mobility scenario



the service control protocol and integrates new real-time multimedia features intended for 3G wireless networks.

3G M-HEALTH SYSTEM ARCHITECTURE

In this section, the 3G m-health system structure is described in detail. The system (see the system components in Figure 2 and the main application graphical user interface (GUI) in Figure 3) has been built using standard off-the-shelf hardware, instead of developing propriety hardware as in Cullen, Gaasch, Gagliano, Goins, and Gunawardane (2001), uses free software and commercially available 3G wireless UMTS cellular data services. In addition, it provides simultaneous transfer of, among other services, videoconference, high-resolution still medical images and medical data, rather than only one media at a time (Kyriacou, 2003; Pavlopoulos, Kyriacou, Berler, Dembeyiotis, & Koutsouris, 1998).

The 3G m-health system consists of different modules that allow the acquisition, treatment, representation and transmission of multimedia information. The modular design of each medical user service allows great flexibility. In addition, there exist other medical user services like chat and electronic whiteboard that allow data exchange in order to guide the operations performed by remote users.

The medical signals module acquires, compresses, codes, represents, and transmits medical signals in real time. The medical signals acquisition devices included are: a portable electrocardiograph that allows the acquisition of 8 real and 4 interpolated leads of the ECG signal, and that follows the standard communication protocol-ECG (SCP-ECG); a tensiometer that provides systolic and diastolic blood pressure values; and a pulsioximeter that offers the blood oxygen saturation level (SpO_2) and the cardiac pulse.

The details of the 3G system architecture are shown in Figure 4 and Figure 5. As it can

Figure 2. 3G m-Health system

Figure 3. m-Health application GUI

be seen, the system comprises of the signalling and session control, medical user services and application control sub-systems, which will be described later.

This architecture allows the 3G system to offer real-time services such as medical data transmission (ECG, blood pressure, heart rate and oxygen saturation), full-duplex videoconference, high-resolution still images, chat, electronic whiteboard, and remote database Web access.

Communication between the remote ambulance personnel and medical specialists is established by means of multipoint multi-collaborative sessions through several network environments capable of supporting the different types of multimedia traffic (Figure 4). The selected conference model (tightly coupled conference model (Rosenberg, 2004)) requires the existence of a MCU (multipoint control unit) to facilitate multipoint operation. The MCU maintains a dialog with each participant in the conference and is responsible for ensuring that the media streams which constitute the conference are available to the appropriate participants. The MCU can belong to mobile's home network (SIP application server) or to a external service platform. Furthermore, the m-health system is developed to support IPv4/IPv6 interworking (Wiljakka & Soinien, 2003) and can be integrated in a 3G network scenario (see Figure 4).

The MCU receives the information generated by each participant in the multipoint conference, processes and forwards it to the appropriate destinations. System users and the MCU exchange information associated with the different services provided (medical user services) and its presentation (application control). Moreover, they exchange information related to communication and service quality management (signalling). Next, a detailed description of the sub-systems is presented.

Signalling and Session Control

The developed signalling allows the exchange of the characteristics associated to the different information flows between system elements and is based on standard protocols that favour interoperability. Signalling tasks, performed by the SIP protocol, begin with the establishment of a SIP dialog with the MCU in which, by means of session description protocol (SDP) messages, the different services are described. In order to do that, each element in the system has a SIP user agent (UA), slightly modified in the MCU to allow the use of multiple simultaneous dialogs.

Figure 4. 3G network scenario

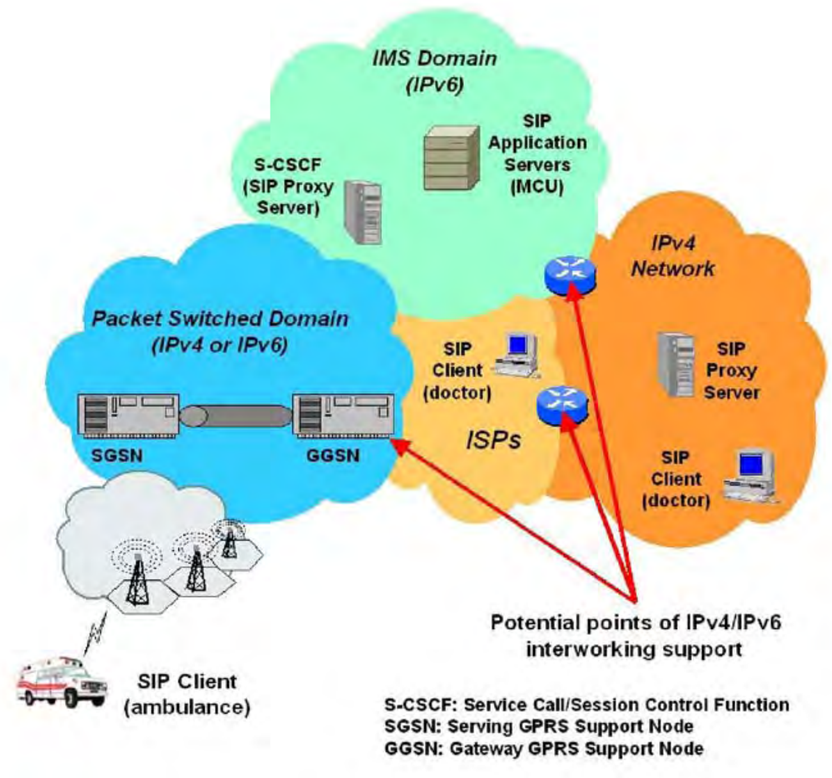


Figure 5. Block diagram of the m-Health system architecture and sub-systems

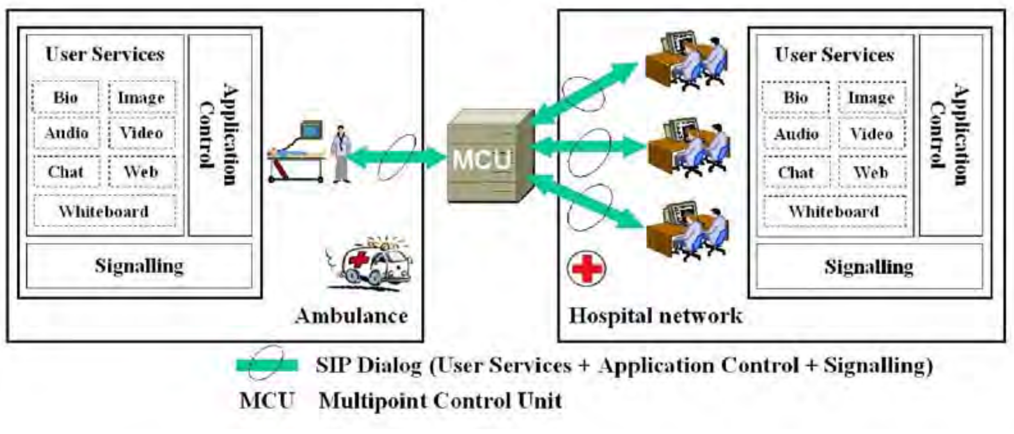


In addition to session control functions (establishment, management and termination of the multipoint conference), the SIP protocol is also useful for user mobility purposes inside the IMS environment.

Multipoint conference establishment, management and termination is performed by exchanging SIP messages between the different users. When a user connects, he creates a SIP dialog with the MCU, joining the conference. During the conference, SIP messages are exchanged between users and the MCU, varying conference characteristics and therefore allowing its management. In a similar process to that of conference joining, when a user wants to leave it, this fact must be communicated to the MCU with the necessary SIP messages. SIP messages also serve as the mean of transport of SDP messages with the description of medical user services.

The QoS in this system is mainly determined by the characteristics of the UMTS link. Mobile links are very variable, therefore a QoS-monitoring process is required in order to obtain a good system performance. This process is especially important in the MCU because it is there where the QoS-related decisions are taken. When the MCU detects that a particular conference participant needs to modify the characteristics of its multimedia session in order to improve QoS, it renegotiates the corresponding session by sending SIP/SDP messages. Hence, conference participants can modify certain upper-level protocol parameters (codecs used, transmission rates, compression ratios, etc.) in order to adapt the transmitted information to network performance.

The QoS monitoring process is possible thanks to a transport library that provides a uniform interface to send the information generated by medical user services and different QoS estimation tools developed for several types of links. This transport library offers different queuing policies and tools designed to measure the following QoS-related parameters: delay, bandwidth and packet loss rate. Due to the variable nature of wireless links, reception buffers have been properly dimensioned to minimize jitter, delay and packet loss.

Wireless Medical User Services

The medical user services included in the m-health system are associated with information shared in a multi-collaborative environment. Specifically, the system has services to share audio, video, medical data information, high-resolution still images, and graphical and textual information, as well as a Web service that allows remote access to clinical information databases. In addition to these services, there is a service designed to exchange control information (application control), which is discussed later.

Each kind of information is associated with a medical user service and uses a transport protocol and a codec according to its characteristics (see Table 1). Hence, real-time services (audio, video, and medical data information) use the real-time transport protocol (RTP), whereas the rest of the services use the transmission control protocol (TCP). Furthermore, the exchanged information can be very sensitive and requires a secure communication. The 3G m-health system uses an IP security protocol (IPSec) implementation supporting public key certificates in tunnel mode. This protocol ensures private communication of selected services.

The ECG signal is stored both in transmission and reception following the SCP-ECG standard. It is well known that for an efficient transmission an ECG compression technique has to be used. In our implementation, a real-time ECG compression technique based on the wavelet transform is used (Alesanco, Olmos, Istepanian, & García, 2003). This is a lossy compression technique, therefore the higher the compression ratio (lower the transmission rate), the higher the distortion at reception. It is clear that there is a trade-off between transmission rate and received ECG signal quality. From the transmission efficiency

Table 1. Codec operation modes for 3G real-time wireless medical user services

	CODEC	CODEC RATE
Audio	AMR*	4.74 5.15 5.9 6.7 7.4 7.95 10.0 12.2 (Kbps)
Video	H.263	5 10 (Frames per second)
Biomedical Signals	WT**	5 10 20 (Kbps)

* *Adaptive Multi-rate*
** *Wavelet Transform*

point of view, a very low transmission rate is desired but from the clinical point of view, a very distorted ECG is useless. Therefore, there exists a minimum transmission rate to be used so as the transmitted ECG is useful for clinical purposes, which was selected in collaboration with cardiologists after different evaluation tests. The minimum transmission rate used in our implementation (625 bits per second and per ECG lead) leads to a clinically acceptable received ECG signal.

Regarding blood pressure, oxygen saturation, and heart rate, these signals have low bandwidth requirements and, therefore, are not compressed.

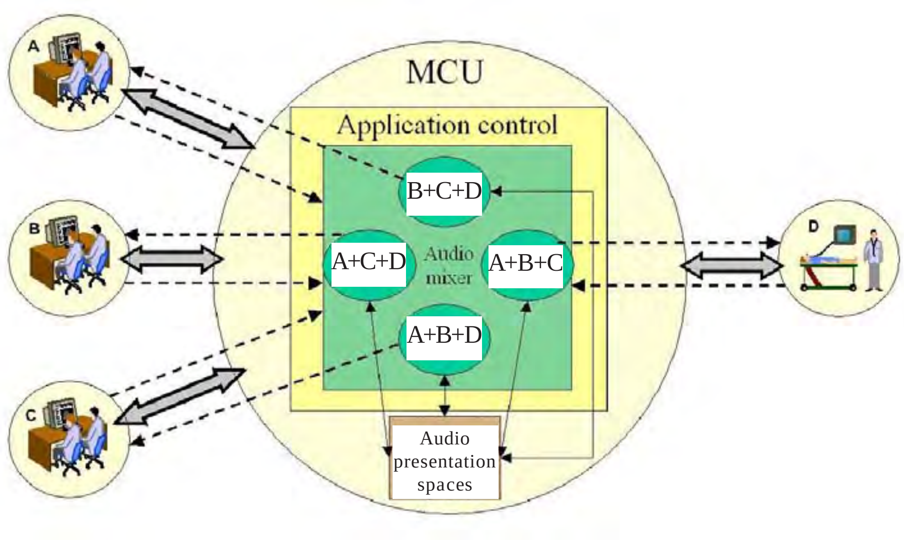
The videoconference module captures, sends, and plays audio and video information obtained by means of a Web camera and a microphone. In order to reduce the bandwidth, these data are compressed and coded. The video signal is compressed following the H.263 standard, whereas the audio signal uses the adaptive multi-rate (AMR) codec, recommended for UMTS by the 3G Partnership Program (3GPP) (3GPP 2005b). This module provides the basic functionality for starting, pausing and stopping video signals acquisition and representation, as well as volume control for the microphone (capture) and the speakers (reproduction). Due to the fact that each participant in the conference receives a unique video signal, the system allows the user to select the particular video signal among all the users connected.

The high-resolution still image module obtains high quality images with a charge copled device (CCD) colour camera connected to the computer through an image acquisition card. This module includes options to preview the captured images and modify their main characteristics in real time: brightness, contrast, hue, etc. Captured images can be stored and transmitted in different formats, with various qualities and compression levels. These images are sent automatically to the electronic whiteboard module of the remote users, allowing to select and mark fixed areas in a multi-collaborative fashion to facilitate a diagnostic clinical procedure.

Application Control

The MCU forwards the information generated by each medical service according to the presentation spaces defined using the control service. Each medical service has a presentation space associated with it that defines the way in which the information has to be transferred and its destination. The MCU simply forwards the information it receives, but has a special treatment for the audio, video, medical data, and control services. Regarding the Audio service, the MCU decodes the signal of each user, mixes it with the decoded signal of the other conference participants and codes the result in order to transfer a unique audio signal to each user (Figure 6). On the other hand, the MCU only forwards one video signal to each conference participant. The particular video

Figure 6. Application control (audio presentation spaces)



signal forwarded to each user is selected by using the control service. Finally, the medical data service is similar to the video service: medical data are only generated in the remote location, whereas the other conference participants can only receive them.

The 3G m-health system was adapted to the critical and emergency medical scenarios. In the first stages of its design, user requirements and functional specifications were established in collaboration with medical specialists, in order to create a portable and modular m-health system that could be easily integrated in any environment, using any underlying network technology capable of supporting IP multimedia services

3G M-HEALTH SYSTEM PERFORMANCE

In order to measure the 3G m-health system performance, several tests have been carried out using the system over 64 Kbps (at IP level) UMTS accesses. Table 2 presents the results about average IP-level bandwidth used by real-time network services.

As it can be observed, considering more audio samples per network packet reduces the used bandwidth, since transmission efficiency (information carried by each packet to total packet size ratio) is increased. However, there is a limit in the number of audio samples per packet that can be used because more audio samples per packet yield more audio delay. For example, a more efficient transmission mode including four audio samples per packet every 80 ms causes four times the delay including only one audio sample per packet every 20 ms. Moreover, if an audio packet is lost, all the audio samples carried by it are lost and, therefore, a reduced number of audio samples per packet is more suitable to error-prone environments. Regarding the video user service, it is worth noting that the bandwidth shown in Table 2 can vary substantially with the movement of the video scene captured. Finally, the medical data service adapts well to the codec rate specified because medical data frame sizes are long enough to obtain a good transmission efficiency.

As it can be checked, the total bandwidth consumed by all real-time medical user services fits in a 64 Kbps UMTS channel, even when the

Table 2. Average IP-level bandwidth used by real-time user services

	Operation Mode		IP Bandwidth (Kbps)
Audio	Samples/packet	Codec rate (Kbps)	
	1	4.75	21.2
	1	12.2	28.8
	3	4.75	10.5
	3	12.2	18.1
Video	Frames per Second		
	5		16
	10		24
Biomedical Signals	Bit Rate		
	5		5.3
	10		10.3

most bandwidth-consuming codec rates and the lowest transmission efficiencies are used. If all medical user services are used (including non real-time services), lower codec rates should be selected. Thus, according to the previous discussions, the codec operation modes selected in this m-health system have been those highlighted in Table 2, achieving a reasonable trade-off between bandwidth, transmission efficiency, delay and loss ratio.

NEXT-GENERATION OF M-HEALTH SYSTEMS

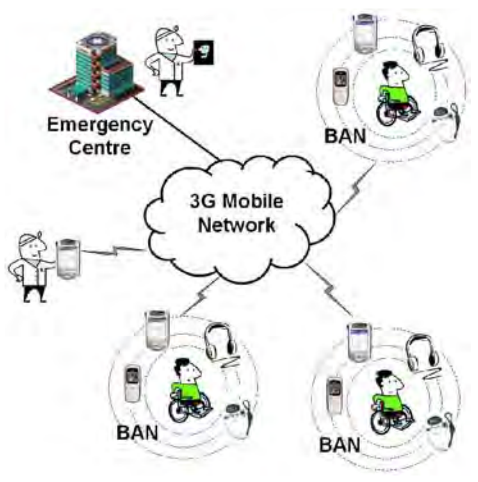
It is evident that organizations and the delivery of health care are being underpinned by the advances in m-health technologies. In the future, home medical care and remote diagnosis will become common, check-up by specialists and prescription of drugs will be enabled at home and virtual hospitals with no resident doctors will be realized.

Hence, the deployment of emerging mobile and wireless technologies will face new challenges: inter-operability between heterogeneous networks (fourth-generation, 4G) and smart medical sensor design integrating sensing, processing, communications, computing, and networking.

With the aid of wireless intelligent medical sensor technologies, m-health can offer healthcare services far beyond what the traditional telemedical systems can possibly provide. The individual sensors can be connected wirelessly to a personal monitoring system using a wireless body area network (WBAN) and can be integrated into the user's clothing, providing wearable and ubiquitous m-health systems. A typical scenario comprises of a WBAN system that communicates with cardiac implantable devices (pacemakers, defibrillators, etc.) and that is linked to the existing 3G infrastructure, achieving "Health Anytime, Anywhere" (Figure 7).

It is expected that 4G will integrate existing wireless technologies including UMTS, wireless LAN, Bluetooth, ZigBee, Ultrawideband, and other newly developed wireless technologies into a seamless system. Some expected key features of 4G networks are: high usability, support for multimedia services at low transmission cost and facilities for integrating services. 4G advances will make easier for mobile patients to interac-

Figure 7. Typical WBAN-3G scenario



tively get the medical attention and advice they need. When and where is required and how they want it regardless of any geographical barriers or mobility constraints.

The concept of including high-speed data and other services integrated with voice services is emerging as one of the main points of future telecommunication and multimedia priorities with the relevant benefits to citizen-centered healthcare systems. The new wireless technologies will allow both physicians and patients to roam freely, while maintaining access to critical patient data and medical knowledge.

CONCLUSION

This chapter has presented a feasible 3G-based m-health system targeted specifically for critical and emergency medical scenarios. The system architecture is based on 3G networks and advanced signalling protocols (SIP/SDP) that allow the integration of real-time multimedia services over multiple access channels that support IPv4 and IPv6 interworking depending on current commercial UMTS releases.

The system has the following features: simultaneous transmission of real-time clinical data (including ECG signals, blood pressure, and blood oxygen saturation), videoconference, high-resolution still image transmission, and other facilities such as multi-collaborative whiteboard, chat, and Web access to remote databases. The system has been optimized specifically to operate over 3G mobile networks using the most appropriate codecs. Evaluation results show a reliable performance over UMTS accesses (64 Kbps in the uplink).

Home telecare and chronic patient telemonitoring are other application areas in which this m-health system can be used, thus further work is currently undergone to adapt it and to evaluate its performance in each particular scenario.

KEY TERMS

4G: The fourth-generation (4G) is the continuation of the first, second, and third generations of mobile networks. It is a wireless access technology that provides high-speed mobile wireless access with a very high data transmission speed (2-20 Mbps) and enables users to be simultaneously connected to several wireless access technologies and seamlessly move between them in an all-IP environment. These access technologies can be any existing or future access technology. Smart antennas, low power consumption, and software-defined radio terminals will also be used to achieve even more flexibility for the user of 4G systems.

IMS: The IP multimedia subsystem (IMS) is a new open and standardized framework, basically specified for mobile networks, for providing Internet protocol (IP) telecommunication services. It offers a next generation network (NGN) multimedia architecture for mobile and fixed services, based on the session initiation protocol (SIP), and runs over the standard IP. It is used by telecom operators in NGN networks (combining voice and data in a single packet switched network), to offer network controlled multimedia services. The aim of IMS is not only to provide new services but to provide all the services, current and future, that the Internet provides. In addition, users have to be able to execute all their services when roaming as well as from their home networks. To achieve these goals the IMS uses IETF protocols. This is why the IMS merges the Internet with the cellular world; it uses cellular technologies to provide ubiquitous access and Internet technologies to provide new services.

IPv6: Internet protocol version 6 (IPv6) is the next generation protocol designed by the Internet Engineering Task Force (IETF) to replace the current version of the Internet protocol, IP version 4 (IPv4). Today's Internet has been using IPv4 for twenty years, but this protocol is beginning to become outdated. The most important problem of IPv4 is that there is a growing shortage of IPv4 addresses, which are needed by all new machines added to the Internet. IPv6 is the solution to several problems in IPv4, such as the limited number of available IPv4 addresses, and also adds many improvements to IPv4 in other areas. IPv6 is expected to gradually replace IPv4, with the two coexisting for a number of years during a transition period.

QoS: ITU-T recommendation E.800 defines the term quality of service (QoS) as "the collective effect of service performance which determines the degree of satisfaction of a user of the service." Service performance comprises of very different parts (security, operability, etc), so the meaning of this term is very broad. In telecommunications, the term QoS is commonly used in assessing whether a service satisfies the user's expectations. QoS evaluation, however, depends on functional components and is related to network performance via measurable technical parameters. A QoS-enabled network has the ability to provide better service (priority, dedicated bandwidth, controlled jitter, latency, and improved loss characteristics) to selected network traffic over various technologies.

SIP: The session initiation protocol (SIP) is a signalling protocol developed by the IETF intended for setting up multimedia communication sessions between one or multiple clients. It is currently the leading signalling protocol for voice over IP, and is one of the key components of the IMS multimedia architecture. The most important functions of SIP include name mapping and redirection (user location), capabilities negotiation during session setup, management of session participants and capabilities management during the session.

Telemedicine: Telemedicine can be defined as the rapid access to shared and remote medical expertise by means of telecommunications and information technologies, no matter where the patient or the relevant information is located. Any application of information and communications technologies which removes or mitigates the effect of distance in healthcare is telemedicine. The terms e-health and tele-health are terms often interchanged with telemedicine.

Chapter 2.9
The M-Health Reference Model:
An Organizing Framework for Conceptualizing Mobile Health Systems

Phillip Olla
Madonna University, USA

Joseph Tan
Wayne State University, USA

ABSTRACT

The reference model presented in this article encourages the breakdown of M-Health systems into the following five key dimensions: (1) Communication Infrastructure: a description of mobile telecommunication technologies and networks; (2) Device Type: the type of device being used, such as PDA, sensor, or tablet PC; (3) Data Display: describes how the data will be displayed to the user and transmitted, such as images, e-mail, and textual data; (4) Application Purpose: identification of the objective for the M-Health system; (5) Application Domain: definition of the area in which the system will be implemented. Healthcare stakeholders and system implementer can use the reference model presented in this article to understand the security implications of the proposed system and to identify the technological infrastructure, business requirements, and operational needs of the M-Health systems being implemented. A reference model that encapsulates the emerging M-Health field is needed for cumulative progress in this field. Currently, the M-Health field is disjointed, and it is often unclear what constitutes an M-Health system. In the future, M-Health applications will take advantage of technological advances such as device miniaturizations, device convergence, high-speed mobile networks, and improved medical sensors. This will lead to the increased diffusion of clinical M-Health systems, which will require better understanding of the components that constitute the M-Health system.

INTRODUCTION

M-Health is defined as "mobile computing, medical sensor, and communications technologies for healthcare" (Istepanian, Jovanov, & Zhang, 2004, p. 405). The first occurrence of the term *M-Health* in the literature was in the "Unwired E-Med" special issue on Wireless Telemedicine Systems (Istepanian & Laxminaryan, 2000). Since then, there has been an increased use of the term, encapsulating various types of healthcare systems. The use of the M-Health terminology relates to applications and systems such as telemedicine (Istepanian & Wang, 2003), telehealth (Istepanian & Lacal, 2003), and biomedical sensing system (Budinger, 2003). Until now, there have been considerable confusion and overlap with the use of these terms (Tulu & Chatterjee, 2005).

Rapid advances in Information Communication Technology (ICT) (Godoe, 2000), nanotechnology, biomonitoring (Budinger, 2003), mobile networks (Olla, 2005a), pervasive computing (Akyildiz & Rudin, 2001), wearable systems, and drug delivery approaches (Amy et al., 2004) are transforming the healthcare sector. The insurgence of innovative technology into the healthcare practice not only is blurring the boundaries of the various technologies and fields but also is causing a paradigm shift that is blurring the boundaries among public health, acute care, and preventative health (Hatcher & Heetebry, 2004). These developments not only have had a significant impact on current e-health and telemedical systems (Istepanian, Jovanov, & Zhang, 2004), but they also are leading to the creation of a new generation of M-Health systems with a convergence of devices, technologies, and networks at the forefront of the innovation.

This article proposes the use of a five-dimensional reference model in order to assist system implementers and business stakeholders in understanding the various components of an M-Health system. The approach used by the this article focuses on identifying different dimensions of a Mobile Healthcare Delivery System (MHDS) (Wickramasinghe & Misra, 2005), which then can be used to identify user security requirements for different categories in an organized manner. These dimensions were driven from our literature review (Bashshur, 2002; Bashshur, Reardon, & Shannon, 2000; Raskovic & Jovanov, 2004; Istepanian, Laxminaryan, & Pattichis, 2006; Jovanov, Milenkovic, Otto, & Groen, 2005; Field, 1996; Moore, 2002; Olla & Patel, 2003), and the model reflects a combination of various classification schemes proposed in earlier studies in order to classify telemedicine and telehealth systems.

Based on the previous definition, M-Health is a broad area that transcends multiple disciplines and utilizes a broad range of technologies. There is a variety of applications, devices, and communication technologies that are emerging in the M-Health arena and that can be combined to create the M-Health system. The dimensions consist of the following:

1. **Communication Infrastructure.** Description of the mobile telecommunication technologies that will be used, such as Bluetooth, wireless local area networks, or third-generation technologies (Olla, 2005a).
2. **Device Type.** Relates to the type of device being used to collect the medical data, such as Personal Digital Assistance (PDA), sensor, or tablet PC (Parmanto, Saptono, Ferrydiansyah, & Sugiantara, 2005).
3. **Data Display.** Describes how the data will be displayed and transmitted to the user through images, e-mail, textual data, and other types of data presentation languages (Tulu & Chatterjee, 2005).
4. **Application Purpose.** Identification of the objective for the M-Health system (Field, 1996).
5. **Application Domain.** Definition of the area in which the system will be implemented, such as clinical (e.g., dermatology, radiology, etc.) or non-clinical (e.g., billing, maintenance, etc.) domains (Bashshur et al., 2000).

Selecting different alternatives in the five dimensions will have implications on the functionality of the system; however, the key focus of this discussion will be the emphasis on how the security and integrity of the M-Health system is maintained, based on the dimension choices.

The rest of the article is organized as follows. "Background of M-Health" features a brief background of the evolution of M-Health. "Mobile Healthcare Delivery System Networks" provides an overview of existing and new mobile technologies suitable for the healthcare sector. "The M-Health Reference Model" introduces the five dimensions of the M-Health reference model. The penultimate section uses the reference model to decompose a real-life mobile health delivery system in order to illustrate the security concerns. This is followed by the conclusion.

BACKGROUND OF M-HEALTH

The phenomenon of providing care remotely using ICT can be placed into a number of areas, such as M-Health, telemedicine, and e-health, but, as summed up by R. L. Bashur, President Emeritus of the American Telemedicine Association, the terminology is not the important aspect. "It does not really matter what we call it or where we draw boundaries. … collective and collaborative efforts from various fields of science, including what we call now telemedicine is necessary" (Bashshur, 2002, p. 7). Emphasis on the various components and objectives of the various types of systems should be the priority, as this will increase the chances of implementing efficient and effective systems, of generating viable business models, and of creating secure systems that meet the needs of the stakeholders (Olla & Patel, 2003). Over the evolution of telemedicine, new terminologies have been created as new health applications and delivery options became available and as application areas extended to most healthcare domains. This resulted in confusion and identification of what falls under telemedicine, and what falls under telehealth or e-health became more complicated as the field advanced. New concepts such as Pervasive Health and M-Health also are adding to this confusion. Before understanding the scope and components of M-Health, it is important to mention briefly the history of telemedicine and the advancements of mobile networks, which are collectively the foundation of M-Health. The evolution and growth of telemedicine is correlated highly with ICT advancements and software development. Telemedicine advancements can be categorized into three eras (Tulu & Chatterjee, 2005; Bashshur et al., 2000).

The first era of telemedicine focused solely on medical care as the only function of telemedicine. This era can be named as the telecommunications era of the 1970s. The applications in this era were dependent on broadcast and television technologies, in which telemedicine applications were not integrated with any other clinical data. The second era of telemedicine, a result of digitalization in telecommunications, grew during 1990s. The transmission of data was supported by various communication mediums ranging from telephone lines to Integrated Service Digital Network (ISDN) lines. During this period, there were high costs attached to the communication mediums that provided higher bandwidth. The bandwidth issue became a significant bottleneck for telemedicine in this era. Resolving the bandwidth constraints has been a critical research challenge for the past decade, with new approaches and opportunities created by the Internet revolution. Now, more complex and ubiquitous networks are supporting telemedicine. The third era of telemedicine was supported by a networking technology that was cheaper and more accessible to an increasing user population. The improved speed and quality offered by Internet is providing new opportunities in telemedicine. In this new era of telemedicine, the focus shifted from a technology assessment to a deeper appreciation of the functional relationships between telemedicine technology and the outcomes of cost, quality, and access.

This article proposes a fourth era that is characterized by the use of Internet Protocol (IP) technologies, ubiquitous networks, and mobile/wireless networking capabilities, which can be observed by the proliferation of M-Health applications that perform both clinical and non-clinical functions. Since the proliferation of mobile networks, telemedicine has attracted a lot more interest from both academic researchers and industry (Tachakra, Istepanian, Wang, & Song, 2003). This has resulted in many mobile/wireless telemedicine applications being developed and implemented (Budinger, 2003; Istepanian & Laxminaryan, 2000; Jovanov, Lords, Raskovic, Cox, Adhami, & Andrasik, 2003; Pattichis et al., 2002; Istepanian & Lacal, 2003; Webb, 2004). Critical healthcare information regularly travels with patients and clinicians, and therefore, the need for information to become securely and accurately available over mobile telecommunication networks is key to reliable patient care and reliable medical systems.

Health organizations are required by the Health Insurance Portability and Accountability Act of 1996 (HIPAA) to maintain the privacy of protected health information and to provide individuals with notice of its legal duties and privacy policies with respect to this information (HIPPA, 2005). Specifically, the law requires the following:

- Any medical information that identifies a person must be kept private.
- Notice of legal duties and privacy practices with respect to protected health information must be made available.
- The organization must abide by the terms of its notices currently in effect.

HIPAA also requires:

- Computers and data containing protected health information (PHI) must be protected from compromise or loss.
- Audit trails of access to PHI must be kept.
- Electronic transmissions of PHI must be authenticated and protected from observation or change.

Failure to comply with these requirements (for both HIPAA privacy and security) can result in civil and criminal penalties ranging from fines of $100 to $250,000 and up to 10 years in prison. Medical information always has been considered sensitive and never more so than now due to the security issues created by mobility. Many countries have imposed strict regulations with heavy penalties in order to ensure the confidentiality and authorized distribution of personal medical information. Following the lead of European Union Directive 95/46/EC that protects both medical and financial personal information, the United States and Canada passed important legislation (HIPAA and PIPED, respectively) that imposes substantial penalties, both civil and criminal, for negligent or intentional exposure of personal medical information to unauthorized parties.

The telecommunication industry has progressed significantly over the last decade. There has been significant innovation in digital mobile technologies. The mobile telecommunication industry has advances through three generations of systems and is currently on the verge of designing the fourth generation of systems (Olla, 2005b). The recent developments in digital mobile technologies are reflected in the fast-growing commercial domain of mobile telemedical services (Istepanian et al., 2006). Specific examples include mobile ECG transmissions, video images and teleradiology, wireless ambulance services to predict emergency and stroke morbidity, and other integrated mobile telemedical monitoring systems (Istepanian, Jovanov, & Zhang, 2004; Future trends: Convergence is all, 2005; Warren, 2003). There is no doubt that mobile networks can introduce additional security concerns to the healthcare sector.

Implementing a mobile trust model will ensure that a mobile transaction safely navigates multiple technologies and devices without compromising the data or the healthcare systems. M-Health transactions can be made secure by adopting practices that extend beyond the security of the wireless network used and by implementing a trusted model for secure end-to-end mobile transactions. The mobile trust model proposed by Wickramasinghe and Misra (2005) utilizes both technology and adequate operational practices in order to achieve a secure end-to-end mobile transaction. The first level highlights the application of technologies in order to secure elements of a mobile transaction. The next level of the model shows the operational policies and procedures needed in order to complement technologies used. No additional activity is proposed for the mobile network infrastructure, since this element is not within the control of the provider or the hospital.

The next section will discuss the mobile network technologies and infrastructure, which is a key component of any M-Health system. The network infrastructure acts as a channel for data transmission and is subject to the same vulnerabilities, such as sniffing, as in the case of fixed network transaction. The mobile networks discussed in the next section are creating the growth and increased adoption of M-Health applications in the healthcare sector.

MOBILE HEALTHCARE DELIVERY SYSTEM NETWORKS

The implementation of an M-Health application in the healthcare environment leads to the creation of a Mobile Healthcare Delivery System (MHDS), which can be defined as the carrying out of healthcare-related activities using mobile devices such as a wireless tablet computer, Personal Digital Assistant (PDA), or a wireless-enabled computer. An activity occurs when authorized healthcare personnel access the clinical or administrative systems of a healthcare institution using a mobile device (Wickramasinghe & Misra, 2005). The transaction is said to be complete when medical personnel decide to access medical records (patient or administrative) via a mobile network either to browse or to update the record.

Over the past decade, there has been an increase in the use of new mobile technologies in healthcare, such as Bluetooth and Wireless Local Area Networks (WLAN) that use protocols different than the standard digital mobile technologies such as 2G, 2.5, and 3G. A summary of these technologies is presented next, and a précis of the speeds and range is presented in Table 1.

These mobile networks are being deployed in order to allow physicians and nurses easy access to patient records while on rounds, to add observations to the central databases, to check on medications, as well as to perform a growing number of other functions. The ease of access that wireless networks offer is matched by the security and privacy challenges presented by the networks. This serious issue requires further investigation and research in order to identify the real threats for the various types of networks in the healthcare domain.

Second Generation Systems (2G /2.5G)

The second-generation cellular systems (2G) were the first to apply digital transmission technologies such as Time Division Multiple Access (TDMA) for voice and data communication. The data transfer rate was on the order of tens of kbits/s. Other examples of technologies in 2G systems include Frequency Division Multiple Access (FDMA) and Code Division Multiple Access (CDMA).

The 2G networks deliver high quality and secure mobile voice and basic data services, such as fax and text messaging, along with full roaming capabilities around the world. Second-generation technology is in use by more than 10% of the world's population, and it is estimated that 1.3 billion customers in more than 200 countries and territories around the world use this technol-

Table 1. Comparison of mobile networks based on range and speed

Networks	Speed	Range and Coverage	Main Issues for M-Health
2nd Generation GSM	9.6 kilobits per second (KBPS)	World wide coverage, dependent on network operators roaming agreements.	Bandwidth limitation, Interference.
High Speed Circuit Switched Data (HSCSD)	Between 28.8 KBPS and 57.6 KBPS.	Not global, only supported by service providers network.	Not widely available, scarcity of devices.
General Packet Radio Service (GPRS)	171.2 KBPS	Not global, only supported by service providers network.	Not widely available.
EDGE	384 KBPS	Not global, only supported by service providers network.	Not widely available, scarcity of devices
UMTS	144 KBPS-2 MBPS depending on mobility	When fully implemented should offer interoperability between networks, global coverage.	Device battery life, operational costs.
Wireless Local Area	54 MBPS	30–50 m indoors and 100–500 m outdoors. Must be in the vicinity of hot spot.	Privacy, security.
Personal Area Networks-Bluetooth	400 KBPS symmetrically 150-700 KBPS asymmetrically	10-100m	Privacy, security, low bandwidth.
Personal Area Networks-Zigbee	20 kb/s-250 KBPS depending on band	30m	Security, privacy, low bandwidth.
WiMAX	Up to 70MBPS	Approx. 40m from base station.	Currently no devices and networks cards.
RFID	100 KBPS	1 m Non line-of-sight and contact less transfer of data between a tag and Reader.	Security, privacy.
Satellite Networks	400 to 512 KBPS new satellites have potential of 155MBPS.	Global coverage.	Data costs, shortage of devices with roaming capabilities. Bandwidth limitations.

ogy (GSM_Home, 2005). The later advanced technological applications are called 2.5G technologies and include networks such as General Packet Radio Service (GPRS) and Enhanced Data rates for GSM Evolution (EDGE). GPRS-enabled networks provide functionality such as always-on, higher capacity, Internet-based content and packet-based data services enabling services such as color Internet browsing, e-mail on the move, visual communications, multimedia messages and location-based services. Another complimentary 2.5G service is EDGE, which offers similar capabilities to the GPRS network.

Third-Generation Systems (3G)

The most promising period is the advent of 3G networks, which also are referred to as the Universal Mobile Telecommunications Systems (UMTS). A significant feature of 3G technology is its ability to unify existing cellular standards, such as code-division multiple-access (CDMA), global system for mobile communications (GSM_Home, 2005), and time-division multiple-access (TDMA), under one umbrella (Istepanian, Jovanov, & Zhang, 2004). More than 85% of the world's network operators have chosen 3G as the underlying technology platform to deliver their third-generation services (GSM-Information, 2004). Efforts are underway to integrate the many diverse mobile environments and to blur the distinction between the fixed and mobile networks. The continual rollout of advanced wireless communication and mobile network technologies will be the major driving force for future developments in M-Health systems (Istepanian, Jovanov, & Zhang, 2004). Currently, the GSM version of 3G alone saw the addition of more than 13.5 million users, representing an annual growth rate of more than 500% in 2004. As of December 2004, 60 operators in 30 countries were offering 3GSM services. The global 3GSM customer base is approaching 20 million and already has been launched commercially in Africa, the Americas, Asia Pacific, Europe, and the Middle East (GSM_Home, 2005), thus making this technology ideal for developing affordable global M-Health systems.

Fourth Generation (4G)

The benefits of the fourth-generation network technology (Istepanian et al., 2006; Olla, 2005a; Qiu, Zhu, & Zhang, 2002) include voice-data integration, support for mobile and fixed networking, and enhanced services through the use of simple networks with intelligent terminal devices. 4G also incorporates a flexible method of payment for network connectivity that will support a large number of network operators in a highly competitive environment. Over the last decade, the Internet has been dominated by non-real-time, person-to-machine communications (UMTS-Forum-Report14, 2002). The current developments in progress will incorporate real-time, person-to-person communications, including high-quality voice and video telecommunications along with extensive use of machine-to-machine interactions in order to simplify and to enhance the user experience.

Currently, the Internet is used solely to interconnect computer networks. IP compatibility is being added to many types of devices such as set-top boxes to automotive and home electronics. The large-scale deployment of IP-based networks will reduce the acquisition costs of the associated devices. The future vision is to integrate mobile voice communications and Internet technologies, bringing the control and multiplicity of Internet application services to mobile users (Olla, 2005b). 4G advances will provide both mobile patients and citizens with the choices that will fit their lifestyle and make it easier for them to interactively get the medical attention and advice they need when and where it is required and how they want it, regardless of any geographical barriers or mobility constraints.

Worldwide Interoperability for Microwave Access (WiMAX)

WiMAX is considered to be the next generation of Wireless Fidelity (WiFi /Wireless networking technology that will connect you to the Internet at faster speeds and from much longer ranges than current wireless technology allows (http://wimaxxed.com/). WiMax has been undergoing testing and is expected to launch commercially by 2007. Research firm Allied Business Research predicts that by 2009, sales of WiMax accessories will top $1 billion (Kendall & Christopher, 2005), and Strategy Analytics predicts a market of more than 20 million WiMAX subscriber terminals and base stations per year by 2009 (ABI Research, 2005).

The technology holds a lot of potential for M-Health applications and has the capabilities to provide data rates up to 70 mbps over distances up to 50 km. The benefits to both developing and developed nations are immense. There has been a gradual increase in the popularity of this technology. Intel recently announced plans to mass produce and release processors aimed to power WiMax-enabled devices (WiMax, 2005). Other technology organizations that are investing in the further advancement of this technology include Qwest, British Telecom, Siemens, and Texas Instruments. They aim to get the prices of the devices powered by WiMax to affordable levels so that the public can adopt them in large numbers, making it the next global wireless standard. There are already Internet Service Providers in metropolitan areas that are offering pre-WiMAX services to enterprises in a number of cities, including New York, Boston, and Los Angeles (WiMax, 2005).

Wireless Local Area Networks

Wireless Local Area Networks (WLAN) use radio or infrared waves and spread spectrum technology in order to enable communication between devices in a limited area. WLAN allows users to access a data network at high speeds of up to 54 Mb/s, as long as users are located within a relatively short range (typically 30–50m indoors and 100–500m outdoors) of a WLAN base station (or antenna. Devices may roam freely within the coverage areas created by wireless access points, the receivers, and transmitters connected to the enterprise network. WLANs are a good solution for healthcare today; in addition, they are significantly less expensive to operate than wireless WAN solutions such as 3G (Daou-Systems, 2001).

Personal Area Networks

A wireless personal area network (WPAN) (Personal area network, n.d.; Istepanian, Jovanov, & Zhang, 2004) is the interconnection of information technology devices within the range of an individual person, typically within a range of 10 meters. For example, a person traveling with a laptop, a personal digital assistant (PDA), and a portable printer could interconnect wirelessly all the devices using some form of wireless technology. WPANs are defined by IEEE standard 802.15 (IEEE 802.15 Working Group for WPAN, n.d.). The most relevant enabling technologies for M-Health systems are Bluetooth (n.d.) and ZigBee Alliance (n.d.). ZigBee is a set of high-level communication protocols designed to use small, low-power digital radios based on the IEEE 802.15.4 standard for wireless personal area networks. ZigBee is aimed at applications with low data rates and low power consumption. ZigBee's current focus is to define a general-purpose, inexpensive, self-organizing network that can be shared by industrial controls, medical devices, smoke and intruder alarms, building automation, and home automation. The network is designed to use very small amounts of power so that individual devices might run for a year or two with a single alkaline battery, which is ideal for use in small medical devices and sensors. The Bluetooth specification was first developed by Ericsson and later formalized by the Bluetooth Special Interest Group established by Sony, Ericsson, IBM, Intel, Toshiba, and Nokia and later joined by many other companies. A Bluetooth WPAN is also called a *piconet* and is composed of up to eight active devices in a master-slave relationship. A piconet typically has a range of 10 meters, although ranges of up to 100 meters can be reached under ideal circumstances. Implementations with Bluetooth versions 1.1 and 1.2 reach speeds of 723.1 kbit/s. Version 2.0 implementations feature Bluetooth Enhanced Data Rate (EDR) and thus reach 2.1 Mbit/s (Bluetooth, n.d.; Wikipedia, n.d.).

Radio Frequency Identification (RFID)

RFID systems consist of two key elements: a tag and a reader/writer unit capable of transferring data to and from the tag. An antenna linked to each element allows power to be transferred between the reader/writer and a remotely sited tag through inductive coupling. Since this is a bi-directional process, modulation of the tag antenna will be reflected back to the reader's /writer's antenna, allowing data to be transferred in both directions. Some of the advantages of RFID that make this technology appealing to the healthcare sector are as follows:

- No line of sight required between tag and reader.
- Non-contact transfer of data between tag and reader.
- Tags are passive, which means no power source is required for the tag component.
- Data transfer range of up to one meter is possible.
- Rapid data transfer rates of up to 100 Kbits/sec.

The use of RFID in the healthcare environment is set to rise and is currently being used for drug tracking. RFID technology is expected to decrease counterfeit medicines and to make obtaining drugs all the more difficult for addicts (Weil, 2005). There are also applications that allow tagging of patients, beds, and expensive hospital equipment.

Satellite Technologies

Satellite broadband uses a satellite to connect customers to the Internet. Two-way satellite broadband uses a satellite link both to send and to receive data. Typical download speeds are 400 to 512 kbps, while upload speeds on two-way services are typically 64 to 128 kbps. Various organizations (Inmarsat announces availability of the 64 kbit/s mobile office in the sky, 2000) have been investigating the development of an ultra-high-data-rate Internet test satellite for making a high-speed Internet society a reality (JAXA, 2005). Satellite-based telemedicine service will allow real-time transmission of electronic medical records and medical information anywhere on earth. This will make it possible for doctors to diagnose emergency patients even from remote areas and also will increase the chances of saving lives by receiving early information, as ambulance data rates of 155 mbps are expected. One considerable drawback associated with using this technology is cost (Olla, 2004).

This section has summarized the various mobile network technologies that are being used in the healthcare sector. The mobile technologies described have a significant impact on the ability to deploy M-Healthcare application and systems; however, there are combinations of other important factors described in the next section. The next section will present a five-layered model that uses mobile network technologies along with device type, data display, application purpose, and application domain to categorize M-Health systems.

THE M-HEALTH REFERENCE MODEL

The financial cost of delivering quality healthcare is increasing exponentially not only in North America but also around the world. To satisfy increasing healthcare challenges, organizations in the healthcare sector are investing innovative technological solutions in order to meet the higher expectations placed on practice management (Wickramasinghe & Misra, 2005; Wickramasinghe & Silvers, 2002). The evolution of M-Health solutions, such as the use of wireless networks to access patient records and other healthcare services such as billing and prescription, are becoming popular, especially in the U.S. and Canada (Goldberg & Wickramasinghe, 2002) and in many European countries (Sorby, 2002). However, these wireless solutions also bring with them their own challenges, with security being one of the most important issues in M-Health. This is because M-Health systems transmit highly sensitive information such as patient data over cyberspace, and there is a need for high-level, end-to-end security, confidentiality, and privacy.

This section presents a reference model to describe each M-Health system in order to address the security challenges. Specifically, we present a reference model and show how our model can facilitate a higher level of end-to-end security in a wireless or mobile healthcare environment. Despite the advancements of wireless technologies, the use of wireless security in healthcare is in its infancy, and a robust mobile healthcare model needs to be developed in order to allow further innovation of M-Health applications and services that will fulfill the growing needs of the healthcare sector.

This section presents a reference model that can be utilized to classify M-Health systems by identifying the system components for a specific M-Health system. As previously indicated, the approach used to develop the reference model concentrated on identifying different dimensions of a Mobile Healthcare Delivery System (MHDS), which provides the capability to identify user security requirements for different categories in an organized manner. The reference model was formulated by reviewing the literature, and the model reflects an amalgamation of various classification schemes proposed by previous experts to categorize telemedicine and telehealth systems. The following subsections will provide a description of these five domains for the M-Health reference model illustrated in Figure 1. These domains include communication infrastructure, device type, data display, application purpose, and application domain.

Mobile Communication Infrastructure

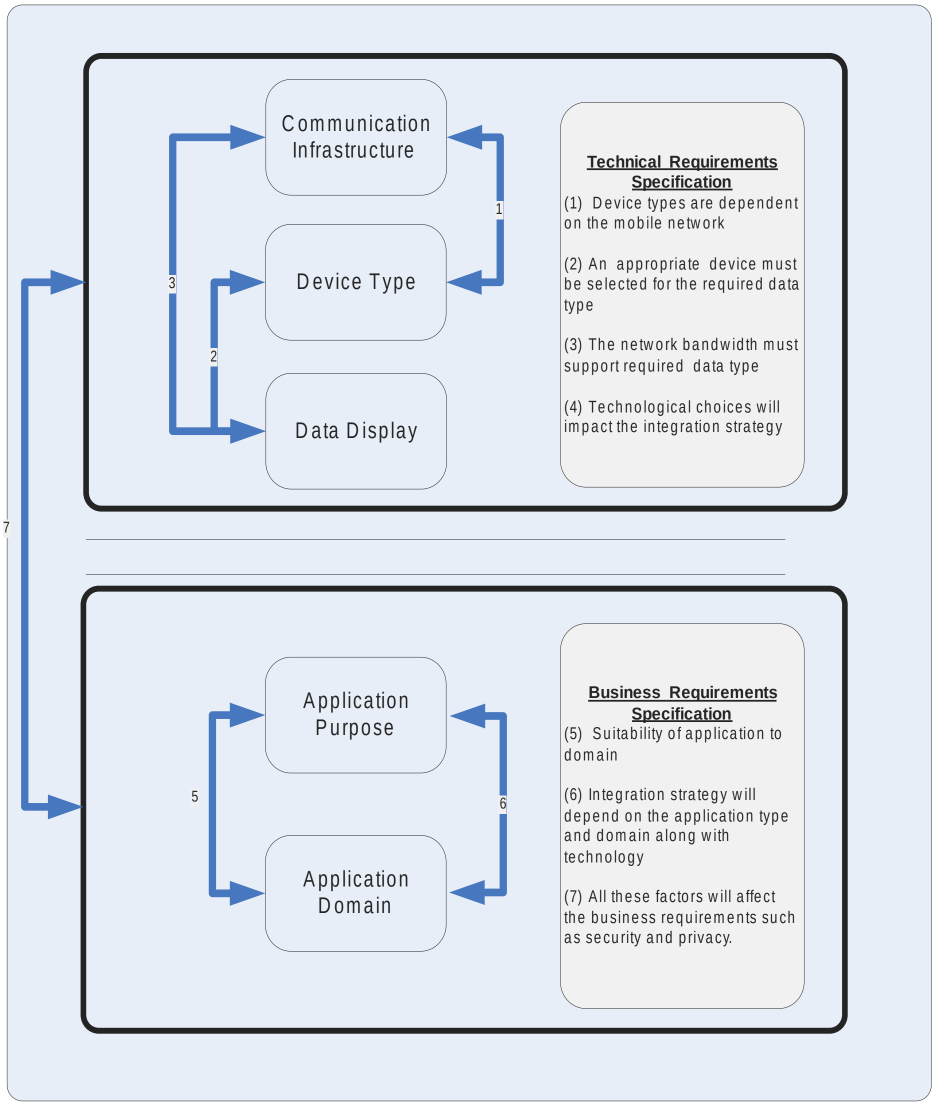
The first dimension defines the mobile infrastructure used to transmit, encode, and receive data. There are numerous wireless infrastructures available from which healthcare providers can choose. Examples of networks that provide personal area networks include Bluetooth and Zigbee. Mobile networks that provide connectivity within buildings include Wireless Local Area Networks (WLAN), which use different protocols from the standard digital mobile technologies such as 2G, 2.5, and 3G, which provide wide area connectivity. A summary of these technologies was provided in "Mobile Healthcare Delivery System Networks."

Device Type

The second section is referred to as Device Type. Due to the advances in medical sensor technologies and handheld computers, M-Health has the potential to deliver services beyond the scope of mobile telemedicine discussed in the previous section. The integration of medical sensors with ICT allows physicians to diagnose, monitor, and treat patients remotely without compromising standards of care. Advances of new materials and signal processing research is allowing the design of smart medical sensors that utilize real-time data recording and processing of multi-physiological signals.

There is a multiplicity of sensors that are available commercially, such as piezo-electrical materials for pressure measurements, infrared sensors for body temperature estimation, and optoelectronic sensors that monitor heart rate and blood pressure. These sensors are being embedded into wearable items and accessories such as sunglasses and rings that can be carried easily. With the continual improvements to the sensors and the miniaturization of computing devices, these wearable devices for monitoring, diagnosing, and treating illnesses are becoming more readily available. Hitachi has developed a wristwatch that can measure the wearer's health conditions such as pulse, moves, and body temperature. The monitoring wristwatch can send data wirelessly via the Internet to remote monitoring services. Hitachi aims to launch the wireless wristwatch commercially within three years (Hitachi's wireless health monitoring wristwatch, 2005), targeting the healthcare service industry for elderly people. The benefit of wearable sensors for physiological data collection is that they can be used to monitor human health constantly without unsettling the patient's day-to-day activities. Examples include rings, vests, watches, wearable intelligent sensors, and systems for e-medicine (Winters, Wang, & Winters, 2003). Wireless communication such as WAN is used for transmitting information

Figure 1. M-health reference model for identifying components of healthcare delivery systems



and accessing healthcare databases wherever appropriate in order to allow free movement of the user (Jovanov et al., 2005).

Personal Digital Assistants (PDAs) have been popular among healthcare practitioners in the last few years. PDA penetration among physicians is at 25%, much higher than the 4% penetration for the general population (Fischer et al., 2003; Holmes, Brown, & Twist, 2001; Harris-Interactive, 2001; Parmanto et al., 2005). Studies have shown that the integration of PDAs into clinical practice has led to decreased medication error rates (Grasso et al., 2002) and the improvement in physicians' adherences to clinical practice guidelines (Shiffman, 1999, 2000).

Although the PDA has great potential to support evidence-based medicine, there are some considerable drawbacks (Parmanto et al., 2005). The small screen is a poor match for information resources designed for full-sized desktop computers. Presenting vast amounts of information in the limited space of the PDA display is a significant technical barrier to the realization of the PDA's potential (Fischer et al., 2003; Larkin, 2001; Peterson, 2002). Other technical PDA drawbacks include low resolution, limited memory, slow processor, and problematic data input. An alternative for the PDA is a tablet PC. These are being adopted in the healthcare sector for information capture at the patient's bedside.

Data Display

This key dimension describes how the information from the M-Health application is to be processed and transmitted. The chosen delivery options can have an important effect on the final quality of the telemedicine event and the outcome. Delivery options in telemedicine can be categorized under two main groups, according to Tulu and Chatterjee (2005): (1) synchronous and (2) asynchronous. Information transactions that occur between two or more participants simultaneously are called synchronous communications. In asynchronous communications, these transactions occur at different points in time. The data displays for both synchronous and asynchronous presentations can be grouped into the following categories: text, data, video, and multimedia (combination).

Application Purpose

The fourth dimension is the Application Purpose. This domain describes the intended use of the application. Field (1996) categorized this field into two main groups: clinical and non-clinical systems.

In 1996, the Committee on Evaluating Clinical Applications of Telemedicine (1996) grouped clinical applications into five categories:

1. Initial urgent evaluation
2. Supervision of primary care
3. Provision of specialty care
4. Consultation
5. Monitoring

Due to rapid advances in the M-Health field, three additional categories were added by Tulu and Chatterjee (2005):

6. Use of remote information and decision analysis resources to support or guide care for specific patients
7. Diagnostic
8. Treatment (surgical and non-surgical)

In addition to these groups, two additional categories have been added by the authors in order to reflect future trends of M-Health systems:

9. Drug delivery
10. Patient identification

The use of M-Health systems for non-clinical purposes includes medical education and administrative duties that do not involve decisions about care for particular patients. Some examples of M-Health non-clinical applications include:

1. Mobile access to the latest drug reference database
2. Bedside access to patient records (increase efficiency by reducing demand for paper records)
3. ePrescribing (mobile prescription writing and verification of drug interactions)
4. Prescription formulary reference (electronically identify most economic pharmaceuticals for a patient)
5. Electronic billing for in-home healthcare workers
6. Patient/drug verification (scan patient and drug bar codes to help to ensure that the appropriate medicine is being administered to the correct patient)
7. Delivery applications (healthcare supply delivery, tracking, and billing)
8. Patient encounter data capture

Application Area

The final dimension is called Application Area. This dimension describes the medical field implementing the M-Health technology. The application area also can be subdivided into clinical and non-clinical use. Clinical use relates to medical departments such as emergency, ophthalmology, pediatrics, and surgery. Non-clinical use relates to maintenance areas such as, charge capture, billing, and administration. The importance of this domain is to highlight the differences in the environments and to identify procedures that are specific to a particular healthcare domain.

In summary, the reference model highlights some of the important elements of an M-Health system. It is important to understand all of the dimensions of the reference model for each mobile healthcare system. Using the previous dimensions to describe an application will allow an M-Health system to be broken down into meaningful components.

The next section presents a case that features the use of an M-health application that uses a PDA to collect private medical data in remote African communities. The case in the next section illustrates how the reference model can be used to derive the components of an M-Health system, which allows issues such as security, privacy, hosting requirements, interference of devices, and integration to be investigated simultaneously.

OVERVIEW OF BLOOD DONOR RECRUITMENT (BDR) PROJECT

As an increased number of healthcare industry professionals adopt mobile-enabled handheld devices to collect, store, and retrieve critical medical information, the need for security has become a top-priority IT challenge. These mobile benefits come with immense corporate and regulatory risk. PDA devices left unsecured while electronic health information is being hotsynced to a PC can become a primary source for the intentional malicious interception of confidential information. Furthermore, the recent adoption of the Patient Privacy and Federal Health Insurance Portability and Accountability Act (HIPPA) is a strong reason not to have protected health information on any unsecured devices, especially a PDA. This section will provide an example of how the reference model described in the previous sections can be used to describe a project initiated by the Red Cross.

The medical informatics data analyst/IT manager of the Uganda Red Cross Society identified a potential weakness in the use of mobile devices in the community health field. One of the authors was consulted to assist in developing a model that addressed data security in order to ensure the main IT security goals: confidentiality, integrity, and availability. Mobile devices were used in Blood Donor Recruitment (BDR) activities to register blood donors' details. The medical history was stored for blood screening purposes. The data are very confidential because some of the blood donors' results are positive for HIV, hepatitis, or syphilis. The system specifications are as follows:

Palm M125 with the following software:

- Palm Desktop software for Windows v. 4.0
- Pendragon form 3.2
- Pendragon Distribution Toolkit 2.0
- Windows XP on the PC
- Microsoft Access 2000
- The volume of data is about 10mb records on the PDA

This information is transferred to the computer server either by wired synchronization (HotSynced) or by wireless network. The hotsync option requires the user to be in the confines of the hospital or office, because it involves the use of the wired cradle. The other alternative that is being considered is the use of a wireless network such as WiFi or GSM to transfer data to the computer. Once the data are stored on the computer, they are manipulated with various software tools.

Using the M-Health reference model described in the previous section, the BDR system was broken down into the various components, as highlighted in Tables 2a and 2b. The following general recommendations were suggested to the client.

1. Upgrade memory on mobile device.
2. Formulate an enforceable end-to-end security policy.
3. Evaluate encryption software that can run both on the PDA and on the PC
4. Implement a solution that ensures that captured data on the PDA can be encrypted before being hotsynced on the PC.
5. Try out software prior to purchase.

There are various software solutions that can be used in order to secure the health system described previously. These solutions vary by encryption method, price, and device compatibility; however, there is no single solution to securing a system. It is important that each scenario be addressed differently, irrespective of how similar they seem.

A software solution that would fulfill the requirements for the scenarios described in Tables 2a and 2b, the PDASecure™by Trust Digital software, provides six different selectable encryption algorithms. Additional protection features include strong password protection to prevent unauthorized synchronizing or beaming of data, unauthorized deletion of files due to viruses or malicious code, and user authentication to devices before data can be decrypted. IT administrators can control who can access data and networks with wireless handheld devices, encrypt 100% of the data, and password-protect devices so that they are useless if stolen or compromised.

Using mobile networks allows data to travel over the open air. When data transmission is wireless, there is a possibility of interception of the radio transmission as well as unauthorized access to the hospital system. Poorly designed WiFi local area networks can be leaky and accessible beyond the intended boundary of use. If an unauthorized access of any kind occurs, it not only could lead to the loss of a patient's privacy but also could lead to other potential consequences.

In Table 2a, the wireless network is not used, and the mobile device must be colocated with the computer system and server in order to transfer and copy data. This option also presents a different set of security problems. Due to the storage capacities of the mobile devices and the growing trend of today's mobile workforce, every port, external disk drive, or JumpDrive can become a security risk. In the corporate environment, IT experts have turned to soldering and gluing USB ports in order to prevent intrusion; they also have installed titanium chastity belts around computers. USB ports and PDA cradles can be used for a variety of functions from input devices as inconspicuous as iPODs, which now are capable of downloading more than 30 gigabits of data.

In summary, using the reference model presented in this article to decompose a Red Cross blood donor system ensured that the security issues were identified and appropriately addressed. The model also was valuable for discovering technical specifications of the system and for understanding what upgrades were required in order to reduce the vulnerabilities of the system. In the future, this model can be improved by the creation of a set of guidelines and standards that are appropriate for a particular type of M-Health system. This will be valuable for governments and private vendors that implement innovative healthcare systems. The model also aids the healthcare stakeholders to identify the technological infrastructure, business requirements, and operational needs for the different types of M-Health systems.

Table 2a. Using the reference model to describe the blood donor system using a cradle solution

System	Purpose	Data	Network	Device	Application Area
Blood Donor Recruitment (BDR)	Blood donor data capture and transfer	Textual data	Fixed cable	Palm PDA	Rural community health
Security Model • Data sent from the PDA and to the PDA must be secured with encryption. • User and server authentication must be in place. • Access to data in the server from a computer or PDA different from where the server runs must be secured with encryption and user / server authentication. • Advances authentication methods such as biometrics will provide added security features.					

Table 2b. Using the reference model to describe the blood donor system using a wireless solution

System	Purpose	Data	Network	Device	Application Area
Blood Donor Recruitment (BDR)	Blood donor data capture and transfer	Textual data	WIFI/ GPRS	Palm PDA	Rural community health
Security Model • Data sent to/from the PDA must be secured with encryption. • User and server authentication must be in place. • No data storage in network operator environment (GPRS/UMTS Operator) • WiFi network must be secured.					

CONCLUSION

In the clinical domain, considerable leaps in the fields of biomedical telemetry, nanotechnology, ICT, and drug delivery techniques will encourage M-Health applications to evolve rapidly over the next decade. These new M-Health applications will take advantage of technological advances, such as device miniaturizations, device convergence, high-speed mobile networks, reduction in power consumption, and improved medical sensors. This will lead to the increased diffusion of clinical M-Health systems, which will impact the reshaping of the healthcare sector.

The non-clinical use of M-Health enterprise systems also will see an increased rate of adoption due to the potential benefits of the mobile solutions. Potential quality improvements may be achieved by implementing platforms that contain functionality that allows organizations to perform clinical results viewing, e-Prescribing, medication administration, specimen collection, charge capture, and physician dictation capture. These systems help to reduce errors by making the patient's medical record and appropriate medical knowledge available at the point of care and at the point of decision.

The reference model presented in this article aids in the breakdown of M-Health systems into the following five key dimensions: (1) Communication Infrastructure — describes mobile telecommunication technologies and networks; (2) Device Type — relates to the type of device being used, such as PDA, sensor, or tablet PC; (3) Data Display — describes how data will be displayed to the user and transmitted, such as images, e-mail, or textual data; (4) Application Purpose — identification of the objective for the M-Health system; and (5) Application Domain — definition of the area in which the system will be implemented.

The reference model described in this article encapsulates the emerging M-Health field and is needed to assist in clarifying the rapid progress in this field. Currently, the M-Health field is disjointed, and it is often unclear what component constitutes an M-Health system. This is addressed by the reference model. Further work is needed in order to identify the appropriate standards and guidelines for implementing the various types of M-Health systems. This would benefit vendors and system implementers by allowing them to understand the various conditions that may apply to a system that uses a specific set of the M-Health reference model variables. The reference model also would benefit from further work that defines how the choice of dimensions can impact the business models and the security policy for the implementation of the system.

Chapter 2.10
Creating a Multimedia Instructional Product for Medical School Students

Mitchell Weisburgh
Academic Business Advisors, LLC, USA

ABSTRACT

Because most medical school textbooks do not adequately address pain management, the American Academy of Pain Medicine wanted to create TOP MED, an online textbook that would address this need for different specialties and which also could be used as a textbook for the Introduction to Pain Management course. This online textbook would cover 11 topics and consist of the latest findings from the most renowned experts in the different disciplines of pain medicine. This case study is a description of the process of designing and producing the online textbook.

INTRODUCTION

The American Academy of Pain Medicine (AAPM) is the medical specialty society representing physicians practicing in the field of pain medicine. Because most medical school textbooks do not adequately address pain management, the academy wanted to create TOP MED, an online textbook that would address this need for different specialties and which also could be used as a textbook for the Introduction to Pain Management course. This online textbook would cover 11 topics and consist of the latest findings from the most renowned experts in the different disciplines of pain medicine.

This case study is a description of the process of designing and producing the online textbook, including how we determined what to cover and how we involved the subject matter experts and translated their content into interactive, entertaining learning segments.

E-LEARNING PROGRAM

The academy had created reference materials online, and they published articles, but this was their first program that was designed for teaching medical professionals. One requirement was that the program have similar production values to television; they did not want something that looked like PowerPoint slides; they did not want talking heads; and they did not want just video. SmartPros, Inc. developed TOP MED for the American Academy of Pain Medicine. The author served as the instructional designer and overall project manager.

ACADEMIC AND ADMINISTRATIVE ISSUES

The academy wanted TOP MED to be an online textbook, not an online class. The typical use would be, say, in a course on pediatrics. When the professor wanted to cover pediatric pain, the students would turn to TOP MED to find out the different ways the children felt pain, how to assess pain in children, how children react differently to drugs, and how pain affects children's, and their family's, lives.

The academy also wanted there to be an assessment at the end of each section so that the professor and the students could determine knowledge acquisition.

The use of video created an interesting problem. The client wanted the course to look as if the video was full screen, but bandwidth considerations prevented the use of full-screen video. One solution could have been to find or build a proprietary solution to serve and access the video. Another could have downloaded the video onto student machines during off-hours. We wanted a more standardized and immediate solution, so we took advantage of a feature in Flash that allowed us to blend video into a Flash animation. We built a virtual "set," which blended in with the video to give the appearance of full screen video without the huge bandwidth requirements.

As a textbook for medical school students, TOP MED has to be authoritative, drawing scientific content from experts. We needed people at the top of their field, individuals who were either conducting or utilizing the latest research. Then we needed to distill and transform their knowledge into lessons for individuals who might become general practitioners, not necessarily pain specialists or researchers.

But if we just wanted to present content, we could have produced a book, audiotape, or video. We wanted to benefit from the unique advantages of a Web-based instructional system, using high quality video, student interaction, assessment and feedback, flexible navigation, tracking, and reporting.

The client wanted the actual lessons to primarily be delivered via video, but they were adamant that the content not be delivered as talking heads with bullet points. They wanted the material to look like full screen video. This is problematic over Internet protocols, because, to be of reasonable production quality, video requires significant bandwidth. We were able to solve this problem by using video embedded in Flash animations. By blending the video in with a digital set, we minimized the size of the video, but the set looked like the video was full screen.

We decided on 12 units, which could later be expanded:

1. Introduction
2. Neurobiology of pain
3. Neuropathic pain
4. Analgesics: NSAIDs and COXIBs
5. Analgesics: Opioids and Adjuvants
6. Patient evaluation
7. Acute and postoperative pain
8. Musculoskeletal pain
9. Cancer pain and palliative care
10. Pediatric pain
11. Misuse and abuse of pain medications
12. Race, culture, and ethnicity in pain management

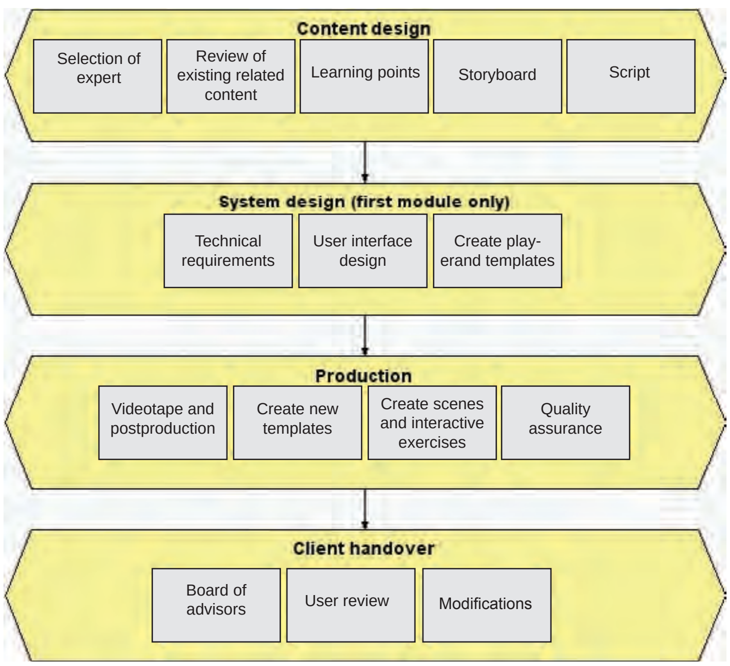
The rationale for sequencing the modules was that we would begin with an introduction to TOP MED and a review of how pain is perceived in the medical community and the population as a whole. The next two units are on how the body reacts to pain and painful stimuli. The two units on analgesics focus on the common medical treatments for pain. Evaluation is necessary for any manifestation of pain. Then the next series of units focus on different common causes and the corresponding treatment for pain. The last two units focus on particular aspects of pain management, which go across all types of pain symptoms and treatments. We started by designing and producing two units: neurobiology of pain and pediatric pain.

Our original goal was that each module should last about a half hour. This was based on initial guidance from the advisory board. We planned the following sections for each module:

1. Introduction: what this topic includes and why it is important.
2. Series of four to eight lessons, each consisting of:
   - 2.1. Introduction to the lesson
   - 2.2. Video lecture with animated, text, and graphic aids
   - 2.3. Summary
   - 2.4. One to three questions, problems, or exercises
   - 2.5. Possible links to supplementary material
3. Conclusion of the topic
   - 3.1. Animated summary of the whole topic with voice
   - 3.2. Quiz of 10 to 20 questions
     - 3.2.1. Each question will have an explanation of how the correct question was arrived at and what learning material was represented
     - 3.2.2. Student responses will be tracked
4. Extra materials
   - 4.1. Printable files of all textual and graphical content
   - 4.2. Glossary with definitions of key terms
   - 4.3. Index of all key topics

Subsequently we decided that the end of module quiz would have a question bank of 30 questions, and that students would get a random

Figure 1. Phases in TOP MED development



sampling of 10 questions each time one took a quiz. Additionally, we combined the index and glossary into a searchable *glindex* that both defines key terms and links to content in the modules.

Our project plan divided our work into four phases. For all modules, there would be a content design phase, a production phase, and a client handover phase. On the first module, we would also perform a system design phase, which would include prototypes that used material from the first module. Figure 1 shows the steps in each phase. The balance of this article will detail how each phase was carried out.

CONTENT DESIGN

Selection of Expert

For this project, the experts were chosen by the client, generally some of the best-known people in the field of pain medicine. In addition to the expert, there was an overall medical editor, who chaired the group that wrote the original federal guidelines on the treatment of pain.

Review of Existing Related Content

AAPM was able to provide videotapes of many of the experts teaching these topics, or at least lecture notes. These videos were generally from 45 minutes to 90 minutes long. The experts also provided copies of materials that they used when they lectured.

Very few of the materials had the production values we needed. There were minimal graphs, grainy unlabeled photographs, and, with one exception, rudimentary animations. But often the content was extremely relevant leading us to conclude that we would have graphic artists recreate and animate graphics and charts.

Learning Points

This phase of development produced an interim and then a final learning points document. The interim document contained a series of learning points with questions for the medical expert, while the final document was used to produce the storyboard.

The instructional designer (ID) first transcribed any video lectures and then outlined the concepts that were covered. There were two key tests for content: (a) would a doctor knowing this information do a better job with a patient (relevance), and (b) if a person did not already know the information, was the way it was presented sufficiently clear to learn from (clarity).

In terms of relevance, if the ID was certain that the information would not help a general practitioner, it was not used. If it was clear from the materials how it was helpful for a doctor, it was included. If there was a question, the information was tagged so that it could be reviewed with the expert. Sometimes the instructional designer could research the topic.

For example, there were concepts that were backed up with intricate descriptions of scientific research. While the concept itself was useful, and the research would have been necessary for people going into pain research, the detailed research explanations were excised from the learning point document, pending approval from one of the content experts.

In terms of clarity, if the explanation was sufficient, it was copied into the learning points. If it was not clear, the subject was researched and/or tagged for discussion with the expert. For example, the following point from the neurobiology of pain module is important to the material and would be understood by those who were already familiar with the topic. But we deemed it too erudite for an introduction to pain management textbook:

There is NMDA receptor-mediated central sensitization that amplifies the input coming both from the injured tissue and also the unharmed tissue surrounding the area of injury.

This statement would be tagged for a more expansive explanation. So that you can see the contrast, refer to Example A for this explanation as it appears in the final script.

And while this text would never make it into a Stephen King best seller, it is something that a second year medical student should be able to understand.

Finally, items were grouped into general topics or sections; all technical terms were defined in footnotes; and a request was made for clinical examples.

The interim learning points document thus had:

- A list of topics that had been covered in lectures or in any additional research.
- Points tagged with, "how is this useful to a doctor?" Or, "why should someone learn this?"
- Other points tagged with, "how else can this be explained?"
- Terms that were tagged with definitions were questioned as, "is an explicit definition necessary in the lecture, or can it just be defined in the glossary?"
- For each topic or section, there was a question, "can you provide a patient history that will illustrate some of the points in this section?"

Once the interim learning points document was assembled, the ID met with the expert face to face. This meeting tended to take about four hours to review all of the questions.

Armed with the answers to the questions and the case studies, the ID would then assemble the final learning point document and submit it to the expert for review. Generally, a one-hour phone meeting was sufficient to review and approve this document.

It also became evident very early on that, for the topics contained in the TOP MED course, modules were going to be 45 to 60 minutes long, not 30 minutes. The learning point documents (Figure 2) tended to run about 20 pages of 12-point font.

Example A.

How does central sensitization occur?

Glutamate appears to play a key role. Glutamate is an amino acid released in excitatory synapses. It affects several types of receptors, both in the spinal cord and in the brain. One of these receptors can be labeled with an artificial reagent, N-methyl D-aspartate (NMDA). That receptor is therefore termed the NMDA receptor.

The NMDA receptor has binding sites for the neurotransmitter glutamate and several other substances that modulate its activity, including glycine, zinc, and various polyamines.

We know that two things have to happen for activation of the NMDA receptor in the spinal cord.

First is the firing of the nociceptor, which causes depolarization and ion flux across its cell membrane, which in turn causes the release of glutamate into the synapse. Prolonged firing by C-fiber nociceptors causes release of glutamate.

Second is the binding of glutamate to the postsynaptic NMDA receptor—keeping in mind that other chemicals also bind and may have additional roles.

Activation of NMDA receptors causes the spinal cord neuron to become more responsive or sensitive to all of its inputs.

Figure 2. Sample learning points page

· *Causes and implications of cancer pain*¶

· Neurology¶

Pain is nociceptive, neuropathic, or both; many cancer patients have a mixture of both¶

Nociceptive¶

- Bone invasion by tumor can be one of the most severe pains associated with metastatic disease.¶
- Infiltration and occlusion of blood vessels can cause ischemia[2] and pain, after which neuropathic pain may be persistent.¶
- Obstruction of a hollow viscous can lead to visceral pain syndromes, which can be quite severe.¶
- Swelling of a structure invested by fascia or periosteum can be very painful.¶
- Necrosis and/or infection of cancerous tissues, with inflammation and ulceration, are tumor-specific pain.¶
- Post-chemotherapy and radiation therapy syndromes are very common, even when a patient is in remission or has been cured.¶
- Any persistent pain syndrome can lead to sensitization and so-called "wind up" of the central nervous, leading to a chronic neuropathic pain state (see TOP MED module on Neurobiology)¶

Neuropathic¶

- Compression or infiltration of nerves, nerve roots or spinal cord is a potent stimulus for acute or persistent neuropathic pain¶
- Concomitant neurological disease, e.g., diabetic neuropathy, post-herpetic neuralgia¶
- Post-surgical, chemotherapy and radiation therapy neuropathies¶

Storyboard

We decided based on the length of the material that we needed to have more than one presenter for each module. We fixed on an intro/review person, an explanatory person, and the medical expert. We also learned that we generally needed to change speakers every minute or so, although a few segments, as long as three minutes, could still maintain interest.

The storyboard document was produced in PowerPoint. The slide showed a stick figure of the actor along with any bullet points or graphics that were going to be displayed, and the speaker notes contained a copy of the learning points that were going to be covered in that scene. If a learning point could be diagrammed, then there would sometimes be a full screen animation along with a voice-over instead of a video.

If there was going to be a graphic, chart, or animation, the ID would create a "wire-frame" from which a graphic artist could work. At the end of each section there were general instructions for an interactive exercise to be completed by the student, generally some type of drag and drop problem. The storyboard was then reviewed with the medical editor. This was also generally a three-hour meeting. The medical editor would typically point out places where the medical expert needed to make his/her sources more explicit, needed more updated references, or, in a few cases, where recent data had modified the assertions.

The comments and storyboard were then reviewed by the medical expert and passed back to the ID. The ID created a final storyboard (Figure 3), which was then reviewed one more time by the editor and medical expert.

Script

The scriptwriting is in three stages. A scriptwriter writes the script. It goes through a review process with the medical editor and instructional designer. Blocking and animation instructions are added. For this project, we used a scriptwriter who had written video scripts for pharmaceutical companies. He provided a fresh perspective to the material. The scriptwriter also wrote any bullets that would appear on the screen and completed

Figure 3. Sample of storyboard page

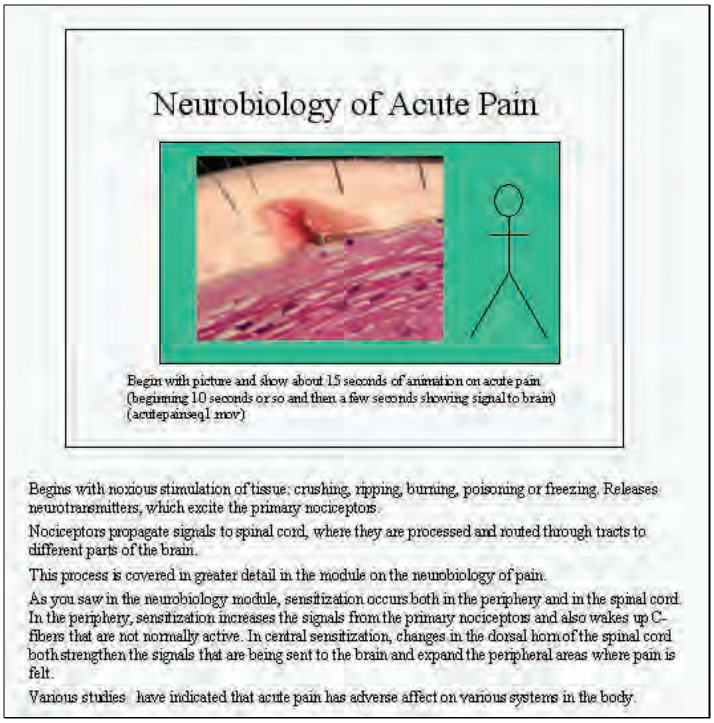


Figure 4. Script sample

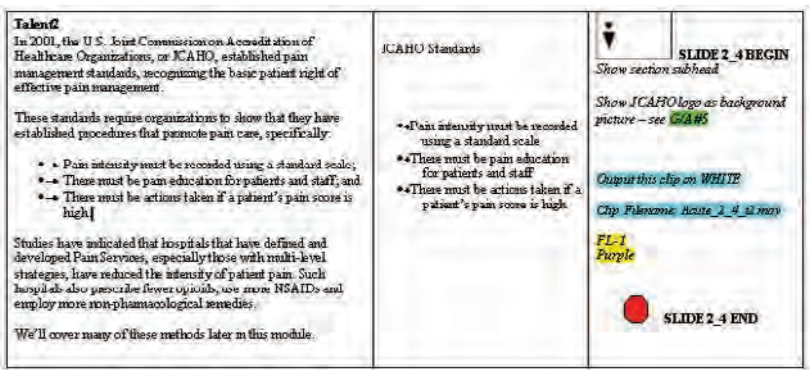


Talent2 In 2001, the U.S. Joint Commission on Accreditation of Healthcare Organizations, or JCAHO, established pain management standards, recognizing the basic patient right of effective pain management. These standards require organizations to show that they have established procedures that promote pain care, specifically: • Pain intensity must be recorded using a standard scale; • There must be pain education for patients and staff; and • There must be actions taken if a patient's pain score is high. Studies have indicated that hospitals that have defined and developed Pain Services, especially those with multi-level strategies, have reduced the intensity of patient pain. Such hospitals also prescribe fewer opioids, use more NSAIDs and employ more non-pharmacological remedies. We'll cover many of these methods later in this module.	JCAHO Standards • Pain intensity must be recorded using a standard scale • There must be pain education for patients and staff • There must be actions taken if a patient's pain score is high	**SLIDE 2_4 BEGIN** *Show section subhead* *Show JCAHO logo as background picture – see G/A#5* *Output this clip on WHITE* *Clip Filename: Acute_2_4_t2.mov* *FL-1* *Purple* **SLIDE 2_4 END**

the end of section exercises. We determined that there should be some bullet or some change to the screen every 5 to 10 seconds in order to maintain interest.

The script (Figure 4) was then reviewed by the instructional designer and then the medical editor, and then the production team added animation, bullet, and stage instructions.

SYSTEM DESIGN

Technical Requirements

There were three broad areas that needed to be defined for TOP MED: (1) the player that would be able to display something that looked like nearly full screen video over the Internet; (2) the features of the learning management system (LMS) that would be used for student registration, tracking, and reporting; and (3) the hosting to meet response time and security requirements.

We knew that we would not be able to send a 600x800 pixel, 15 frames per second video over the Internet. It would be too large, requiring too much bandwidth on both the hosting and the user side. On the other hand, we knew that the end product needed a high production value; students and professors would want something comparable to what they see on television. We also knew that the target audience would have access to high-speed Web access, using advanced desktop and laptop computers.

Our conclusion was to use Flash Video. We would tape all segments on a chroma-key background and then blend the video image into the rest of the Flash stage in order to give the appearance of full screen video, cutting the bandwidth requirements by over 75%. Of course, it sounds simpler than it is; but the SmartPros Interactive staff was able to work out all the glitches and make the process relatively straightforward.

The lesson player also needed to be SCORM compliant so that the lessons could be easily ported to different LMSs. We also knew we were going to work with the SmartPros LMS: the Professional Education Center (PEC). The LMS gave us the capabilities to interface with the Flash player, register students, track student progress, provide end of module quizzes, and create custom reports for medical schools and for the AAPM. We needed to define the specific information that needed to be sent back and forth between the LMS and the player and also to specify the key data that the AAPM wanted to maintain.

Hosting presented an interesting conundrum. Between the U.S. and Canada there are over 140 medical schools. What if all the medical schools were using the program and 16,000 medical students needed to access lessons or answer questions at the same time? What would we need for hosting? On the other hand, since we would be starting off with just a few schools for the first semester, why should the client pay for excess capacity that they were not using? On the other hand, the number of students could change rapidly, in as little as a few weeks and with little advance notice.

For us, one of the strong attractions to the SmartPros PEC was that it was already serving hundreds of thousands of users, with bandwidth, processing, and storage to accommodate spikes in demand. If we started with just a few schools and the numbers of students increased by a factor of five three months in a row, it would not be a significant jump in the demands faced by the overall system.

User Interface Design

The user interface design involved both the LMS and the lesson player. For each, we first defined the types of operations a student was likely to perform. From the LMS, a student would need to register, logon, go to a specific module, take a test for a specific module, view results from previous tests, and view descriptions of the different modules. The priority for the LMS was to make these as easy as possible and keep the screen as simple as possible.

A student would be looking at a particular module from the player. From within that module, a student would want to continue, go to a particular section, fast forward or backward, pause, turn off the sound, take a quiz, see results for the previous quiz, look up a word, find where a topic is covered, and go back to the LMS.

We wanted to make these tasks simple; we wanted a unified color scheme and slide layout, but with a few different options to maintain interest. We initially brainstormed the different ways that the features could work and how they would relate to each other. A graphic designer then created screen layouts for five different looks, which were discussed with the client and sample users. Once we had narrowed the look down to two, we created working prototypes using the materials from the first module. These were again discussed with the same groups, and we ended up with our final look and feel.

Player and Template Creation

In order to allow for multiple developers to work on the material, we created the Flash player. All navigation and media controls were built into this player. Inside the player, there was a stage area. The player was designed to run each scene on that stage. The scene developer thus only had to worry about the specific content that was going to be deployed in that scene.

We then created different digital set templates for the different types of scenes: Introduction, Summary, Activity, person on left, person on right. The scene developer would receive a flash video file (flv file), a list of animation elements and/or bullets, and background photographs. The job of the developer was to assemble these source materials and choreograph them with the video. Figure 5 is a sample of the player with a digital set running.

PRODUCTION

Videotape and Post Production

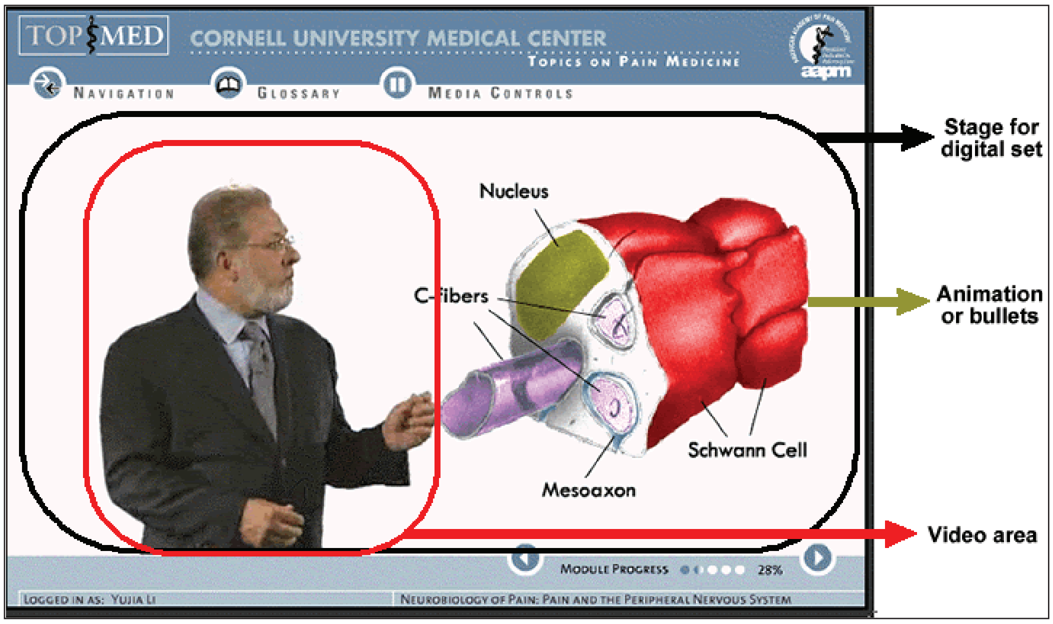
Videotaping was performed in a green room with a teleprompter on the main video camera. Before each scene the actor would be coached on how to enter the frame, when to gesture, and where to stand.

With the medical experts, our challenge was to get them to relax and move freely in front of the camera. With the actors, it was pronunciation of medical terms like parenterally, NSAID, and allodynia. We found that one-hour of video required about one and one half days of shooting. The good takes were then transferred to flash video files and the sound was normalized.

Create New Templates

As we progressed with additional modules, we found we periodically needed to add to the number of templates, for example, person starting on left moving to right, person starting on right moving

Figure 5. Sample player view



to left, and voice over with animation were all added to the original templates.

Create New Scenes and Exercises

We created a styles document and sample scenes that were given to the developers along with the templates and objects that were relevant to them. Before development started we had a kickoff meeting to discuss the purpose and audience of TOP MED, the story for that particular module, the graphics, bullets, and animations for each scene, and how to use the style document and templates.

Quality Assurance

There were two initial rounds of quality assurance for each module, with four individuals going through each scene. For the third round, the medical editor and two representatives of AAPM also participated in the review. The status of all suggestions and findings was maintained in a database that was accessible to all of the QA staff. The project manager was responsible for discussing each finding with the QA individual(s) who found it, verifying it, and then ensuring that the developer understood the changes.

CLIENT HANDOVER

Board of Advisors Review

In February 2005, the board of directors of the American Academy of Pain Medicine viewed the first two modules, and the result was very well received. In fact, one of the directors mentioned that this would be a good prototype for the way medical textbooks should be produced. The general comments were that the length of the modules was appropriate, the content was current, relevant, and focused, and the presentation would maintain the interest of the target student.

User Review

There have been quite a few doctors, residents, and students who have viewed the material. More formal review with medical school classes is also planned.

Modifications

There were three main changes that were requested from our initial feedback. First, since the first impression is going to be from the introduction to each module, we needed to make the intro compelling, and we have added graphics and animations to the background of these sections.

Second, while we initially felt the washed out colors would reduce learner fatigue, the feedback was that we needed a brighter color scheme. We have increased the color contrast for the second and third modules. Third, the initial feedback on the second module was that we needed to add a few animations, which we have done. We also increased our use of animations in the second two modules.

Program Evaluation

A panel of medical experts evaluated all contents for accuracy, currency, and relevance before the program was created. Since the first modules were created, the program has not yet been fully evaluated. We have shown the program to doctors, nurses, and med school students. The feedback has been very positive, but we do have a punch list of changes, most of which are minor. Currently the academy is waiting for the next level of funding to conduct a full evaluation and complete the additional modules.

Networking and Collaboration

TOP MED was designed to be run asynchronously; there is no collaboration built into the program itself. Instead, it is designed as a tool to be used by a professor to provide content to students, with projects to be assigned by the professor as part of the class.

Policy Implications

The advisory board of the AAPM has indicated that they would like to provide more materials in this fashion and that the cost for creating this course was similar to the cost of developing a textbook with similar content. They feel that this style more closely addresses how the current generation of doctors will want to study.

SUSTAINABILITY AND CONCLUSION

TOP MED was designed in such a way that additional modules could be added. Because of the use of video, though, it will be difficult to edit existing modules should methods become obsolete; it is difficult to splice in a new video and have it look continuous.

By having the project sponsored, the AAPM is ensuring that there are no monetary hurdles for students to obtain the content. On the other hand, TOP MED is dependent on the ability of the AAPM to find partners who can afford the approximately $75,000 it takes to create each one-hour module.

Lessons Learned and Best Practices

We thought that the process of defining the content, developing scripts, building in interactivity, and then taping, developing, and editing worked very well. After watching the first two modules, we learned how to make additional transitions to keep the students' attention and the importance of frequent reviews, especially reviews that explain the content in a different manner that when it is first explained.

The three actions that can be identified as best practices are:

1. Determine the needs and content that is needed before doing any of the work. This means pulling the content from a variety of sources and having it checked by content experts.
2. Develop a script with stage and animation instructions before any videotaping or animation development. It is very valuable to have these instructions reviewed by people experienced in animation and video to make sure that what you have envisioned will maintain the interest of the audience and to see if there are alternatives that might be lower cost but just as effective.
3. Flash was a great tool to work with, but you do need experts in Flash, and you need to build in four to five quality assurance rounds. You need to test to see if the product functions and also if it works for the intended audience.

Chapter 2.11
Intelligent Agents Framework for RFID Hospitals

Masoud Mohammadian
University of Canberra, Australia

Ric Jentzsch
Compucat Research Pty Ltd., Canberra, Australia

ABSTRACT

When dealing with human lives, the need to utilize and apply the latest technology to help in saving and maintaining patients' lives is quite important and requires accurate, near-real-time data acquisition and evaluation. At the same time, the delivery of a patient's medical data needs to be as fast and as secure as possible. One possible way to achieve this is to use a wireless framework based on radio-frequency identification (RFID). This framework can integrate wireless networks for fast data acquisition and transmission while maintaining the privacy issue. This chapter discusses the development of an agent framework in which RFID can be used for patient data collection. The chapter presents a framework for the knowledge acquisition of patient and doctor profiling in a hospital. The acquisition of profile data is assisted by a profiling agent that is responsible for processing the raw data obtained through RFID and a database of doctors and patients.

INTRODUCTION

The use and deployment of radio-frequency identification (RFID) is a relatively new area and it has been shown to be a promising technology (Glover & Bhatt, 2006; Lahiri, 2005; Shepard, 2004). This technology has the capability to penetrate and add value to nearly every field, lowering costs while improving service to individuals and businesses. Although many organizations are developing and testing the deployment of RFIDs, the real value of RFID implementation is achieved in conjunction with the use of intelligent systems and intelligent agents. The real issue is how intelligent-agent technologies can be integrated with RFID to be used to achieve the best outcome in business and services areas.

In this research, a new method for integrating intelligent-agent technologies with RFIDs in managing patients' healthcare data in a hospital environment is given. Knowledge acquisition and profiling of patients and doctors in a hospital are assisted by a profiling agent that is responsible for processing the raw data obtained through RFID data that are stored in a hospital database. There are several perspectives for profiling that could be used in a healthcare and hospital environment.

An intelligent agent can assist in profiling patients based on their illness and ongoing diagnostics as reported by the RFIDs. There are certain data and knowledge about each patient in the hospital. This knowledge could be the description of what the patient's symptoms are, monitoring status, and why the patient was admitted to the hospital. Using this information, an evolving profile of each patient can be built.

This data and knowledge can assist in deciding what kind of care he or she requires, the effects of ongoing care, and how to best care for this patient using available resources (doctors, nurses, beds, etc.). The intelligent agent will build a profile of each patient. Along with a profile of each patient, a profile for each doctor can also be developed. Then the patient and doctor profiles can be correlated to find the best doctor to suit the patient.

The patient-doctor profiling can be useful in several situations:

- Providing personalized services to a particular patient, for example, by identifying the services that a patient requires and hence speeding his or her recovery progress in or even out of the hospital.
- Disambiguating a patient's diagnostic based on the patient profile and matching this profile to the available doctor's profile. This may help in matching doctors with the suitable specialization to a patient.
- Providing speedy, reliable reentry of patients into the hospital by having the patients allocated to visit the relevant doctors.
- Presenting information in a way suitable to the doctor's needs, for example, presenting the information about the patients on a continuous basis for the doctors.
- Providing tailored and appropriate care to assist in cost reduction.

Personalization, user modeling, and profiling have been used for many e-commerce applications by IBM, ATG Dynamo, BroadVision, Amazon, and Garden. However, the use of such systems in hospital and personal care and profiling has not been reported. It should be noted that the definitions of personalization, user modeling, and profiling that these companies discuss are not quite the same as our intended meanings.

Many user models try to predict the user's preference in a narrow and specific domain. This works well as long as that domain remains relatively static and as such the results may be limited.

One of the main aims of profiling and user modeling is to provide users with correct and timely responses for their needs. This entails an evolving profile to ensure that as the dynamics of the user and real world change, the profile and user model reflects these changes.

A patient's visit to the hospital can simply be classified as a regular visit, an emergency visit, or an ad hoc appointment (on a need basis). In each of these situations, the needs of the patients are different. During a regular visit, the patient visits the hospital at a regular interval and usually a doctor is assigned to that patient. The patient's profile can assist the patient in a situation where the assigned doctor suddenly becomes unavailable. In this situation, the profile of the patient can be matched with the available doctors with suitable specializations for the needs of the patient. The patient-doctor assignment here is a kind of timetabling problem as we know the profile of the patient and doctors as well as the available doctors. Timetabling of doctors is out of the scope of this research study.

However, in an emergency visit, there is no assigned doctor for such a patient. The doctor in the emergency section of the hospital will provide information about a patient after examination, and a patient profile then can be created. In this case, the intelligent agent can assist the patient by matching the profile of the patient with the doctors suitable for the needs of the patient. Also, the doctors can be contacted in a speedier manner as they are identified and their availability is known.

An appointment visit is very similar to a regular visit, but it may happen only once and therefore the advantages mentioned for regular patients apply here.

We will endeavor to describe several of these, but will expand on one particular potential use of RFIDs in managing patient health data. First some background on RFIDs will be presented in this chapter including some definitions. We will discuss the environment that RFIDs operate in and their relationship to other available wireless technologies such as the IEEE (Institute of Electrical and Electronics Engineers) 802.11b, IEEE 802.11g, and so forth in order to fulfill their requirements effectively and efficiently.

This research is divided into five main sections. The following is based on the patient-doctor profiling and intelligent agents. Then the chapter gives an RFID background that will provide a good description of RFIDs and their components. This section discusses several practical cases of RFID technology in and around hospitals. It lists three possible applicable cases assisting in managing patients' medical data. Next we discuss the important issue of maintaining patients' data security and integrity, and relate that to RFIDs. Finally, the conclusion and further research directions are given.

PATIENT-DOCTOR PROFILING

A profile represents the extent to which something exhibits various characteristics. These characteristics are used to develop a linear model based on the consensus of multiple sets of data, generally over some period of time. A patient or doctor profile is a collection of information about a person based on the characteristics of that person. This information can be used in a decision situation between the doctor, domain environment, and patient. The model can be used to provide meaningful information for useful and strategic actions. The profile can be static or dynamic. The static profile is kept in prefixed data fields where the period between data-field updates is long, such as months or years. The dynamic profile is constantly updated as per evaluation of the situation. The updates may be performed manually or automated. The automated user-profile building is especially important in real-time decision-making systems. Real-time systems are dynamic. These systems often contain data that are critical to the user's decision-making process. Manually updated profiles are at the need and discursions of the relevant decision maker.

The profiling of patients and doctors is based on the patient-doctor information:

- The categories and subcategories of doctor specialization and categorization. These categories will assist in information processing and patient-doctor matching.
- Part of the patient's profile is based on symptoms (past history problems, dietary restrictions, etc.) and can assist in the prediction of the patient's needs specifically.
- The patient's profile can be matched with the available doctor profiles to provide doctors with information about the arrival of patients as well as presentation of the patient's profile to a suitable available doctor.

A value denoting the degree of association can be created from the above evaluation of the doctor-patient profile. The intelligent-agent based on the denoting degrees can identify (and allocate) an appropriate available doctor to the patient.

In the patient-doctor profiling, the intelligent agent will make distinctions in attribute values of the profiles and match the profiles with the highest value. It should be noted that the intelligent agent creates the patient and doctor profiles based on data obtained from the doctors and patient using the following:

- Explicit profiling based on the data entered by hospital staff about a patient.
- Implicit profiling by filling that gap for the missing data by acquiring knowledge about the patient from his or her past visit or other relevant databases if any, and then combining all these data to fill in the missing data. Using legacy data for complementing and updating the user profile seems to be a better choice than implicit profiling. This approach capitalizes on the user's personal history (previous data from previous visits to the doctor or hospital).

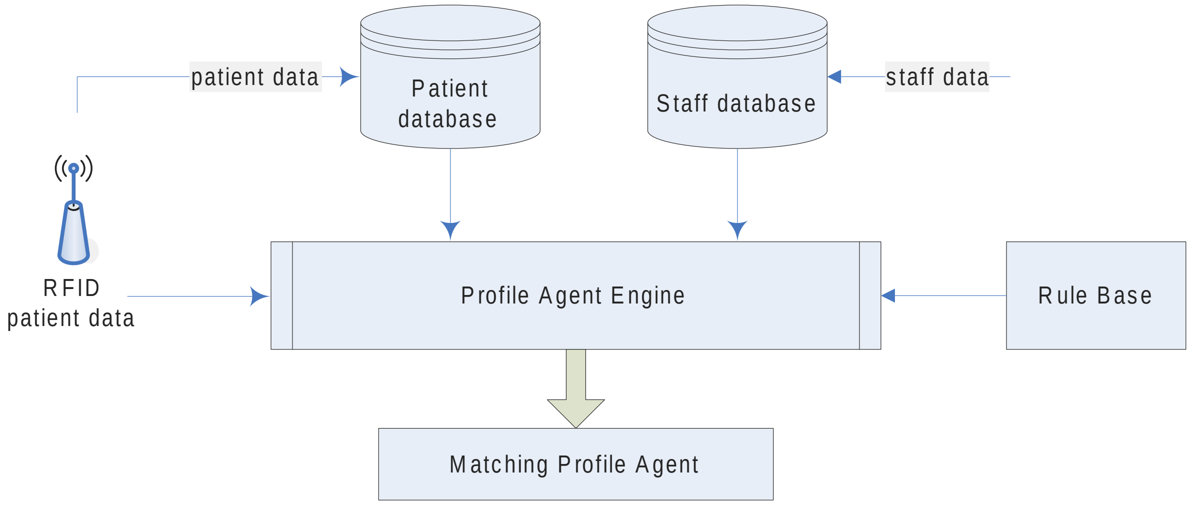
The proposed intelligent-agent system architecture allows user profiling and matching in such a time-intensive and important application. The architecture of the intelligent-agent profiling system using RFID is given in Figure 1.

INTEGRATION OF INTELLIGENT AGENTS, RFID TECHNOLOGIES, AND PROFILE MATCHING

Intelligent agents have been used in order to provide the needed transformation of RIFD passive data collection into an active organizational knowledge assistant. An intelligent agent should be able to act on new data and already stored profile knowledge and thereafter examine its current actions based on certain assumptions. It then inferentially plans its activities. Furthermore, intelligent agents must be able to interact with other agents if required (Bigus & Bigus, 1998; Watson, 1997; Wooldridge & Jennings, 1995) and be able to substitute for a range of human activities in a situated context. In our case, the activities are medical patient assignment and the context is a hospital environment. The integration of RFID capabilities and intelligent-agent techniques provides promising development in the areas of performance improvements in RFID data collection, inference and knowledge acquisition, and profiling operations.

Profile matching is based on a vector of weighted attributes. To get this vector, a rule-based system can be used to match the patient's

Figure 1. Intelligent-agents profiling model using RFID



attributes (stored in the patient's profile) against a doctor's attributes (stored in the doctor's profile). If there is a partial or full match between them, then the doctor will be informed based on his or her availability from the hospital doctor database. The matching is done through the rule-based system by examining the attributes of the patient profile and matching them using the rules already created to the doctor's profile based on the availability of doctors. Figure 1 displays the integration of intelligent agents, RFID technologies, and the profile-matching module.

RFID Description

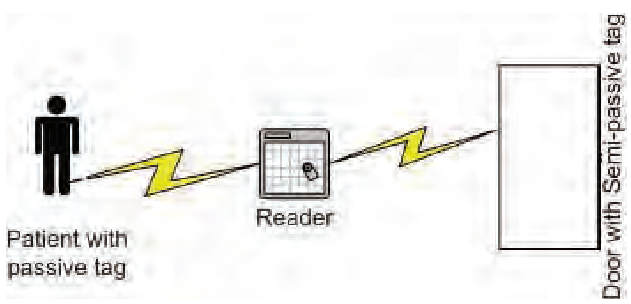
RFID is a progressive technology that has been said to be easy to use and is well suited for collaboration with intelligent agents. Basically, an RFID can be read only, volatile read and write, or write once and read many (WORM) times. RFIDs are non-contact and non-line-of-sight operations. Being non-contact and non-line-of-sight will make RFIDs able to function under a variety of environmental conditions while still providing a high level of data integrity (Glover & Bhatt, 2006; Lahiri, 2005; Shepard, 2004). A basic RFID system consists of four components. These are the RFID tag (sometimes referred to as the transponder), a coiled antenna, a radio-frequency transceiver, and some type of reader for the data collection.

The RFID tag (transponder) emits radio waves in ranges of anywhere from 2.54 centimeters to 33 meters. Depending upon the reader's power output and the radio frequency used, and if a booster is added, that distance can be somewhat increased. When RFID tags pass through a specifically created electromagnetic zone, they detect the reader's activation signal. Transponders can be online or off line and electronically programmed with unique information for a specific application or purpose. A reader decodes the data encoded on the tag's integrated circuit and passes the data to a server for data storage or further processing.

RFID tags can be categorized as active, semi-active, or passive. Each has and is being used in a variety of inventory-management and data-collection applications today. The condition of the application, place, and use determines the required tag type.

Active RFID tags are powered by an internal battery and are typically read-write. Tag data can be rewritten and/or modified as the need dictates. An active tag's memory size varies according to manufacturing specifications and application requirements; some tags operate with up to 5 megabytes of memory. For a typical read-write RFID work-in-process system, a tag might give a machine a set of instructions, and the machine would then report its performance to the tag. This encoded data would then become part of the tagged part's history. The battery-supplied power of an active tag generally gives it a longer read range. The trade-off is greater size, greater cost, and a limited operational life that has been estimated to be a maximum of 10 years, depending upon operating temperatures and battery type.

Figure 2. Semi-passive tag



The semi-active tag comes with a battery. The battery is used to power the tag's circuitry and not to communicate with the reader. This makes the semi-active tag more independent than the passive tag, and it can operate in more adverse conditions. The semi-active tag also has a longer range and more capabilities than a passive tag. Linear bar codes that reference a database to get product specifications and pricing are also data devices that act in a very similar way. Semi-passive tags are preprogrammed, but can allow for slight modifications of their instructions via the reader or interrogator. However, they are bigger, weigh more, and are more complete than passive tags. A reader is still needed for data collection.

Passive RFID tags operate without a separate external power source and obtain operating power generated from the reader. Passive tags have no power source embedded in them and are consequently much lighter than active tags, less expensive, and offer a virtually unlimited operational lifetime. However, the trade-off is that they have shorter read ranges than active tags, and require a higher powered reader. Read-only tags are typically passive and are programmed with a unique set of data (usually 32 to 128 bits) that cannot be modified.

RFID systems can be distinguished by their deployment and frequency range. RFID tags generally operate in two different types of frequencies that make them adaptable for nearly any application. These frequency ranges are as follows.

Low-frequency (30 KHz to 500 KHz) systems have short reading ranges and lower system costs. They are most commonly used in security access, asset tracking, and animal-identification applications.

High-frequency (850 MHz to 950 MHz, or in industry, science, and medical applications, 2.4 GHz to 2.5 GHz) systems offer longer reading ranges (greater than 33 meters) and high reading speeds. These systems are generally used for such applications as railroad-car tracking, container dock and transport management, and automated toll collection. However, the higher performance of high-frequency RFID systems incurs higher system-operating costs.

The coiled antenna is used to emit radio signals to activate the tag and read or write data to it. Antennas are the conduits between the tag and the transceiver that controls the system's data acquisition and communication. RFID antennas are available in many shapes and sizes. They can be built into a door frame, mounted on a tollbooth, or embedded into a manufactured item such as a shaver or software case so that the receiver tags the data from things passing through its zone. Often, the antenna is packaged with the transceiver and decoder to become a reader. The decoder device can be configured either as a handheld or a fixed-mounted device. In large, complex, often chaotic environments, portable or handheld transceivers would prove valuable.

RFID for Hospital Environment

In hospitals, systems need to use rules and domain knowledge that is appropriate to the situation. One of the more promising capabilities of intelligent agents is their ability to coordinate information between the various resources.

In a hospital environment, in order to manage patient medical data, there is a need for both types: fixed and handheld transceivers. Transceivers can be assembled in ceilings, walls, or door frames to collect and disseminate data. Hospitals have become large complex environments.

Nurses and physicians can retrieve the patient's medical data stored in transponders (RFID tags) before they enter a ward or patient's room.

Given the descriptions of the two types of RFID tags and their potential use in hospital patient data management, we suggest the following:

- It would be most useful to embed a passive RFID transponder into a patient's hospital wristband.
- It would be most useful to embed a passive

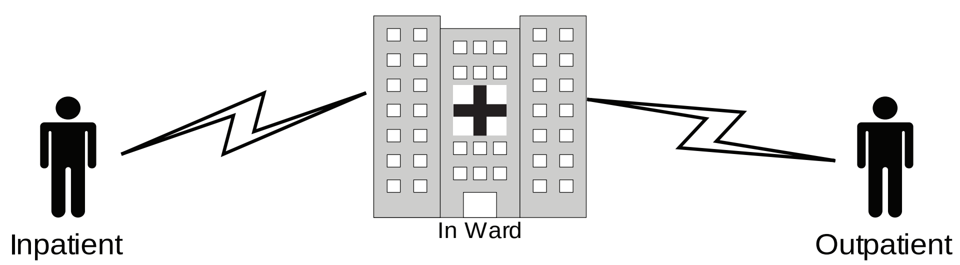
RFID transponder into a patient's medical file.

- Doctors should have PDAs (personal digital assistants) equipped with RFID or some type of personal area network device. Either would enable them to retrieve some patient information whenever they are near the patient instead of waiting until the medical data is pushed to them through the hospital server.
- Active RFID tags are more appropriate for the continuous collection of patient medical data since the patient's medical data need to be continuously recorded to an active RFID tag and an associated reader needs to be employed. Using an active RFID means that the tag will be a bit bulky because of the needed battery for the write process, and there is a concern about radio-frequency emissions. Thus, it is felt that an active tag would not be a good candidate for the patient wristband. However, if the patient's condition is to be continuously monitored, the collection of the data at the source is essential. The inclusion of the tag in the wristband is the only way to record the medical data on a real-time basis using the RFID technology. As more organizations get into the business of manufacturing RFIDs and the life and size of batteries decrease, the tag size will decrease and this may be a real possible use.
- Passive RFID tags can be used as well. These passive tags can be embedded in the doctors PDA, which is needed for determining their locations whenever the medical staff requires them. Also, passive tags can be used in patients' wristbands for storage of limited amount of data on an off-line basis, for example, information such as the date of hospital admission, medical record number (MRN), and so forth.

Low-frequency-range tags are suitable for the patients' wristband RFID tags since it is expected that the patients' bed will not be too far from an RFID reader. The reader might be fixed over the patient's bed, in the bed itself, or over the door frame. The doctor using his or her PDA would be aiming to read the patient's data directly and within a relatively short distance. High-frequency-range tags are suitable for the physician's tag implanted in the PDA. As physicians move from one location to another in the hospital, data on their patients could be continuously being updated.

Finally, the transceivers and interrogators can differ quite considerably in complexity, depending upon the type of tags being supported and the application. The overall function of the application is to provide the means of communicating with the tags and facilitating data transfer. Functions performed by the reader may include quite sophisticated signal conditioning and parity error checking and correction. Once the signal from a transponder has been correctly

Figure 3. Patient and outpatient



received and decoded, algorithms may be applied to decide whether the signal is a repeat transmission, and may then instruct the transponder to cease transmitting or temporarily cease asking for data from the transponder. This is known as the command-response protocol and is used to circumvent the problem of reading multiple tags over a short time frame. Using interrogators in this way is sometimes referred to as hands-down polling. An alternative, more secure but slower tag polling technique is called hands-up polling. This involves the transceiver looking for tags with specific identities, and interrogating them in turn. A further approach may use multiple transceivers multiplexed into one interrogator.

Hospital patient data management deals with sensitive and critical information (patients' medical data). Hands-down polling techniques in conjunction with multiple transceivers that are multiplexed with each other form a wireless network. The reason behind this choice is that there is a need for high-speed transfer of medical data from medical equipment to or from the RFID wristband tag to the nearest RFID reader and then through a wireless network or a network of RFID transceivers or LANs (local area networks) to the hospital server. From there it is a short distance to be transmitted to the doctor's PDA, a laptop, or a desktop through a WLAN (wireless LAN) IEEE 802.11b or 803.11g, or a wired LAN, which operates at the 5.2 GHz band with a maximum data transfer rate of 54 Mbps.

The hand-down polling techniques, as previously described, provide the ability to detect all detectable RFID tags at once (i.e., in parallel), preventing any unwanted delay in transmitting medical data corresponding to each RF tagged patient.

Transponder programmers are the means by which data are delivered to WORM and read-write tags. Programming can be carried out off line or online. For some systems, re-programming may be carried out online, particularly if it is being used as an interactive portable data file within a production environment, for example. Data may need to be recorded during each process. Removing the transponder at the end of each process to read the previous process data and to program the new data would naturally increase process time and would detract substantially from the intended flexibility of the application. By combining the functions of a transceiver and a programmer, data may be appended or altered in the transponder as required without compromising the production line.

Practical Cases using RFID Technology

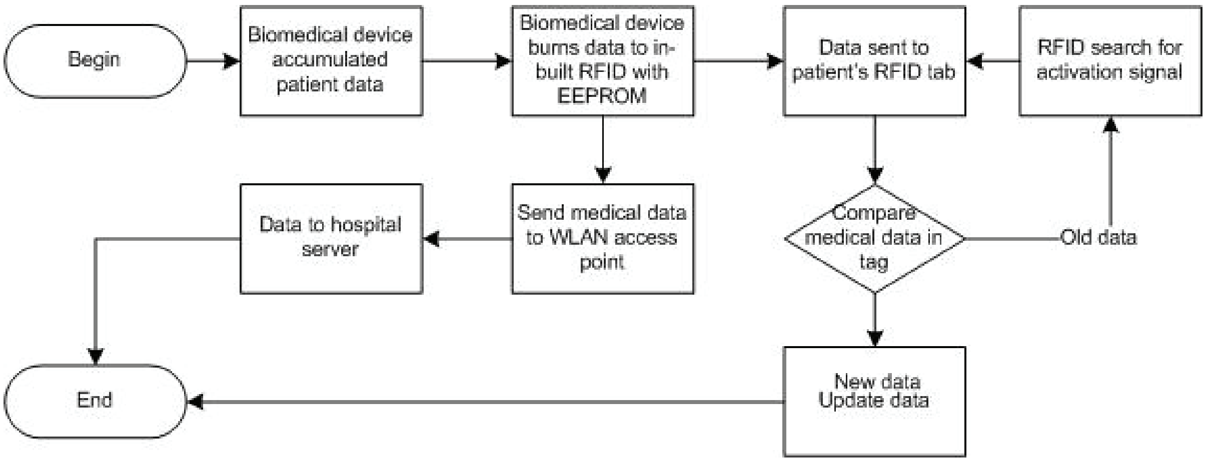
This section explains in detail three possible applications of the RFID technology in three applicable cases. Each case is discussed step by step and then represented by a flowchart. These cases cover issues of the acquisition of a patient's medical data, locating the nearest available doctor to the patient's location, and how doctors stimulate the patient's active RFID tag using their PDAs in order to acquire the medical data stored in it.

Case 1: Acquisition of Patient's Medical Data

Case 1 will represent the method of acquisition and transmission of medical data. This process can be described in the following points as follows:

- A biomedical device equipped with an embedded RFID transceiver and programmer will detect and measure the biological state of a patient. This medical data can be an ECG (electrocardiogram), EEG (electroencephalogram), BP (blood pressure), sugar level, temperature, or any other biomedical reading.
- After the acquisition of the required medical data, the biomedical device will write this data to the RFID transceiver's EEPROM (electronically erasable programmable

Figure 4. Acquisition of patient data



read-only memory) using the built-in RFID programmer. Then the RFID transceiver with its antenna will be used to transmit the stored medical data in the EEPROM to the EEPROM in the patient's transponder (tag) that is around his or her wrist. The data received will be updated periodically once new fresh readings are available by the biomedical device. Hence, the newly sent data by the RFID transceiver will be accumulated with the old data in the tag. The purpose of the data stored in the patient's tag is to make it easy for the doctor to obtain medical information regarding the patient directly via the doctor's PDA, tablet PC (personal computer), or laptop.

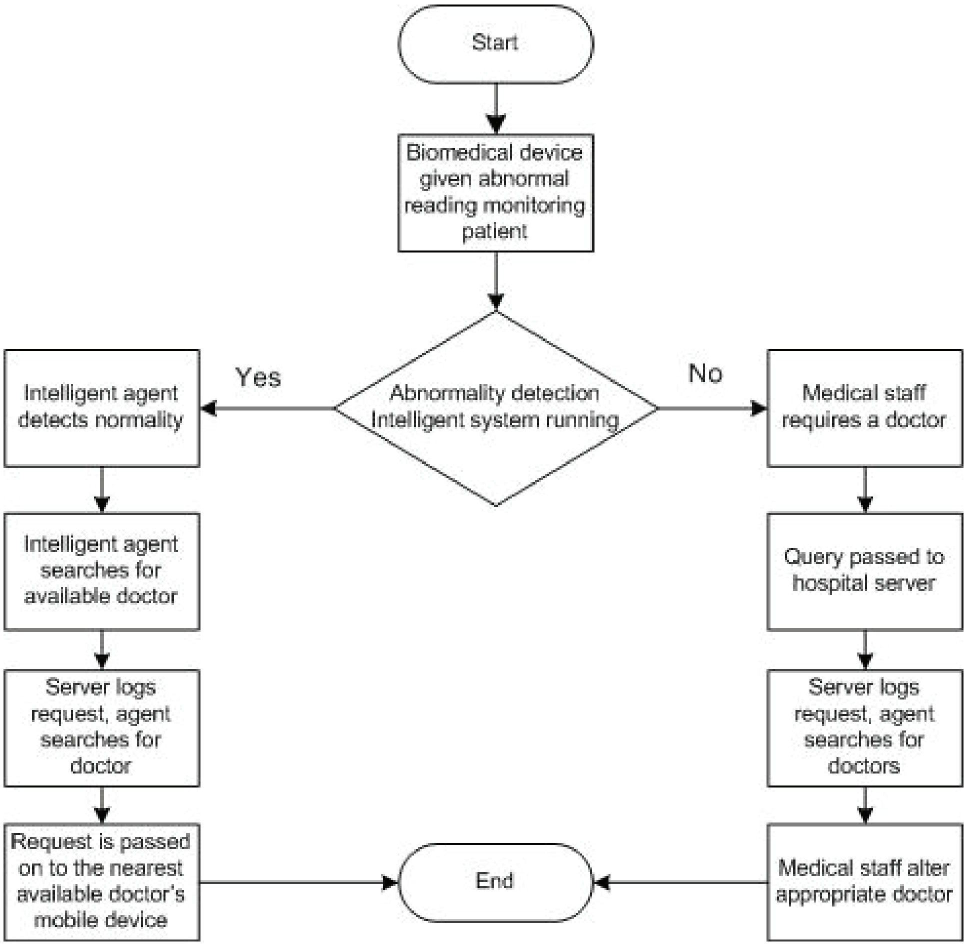
- Similarly, the biomedical device will also transfer the measured medical data wirelessly to the nearest WLAN access point. Since a high data-transfer rate is crucial in transferring medical data, IEEE 802.11b is recommended for the transmission purpose.
- The wirelessly sent data will then be routed to the hospital's main server to be sent (pushed) to the following:
  - Other doctors available throughout the hospital so they can be notified of any newly received medical data.
  - An online patient-monitoring unit or a nurse's workstation within the hospital.
  - An expert (intelligent) software system running on the hospital server to be then compared with other previously stored abnormal patterns of medical data and to raise an alarm if any abnormality is discovered.
- Another option could be using the embedded RFID transceiver in the biomedical device to send the acquired medical data wirelessly to the nearest RFID transceiver in the room. Then the data will travel simultaneously in a network of RFID transceivers until reaching the hospital server.

Case 2: Locating the Nearest Available Doctor to the Patient's Location

This case will explain how to locate the nearest doctor, who is needed urgently, to attend an emergency medical situation. This case can be explained as follows:

- If a specific surgeon or physician is needed in a specific hospital department, the medical staff in the monitoring unit (e.g., nurses) can query the hospital server for the nearest available doctor to the patient's location. In our framework, an intelligent agent can perform this task.

Figure 5. Locating nearest doctor



- The hospital server traces all doctors' locations in the hospital through detecting the presence of their wireless mobile device, for example, PDA, tablet PC, or laptop in the WLAN range.
- Another method that the hospital's server can use to locate the physicians is making use of the RFID transceivers built into the doctor's wireless mobile device. Similar to the access points used in WLAN, RFID transceivers can assist in serving a similar role of locating a doctor's location. This can be described in three steps.
    - The fixed RFID transceivers throughout the hospital will send a stimulation signal to detect other free RFID transceivers, which are in the doctors' PDAs, tablets, laptops, and so forth.
    - All free RFID transceivers will receive the stimulation signal and respond back with an acknowledgement signal to the nearest fixed RFID transceiver.
    - Finally, each free RFID transceiver cell position would be determined by locating to which fixed RFID transceiver range it belongs to or currently is operating with.
- After the hospital server locates the positions of all available doctors, the RFID determines the nearest requested (condition evaluation) physican (pediatries, neuologist, etc...) to the patient's location.

- Once the required physician is located, an alert message will be sent to his or her PDA, tablet PC, or laptop indicating the location to be reached immediately. This alert message would show the following.
  - Case profile over application period
  - The building, floor, and room of the patient (e.g., 3C109).
  - The patient's case (e.g., heart stroke, arrhythmia, etc.).
  - A brief summary description of the patient's case.
- If the hospital is running an intelligent agent on its server as described in our proposed framework, the process of locating and sending an alert message can be automated. This is done through comparing the collected medical data with previously stored abnormal patterns of medical data, then sending an automated message describing the situation. This system could be used in the patient-monitoring unit or the nurse's workstation, who observe and then send an alert message manually.

Case 3: Doctors Stimulate a Patient's Active RFID Tag using Their PDAs in Order to Acquire the Medical Data Stored in It

This method can be used in order to get rid of medical files and records placed in front of the patient's bed. Additionally, it could help in preventing medical errors (reading the wrong file for the wrong patient) and could be considered an important step toward a paperless hospital.

This case can be described in the following steps:

- The doctor enters the patient's room or ward. The doctor wants to check the medical status of a certain patient. Instead of picking up the hard-copy paper medical file, the doctor interrogates the patient's RFID wrist tag with his or her RFID transceiver equipped in a PDA, tablet PC, laptop, or so forth.
- The patient's RFID wrist tag detects the signal of the doctor's RFID transceiver coming from his or her wireless mobile device and replies back with the patient's information and medical data.
- If there was more than one patient in the ward possessing RFID wrist tags, all tags can respond in parallel using hands-down polling techniques back to the doctor's wireless mobile device.
- Another option could be that the doctor retrieves only the patient's number from the passive RFID wrist tag. Then, through the WLAN, the doctor could access the patient's medical record from the hospital's main server.

RFID technology has many potential important applications in hospitals, and the three cases discussed are real practical examples. Two important issues can be concluded from this section. WLAN is preferred for data transfer given that IEEE's wireless networks have much faster speed and greater coverage area as compared to RFID transceiver and transponder technology. Yet, RFID technology is the best for data storage and locating positions of medical staff and patients as well.

Here there is a need for the RFID transceiver and programmer to be embedded in biomedical devices for data acquisition and dissemination. A RFID transceiver embedded in a doctor's wireless mobile device enables the doctor to obtain medical data. With the progress of the RFID technology, it could become a standard as other wireless technologies (Bluetooth, for example) and eventually manufacturers will be building them in electronic devices, or biomedical devices, in our case.

Maintaining Patients' Data Security and Integrity

Once data are transmitted wirelessly, security becomes a crucial issue. Unlike in wired transmission, wirelessly transmitted data can be easily sniffed out, leaving the transmitted data vulnerable to many types of attacks. For example, wireless data could be easily eavesdropped on using any mobile device equipped with a wireless card. In worst cases, wirelessly transmitted data could be intercepted and then possibly tampered with, or in best cases, the patient's security and privacy F be compromised. Hence emerges the need for data to be initially encrypted from the source.

This section of the chapter discusses how we could apply encryption to the designed wireless framework that was explained in the previous section, suggesting exactly where data need to be encrypted and\or decrypted depending on the case that is being examined.

Next, a definition of the type of encryption that would be used in the design of the security (encryption or decryption) framework will be discussed, and this will be followed by a flowchart demonstrating the framework in a step-by-step process. There are two layers of encryption that are recommended to be used.

- **Physical:** (hardware) layer encryption means encrypting all collected medical data at the source or hardware level before transmitting them. This ensures that the patient's medical data would not be compromised once exposed to the outer world on its way to its destination. Even if a person with a malicious intent and also possessing a wireless mobile device steps into the coverage range of the hospitals' WLAN, this intruder will gain actually nothing since all medical data are encrypted, making all intercepted data worthless.
- **Application:** (software) layer encryption means encrypting all collected medical data at the destination or application level once receiving it. Application-level encryption runs on the doctor's wireless mobile device (e.g., PDA, tablet PC, or laptop) and on the hospital server. Once the medical data are received, they will be protected by a secret password (encryption or decryption key) created by the doctor who possesses this device. This type of encryption would prevent any person from accessing the patient's medical data if the doctor's wireless mobile device gets lost, or even if a hacker hacks into the hospital server via the Internet, intranet, or some other means.

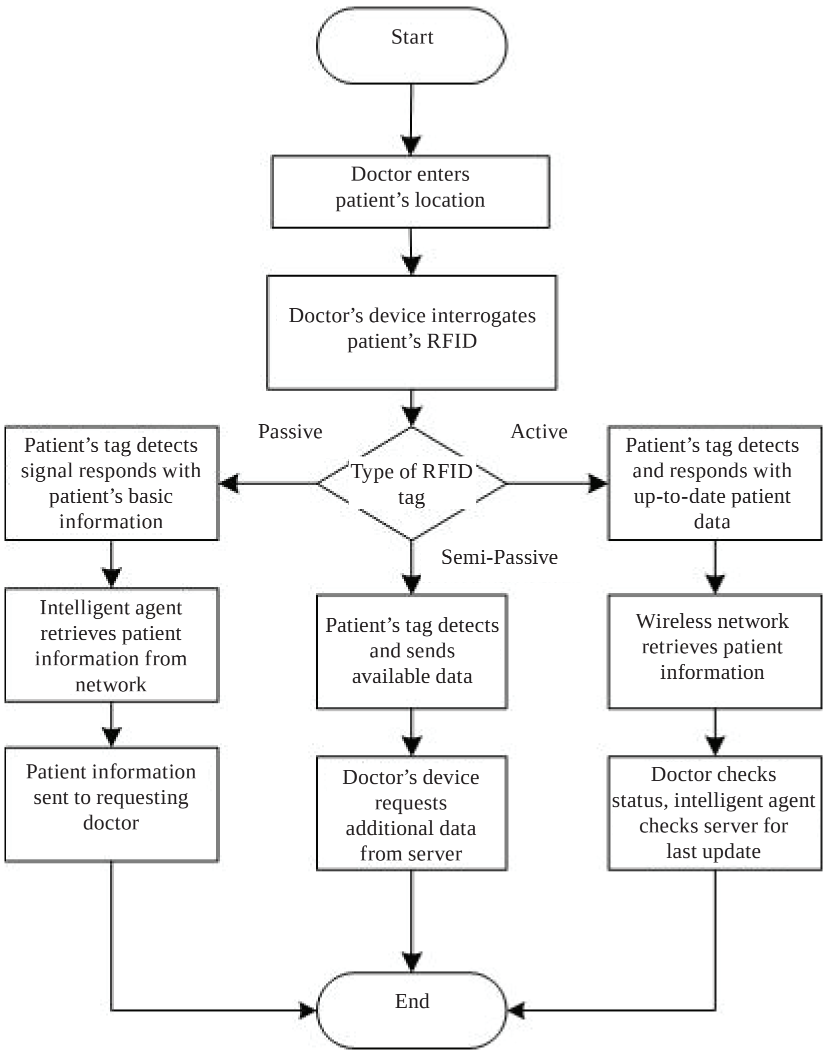
Framework of Encrypting a Patient's Medical Data

The previous section (practical cases using RFID technology) focused on how to design a wireless framework to reflect how a patient's medical data can be managed efficiently and effectively leading to the elimination of errors, delays, and even paperwork. Similarly, this section will focus on the previously discussed framework from a security perspective, attempting to increase security and data integrity during the acquisition of a patient's medical data and when doctors stimulate the patient's active RFID tag using their wireless mobile devices in order to acquire the medical data stored in it. The third case on locating the nearest available doctor to the patient's location is more concerned about locating doctors than transferring a patient's data and it is not discussed here.

The lower part of Figure 6 represents the physical (hardware) encryption layer. This part is divided into two sides. The left side demonstrates the case of a doctor acquiring a patient's medical data via a passive RFID tag located in a band around the patient's wrist. The passive RFID tag contains only a very limited amount of information such as the patient's name, date of admission to the hospital, and above all his or her MRN, which will grant access to the medical record containing the acquired medical data and other information regarding the patient's medical condition. This process is implemented in six steps, and involves two pairs of encryption and decryption. The first encryption occurs after the doctor stimulates the RFID passive tag to acquire the patient's MRN, so the tag will encrypt and reply back with the MRN to the doctors PDA, for example. Then the doctor will decrypt the MRN and use it to access the patient's medical record from the hospital's server. Finally, the hospital server will encrypt and reply back with the medical record, which will be decrypted once received by the doctor's PDA.

The right side of Figure 6 represents a similar case, but this time using an active RFID tag. This process involves only one encryption and decryption. The encryption happens after the doctor stimulates the active RFID tag using a PDA that has an equipped RFID transceiver, so the tag replies with the medical data encrypted. Then the received data is decrypted through the doctor's PDA. The upper part of Figure 6 represents the application encryption layer requiring the doctor to enter a password to decrypt and then access the stored medical data. So, whenever the doctor wants to access a patient's medical data, he or she simply enters a certain password to get

Figure 6. Functional flow



access to either the wireless mobile device or a hospital server, depending on where the medical data actually resides.

Securing medial data seems to be uncomplicated, yet the main danger of compromising such data comes from the people managing it, for example, doctors, nurses, and other medical staff. We have seen that even though the transmitted medical data are initially encrypted from the source, doctors have to run application-level encryption on their wireless mobile devices in order to protect the important data if the device gets lost, left behind, stolen, and so forth. Nevertheless, there is a compromise. Increasing security through using multiple layers and increasing the length of encryption keys decreases the encryption-decryption speed and causes unwanted time delays, whether we are using application- or hardware-level encryption. As a result, this could delay medical data being sent to doctors or online monitoring units. Figure 6 represents the case of high and low levels of security in a flowchart applied to the previously discussed two cases.

We conclude that there are two possible levels of encryption: the software level (application layer) or hardware level (physical layer) depending on the level of security required. Both physical-layer and application-layer encryption are needed in maintaining collected medical data on hospital servers and doctors' wireless mobile devices. Encrypting medical data makes the process of data transmission slower, while sending data unencrypted is faster. Here there is a need to compromise between speed and security. For medical data, it has to be sent as fast as possible to medical staff, yet the security issue has the priority.

CONCLUSION

Managing patients' data wirelessly (paperless) can prevent errors, enforce standards, make staff more efficient, simplify record keeping, and improve patient care. In this chapter, both passive and active RFID tags were used in acquiring and storing medical data, and in linking to the hospital's server via a wireless network. Moreover, three practical applicable RFID cases were discussed and it was explained how the RFID technology can be put in use in hospitals while at the same time maintaining the acquired patient data's security and integrity.

This research in the wireless medical environment introduces some new ideas in conjunction with what is already available in the RFID technology and wireless networks. The aim here is to link both technologies with each other to achieve the research's main goal, which is delivering patient medical data as fast and secure as possible to pave the way for future paperless hospitals.

ABSTRACT

Public Health (PH) applications in County of Los Angeles (LAC), Department of PH have been developed to meet individual PH program's goals. This resulted in lack of county-wide PH data integration, efficiency, and usefulness. LAC encouraged the development of web-based applications utilizing standards-based PH Information Network interoperable service-oriented architecture (SOA). The goal was to stop the evolution of fragmented health data systems which place limitations on the PH mission of safeguarding and improving the health of the community as well as responding to large-scale threats to PH. PH Nursing case management is one example of LAC's initiative for promotion of web-based tools which will be utilized within this SOA. This PH architecture is capable of supporting electronic data exchange from PH partners using a HL7 integration hub. It promotes the development of management tools and applications to assist PH response and recovery activities while providing resources to support departmental integration.

INTRODUCTION

Public health applications in the County of Los Angeles, Department of Public Health have been traditionally developed to assist public health programs in meeting individual program's goals and objectives. This led to the development of systems that collect data only for a specific program area leading to a lack of county-wide public health data integration, efficiency, and usefulness. The existing Program Area Modules (PAMs) do not conform to the National Electronic Disease Surveillance System (NEDSS) nor Public Health Information Network (PHIN) standards recommended by the Centers for Disease Control and Prevention's (CDC, US Govt.) for an interoperable information systems in organizations that participate in public health (Public Health Information Network, 2004; National Electronic Disease Surveillance System, 2004).

The PAMs use a variety of user interfaces, business logic, directory structures, workflow, and data storage systems and are not accessible outside public health firewall. The user and electronic interface for these modules have been implemented differently and do not present a common user or electronic interface for these modules, thereby significantly increasing the cost of data collection and analysis. These modules exist as stand-alone entities each with functionality for disease reporting, incident management, and data storage for specific program areas, and in most cases do not communicate at all with each other or external healthcare partners. A limited number of modules have ad-hoc implementation for electronic data exchange with laboratories as well as some other capabilities needed by the application users.

It was determined that under the standards based architecture, PAMs only handle specialized functionality for each specific area of health care or resource management. All common functionality like user authentication, directory serices, data storage, and so on should be handled by Common Area Modules (CAMs), modules common to all PAMs. An internal message and data broker module will be used for electronic data transfer with partner systems. This initiative will also require that existing investments in legacy systems be leveraged and merged with standards-based Web enabled systems to provide a synchronized view of public health data and resources across all program areas.

The nursing practice management system (NPMS) case management PAM is an example of the Los Angeles County's initiative in promotion of Web-based tools which is to be utilized within the interoperable standards based architecture. This PAM has won several awards since it was implemented including the Los Angeles County Public Health Innovation Award in 2003 and the National Association of Counties Nursing Achievement Award in 2004 (see Figure 1).

The public health nursing unit of Los Angeles County promotes the well being of the community at large and prevents disease, disability, and premature death. Public health nurses (PHNs) make home visits to families with communicable diseases; emphasize nutrition, disease prevention, and health; and improve the quality of neighborhood life by working in partnership with the community. This system tracks multiple interventions given over a period of time by index case, family, and household. It provides a powerful and secure departmental work-flow, assignment/task management and reporting tool with an intuitive interface design that minimizes training and transition costs. The "open" architecture allows the system to communicate with other Public Health programs. This system involves epidemiological data entry during assessments of cases by Public Health Nurses and serves as an efficient tracking system for nurses and supervisors, ensuring that members of the community are assessed and that interventions are made in a timely manner.

The investment into the approach for an enterprise architecture within an existing infrastructure was done with the view that investment of pre-

Figure 1. The "open" architecture allows the system to communicate with other Public Health programs.

existing assets which include people, facilities, and services must now also include information technology as an asset. It was important for County personnel to determine that services must be governed similar to business returns in the corporate environment for maximal return on investment. The decision to implement this architecture was done keeping in mind that there would be large scale reuse of preexisting programs, improved flexibility for change management and improved comprehensibility of software functionality for a clear relationship between services and function (Sprott, 2004)

To help alleviate the evolution of these separate, fragmented public health data systems which over a period of time place limitations on local public health agencies to accomplish the mission of safeguarding and improving the health of the community and to respond effectively to large-scale threats to public health, the County of Los Angeles has been promoting the development of Web-based applications which will utilize a standards-based interoperable service-oriented architecture (SOA).

Service-oriented modeling and architecture was announced by IBM as the first SOA-related methodology in 2004 (IBM, 2005; Arsanjani, 2004). Since 2004, efforts have been made to move towards greater standardization and the involvement of business objectives.

SOA can also be regarded as a style of information systems architecture that enables the creation of applications that are built by combining loosely coupled and interoperable services (Tsai, Chen, & Fan, 2006). These services inter-operate based on a formal definition (or contract, e.g., WSDL) that is independent of the underlying platform and programming language. The interface definition hides the implementation of the language-specific service. SOA based systems can therefore be independent of development technologies and platforms (such as Java, .NET etc). In addition, applications running on either platform can consume services running on the other as Web services (Utschig, Rodriguez, & Buelow, 2006).

The Service Oriented Model is a complex architectural models and it revolves around a few key ideas (Spewak & Hill, 1992). A service is realized by one agent and used by a different agent. Services are mediated by means of the messages exchanged between requester agents and provider agents.

Another important aspect of services is their relationship to the real world: services are mostly deployed to offer functionality in the real world. We model this by elaborating on the concept of a service's owner—which, whether it is a person or an organization, has a real world responsibility for the service. In addition, Service Oriented Model makes use of meta-data, which is a key property of Service Oriented Architectures. This meta-data is used to document many aspects of services: from the details of the interface and transport binding to the semantics of the service and what policy restrictions there may be on the service.

SOA is a mechanism for defining business services and operating models and therefore providing a structure for information technology to deliver the actual business requirements and adapt in a similar way to the business needs (Utschig, Rodriguez, & Buelow, 2006). The purpose of using SOA as a business mapping tool is to ensure that the services created properly represent the business view and are not just what technologists think the business services should be. At the heart of SOA planning is the process of defining architectures for the use of information in support of the business, and the plan for implementing those architectures (Spewak & Hill, 1992).

SOA has also faced some criticisms including concern that Web Services standards and products are still evolving (e.g., transaction, security), and SOA can thus introduce risk unless properly managed and estimated with additional budget and contingency for additional Proof of Concept work (Utschig, Rodriguez, & Buelow, 2006). Web services are designed to support interoperable machine-to-machine interaction over a network. Web Service has an interface which can be processed by a machine in a specific format (specifically WSDL). Other systems interact with the Web service in a manner prescribed by its description using SOAP messages, typically conveyed using HTTP with an XML serialization in conjunction with other Web-related standards

ARCHITECTURE

The Los Angeles County Operational Data Store (LAC-ODS) architecture is based upon recommendations of the Public Health Information Network (PHIN) initiative by Centers for Disease Control (CDC).

In order to maximize the use of pre-existing applications and bring together interoperability the architecture was developed for utilization of the common services while promoting interfaces to new systems with minimal impact on existing systems (LACDHS, 2003).

The architectural design was developed from the premise that change within the county environment is a fact of life and process. The County of Los Angeles continues to provide comprehensive public health programs and services over 17 million people. Therefore the approach to the architecture was to lay out a foundation which could handle change management while stressing on functions and interoperability. The need to reuse preexisting software applications was a major need since this would enable a more effective support of this initiative with greater inputs from the users. The technology capabilities were targeted to be implemented phase wise in order to have optimal feedback and collaborative construction of the architecture (Schuschel & Weske, 2004).

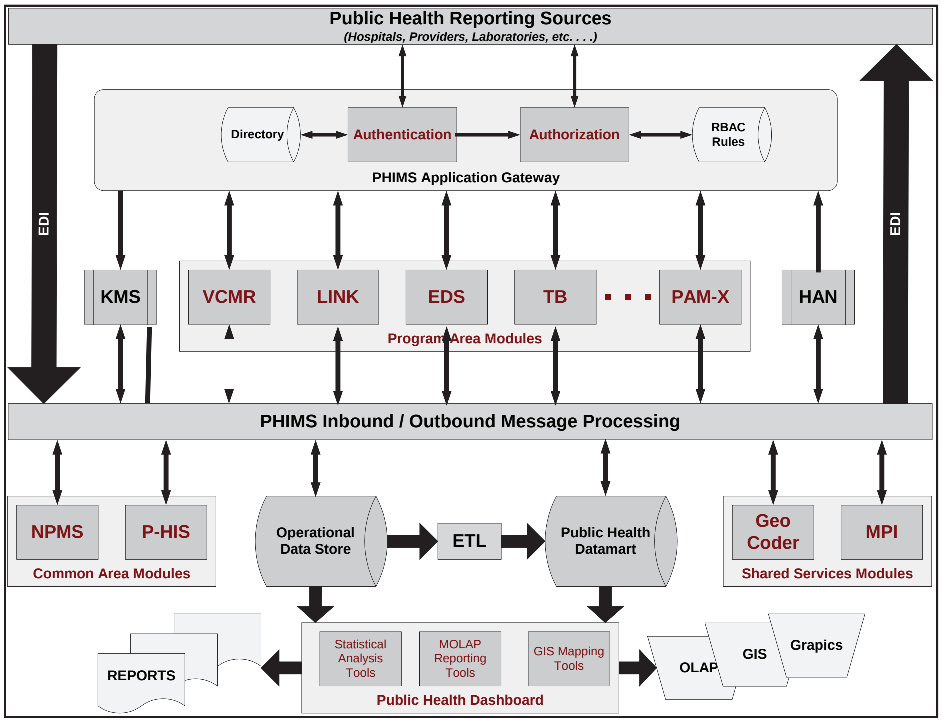
The primary focus of the architecture also kept in mind that the architecture should focus on the services rather than the application. This was done keeping in mind that there was care to adopt a broader scope from building from an existing infrastructure so that an open and flexible architecture on which applications and services can be run. This also eliminated the dependencies on databases supported by vendors. The flexibility of the architecture was ensured by adoption of standard technologies for all layers of the architecture and the messaging itself. There was care taken to design a modularized system to ensure services continuity (LACDHS, 2005).

The decision was to have HL7 RIM V3 as the messaging format for this architecture (Mead, 2005; Regio & Greenfield, 2006). HL7 is a healthcare standard for messaging which is widely being adopted by healthcare and related service providers in their initiative for unified interoperable electronic health standards and implementation of nation wide Electronic Health records. HL7 V3 is currently implemented in UK, Netherlands, Canada, Mexico, Croatia and Germany. Within the US agencies such as Centers for Disease control, Food and Drug Administration and Veterans Administration have adopted the V3 for large scale integration. The messaging included a layer of abstraction in the form of an intermediate XML format. There was a multi version support of the application for database structure and application behaviors for easy change/upgrade and switching functionalities. We created a clearly defined mapping from the physical data model onto the logical data model and from the triggers used by the application to those used in the interfaces. The messaging hub has robust tracking and logging system, which logs everything (including wrappers, etc.) that which is actually send/received is crucial. The design also addressed issues related to failure of real-time interaction and how the message would be handled for receipt and delivery of message. There was also consideration of data synchronization for queries, queues, and so forth (Klein, 2005).

The scope and function of each of the architectural components is as follows (see Figure 2):

1. **Authentication and Authorization**. This portion of the architecture provides technologies and processes used to authenticate users and authorize their access to system applications and resources. Authentication uses a LDAP implementation to authorize personnel and resources to access application system. The directory includes identification, demographic, and authentication credentials for each registered system user. Upon entry to any of the public health applications the user is prompted to provide their identification data and authorization credentials. Upon verification of the authentication credentials for the identified user access is granted to applications for which the authenticated user is authorized.
2. **Health Alert Network (HAN)**. This portion of the architecture provides technologies and processes used to communicate notifications, warnings, and alerts. The alerts may be initiated by an authorized user or by detection of triggering events within application systems. A personnel directory is used to maintain the identification, demographics, and communication addresses for potential alert recipients. A customizable set of rules is used to determine the appropriate communication mode to use for a given type of alert (telephone, email, pager, or fax) and to determine the escalation required for communications that are not acknowledged by the recipient within a predetermined threshold of time.
3. **PHIMS Inbound Message Processing**. This portion of the architecture provides the technologies and processes necessary to receive data electronically from external partners (e.g., Hospitals, Laboratories, and Physician Offices) and internal application systems. The inbound message processing component is configured to accept data in a variety of standard and proprietary formats. Supported standard formats include HL7 v2,

Figure 2. This figure details the existing functional program area modules shown as examples. The inbound and outbound messaging components relationship with the functional program area modules is clearly depicted and shows their role as the communication bus for all data interchange.



v3 and CDA, X12, and NCPDP. Proprietary formats include any form of ASCII file including XML documents, delimited and non-delimited flat files, and encapsulated files such as PDFs and images. Data are extracted from inbound transactions and placed into a staging area for use in importing into the Operational Data Store (ODS) and creation of outbound messages.

4. **PHIMS Outbound Message Processing**. This portion of the architecture provides the technologies and processes necessary to send data electronically to external partners (e.g., Hospitals, Laboratories, and Physician Offices) and other application systems. The outbound message processing component is configured to create outbound transactions in a variety of standard and proprietary formats depending upon the requirements of the receiving application. Supported standard formats include HL7 v2, v3, and CDA, X12, and NCPDP. Proprietary formats include any form of ASCII data file. Data for outbound transactions are retrieved from a staging area populated from the operational data store (ODS) or directly from functional area modules. Outbound message processing transforms the data in the staging areas into the appropriate transaction format for the recipient.

5. **Knowledge Management System (KMS)**. This component of the architecture provides the technologies and processes necessary to maintain coded terminologies and lexicons used in inbound and outbound messages, the ODS, and functional area modules. The KMS component is configured to import clinical terminologies such as SNOMED,

LOINC, and CPT as well as proprietary coding systems. Linkages are maintained between coded terminologies that facilitate the translation of codes from one terminology to another as well as provide a knowledgebase for use in rules processing, inference logic, and workflow management.

6. **Public Health Datamart**. This component of the architecture provides the technologies and processes necessary to extract, transform, and load data from the ODS and inbound message staging area into a star-schema based data structure used for analytical reporting. The data mart is a collection of fact tables and conforming dimension tables designed to provide an integrated multidimensional view of public health data. Common dimensions include factors such as time, location, demographics, and organization. Facts include items such cases, admissions, and observations.
7. **Business Intelligence Environment (Public Health Dashboard).** This component of the architecture provides the technologies and processes necessary to provide access to data in the datamart for use in analysis and visualization. The Business Intelligence Environment included multidimensional analysis tools, statistical tools, and geo-mapping tools to provide a comprehensive view of public health data. The Business Intelligence Environment includes a public health dashboard application that provides a set of measures declared by county management to be of greatest interest, quick links to information of interest, and Web services that expose information from other PAMs and external serices. Users of the dashboard application can drill down into the numbers which influence the measures from there they can slice, dice, and pivot the data as needed. The mapping software enables the data to be plotted on maps that can also be drilled and customized to fulfill a particular analytical need.
8. **Operational Data Store.** This component of the architecture provides the technologies and processes necessary to integrate data from inbound processing and functional area modules into a single data store. The design of the ODS is based upon the Health Level Seven (HL7) Reference Information Model (RIM). The data store is highly abstracted allowing it to collect any data that can be mapped to the entity, role, participation, act paradigm of the HL7 RIM. Data to be imported into the ODS are first placed into a staging area and are then transformed and imported into the ODS. An ODS API is under construction. The API will accept any HL7 v3 styled transactions and generate RIM objects. The RIM objects are then stored in the ODS using ORM software (i.e., Hibernate). The API will simplify the importing of data into the ODS. Inbound messages of any type can be transformed into HL7 v3 styled transactions and automatically mapped for import into the ODS.
9. **Functional Area Modules (PAMS, CAMS and Shared Services).** This component of the architecture is the most essential. The functional area modules include the applications, common routines, and services used to address tactical public health information processing requirements. Applications such as communicable disease reporting, nursing practice management, and laboratory information management make up the functional area modules as well as services such as geo-coding, identity managements, and record locator.

IMPLEMENTATION

An Enterprise Service Bus (ESB) for used for our deployment of SOA at the County of Los

Angeles. The deployment of the SOA required the conversion of existing systems into services. The task involved in achieving this SOA is ongoing for each system and a common set of components (HAN, CAMS, and Shared Services, etc.) are providing additional functionality (such as security and auditing). The bus is a collection of servers and components that will provide functions and set of tools to assist in the conversion of existing systems to functional services.

The SOA implemented in County of Los Angeles used the following major steps and technologies: Existing systems were used core services and business services were derived from these core services. In turn, process modeling was derived from the business services. Microsoft Technologies such as Microsoft.NET and Web Services, Microsoft BizTalk Server and Web Services Enhancements for .NET were utilized for this implementation.

Microsoft BizTalk was used for PHIMS inbound and outbound message processing and transformation. Microsoft SQL Server is used as the relational database management system for the integrated data repository designed after the Public Health Logical Data Model (PHLDM) and the Health Level Seven Reference Information Model (HL7 RIM). COGNOS and ESRI solutions are used to provide multi-dimensional online analytical processing (MOLAP) in a business intelligence environment that supports GIS, statistical analysis, and reporting. Information standards used within the architecture include HL7 Version 2 ADT and ORU messages; HL7 Version 3 RIM, Vocabulary, and data type specifications; and the Common Alerting Protocol (CAP) data interchange format.

We have used the following technology stack in Web services:

- WSDL provides description of service behavior and the interface contract.
- The HTTP protocol for network service. SOAP provides a platform independent protocol for sending messages across the wire.
- UDDI provides the means to discover the service both at design time and at run time.
- XML is the technology that underpins it all. Since XML is text based, it can be read by virtually any machine on any platform giving a high degree of interoperability. WSDL, UDDI, and SOAP are all XML based.

The implementation of this architecture consisted of specific focus on the following functional areas based for creation of a service centric approach.

- **Authentication and Authorization.** Security services provide a single point of entry for user authentication and system access authorization. User authentication service used multifactor authentication methods including passwords, RDS Secure ID tokens and X509 certificates which work with Microsoft single sign on architecture implemented with the help of Microsoft SharePoint Portal Server.

An LDAP based directory and RBAC defined system access privileges and rules control which public health application authenticated user are allowed to access. This is implemented using Microsoft Windows 2003 Active Directory.

Alerting services provided the necessary technical infrastructure to facilitate the distribution of notifications, warnings, reminders, and alerts to public health personnel and partner organizations. This is implemented using combination of MIR3 Enterprise server and custom developed components in Microsoft.NET technologies.

- **PHIMS Inbound/Outbound Message Processing.** The PHIMS Inbound/Outbound Message Processing area of the architecture is a collection of technologies and processes that enable the electronic exchange of information between the county public health application systems and external information systems. PHIMS Inbound/Outbound Message Processing implements standard and proprietary message formats for data exchange. Electronic trading partners include entities external to County of Los Angeles such as healthcare providers, state health department, laboratories, and public health partners. PHIMS

Inbound/Outbound Message Processing can receive and send messages in various standards and legacy formats like HL7 v2.x, HL7 v3, HL7 CDA, CSV, ASCII Files etc. This is implemented using combination of custom developed Microsoft. NET applications and Microsoft BizTalk server.

- **Functional Area (PAMS, CAMS and Shared Services).** The Functional area of the architecture is a collection of program area modules, common area modules, and information routing technologies and processes used to manage conditions and events of public health interest. PAMs support the information and processing needs of a particular public health program such as communicable disease surveillance, environmental health, and bio-terrorism response management. CAM supports information and processing needs that transcend program areas such as laboratory information management, event detection, and controlled medical terminology services. PHIMS information routing technologies and processes include message parsing, transformation, and routing technologies and an integrated operational data store. The centralized operational data sore is developed based on HL7 V3 Reference Information Model (RIM) and implemented in Microsoft SQL Server 2000.
- **Public Health Datamart and Public Health Dashboard.** This is a collection of technologies and processes that facilitate analysis, visualization, and reporting of public health information. The data mart integrates data from multiple county public health, clinical, and administrative systems. The data are organized into facts and dimensions that allow multidimensional online analytical processing. The Public Health Datamart functions as a single source of truth for detail and aggregate public health data for use by a variety of business intelligence tools and applications. Business Intelligence services include both data analysis components and GIS components.

Data integration in healthcare has become a significant factor for any organization. In particular, County of Los Angeles goals are to have public health data be utilized for monitoring its population health dynamics and better plan for large scale health crises.

The decision to have data integration synchronized by use of HL7 healthcare standard messaging was in part to take into account the disparate applications and vendors already in existence in county.

The implementation of this integrated standards-based system in LAC provides a synchronized view of public health data and resources across all *program areas* (see Figure 2). High level implementation and testing strategies were put into place prior the development process. All processes were documented in depth for ongoing integration of PAMS and for future planning.

EVALUATION

The key components of the architecture include (see Figure 2) (1) Infrastructure & housekeeping services to provide authentication, directory and security services for the system and enable single sign-on. (2) A knowledge management module that manages translation and mapping of coded data from other systems to the Operational Data Store (ODS) in a standardized nomenclature. (3) Provision for single sign-on portal for authentication & entry into the system. It also incorporates an event alerting mechanism. (4) An electronic interface to systems that need to send data and receive data from the ODS, program area modules, and external data sources. (5) Analysis and Visualization services and data mart provide data analysis, reporting and GIS services through a dashboard. (6) Operational data store to save integrated data from functional area modules and external data sources.

The architecture provides the necessary infrastructure for a service oriented approach to development of functional area modules. Functional area modules support the business functions of public health. Some functional area modules are program specific (PAM), some are common to multiple program areas (CAM), and others are services invoked by PAMs and CAM. The services included in the architecture not only implement business functions but are essential infrastructure functions; security, alerting, messaging, terminology, and business intelligence. The development of functional area modules is streamlined due to the existence of these foundational features. The inbound and outbound messaging features enable functional modules integration and interoperability.

Web-enabled data management, tracking, decision support, and business intelligence systems, (including NPMS) have been developed for diverse agencies and departments within the Public Health system of Los Angeles County. All iterations from the design and planning phases to development, implementation and expansion were carefully evaluated with program users, administrative staff, and technology experts. The involvement of the user departments at all stages helped to develop systems that were easy and convenient to use.

The use of a model driven SOA has allowed the County of Los Angeles to take advantage of state-of-the-art information technologies while at the same time leveraging the investment made in its legacy application system. The use of industry standards positions the system to be interoperable with similar efforts conducted in other jurisdictions such as in neighboring Counties, the state of California, and the CDC.

It is proving to be a useful tool in assisting the County in coordinating the work of its multiple vendors, ensuring the coherent application of technologies to daily operations and preparedness activities, as well as, fostering collaboration between Los Angeles County Public Health and its partners.

In addition to design and development of a SOA architecture several other issues were brought up which helped in the implementation and planning of this architecture for public health in Los Angeles County. The vision by key county personnel expressing the necessity of data sharing and leveraging data as a department wide asset was clearly communicated. The CDC defined standards for use in enabling a public health information network has reached a level of maturity that could be utilized for the design elements of this architecture. The national recognition of the vulnerability of our public health system has motivated the United States Congress to allocate the funds necessary to underwrite the cost of development. Issues that continue to be part of the long term planning of this implementation include the inertia and tradition of autonomy enjoyed by program area leaders. The existence of silos in the program areas continue to yield challenges in navigation through the silo boundaries. The large scope of the implementation of this system and the presence of multiple vendors brings up coordination issues for business and technical needs and understandings for common grounds. The process of funding and resource limitations also becomes significant factors in the development process periodically.

CONCLUSION

Towards the end of 2003, a project team was assembled to study the requirements of Public Health Information Management System (PHIMS) at Los Angeles County. The objective was to design a system architecture that met CDC's Public Health Information Network (PHIN) standards. The design of the PHIMS architecture was completed in March 2004. The remainder of 2004 was spent on evaluations and analysis of the design with internal and external stakeholders. In addition the specifications were subjected to further refinement in conjunction with vendors. The vendors and County personnel were committed to assume accountability for implementing portions of the design, and developing plans for phased implementation of the architecture. By August 2005, core features of the architecture were implemented in a lab environment including prototype implementations of key functional components of the architecture. The entire countywide architecture is in the process of transitioning into production. There is ongoing emphasis in Los Angeles County Public Health to identify and prioritize PAMs which should be integrated into this architecture. The functional requirements of program area modules and the definition of an action plan for incorporating well-architected functional solutions into the technical infrastructure is ongoing.

It is expected that the Public Health Information Network System effort will expedite the consolidation of critical clinical and public health data across diverse individual IT systems (Verma et al., 2005). It will leverage existing investments in legacy systems and merge them with standards-based Web-enabled systems to provide a synchronized view of public health data and resources across all program areas. The LAC-ODS can be queried for a person-centric view of health-related data across all program areas. The visualization services provide a dashboard view and drill-down report capabilities for decision support and alignment of critical public health resources.

The PHIN compliant systems will specifically address the following (Health Alert Network, 2002; Los Angeles County Department of Health Services, 2004): (a) The development of a Web-based system architecture for Public Health programs and health districts that is capable of supporting electronic data exchange from public health partners using a HL7-based integration hub, (b) the development of management tools and applications to assist public health response, and (c) recovery activities while providing resources to support departmental integration. The PHIN/NEDSS systems will leverage individual system components for the overall improvement of public health information technology infrastructure while contributing to the development of a common enterprise data warehouse that will unify public health and clinical data under a unique person identifier.

There are multiple systems in place that support communications for public health labs, the clinical community, and state, and local health departments. However, most of these systems operate in isolation. Numerous benefits will start accruing as parts of the system are built and integrated into the business processes of the local health services. The implementation of a unifying system will further improve access to laboratory data and response protocols, advanced capabilities for rapid notification of public health partners, response agencies, the media, and the general public. There will be an enhanced capability to train public health staff and a uniform data exchange standard for exchanging data between the public health partners. Real-time collection of data from heterogeneous healthcare systems, program area modules, consolidation, and cross-indexing of data, integrated directory infrastructure for public health personnel and identity management, integration of related healthcare, and patient data from heterogeneous systems into a common interface, provide access through a ubiquitous Web-based portal that will obviate the necessity of client-side implementations of application systems, provide a mechanism to disseminate critical and public-interest information to the community in general are additional benefits.

ACKNOWLEDGMENT

This work was performed by CAL2CAL Corporation at the LAC-Department of Public Health. The ODS and ODS related applications are developed under a grant from the CDC to state and local jurisdictions to support public health preparedness and response to bioterrorism (Los Angeles County Department of Health Services, 2003). This work was done in collaboration with Public Health Information Systems—Los Angeles County Department of Public Health.

Chapter 2.13
The Development of a Health Data Quality Programme

Karolyn Kerr
Simpl, New Zealand

Tony Norris
Massey University, New Zealand

ABSTRACT

Data quality requirements are increasing as a wider range of data becomes available and the technology to mine data shows the value of data that is "fit for use." This chapter describes a data quality programme for the New Zealand Ministry of Health that first isolates the criteria that define "fitness" and then develops a framework as the basis of a health sector-wide data quality strategy that aligns with the sector's existing strategies and policies for the use of health information. The framework development builds on existing work by the Canadian Institute for Health Information, and takes into account current data quality literature and recognised total data quality management (TDQM) principles. Strategy development builds upon existing policy and strategy within the New Zealand health sector, a review of customer requirements, current sector maturity and adaptability, and current literature to provide a practical strategy that offers clear guidelines for action. The chapter ends with a summary of key issues that can be employed by health care organisations to develop their own successful data quality improvement programmes.

INTRODUCTION

The New Zealand health sector data quality improvement programme attempts to provide a structure for managing data to prevent data quality errors at the source of collection and to maintain the meaning of the data as they move throughout the health sector. This approach requires viewing data quality from a holistic perspective — going beyond a one-dimensional assessment of quality based only on accuracy — and assessing other dimensions (Ballou & Tayi, 1999) such as relevance, timeliness, comparability, usability, security, and privacy of data.

As data quality affects everyone in the health sector, the whole sector is responsible for maintaining and improving data quality. The role of the New Zealand Ministry of Health is one of leadership and support, whilst data collectors need to employ all possible processes to ensure only high quality data are collected, using agreed national and international standards, where available. Data quality needs to be the responsibility for high-level managers in an organisation to ensure the entire organisation makes the required changes for improvement. "All too often data quality is seen as something that is the responsibility of informatics staff alone and is often seen with disinterest by clinicians and managers, despite being so critical to the quality of the decisions they make" (Data Remember, UK National Health Service, 2001; UK Audit Commission, 2002).

This chapter describes the development of a data quality evaluation framework (DQEF) and underpinning strategy for the Ministry of Health in New Zealand and outlines the process to "institutionalise" total data quality management throughout the whole of the health sector.

THE IMPORTANCE AND ELEMENTS OF DATA QUALITY PROGRAMMES

Bill Gates (1999) states:

The most meaningful way to differentiate your company from your competition, the best way to put distance between you and the crowd, is to do an outstanding job with information. How you gather, manage and use information will determine whether you win or lose.

Organisations are becoming more and more dependent on information. Virtually everything the modern organisation does both creates and depends upon enormous quantities of data. A comprehensive data management programme is therefore essential to meet the needs of the organisation (Pautke & Redman, 2001). Many authors, for example, Levitin and Redman (1993), also draw attention to the importance of data quality in managing information as a resource of the organisation.

The first step in setting up a data quality (improvement) programme is therefore to decide the determinants that define quality. A framework is then required to apply these determinants and their associated metrics that can assess the level of data quality and establish processes such as collection, storage, access, and maintenance that lead to quality improvements where they are necessary. Finally, whilst a data quality framework models the data environment, it must be underpinned and supported by a strategy that is broader in scope. This strategy establishes the business purpose and context of data and aims to make the framework a routine tool and part of day-to-day operations.

These three elements, quality determinants, assessment framework, and implementation strategy are the core components of a data quality programme and we now look at these stages in more detail.

Data Quality Determinants

Strong, Lee, and Wang (1997) take a consumer (people or groups who have experience in using organisational data to make business decisions) focused view that quality data are "data that are fit for use," and this view is widely adopted in the literature (Wang, Strong, & Guarascio, 1996). Redman (2001) comes to the following definition based on Juran and Godfrey (1999):

Data are of high quality if they are fit for their intended uses in operations, decision-making, and planning. Data are fit for use if they are free of defects and possess desired features.

Clearly, however, fitness for purpose depends upon the purpose and so the set of data quality determinants will vary according to the application. In addition, modern views of data quality have a wider frame of reference and many more features than the simple choice of attributes such as accuracy and currency. There are therefore multiple approaches to designing and applying data quality systems as well as competing terminologies to trap the unwary (Canadian Institute for Health Information, 2005; Eppler & Wittig, 2000). The approach we have adopted here is based on a hierarchical system (see next section) developed by the Canadian Institute for Health Information (CIHI) (2003a, 2005). At the uppermost level are the familiar attributes such as accuracy, relevance, and so forth. These attributes are referred to in the scheme as "dimensions." Each dimension is defined in context by appropriate determinants known as "characteristics." For example, characteristics of the accuracy dimension might include the tolerated level of error and the population to which the data accuracy must apply. Characteristics require answers to "what is/are" questions. Underpinning these characteristics are "criteria" that define processes and metrics used to assess the presence of potential data quality issues. Thus, the level of error characteristic might be assessed by asking if the error falls into a predefined range and if the level of bias is significant. Criteria typically demand "yes" or "no" answers. In this chapter we are concerned mainly with data quality dimensions and criteria although we describe the hierarchical process for their selection.

Data Quality Evaluation Frameworks

At its most basic, a data quality evaluation framework (DQEF) is defined by Wang et al. (1996) as "a vehicle that an organisation can use to define a model of its data environment, identify relevant data quality attributes, analyse data quality attributes in their current or future context, and provide guidance for data quality improvement."

In our terminology, a DQEF enshrines and enacts the processes and metrics (criteria) that assess whether the level of a dimension (e.g., accuracy) is acceptable or not. However, Eppler and Wittig (2000) describe a data quality framework as:

A point in time assessment and measurement tool, integrated into organisational processes, providing a benchmark for the effectiveness of any future data quality improvement initiatives and a standardised template for information on data quality both for internal and external users.

The same authors also add that a framework should not only evaluate but also provide a scheme to analyse and solve data quality problems by proactive management.

Ideally, therefore, a DQEF goes beyond straightforward quality assessment and becomes an integral component of the processes that an organisation puts in place to deliver its business goals (Willshire & Meyen, 1997). The framework then uses data quality to target poor quality processes or inefficiencies that may reduce profitability or lead to poor service (Wang et al., 1996). The implication of this extended framework is that the organisation will need to engage in a certain amount of business process reengineering. That is why the framework needs to be part of an organisational improvement programme and strongly tied to a data quality strategy.

Data Quality Strategies

Thus far, little has been published on what constitutes a data quality strategy, let alone an evaluation of a structured and tested improvement programme. Recently, however, this type of strategy has become increasingly important as a core requirement for many businesses. It is likely that some large organisations do have such strategies, improvement programmes, or components of them, but these are not currently documented and available in the literature. Davis (2003), publishing on the FirstLogic Web site, wrote several articles on his vision of a data quality strategy. According to Davis, a data quality strategy should include:

- A statement of the goals (what is driving the project)
- A description of the primary organisational processes impacted by the goals
- A high-level list of the major data groups and types that support the operations
- A description of the data systems where the data groups are stored
- A statement of the type of data and how they are used
- Discussion of cleansing solutions matching them to the types of data
- Inventory of the existing data touch points
- A plan for how, where, and when the data can be accessed for cleansing
- A plan for how often the cleansing activity will occur and on what systems
- A detailed list of the individual data elements

Whilst Davis' list is a useful starting point, it is based on an information providers' perspective. Other components should be added to incorporate the needs of consumers and to define and document these. This is still not easy to do given that customers often do not know what their needs are (Redman, 2001). A first step would be the identification of the organisation's customers, or important customer groups, where there are too many individual customers for initial improvement programmes.

With this survey of the elements of data quality improvement programmes we can now look briefly at international attempts to apply the principles to health care.

INTERNATIONAL HEALTH DATA QUALITY PROGRAMMES

Health care delivery and planning rely heavily on data and information from clinical, administrative, and management sources, and quality data lead to quality and cost-effective care, improving patient outcomes and customer satisfaction. Data for health care delivery range from the clinical records of individual patients, detailing their interactions with medical services, to the administrative data required to manage the complex business of health care. When abstracted and aggregated in warehouses, and informed by other management and policy information, these "unit level data" produce knowledge bases for heath care planning and decision support. The totality of data from these various sources can then be used for further policy development (Al-Shorbaji, 2001). A prime example is the planning at government level to provide services that address the prevalence and distribution of diseases such as diabetes in a population. Clearly, any programme that improves the quality of data at all levels will improve the quality and cost-effectiveness of care and patient outcomes.

A review of international data quality improvement programmes in health care, including the National Health Service (NHS) (Department of Health, 2004) in the United Kingdom, the Canadian Institute for Health Information (CIHI) (2003b), HealthConnect Australia (Department of Health and Aging, 2003), and the United States Department of Health and Human Services (2002) identified similarities between the various programmes. All of the reviewed programmes note the multilevel, multidimensional complexity of data quality improvement initiatives. They seek to manage data proactively and ensure integrity by preventing data quality problems using a systematic total data quality management (TDQM) approach (Wang, 1998). There is also commonality of role expectations — the data suppliers are responsible for the quality of the data they provide to the central government, whilst central government is required to provide leadership and assistance to data suppliers by developing sectorwide standards and best practice guidelines.

The NHS in particular outlines clearly, and in detail, the substantial work that is required by any health care provider to ensure good data quality. The NHS developed an accreditation scheme that was initially thought to be all that would be needed to ensure the supply of good quality data. The scheme is extensive and was found to be very successful but did not sufficiently identify the responsibilities of the data supplier; central government was still monitoring more than it was leading. This discovery led to the more extensive guidelines developed around principles of data quality supported within the NHS. Several NHS Trusts have published data quality strategies on their Web sites that align to the NHS core strategy requirements. These efforts have been recognised in a recent review of the programme by the UK Audit Commission (2004), which found significant improvements to levels of data quality. However, similar issues to those initially found are still apparent after five years of targeted improvements and the report recommended:

- The development of a more coordinated and strategic approach to data quality
- Development of an NHS-wide strategy for specifying, obtaining, and using both national and local information
- Making more and better use of patient-based information
- Involving Trust board members
- Training and developing staff
- Keeping systems up to date

In Canada, the CIHI also briefly discusses accreditation for enhancing collaboration with data suppliers. They have undertaken extensive work on data quality through collaborative work with experienced statisticians from Statistics Canada and base their theories on research by the Massachusetts Institute of Technology in the U.S.

We now look at the relevance of this international experience in health data quality programmes to New Zealand health.

TOWARDS A HEALTH DATA QUALITY PROGRAMME IN NEW ZEALAND

The New Zealand Health Information Service (NZHIS) is a specialised group within the Ministry of Health responsible for the collection and dissemination of health-related data. NZHIS has as its foundation the goal of making "fit-for-purpose" information readily available and accessible in a timely manner throughout the health sector to support the sector's ongoing effort to improve the health status of New Zealanders. The vision of NZHIS is to be a leader in the provision of health information services in New Zealand, and to be recognised and respected as a leading organisation internationally. Effective and timely use of information is crucial to achieving this vision. NZHIS has responsibility for:

- The overall collection, processing, maintenance, and dissemination of health data, health statistics and health information
- The ongoing quality improvement of data entering the national data collections1
- The continuing maintenance and development of the national health and disability information systems
- The provision of appropriate databases, systems, and information products
- The development and provision of health and disability information standards and quality-audit programmes for data
- Coordination of ongoing national health and disability information collections and proposals for their development
- Analysis of health information, performance monitoring, benchmarking, and advice on the use of information obtained from NZHIS

Thus, while the NZHIS is responsible for the lead on data quality, this does not mean that it is solely accountable for solving data quality problems. The role of the NZHIS is rather to define data quality criteria and establish a framework in which health care organisations can assess the quality of their own data. This framework must also ensure that data quality does not degrade when data are moved between organisations. These data move with the patients they refer to creating reciprocal dependence between the organisations so that poor data management in one organisation can adversely and incrementally affect other organisations and the care a patient receives. A national "systems" framework is therefore needed to certify that data used for decision making meet the same quality criteria and standards both within and between organisations.

Assessment of the national health collections at NZHIS (2003) showed that the required framework was unlikely to lead to sustainable improvements unless it was placed in the context of a national strategy that would reengineer data processes and embed the quality-centric revisions in normal, everyday practice. The resources to improve quality were already available, but they were being applied to the wrong processes and without consistency or direction. In addition, short-term priorities needed to focus on areas where benefits could be realised easily with long-term projects concentrating on implementing change.

Thus, as suggested by the previous discussion, the approach to the New Zealand Health Data Quality Improvement Programme is seen to consist of three stages.

1. Determination of the criteria needed to judge health data quality in a New Zealand context
2. Development of a practical framework to apply these criteria to existing and new database collection
3. Development of a strategy to implement the framework and embed it in normal practice

The next sections describe the research methodology and the design and application of these three stages.

RESEARCH METHODOLOGY FOR THE PROGRAMME DEVELOPMENT

The research utilised several qualitative methodologies — action research, semi-structured interviews, focus groups, and a questionnaire to develop and formally assess a health data quality framework that could be tied to an implementation strategy and promulgated as a data quality programme. The two focus groups were derived from a Ministry Data Quality Team (MDQT) formed specifically to look at ways of improving quality in a consistent way across the organisation. Membership of the MDQT was selected from across the ministry to bring together business units that appeared to have similar issues with data quality but at that time had no formal infrastructure to coordinate quality initiatives. Members were mostly "information users" such as information analysts and business intelligence staff, but some were also members of the already existing operational Clinical Analysis Team. All regularly used data for a wide range of different purposes.

A grounded theory (Strauss & Corbin, 1998) approach was used to analyse the data for content themes that could reveal new concepts. The research concentrated on eliciting the opinions of the participants on areas such as:

- The applicability of the criteria, characteristics, and dimensions for the assessed collection
- Proposal of other dimensions that may be applicable
- The language used in the framework
- The language and examples provided in the user manual
- The length of time required to complete the assessment using the framework

- The value to users of the information provided from using the framework
- The table of contents for the data quality documentation folder

The DQEF then went through a pilot evaluation process using two health data collections. Initial assessment was made on the mortality data collection which is a national health collection considered to have good data quality in relation to other collections. The mortality collection has been established to provide data for public health research, policy formulation, development and monitoring, and cancer survival studies. A complete dataset of each year's mortality data is sent to the World Health Organization to be used in international comparisons of mortality statistics.

The second data collection consisted of clinical data held in a local hospital setting. These data are used to determine best health outcomes for clinical care pathways and they are consequently stored at a more granular level than the national health data.

Further details of methodology are given with the discussion of the research findings.

RESEARCH FINDINGS

Selection of Health Data Quality Dimensions

The development of suitable dimensions for assessing health data quality in a New Zealand context was based as indicated on the Canadian Institute of Health Information (CIHI) data quality framework (Long, Richards, & Seko, 2002). This framework is itself based on Statistics Canada guidelines and methods, information quality literature, and the principle of continuous quality improvement (Deming, 1982). The CIHI is comparable in function to NZHIS and the health care systems of the two countries are also similar in many respects.

The CIHI data quality framework operationalises data quality as a four-level conceptual model (Long & Seko, 2002). At the foundation of the model are 86 criteria and these are aggregated using the framework algorithm into the second level of 24 characteristics that in turn define 5 dimensions of data quality: accuracy, timeliness, comparability, usability, and relevance. Finally, the five dimensions can be reduced using the algorithm into one overall database evaluation. Figure 1 provides a summary of the four-level conceptual CIHI model.[2]

The CIHI framework was first assessed for completeness, applicability, and ease of adaptation in New Zealand against current ministry information strategy documents. These include regional health care providers strategic plans and the WAVE report (working to add value through e-information) (WAVE Advisory Board, 2001), which is New Zealand's national information management strategy for health. Compliance with New Zealand legislation was also considered.

The MDQT focus groups made minimal changes to the basic content of the CIHI framework retaining the hierarchical approach but removing some criteria that were thought inappropriate and adding others that were considered important in the New Zealand context, yielding a total of 69 from the original 86. The most significant change was the inclusion of an additional dimension, privacy and security, to satisfy New Zealand concerns. The CIHI states that privacy and security are implicit requirements that are embedded in all their data management processes. Whilst the same could also be said of the Ministry of Health, the pervading culture in New Zealand requires that privacy and security of information, in particular health information, are paramount. Therefore, the MDQT felt there was a requirement for explicit and transparent consideration of these quality dimensions. The underpinning characteristics for these new dimensions were developed by the senior advisors on health sector privacy and security to ensure alignment with the ongoing development of new privacy and security policies.

The six data quality dimensions chosen for the DQEF by analysis of the feedback from the focus groups are as follows with accuracy as the most important:

1. Accuracy is defined within the framework as how well data reflect the reality they are supposed to represent.
2. Relevancy reflects the degree to which a database meets the current and potential future needs of users.
3. Timeliness refers primarily to how current or up-to-date the data are at the time of use.
4. Comparability is defined as the extent to which databases are consistent over time and use standard conventions (such as data elements or reporting periods), making them similar to other databases.
5. Usability reflects the ease with which data may be understood and accessed. If data are difficult to use, they can be rendered worthless no matter how accurate, timely, comparable, or relevant they may be.
6. Security and privacy reflect the degree to which a database meets the current legislation, standards, policies, and processes.

Within the research participant group the understanding of the meaning of these dimensions varied. No one definition could be found for even the most commonly used data quality dimensions (Wand & Wang, 1996). For this reason it is important for the development of the DQEF to explicitly define each dimension. It was decided to utilise the definitions provided by the CIHI Framework where possible, as these aligned with the characteristics and criteria adopted throughout the framework. Importantly, the dimensions were found to be mutually exclusive and collectively exhaustive.

Definition of the Health Data Quality Evaluation Framework

The development of the health DQEF began with a current state analysis (New Zealand Health Information Service, 2003) through a preliminary survey of managers and users from across the ministry. This survey consisted of open questions requiring free-text answers to elicit information on a set of factors including historical and contextual information about the collection, the data collection processes, any changes made to data from within the ministry, what the data are used for, where they reside, and the nature and perceived effectiveness of existing data quality initiatives.

The gathering of this information proved difficult. The survey results showed there were currently no compiled and complete records of data quality for any of the national data collections administered or managed by the Ministry of Health and neither was there clear accountability for data quality in the health sector. The information is spread over a range of business units, people, and documents so that the Ministry cannot easily assess the scope or effectiveness of its data quality measures. Furthermore, the varying requirements for quality between centrally held and managed collections and those "at the coalface" led to considerable uncertainty as to what "quality" entailed. This situation and extensive discussions with data users involved in the development of the Ministry of Health Information Systems Strategic Plan served only to confirm the need for the DQEF and the availability of assessment tools that could provide information on the nature and levels of data quality and identify the sources of problems so as to allocate responsibilities.

For the New Zealand Ministry of Health, therefore, the DQEF takes the form of a tool that allows a consistent and accurate assessment of data quality in all national health data collections, enabling improved decision making and policy development in the health sector through better information. The DQEF standardises information on data quality for users, provides a common objective approach to assessing the data quality of all health information databases and registries, and enables the identification and measurement of major data quality issues.

The draft DQEF, consisting of the aligned set of quality criteria, characteristics, and dimensions, was sent to all group participants. A presentation to the MDQT was made prior to the focus groups to ensure all participants had a common understanding of the purpose of the DQEF and the desired outcome goals. The group participated in two focus groups of two hours each. A member of the Ministry's Health Information Strategy and Policy Group (the researcher) led the focus groups and an administrator was present to make audio recordings and to later transcribe the recordings, noting also the interaction between group members on discussion points.

A template was developed to assist data managers and users to assess and document the effectiveness of the DQEF, its user manual, and the proposed data quality documentation folder for each data collection. The documentation folder houses all information pertaining to the quality of each data collection and makes it available in both paper and online format for access by all staff at the Ministry of Health. Following the focus group sessions, a second review of the DQEF, assessed using criteria developed by Eppler and Wittig (2000) ensured that the DQEF remained robust after localised changes.

The information provided by the DQEF evaluation highlighted data quality problems that were already known to the data custodians who had already initiated work to make improvements. However, several other deficiencies were highlighted, indicating where improvements in the current data quality work could be made, or in the case of timeliness, highlighting known issues that perhaps should be made a priority for improvement.

The issue of timeliness of the suicide in the mortality data collection data highlights a trade-off debate between dimensions. For example, data users are aware that some datasets are likely to be incomplete; then the data can be released without delay making them become usable at an earlier date. Eppler and Wittig (2000) note that trade-offs are not commonly addressed in frameworks. Research participants did not raise this issue and the DQEF does not explicitly address trade-offs between dimensions. However, an analysis of possible trade-offs and their implications could be included in the user manual. Different trade-offs would apply to different collections, and again may be different for specific uses of the data (Ballou & Pazer, 2003).

An issues register was kept to supply feedback to the researcher on the usability of the DQEF and user manual. Overall, the DQEF was found to provide useful data quality information by collection users and custodians and to provide sufficient information to make at least preliminary prioritised lists of essential data quality improvement projects. A detailed analysis of the feedback is provided.

Training

Further training was required to ensure that evaluators use the DQEF consistently and that it is a practical and easy tool to use. During training sessions it was found that many users of the DQEF initially made assumptions about the meaning of criteria and needed to refer to the metrics and definitions contained in the user manual. Consistency of meaning of criteria is important since many different users complete the evaluation both within an evaluation cycle and also from one evaluation to the next. For this reason a section was included under each criterion that asked the evaluator to describe in free text how they came to their decision, including references to any data quality information used to make their decision. This requirement also aids any subsequent evaluation of a collection.

Time Taken to Complete Evaluations

As noted in the findings of the Current State Analysis of Data Quality in the Ministry of Health, data quality information is held in many different locations and finding this information takes considerable time. The time taken to complete an evaluation of a data collection by already busy staff was estimated to be a minimum of four hours when all relevant documentation was available. In practice, the information was held in disparate locations by different staff and the initial evaluations took far longer. Repeated evaluations of the same collections would be completed much more efficiently, as much of the information could remain the same or merely need updating.

Intended Unit of Analysis

The researcher and participants also discussed the granularity of evaluation or intended unit of analysis. Participants asked, "was the DQEF able to evaluate a collection as a whole and also a column within a collection?" Price and Shanks (2005) found similar issues when implementing a data quality framework and noted the limitations of a framework on data that are not uniquely identifiable, such as those found in non-key columns. It was therefore decided to measure each collection as a whole. However, there are specific data elements that can be assessed individually and are extensively used for analysis and decision making. An example would be a registry, such as the National Health Index (NHI, a unique patient identifier), where each field of demographic information is the reference for other collections and provides information to prevent duplicate allocation. In this case, the DQEF can be used as a two-dimensional tool, assessing the registry as a whole and then each element.

User Manual

Extensive changes to the CIHI user manual were required to make it useful to the New Zealand health care environment. The findings show that the target audience for the accompanying DQEF user manual needed careful definition to ensure that the language was appropriate and the documents easy to use. In particular, the language used in the original CIHI version was found to be too simplistic for the intended audience. DQEF users are likely to be systems administrators, data quality advisors, and members of the Business Intelligence Team, but the language assumed little underlying knowledge of data and systems. The user manual could also be shortened by moving some of the underlying theory used to develop the Data Quality Improvement Programme to other documents intended for potential users taking part in education programmes.

Extent of Data Quality Information

Initial feedback from the data quality team at NZHIS showed that the DQEF did not provide sufficient information to make decisions on the quality of data. There appeared to be insufficient detail to manage data quality effectively. However, once the team became more familiar with the DQEF and began to understand the context of its use, the feedback became more positive. Users realised that the purpose of the DQEF was to provide guidance on the regular processes and measures needed to answer criteria questions. By presenting a more complete view of the data quality of a collection, these "answers" suggested new measures, not previously thought of by the data quality team. In effect, the DQEF is an invaluable guide or checklist that facilitates the consistent application of appropriate and wide ranging measures across all collections. It has the ability to raise the standard of work expected in data quality by bringing about awareness of areas of deficiency in the current work programme.

Interestingly, findings from the mortality data collection evaluation show that the Business Intelligence Team (as data consumers) required the most detailed information on how the assessment was made for each criterion, whereas managers required only summary information. This variation reflects the different decisions made by the different groups and hence the distinctive uses and required granularity of data quality information. Clearly, reports on the outcomes of assessments should be tailored to provide this information specific to audience requirements. In support of this observation, Chengalur-Smith, Ballou, and Pazer (1999) noted the importance of information format in their research on the impact of data quality information on decision making. They found that users required complex data quality information to make simple decisions but that they did not make use of this information for complex decisions. We consider this reciprocity may be due to "information overload" where too much information can be counterproductive to decision making in more complex decision environments.

Although decisions made in the health care environment are often "complex," what a complex decision is to one user may not be to another. This implies that users need to have input into decisions on the granularity of the supplied data quality information. Chengalur-Smith et al. (1999) note that it may be most effective to provide users with data quality information that focuses on one or two key criteria that exhibit the greatest impact on the data.

A later study by the same group (Fisher, Chengalur-Smith, & Ballou, 2003) observes the impact of experience on the decision maker, whereby increasing use of data quality information is found as experience levels progress from novice to professional and suggests that data quality information should be incorporated into data warehouses used on an ad-hoc basis.

Metrics

The DQEF uses subjective metrics for data criteria that have been developed by the collections' data custodians. Whilst this is a valid form of measurement, the robustness of the DQEF requires additional objective metrics and these are derived from a structured system based on statistical process control (Carey & Lloyd, 2001). The metrics include measures that assess customer requirements for levels of data quality, trends in historical data within the national health collections, current key performance indicators for contracted data suppliers, and legislative requirements for the provision of data by health care providers and the Ministry of Health to international bodies such as the World Health Organisation. Further work is still required to develop applicable metrics.

In summary, the pilot of the DQEF in the NZHIS environment elicited these issues:

- Training was required before using the DQEF.
- Users felt considerable time was needed to complete the evaluations.
- The extent and detail of information (particularly about how evaluation decisions are made) provided by the DQEF assessment process must meet the needs of data users, such as the Business Intelligence Team.
- Granularity/units of analysis need to fit the type of collection; registries such as the NHI require more granular, element level analysis.
- Language in the user manual and DQEF is an important consideration.
- Further work is required on metrics development.

Overall, collection users and managers found the DQEF to offer sufficient information on data quality to make preliminary, prioritised lists of essential data quality improvement projects. Further training has been necessary to ensure assessors use the DQEF consistently and that it is a practical and easy tool to use. The CIHI also found considerable training and change management were necessary to implement the CIHI Framework due in part to already heavy workloads (Long & Seko, 2002).

Pilot of the Framework in a Hospital Environment

The purpose of this pilot was to assess the application of the DQEF to the clinical integrated system (CIS) model that is currently used in clinical practice at Auckland District Health Board (A+). The assessment would indicate the applicability of the DQEF and its chosen data quality dimensions in the wider health sector. The CIS Model is an interdisciplinary computerised model of patient care that replaces paper notes and requires all staff members to document care via the computer. The software programme was developed by the A+ Network Centre for Best Patient Outcomes. This model has been in clinical practice since 2000 and has been used for 6,000 patients (Fogarty, 2004). The main objectives were to review the DQEF criteria against the CIS model database to:

- Determine the appropriateness of the criteria for a clinical database
- Assess the documented data quality of the CIS model against the DQEF criteria
- Assess the clarity of DQEF documentation

Positive feedback was given on the usefulness of the information provided by the assessment process and the applicability of the DQEF. The majority of the criteria could be applied to an external clinical database as shown in Table 1. This table highlights that 52 out of the possible 69 criteria used in the DQEF conform to the data quality requirements of the clinical database held at the local hospital level. The language used in the DQEF was further improved to ensure consistent understanding using the detailed feedback on each criterion provided by this assessment.

The DQEF evaluation process also proved valuable to the hospital submitting the clinical data set. It was suggested by the hospital data analyst who completed the evaluation that some formal, sectorwide criteria based on the DQEF, together with a certification process such as accreditation, would help to ensure that clinical databases are valid and reliable.

Evaluation of the Framework Against Eppler and Wittig Criteria

The resulting DQEF, with changes as recommended by focus group participants and the hospital environment, was assessed using Eppler and Wittig's (2000) criteria. The feedback can be found in Table 2. The recommendations centre on the development of business processes that support the effective use of the DQEF in the Ministry of Health environment and the content of the manual that instructs users on the implementation methodology. This supports Eppler and Wittig's (2000) theory that a framework requires tools, such as guidelines and manuals, to be effectively implemented. CIHI also found that a detailed step by step guiding process is required to implement a framework (Long & Seko, 2002).

The summary information gained from evaluations of all national health data collections was collated to form a prioritised list of data quality improvement initiatives across the ministry. Ongoing assessment using the DQEF will provide information on the success of such initiatives. The DQEF remains an iterative tool, whereby those that use the tool will improve its usefulness with growing knowledge of data quality theory, the level of data quality of the national health collections, and the priorities for improvement. In particular, the data quality improvement strategy described in the remainder of the chapter will support the ongoing refinements to the DQEF.

Development of the Health Data Quality Strategy

As mentioned earlier, little has been published on what constitutes a data quality strategy, let alone an evaluation of a structured and tested improvement programme. It is particularly important to note that a data quality improvement strategy is not an "information technology strategy," nor an "information systems strategy." Although such strategies may provide insight and tools to underpin a data quality improvement strategy, data quality improvements cannot be attained merely through information technology; the problem is one of processes and people. As noted in Ward and Peppard (2002), "clearly, technology on its own, no matter how leading edge is not enough."

Technology can support the achievement of an organisation's business goals at an operational level by increasing efficiency and at a strategic level by reengineering the business processes to be more effective. At both levels, however, the technology is merely an enabler and it is information and its management that makes the difference. Since the quality of the information rests on the quality of the raw data used to derive it, data quality is a critical issue. Technology can be used to improve data quality in some processes and also to exploit the superior quality for better business outcome in others.

Unfortunately, whilst the technical aspects of data quality assurance are usually well-documented, documentation of the business processes that support good data quality is often lacking. Information processes must be carefully documented to make the meaning of data transparent to all users. For example, data sources should always be identified to provide the data user with context around the data collection process. Imposing standards and maintaining consistency across business units with data definitions, business rules, and even systems architecture can lead to greater data integration and utility and hence perceived quality. This is where a "whole of health sector" strategy begins to have a significant effect on the quality of data and where centralised leadership is required to ensure that the views of all those who manage and use data are taken into account. Thus, good documentation carries the two-fold importance of establishing standards and managing change.

Change management is the main driver of the health data quality strategy (DQS) that, together with the data quality dimensions and framework, comprise the overall Data Quality Improvement Programme at the New Zealand Ministry of Health.

The DQS uses the dimensions derived in the DQEF to set data quality standards for designing, developing, and maintaining the national health data collections and data management throughout New Zealand. A practical strategy has to consider the complexity of the health sector since the data, their structure and use, and the products, are potentially much more varied than are found in financial or manufacturing organisations.

The development of the strategy was informed throughout by several stakeholders. Ongoing communication with health sector groups, including the Ministry of Health staff was essential to ensure sector buy-in and to maintain input and interest in the strategy development and implementation. Full consultation with a wide range of data suppliers and users was also necessary. Finally, surveys and discussions with organisations outside of health, both within New Zealand and overseas, on the management of data quality and implementation of strategy help to inform the ongoing and iterative development of the strategy.

The standards established by the DQS aim to achieve the improved health outcomes by:

- Better decision making to target areas of improvement in national health data collections with a transparent prioritisation tool for data quality improvement projects
- Improved relationships with data suppliers, developing a whole-of-sector responsibility for data quality

- Improved awareness of a data quality culture throughout the sector
- Improved understanding of the processes involved in developing an information product
- The development of best practice guidelines leading to accreditation of data suppliers
- Education and support to data suppliers
- Minimum data quality requirements for existing and new national collections
- Minimum requirements for regular operational data quality initiatives across all national health collections and an approach to rooting out persistent quality errors

In particular, the last bullet point demands a systematic approach to data quality management such as total data quality management (TDQM) mentioned earlier in the chapter.

Some approaches to data quality management target specific errors within a collection or an entire collection but often do not devise solutions to prevent systemic problems. In contrast, TDQM focuses on two key aspects of data management: the data flow processes that constitute the organisation's business and the recognition that information is a product, rather than a by-product, of these processes (Wang, 1998). Regarding the processes themselves, TDQM seeks to ensure that none of them changes the initial meaning of the data leading to systematic errors and repeated data quality problems. Systematic process errors can be prevented by several means, some of which will depend upon the nature of the business unit and its data. However, we can identify generic prevention mechanisms across business units to include:

- The systematic and ongoing education of data suppliers
- Education within the Ministry of Health
- Regular reviews of recurrent data quality problems from suppliers and information feedback to suppliers on issues with support provided for improvement
- Internally developed data quality applications to reduce time spent on assessment of data quality problems (limited in use for complex health data)
- A continuous cycle of define, measure, analyse, and improve using the framework to inform the assessment process

Concerning the role of information as a product of process, TDQM draws attention to the need to manage information so that organisations:

- Know their customers/consumers of the information and their information needs
- Understand the relationship between technology and organisational culture
- Manage the entire life cycle of their information products
- Make managers accountable for managing their information processes and resulting products

TDQM at the Ministry of Health

The foundation of the New Zealand data quality strategy is the institutionalisation of TDQM principles by which data quality management processes are embedded in normal business practice and accepted at all levels in the sector. This installation is achieved by the "define, measure, analyse, improve" sequence, as described in the next four sections.

Define

The definition of what data quality means to health sector professionals is clearly a fundamental requirement and this was done through the development of the data quality dimensions and the data quality framework. The dimensions define what health care data collectors, custodians, and consumers consider important to measure.

A cross-organisational data quality group is used to facilitate the discussion of data quality issues from an organisation-wide perspective. The group includes representatives of business units that collect, manage, or use data, as well as clinicians and clinical coders. The strategy then provides for whole of sector input into the data quality dimensions considered important, where data quality improvement should be targeted, and how and where accountability should lie. Continual assessment of the needs of data customers is required and will be managed through a yearly postal survey of customers and discussions at forums and training sessions.

Measure

Active and regular measurement of data quality avoids a passive reliance on untested assumptions as to the perceived quality of the data. Reporting on data quality levels becomes transparent and justifiable. The regular measurement programme involves:

- Regular use of the data quality dimensions and evaluation framework on national collections
- Developing appropriate statistical process control (SPC) measures
- Developing data production maps for all major information products outlining flow of data around the organisation and the health sector and possible areas of data quality issues
- Checking the availability of data quality assessment software or the potential for in-house development

Measuring the quality of data supplied by organisations to the national collections involves performance measurement based on key performance indicators (KPIs) developed through SPC (Carey & Lloyd, 2001). SPC uses historical information to define the ranges of acceptable data so that outliers or variations identify areas for improvement that can be negotiated with data suppliers.

Data production maps for all major information products are another active management tool for improving data quality. These maps model the flow of data around the organisation and highlight potential quality issues by detecting points where data quality may be compromised. When properly developed and supported by senior management, they can be effectively applied to solve complex, cross-functional area problems (Wang, Lee, Pipino, & Strong, 1998). Where data cross from one organisation to another, significant data quality issues can arise, and this is evident within the New Zealand health care system. Maps can also be used to summarise issues for managers and provide them with a tool to understand the implications of data quality.

Analyse

The complexity of health care requires an extensive range of decisions, both administrative and health-related, and a single data element can substantiate many decisions and carry impacts across the sector. But what level of data quality do we need to make good decisions? The importance of data quality analysis is that it allows us to determine the appropriate quality levels and identify areas for improvement where current processes do not support good data quality work. Analysis can draw upon:

- **Clinical analysis and data modelling:** what cannot be done due to data quality
- Surveys of customer needs
- Consideration of current and future uses of data
- Realistic expectations vs. expectations of stakeholders
- **Corporate knowledge:** what the organisation already knows is important and/or relatively easy to fix
- **International standards:** does the organisation compare well with appropriate standards and are our expectations realistic?
- Resources available to make improvements

Improve

Actively finding data quality issues before they cause problems is made easier by the regular assessment of collections using the data quality measurements outlined previously. Prevention, rather than cure, is now a large part of the ministry's work through the proactive approach outlined here:

- Regular minimum data quality initiatives for all collections with specific initiatives for single collections only
- Preventing poor data quality in new collections through a "data quality plan" developed in the early phases of projects with full involvement of the data quality team. Data quality is embedded in the system and processes of the new collection prior to going live
- Continuing "what works" as the data quality team have learnt a considerable amount about the operational requirements of maintaining data quality levels
- The endorsement of standards for the collection, management, storage, and use of specific data elements by the Health Information Standards Organisation; this way all stakeholders know and agree to all steps in the data flow process
- Stewardship and data access policies that provide clear ownership and access guidelines for the data
- The proposed development of a National Data Dictionary to address the standardisation of the major data elements found in the National Health Data Collections. This standardisation is likely to provide for considerable improvement to data quality through a nationally consistent understanding of data definitions

Through these initiatives it is expected that expensive, one-off projects can be avoided and money can be allocated for regular operational requirements that will enable an ongoing prevention programme. Projects may only improve processes and data in one collection, whereby regular prevention mechanisms help to ensure all data are of high quality.

TDQM in the Wider Health Sector

Some of the wider benefits of institutionalising TDQM through the strategy include:

- Getting everyone talking about data quality through the agreement of a strategic direction
- Raising the profile of data quality within health care organisations through organisation-wide data quality groups
- Getting the sector moving in the same direction through the development of organisation-wide data quality strategies that align with the national strategic direction
- Drawing on current practice/knowledge through best practice guidelines developed by the sector and widely disseminated
- Clear expectations of data suppliers through accreditation/KPIs/contracts
- Actively reviewing strategic direction regularly

A key issue raised by the data quality proposals described in this chapter is how to identify and disseminate best practice and embed it in normal day-to-day operation. The approach favoured in New Zealand is accreditation rather than audit. Accreditation suggests devolvement, ownership, and a supporting role from the ministry. For example, the ministry requires District Health Boards to produce annual plans but the boards themselves will be responsible for addressing data quality issues within a national framework and getting them approved at the highest level of regional health care funding and provision.

The ministry, through the Quality Health New Zealand and/or the Royal Colleges health care provider's accreditation process, will provide sector organisations with clear guidelines on how to achieve accreditation as good data suppliers. The accreditation process will be developed in consultation with the sector following the development and testing of best practice guidelines. Those organisations that have been able to implement extensive data quality programmes, as outlined previously, will be accredited as good data suppliers. This should lead to a reduction in the need for peer review and audit.

The proposed sector work programme requires that health care organisations can achieve accreditation if they:

- Take part in a sector peer review/audit process
- Meet KPIs
- Implement an in-house data quality education programme
- Develop and implement a local data quality improvement strategy
- Organise regular meetings with a cross-organisational data quality group
- Align with best practice guidelines (when developed)

CONCLUSION

This chapter has described the development of a health data quality programme for the Ministry of Health in New Zealand. The ministry's purpose is to realise the full value and potential of the data that it collects, stores, and manages. Building "trust" in the data throughout the health sector will ensure that data are used frequently and to their greatest possible benefit. With the right framework and strategy, data that are highly utilised for a range of reasons will incrementally improve in quality. Extensive data mining, combining currently disparate collections, will also provide far more granular information and knowledge to improve these collections. A data quality strategy will provide coherent direction towards total data quality management through a continuous cycle of work. The improved data quality will then ensure that the health sector is better able to make informed and accurate decisions on health care policy and strategy.

These aims are relevant to national and regional health authorities and providers in many countries and the key principles, described here and developed from pioneering work by the Canadian Institute for Health information, can be deployed successfully in many health care and related scenarios.

In summary, for the development and application of the data quality evaluation framework, it is important to:

- Define the underpinning data quality criteria carefully involving all stakeholders to ensure common understanding and direction
- Consider the critical quality dimensions that reflect how the organisation uses data and how data flow throughout the business processes
- Document business processes identifying data sources and their reliability
- Appreciate that the framework requires practical supporting tools (e.g., documentation) to make it effective
- Customise the language of the data quality user manual with regard to the level and experience of the intended users
- Be aware of the importance of both education and training at all necessary stages and levels; training is essential to affect the culture change that must accompany the realisation of the importance of data quality
- Be aware that application of the framework is an iterative, ongoing process; the required outcomes cannot be achieved in a single pass

For the data quality improvement strategy, it is important to:

- Derive and impose standards that facilitate data and information transfer whilst preserving quality
- Reengineer the business processes to deliver the quality data needed for efficient service planning and the effective practice of integrated patient care
- Identify and disseminate best practice to reduce the development time needed to improve data quality
- Ensure data quality levels are not unnecessarily rigorous to maintain user ownership and workloads at reasonable levels
- Define user accountabilities for data quality and the mechanisms to enforce them
- Seek to embed the search for data quality in normal working practices and recognise its achievement in appropriate ways such as with accreditation

Work on extending and improving the health data quality programme continues, particularly with regard to the formulation of objective metrics for the underlying data quality criteria.

ENDNOTES

[1] A national collection is either a long-term collection of nationwide data or a reference dataset, of which NZHIS is the custodian on behalf of the sector, and which is used for analysis and information provision to improve the services and capabilities of the publicly funded health and disability sector.

[2] Version 1 of the CIHI Framework was superseded by a revised version 2 in June 2005 after this work was completed. The two versions (Canadian Institute for Health Information, 2003a, 2005) are essentially the same although the newer version has fewer criteria (58) but has added "documentation" as a sixth dimension.

Chapter 2.14
QoS Provisioning in Sensor Enabled Telemedicine Networks

Chunxiao Chigan
Michigan Tech, USA

Vikram Oberoi
Highmark Inc., USA

ABSTRACT

Enabled by the advances of the wireless sensor network technologies, wireless LANs will play a critical role in providing ubiquitous connectivity for future telemedicine applications. This paper focuses on how to provide QoS over the wireless channel between the Body Sensor Network (BSN) Gateway and the wireless Access Points (AP). Telemedicine applications require the periodic report data and the emergency messages transmitted to the remote health care center in a timely manner. However, unlike the voice and multimedia applications which can be supported by traditional QoS techniques, the sporadic nature of the emergency data in telemedicine systems makes it nontrivial to provide sufficient QoS. This article investigates several alternative schemes for QoS support in the telemedicine systems, and an express dual channel (EDC) based QoS mechanism is proposed. Not only is the proposed mechanism simple and resource efficient, but also it provides the bounded maximum delay guarantee for the unpredictable emergency data transmission for telemedicine applications.

INTRODUCTION

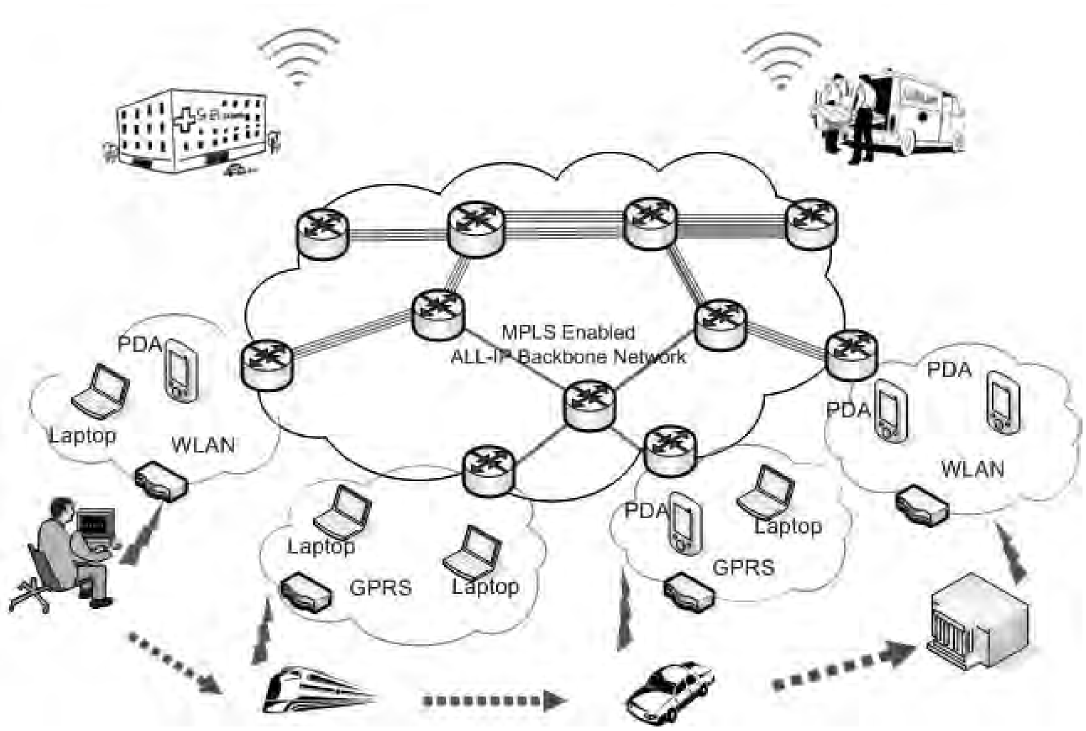
With the advances in wireless technology, the realization of seamless connectivity to support "anywhere" and "anytime" communications becomes more and more plausible. One of the most important advancements is the development of low cost wireless sensors networks to collect data in various environments. In this paper, we explore one such environment, namely the telemedicine systems. Chronic diseases such as diabetes and heart attacks are the most common and costly health problems in the United States. Fortunately, with the help of adequate support infrastructure and seamless connectivity, many fatal situations may be prevented. If the data related to the periodic monitoring reports and potential emergency situations of the patients can get across to medical facilities in a timely manner, even though the patient is free to roam about, many life-death critical situations can be taken care of.

A telemedicine system which can support such application, is depicted in Figure 1, where the data regarding various physiological parameters such as heart rate, blood pressure, and so forth, collected by the in-body sensors, is fed to and aggregated by the Body Sensor Network (BSN) gateway which can be some handheld device (e.g., a modified palmtop or PDA). This BSN gateway then sends this data to a wireless Access Point (AP, supported by IEEE 802.11) connected to the Internet, which further relays the data to the remote medical facilities. In such a telemedicine system, the BSN gateway fuses information from wearable, ingestible, and implantable sensors to provide continuous diagnostic monitoring and generate early warnings. It may also provide control over critical implantable devices such as drug delivery pumps. The emergency or the periodic data fused by a BSN gateway is then relayed via a WLAN access point to remote health care centers. The communication between the WLAN access point and remote health care center takes place via an all IP-based network.

To deploy such a telemedicine application which is life-death critical, certain QoS guarantees have to be provisioned so the data can reach the remote health care center in a reliable and timely manner. This paper focuses on the QoS provisioning between the BSN gateway and the wireless access points (e.g., IEEE 802.11 based Hot Spots) in the telemedicine applications.

We assume that the underlying media access control (MAC) protocol of the WLAN access point network is the IEEE 802.11e standard which supports the traditional QoS service to various classes of applications. Compared to the baseline IEEE 802.11 which does not support any QoS service, IEEE802.11e provides a basic platform to support different priority of the wireless media access to different data traffics if the traffic

Figure 1. Conceptual system architecture of the sensors-enabled telemedicine system



pattern is of certain predictability. However, the occurrence of emergency events in telemedicine application is extremely sporadic and its traffic pattern is totally unpredictable. Therefore, the QoS provisioning for such applications is not trivial. Rather, it can be an extremely difficult task if the traditional scheduling-based QoS approaches or the traditional contention based on-demand QoS approach patterns are applied for the QoS provisioning in telemedicine systems.

In this article, we propose a completely new method of providing QoS support for telemedicine applications with very little complexity and cost-effective QoS guarantees. The rest of the article is organized as follows. In the second section, we present the related work and discuss the uniqueness of the QoS requirements in telemedicine applications. In addition, four alternative potential approaches to support QoS in telemedicine applications are also investigated in this section. The third section presents the details of our proposed Express Dual Channel (EDC) based QoS solution for telemedicine applications. In the fourth section, we present our simulation results, and the fifth section concludes the paper by presenting conclusions and future work.

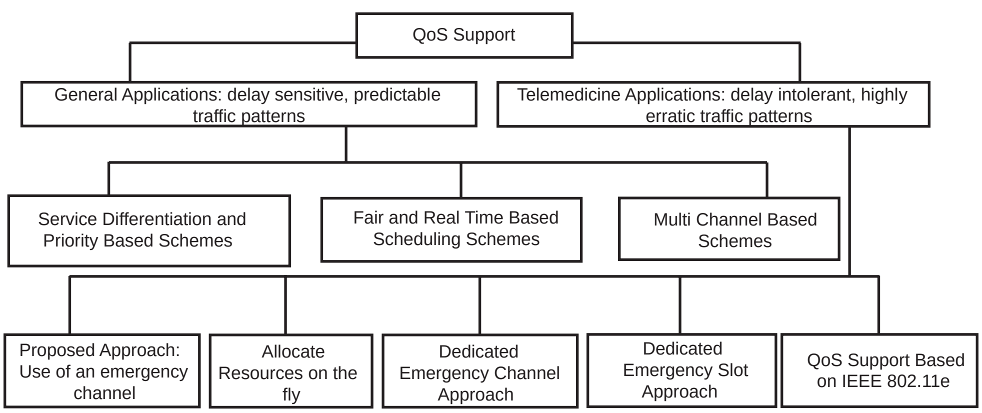
RELATED WORK

In this section, we present the existing approaches providing traditional QoS services and identify the unique challenges of QoS provisioning in telemedicine systems. We then explore the potential approaches to meet these unique QoS requirements in telemedicine applications.

Current QoS Approaches (Traditional QoS)

There are many solutions proposed to support the traditional wireless QoS applications where different classes of data demands are known in advance. For example, it is known that some applications (e.g., video, voice) are more delay sensitive than the others (e.g., data). Because the traffic patterns of these delay sensitive data (video and voice) have been extensively studied and well understood, we refer to the solutions providing QoS to applications of predictable traffic patterns as *traditional QoS* approaches. The current approaches to support traditional QoS requirements can be grouped into various categories. We have classified (refer to Figure 2) some of these approaches which are closely related to our work into three categories. The following is a brief overview of these approaches.

Figure 2. Diagrammatic representation of classification of QoS various approaches



Service Differentiation and Priority (SDP) Based QoS Schemes

The schemes under this category basically use different values of various contention parameters such as contention window size and so forth, to assign different priorities to different services. The work by Ada and Castelluccia (2003), Xiao (2003), and Veres, Campbell, Barry, and Sun (2001) belong to this category. One such scheme has been proposed in Ada and Castelluccia (2003), wherein the authors present four service differentiation schemes for IEEE 802.11. The first scheme is based on scaling the contention window according to the priority of each *flow* or *user*. For different users with different priorities, the second, the third, and the fourth mechanisms assign different minimum contention widow values, different interframe spacing and different maximum frame lengths, respectively. The SDP-based QoS approach can also be used to provide priorities to real-time applications (Xiao, 2003). By differentiating the initial window size, the window-increasing factor and the maximum backoff stage, an analytical model for assigning priorities to real-time applications was proposed in Xiao (2003).

In the SDP-based QoS approach, service differentiation can also be introduced using a fully distributed approach. In Veres et al. (2001), based on the IEEE 802.11 Distributed Coordination Function (DCF) mode, two distributed estimation algorithms are proposed. A Virtual MAC (VMAC) algorithm passively monitors the radio channel and estimates locally achievable service levels. VMAC estimates key MAC level statistics related to service quality such as delay, delay variation, packet collision, and packet loss.

In all of the above schemes, priority is assigned to different services by assigning favorable contention parameters. Therefore, data demanding high priority can only achieve best-effort QoS with unbounded maximum delay. This is due to the fact that the high priority data still has to contend for channel access with the lower priority and equal priority services.

Fair and Real-Time Scheduling (FRS) Based QoS Schemes

The protocols under this category use fair queue scheduling principles to attain QoS. Vaidya, Bahl, and Gupta (2000), Adamou, Khanna, Lee, Shin, and Zhou (2001), and Ranasinghe, Andrew, Hayes, and Everitt (2001) fall into this category, wherein the scheduling can be done based on the traffic analysis for different applications.

Using one or more parameters, such as finish time for a packet, some scheduling policies are developed. One such approach presented in Vaidya et al. (2000) is based on the Self Clocked Fair-Queuing approach of transmitting the packet whose finish tag is the smallest, as well as its mechanism for updating the virtual time. A distributed approach for finding the smallest finish tag is employed, using the back off interval mechanism of IEEE 802.11 MAC. The essential idea is to choose a backoff interval that is proportional to the finish tag of the packet to be transmitted.

The approaches under this category try to attain a specific scheduling goal depending upon the nature of the application. For instance in Adamou et al. (2001), the authors present four different algorithms designed to attain certain specific scheduling goals. The first two are EDF (Earliest Deadline First) and GDF (Greatest Degradation First) that consider only one aspect of the scheduling goal, respectively. EDF is naturally suited for maximizing throughput, while GDF seeks to minimize the maximum degradation. The next two are algorithms, called EOG (EDF or GDF) and LFF (Lagging Flows First), which consider the two aspects of the scheduling goal. EOG simply combines EDF and GDF, whereas LFF tries to favor lagging flows in a nontrivial manner.

Similar to different scheduling goals, the QoS objectives can also be differentiated according to the nature of the application (Ranasinghe et al., 2001). One QoS objective could be to maximize the number of customers receiving good service for real time data services such as multimedia data, MPEG, video streaming, IP telephony, and so forth. In Ranasinghe et al. (2001), a new scheduling scheme called the Dual Queue discipline is proposed which has the flexibility to satisfy a variety of QoS objectives, ranging from existing notions of fairness to maximizing the number of customers receiving good service.

All the schemes under this category, however, require the prior knowledge of the different traffic patterns, which is unavailable in telemedicine applications wherein the traffic pattern of emergency messages is highly unpredictable.

Multi Channel (MC) Based QoS Schemes

In MC-based QoS schemes, usually separate control messages are used to set up a separate dedicated channel or reserve the primary channel for data transmission. Dedicated Channel for Streaming Services (DCSS) (Tsai & Wang, 2005) uses some new control frames to assign a new dedicated channel for heavy traffic or streaming services. On the other hand, Dynamic Channel Assignment (DCA) (Wu, Lin, Tseng, & Sheu, 2000) divides the overall bandwidth into one control channel and “n” data channels. Whenever a node wants to communicate with another node, it sends control packets over the control channel to obtain rights to access one of the data channels. The data channels carry only the Data and the Acknowledgements packets.

Another QoS mechanism is to use different reserved channels for communicating with different neighbors. Sequenced Neighbor Double Reservation (SNDR) (Cai & Lu, 2000) is one such MAC protocol for Multi-Channel Ad Hoc networks. The basic idea is that, for a given node A, if one of its neighbors B wants to send data to A, B must use the same code sequence preassigned to A to send data. In other words, A can receive data only on the channel it has been preassigned. If more than one neighbor wants to send data to A, then they use TDM over that channel.

One of the drawbacks of the schemes mentioned in this category is the delay caused in setting up the separate channel or gaining access to the main data channel. In addition, valuable resources may be underutilized because of reservation of separate channels for separate nodes.

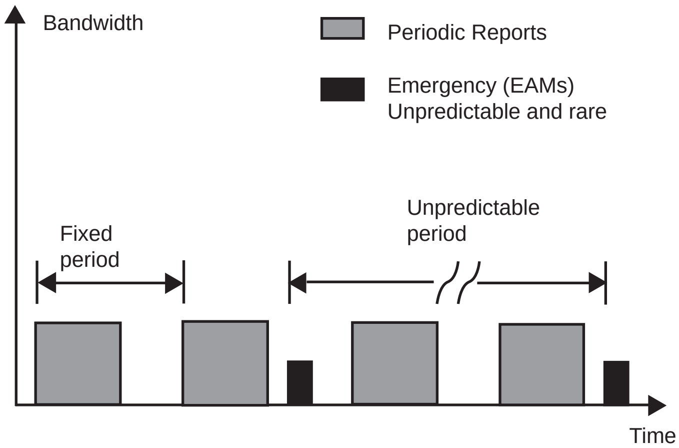
Alternative Approaches (QoS in Telemedicine Applications)

In this section, we first discuss the unique QoS requirements and challenges for telemedicine applications. Then we discuss why the previously surveyed existing approaches may not work well to provide QoS support for such applications. Certain approaches that may be employed for providing QoS guarantee for telemedicine applications are then explored. We use the sensor enabled telemedicine systems illustrated in Figure 1 as an example in the rest of paper for discussion purpose. The QoS issues and principles discussed in this paper, however, are applicable to a variety of sensor enabled telemedicine systems.

Unique QoS Requirements of Telemedicine Applications

As described above, there are many traditional solutions proposed to support the traditional wireless QoS applications where different classes of data demands are known in advance. However, as shown in Figure 3, telemedicine application usually comprises of two types of data: the regular periodic report data which are sent at fixed time intervals and are of predictable nature, and the emergency messages that have highly erratic natures. Therefore, providing QoS support for emergency situations can be very tricky because of this erratic nature.

Figure 3. Traffic pattern for a telemedicine application with emergency situations



To highlight the uniqueness of QoS requirements for emergency data, let us compare its properties with that of traditional QoS applications such as voice streaming and multimedia traffic.

First, the emergency events in telemedicine application are extremely sporadic and unpredictable, therefore may occur just once in several months/years. However, although emergencies occur sporadically, emergency telemedicine data is extremely delay-intolerant and demands bounded maximum delay guarantee. Hence, traditional resource reservation and the scheduling-based QoS approach cannot be applied to this kind of telemedicine applications efficiently. On the other hand, the traditional on-demand QoS approaches are contention-based and may lead to unbounded maximum delay, and therefore cannot ensure the QoS requirements of the delay intolerant telemedicine applications either. Thus, all traditional QoS approaches (resource reservation and scheduling based, or contention based on-demand approach) can hardly suit the telemedicine applications.

Indeed, none of the traditional QoS approaches discussed previously can work well in telemedicine applications. The *SDP Based QoS Schemes* may experience unbounded maximum delay for gaining the channel access due to the contention among different and same priority services. The *FRS Based QoS Schemes* require traffic analysis and thus demand the prior knowledge of traffic patterns that is not available for telemedicine applications. And the *MC Based QoS Schemes* may require unbounded maximum delay in establishing a separate channel or gaining access to one of the data channels. This is also due to the contention and collisions that may occur over the control channel.

Alternative Approaches for Telemedicine QoS

Next, we explore potential approaches that might be applicable for QoS in telemedicine applications.

1. **Allocate Resources On-the-Fly:** Anytime a device with emergency message to be delivered via the access point (AP), it probes the availability of an AP in its vicinity (or passively listens for a beacon from an AP). Then it associates with the AP. After the association phase, it ***contends*** for the channel and can only send the emergency data after obtaining channel access. The obvious limitation of this approach is the nondeterministic delay introduced. In the worst case (with unbounded maximum delay) the

device with emergency event may not get the channel access in the acceptable delay period.

2. **Dedicated Emergency Channel Approach:** Another approach could be to reserve a whole separate channel for transmitting the emergency data. However, as emergencies occur rarely and follow the bursty pattern, this often leads to significant wastage of the resources.
3. **Dedicated Emergency Slot Approach:** A similar approach is that the AP reserves a slot of channel access for the telemedicine application by the periodic beacon signal it sends out. If the application indicates that there is an emergency event in this slot, the AP grants the channel to the telemedicine application. However, the beacon is sent out following the scheduled (determined) intervals, whereas emergencies are of highly unpredictable nature. Thus, if the emergency event occurs after the beacon was sent out, the emergency data cannot be transmitted until the next beacon period. In addition, because the emergency data has to be transmitted within the reserved slot, the periodic share of wireless channel access needs to be large enough to support at least one telemedicine application at a time. With the unpredictable nature of the emergency message, this *slot reservation based approach* is therefore subject to the same wastage of resources as the *dedicated channel based approach*. In general, the larger the reserved slot, the less access delay the telemedicine applications (one or more) experience, while the more significant the resource wastage is.
4. **QoS Support Based on IEEE 802.11e:** This approach uses the Hybrid Coordination Function (HCF) in the IEEE 802.11e standard (refer to appendix for details) to provide higher priority for the telemedicine applications. Under the HCF mode, because the AP is given the highest priority for the wireless media access, it can grant access to nodes with different priorities based on certain criteria. During the Contention Free Period (CFP), the AP can issue a QoS Contention Free (CF) Poll to a particular station to grant it a channel access. The AP schedules these polls based on the traffic analysis sent to it by each station regarding their queue length, and so forth. During the Contention Period (CP), all the stations contend for channel access via Enhanced Distributed Coordination Function (EDCF). In this case, if the AP is triggered properly by the emergency demands, it can grant channel access to the telemedicine stations by sending out a beacon signal. However, for telemedicine applications, the traffic is of a highly unpredictable nature which could render the traffic analysis/predication a very complex issue. Therefore, it would be very difficult to design a scheduling algorithm that can capture the unpredictable nature of the emergency data.

In this paper, we propose a novel mechanism to provide QoS for telemedicine applications. Not only is this mechanism simple and resource efficient, but also it provides bounded maximum delay for the unpredictable emergency data transmission.

EXPRESS DUAL CHANNEL (EDC) BASED QOS PROVISIONING FOR TELEMEDICINE APPLICATIONS

In this section, we present an entirely new and radical approach for providing QoS support in telemedicine applications. We use the telemedicine system depicted in Figure 1 as an example for explanation, but the proposed approach is applicable to most of the telemedicine applications where wireless media access controls are involved.

As described in the first section, for a sensor enabled telemedicine system, the patients are equipped with in-body or wearable sensors which can send the data from different parts of the body to the Body Sensor Network (BSN) Gateway (e.g., modified handheld devices such as PDAs or Palmtops). The BSN gateway sends the aggregated data (periodic reporting data, and unpredictable emergency data) to the remote health care centers via the public Wireless Access Points (APs, e.g., WiFi) which are connected to the Internet. Because APs often support many other applications in the public domain, there are contentions among different applications to gain the wireless channel access from different nodes. Furthermore, multiple telemedicine applications within one AP also contend among each other to gain channel access. In this context, our paper focuses on the QoS support for telemedicine applications by guaranteeing maximum (worst) delay of the public APs access, and at the same time minimizing the resource wastage due to the unpredictability of the emergency data.

Assumptions and Notations

The assumptions that were made are listed below:

- The AP is able to transmit and receive data simultaneously.
- The level of interference experienced by two nodes is the same in both directions (transmission and receiving). The interference level does not change during the transmission period.
- Nodes send association and disassociation messages to the AP when they enter and leave the network, respectively.

The following is the summary of the notations (IEEE 802.11e compatible) used in this paper:

- SIFS—Short Interframe Space
- PIFS—Point Interframe Space
- DIFS—Distributed Interframe Space
- HC—Hybrid Coordinator
- AP—Access Point
- TXOP—Transmission Opportunity
- TBTT—Target Beacon Transmission Time

Network Dynamics in Telemedicine Applications

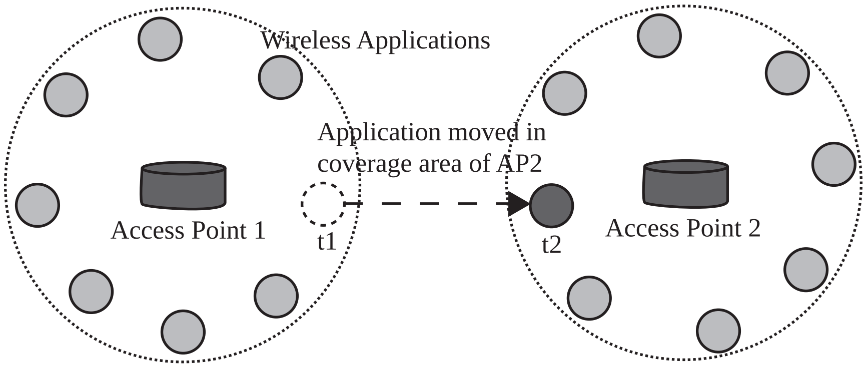
To enable the BSN gateway sending data to remote health center seamlessly, APs at different locations (different spots on campus, shops, airports, etc.) can be used to provide pervasive network connection. In this case, the individual wireless local area network is in infrastructure mode. However, the telemedicine applications supported by enormous numbers of APs are still of ad hoc nature because the BSN gateway can be one time within the coverage of one AP, and another time move to the vicinity of a different AP. This demands a perfect hand-off technology for the WLAN networks, which is beyond the scope of this article.

The above situation is depicted in Figure 4. The network configuration (in which a telemedicine device connected to) at time t1 is different from that at time t2 when some telemedicine applications have moved from the coverage area of AP1 to the coverage area of AP2.

Revisit: Traffic Patterns and Unique QoS Requirements in Telemedicine Applications

As discussed previously, the QoS support required by the telemedicine applications is different to that of conventional applications due to the extreme unpredictability of the emergency data pattern. Conventional techniques for providing QoS, which are based on analyzing the traffic patterns of different flows, do not suit such kinds of telemedicine

Figure 4. Network configuration at time t1, t2



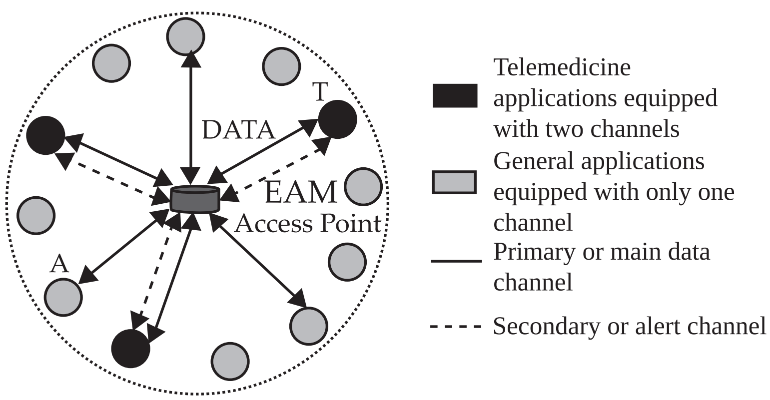
applications due to the highly unpredictable nature of the traffic. In general, for such applications, the emergency events occur very infrequently, and therefore often it is desirable to have the periodic report messages (probably with a slow repetition cycle) sent for event monitoring/predication purpose and to maintain the presence of the telemedicine devices and their association with the network access point.

Supporting Emergency QoS in Telemedicine System: Express Dual Channel-Based Mechanism

To provide QoS guarantee for telemedicine applications supported by wireless LAN, we propose the use of an unsymmetrical dual channel mechanism. With such a dual channel mechanism, the primary channel is dominated for all data transmission, and the secondary channel is very slim, which is dedicated to the short emergency alert message (EAM) transmission.

Figure 5 depicts a scenario where such a dual channel mechanism is used to provide QoS support for a telemedicine application in case of an emergency. Before an emergency occurred, a general application device A was sending data to an AP. Now, as soon as the emergency occurred, the telemedicine application device T sends out a short Emergency Alert Message (EAM) through the reserved secondary, or alert channel. Upon receiving the EAM alarm, the AP schedules (with the highest priority) to send out a beacon to all the applications in the network, indicating the reservation of resources for device T.

Figure 5. Diagrammatic representation of channel access via the use of dual channel



The AP can gain access to the channel anytime because of its highest priority to access the channel under the Hybrid Coordination Function (HCF) mode supported in IEEE 802.11e. Upon receiving the beacon frame, telemedicine device T can send out the emergency data over the primary data channel. At the same time, the regular application device A losses its access to data transmission channel. Only devices with telemedicine requirements are equipped with this dual channel. A separate secondary channel is reserved for sending the short EAM to the AP. Whenever an emergency occurs, the BSN gateway sends a short EAM over this reserved channel to the AP to request the channel access for its emergency data. With this reserved secondary channel, the short EAM can arrive in a timely manner at the AP. Upon receiving the EAM, the AP can schedule to send out a beacon frame indicating an instant/highest priority reservation of resources for this station over the primary (normal) channel for its emergency data transmission. Once the requesting station is granted to access the medium, it can then send the complete emergency data over the primary data transmission channel.

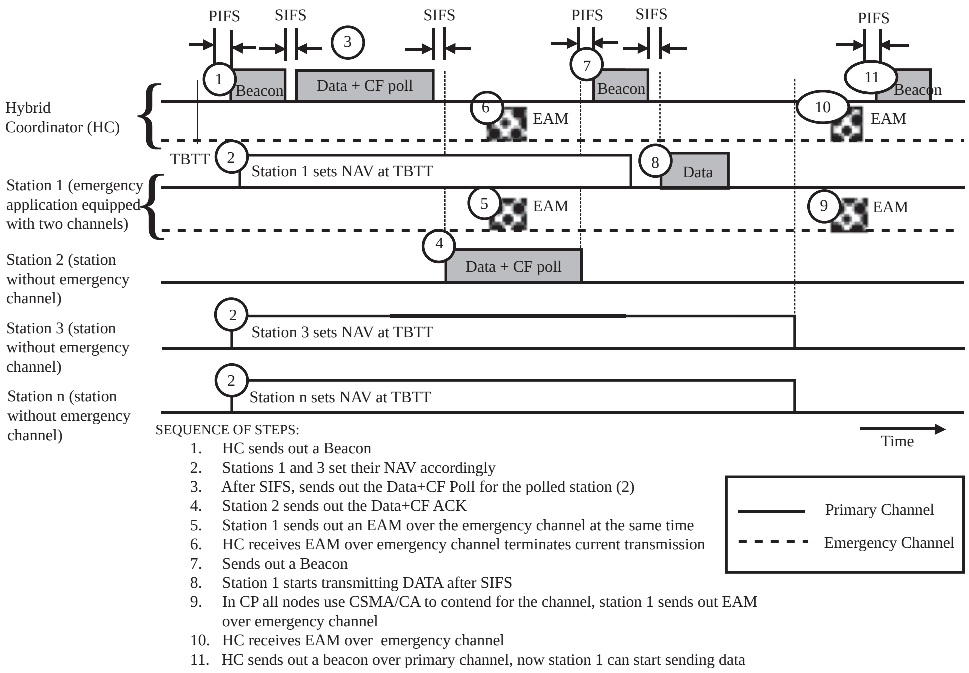
The reserved secondary channel therefore requires a very small amount of bandwidth as the EAMs are very short messages to report the occurrence of the emergency event. Consequently, such a static secondary channel reservation at the APs for the telemedicine applications will not be costly even when there are no devices of telemedicine applications associated with the APs.

Because there could be more than one device of telemedicine applications within one AP's coverage, there can be a contention over this reserved secondary channel too. To resolve such a complication, the AP can apply a Time Division Multiplexing (TDM) scheme over the reserved secondary channel to allow a fixed number of such applications that it can accommodate to associate with itself. This number will depend on the maximum delay these telemedicine applications can tolerate and the statistics of the specific telemedicine applications. Once the EAM reaches the AP through the reserved secondary channel, the primary data channel access will then be scheduled for that application, and thus emergency requests can be processed within a certain time, and hence the delay in processing multiple such requests will be deterministic. To allocate the available bandwidth between the dominant primary data channel and the slim secondary emergency alert channel, Orthogonal Frequency Division Multiplexing (OFDM) (Tutorial: Multi Carrier Modulation and OFDM. http://zone.ni.com/devzone/cda/ph/p/id/150), (Lawrey, 1997) or Frequency Division Multiplexing (FDM) (Tutorial: Multi Carrier Modulation and OFDM. http://zone.ni.com/devzone/cda/ph/p/id/150) or Code Division Multiple Access (CDMA) can be used. Details of these methods can be found in Lawrey (1997). Because these are all mature commercial technologies, the cost of the hardware introduced to support our proposed express dual channel (EDC)-based QoS solution will be rather low.

Figure 6 gives an in-depth description of the wireless channel acquisition for the proposed dual channel-based QoS support for telemedicine applications. Station 1 is a telemedicine application device and is equipped with two channels. Stations 2 and 3 are regular application devices and can send messages over the primary data channel only. The whole process is divided into two periods, the Contention Free Period (CFP) and the Contention Period (CP). The CFP is fixed and bounded by two TBTT (Target Beacon Transmission Time). During the Contention Free Period (CFP), the AP or the Hybrid Coordinator (HC) polls the stations for data transmission by sending a beacon, whereas during the CP, the nodes contend for channel access (refer to appendix for details).

First, let us have a look at channel access during CFP. Let us assume at time 0, the AP has polled and given the Transmission Opportunity (TXOP) to station 2. Station 1 and 3 set the Network Allocation Vector (NAV) to the next Target

Figure 6. Channel access during contention free period (CFP) and contention period (CP) in express dual channel based QoS Mechanism



Beacon Transmission Time TBTT, assuming that all the polling slots are full and it will not have the TXOP during this period. Thus, station 2 can send its data to the AP during its TXOP over the primary data channel.

Now, when an emergency happens at telemedicine station 1, it sends out an EAM over the secondary emergency alert channel to the AP. Once the AP receives this EAM, it terminates the TXOP of station 2 and sends out a beacon frame over the primary channel after waiting for the Point (coordination function) Interframe Space (PIFS) duration. This beacon indicates the reservation of the primary channel for telemedicine station 1 and grants the TXOP to station 1 for the required duration. Stations 2 and 3 can set their NAVs accordingly.

Now let us consider the Contention Period (CP). During the Contention Period (CP), all the stations contend for channel access via Enhanced Distributed Coordination Function (EDCF) (refer to appendix for details). But the AP still can grant access to the channel by broadcasting a beacon. Thus, when station 1 detects an emergency, it sends an EAM over the secondary emergency channel. Upon receiving this EAM, AP broadcasts a beacon over the primary channel. Now, station 1 can send its emergency data over the primary data channel.

To provide QoS support for regular report data for telemedicine applications, we apply the IEEE 802.11e standard. For details of IEEE 802.11e MAC, please refer to the appendix. Such periodic data reports of telemedicine applications are grouped into a separate category with the second highest access priority at the primary data channel. The number of retransmission of such periodic report data is limited by the time after which the report will be outdated and not by a certain threshold number as in IEEE 802.11e standard. When operating in the EDCF mode, the telemedicine applications get the second highest priority to access the primary data channel and when operating in the Hybrid Coordinator (HC) mode, the Hybrid Coordinator (HC) located at the Access Point (AP) polls the telemedicine applications first. As the regular report data will be generated in a periodic manner, the AP can schedule its polling for these applications after it analyses their traffic patterns.

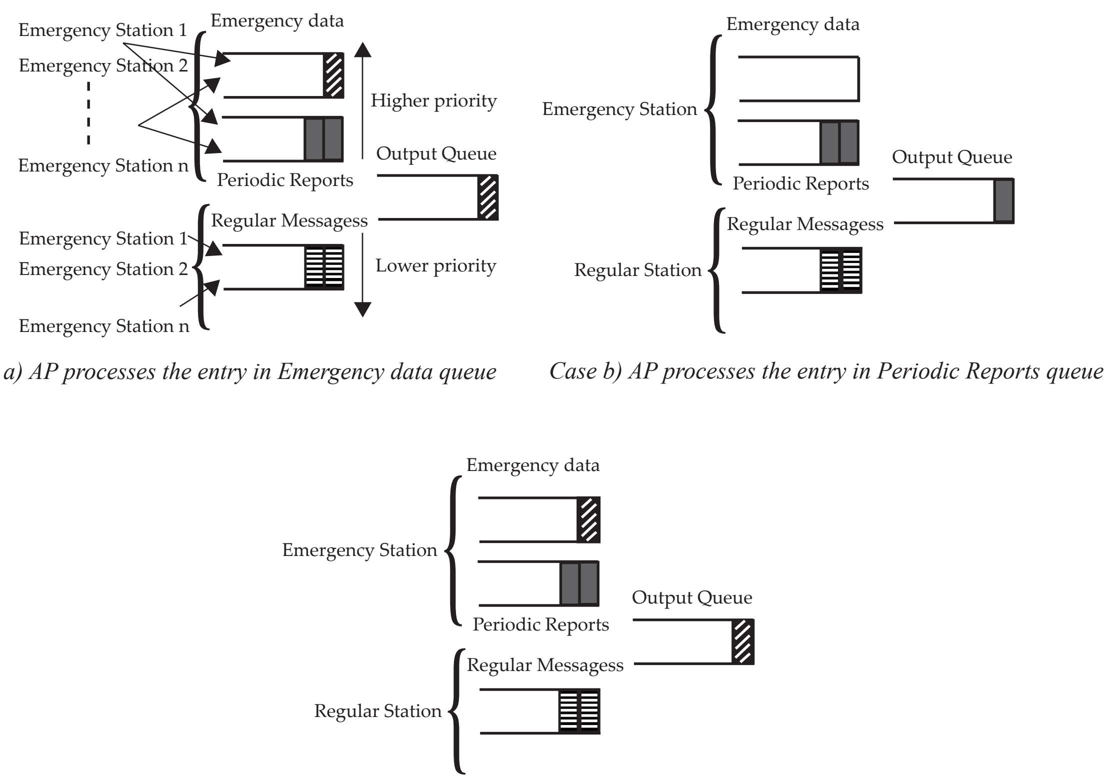
Queue Formation and Processing of Queue Entries at the AP

There are 3 classes of queues maintained at the AP in the proposed telemedicine QoS mechanism. The emergency data queue (EAM queue) has the highest priority. The queue with the second highest priority is dedicated to the periodic report data of the telemedicine applications. The queue dedicated to the other messages (regular applications) has the lowest priority. As shown in Figures 7 and 9, the entries in the EAM queue at the AP are given the highest priority. As long as there is an entry in the EAM queue it will be processed first, thus resulting in very small processing delay for such applications. Thus, as soon as an emergency occurs, the EAM can be sent to the AP without further access contention. When a station leaves the network, it sends a disassociation message to the AP and the AP can release the resources that were allocated to this station.

The proposed Hybrid "Emergency First" and "Fair Queue" algorithm works as follows (refer to Figure 8): the AP processor always checks the EAM queue first. If there is a message in this queue, it processes it; otherwise it goes on to check the queue of the periodic reports. Upon the completion of any message processing, the AP proceed to check the EAM queue first and then the other queues.

In Figure 7 of case "a", at the starting point, there was an entry in the EAM queue, so the processor at AP processes it. In case "b", as there is no entry in the EAM queue, the processor moves on to periodic data reports queue, and processes one entry and then again proceeds to check the EAM queue. If there is an entry in EAM queue,

Figure 7. Hybrid "Emergency First" and "Fair Queue" scheduling at the AP



Case a) AP processes the entry in Emergency data queue

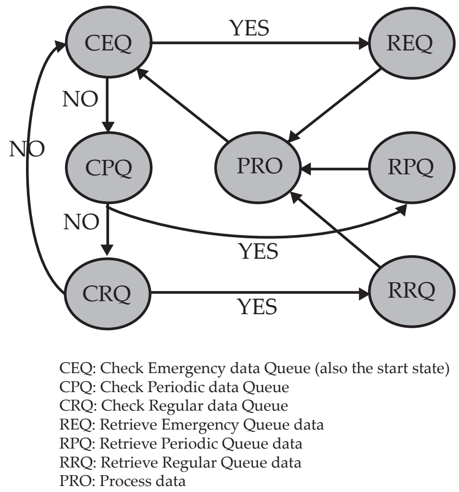
Case b) AP processes the entry in Periodic Reports queue

Case c) AP processes the entry in Emergency data queue

Figure 8. Hybrid "Emergency First" and "Fair Queue" algorithm

1. Check Emergency data Queue
   a. If entry exists,
      • retrieve data, go to Process,
      • go to step 1
   b. Else, go to step 2.
2. Check Periodic Reports Queue
   a. If entry exists,
      • retrieve data, go to Process,
      • go to step 3
3. Check Regular messages Queue
   a. If entry exists,
      • retrieve data, go to Process,
      • go to step 1
   b. Else, go to step 1

Figure 9. Finite state machine (FSM) of queue processing at AP



the AP will process it first and then move on to other queues. This is depicted in case "c". Notice that there can never be more than one message in the output queue at a time. This is due to the fact that the processor only processes one message at a time and then checks the different queues first before processing the next message. Thus, the maximum delay experienced by the emergency data after it reaches the AP is the time required to process one single data message request.

Figure 9 depicts the Finite State Machine (FSM) of our Hybrid "Emergency First" and "Fair Queue" Algorithm, which is described in detail in Figure 8. The FSM diagram and the algorithm (refer to Figure 8) depict the processing flow of queue entries at the Access Point. An EAM basically triggers the AP to reserve resources for its telemedicine application. As soon as an EAM reaches the AP, it sends out a beacon indicating the reservation of resources for the telemedicine application associated with the EAM.

This beacon also acts as an acknowledgment for the telemedicine station that its EAM has reached the AP. For periodic reports, the standard ACK packets can be used as the confirmation of their reception. Once the emergency data reaches the AP, it is placed in Emergency data queue. This queue is given the highest priority. All the queues are scanned by the AP in a round robin fashion, as described in Figure 8.

SIMULATIONS

As discussed in the second and third sections, our proposed Express Dual Channel Based QoS Mechanism can guarantee bounded *maximum delay* experienced by the emergency message transmission, and it can therefore ensure the QoS requirement of the telemedicine applications wherein the occurrence of the emergency event is rare and highly unpredictable. Indeed, without *a prior* knowledge of the traffic pattern of the emergency messages available, it is impossible for the traditional schedule-based QoS approaches to prereserve channel resources for telemedicine applications efficiently. On the other hand, the traditional on-demand QoS approaches are contention-based and may lead to unbounded *maximum delay*, and therefore cannot ensure the QoS requirements of the delay intolerant telemedicine applications either. In this section, we will evaluate the performance of our proposed QoS scheme in terms of the *average end-to-end transmission delay*, and the *percentage of the dropped data bits* via simulation.

We used OPNET, version 8.1A, for simulating the proposed QoS solution in WLAN networks. Various parameters used and their values are shown in Table 1. A total of 10 nodes were placed randomly, but all within the transmission range of the Access Point (AP). The underlying MAC protocol is the IEEE 802.11. IEEE 802.11e has not been simulated in OPNET. For the time being, we used IEEE 802.11 standard as the underlying MAC. The network is operating in infrastructure mode where all the nodes have PCF functionality enabled. For telemedicine stations, only the emergency data is considered, and the periodic report data is not included.

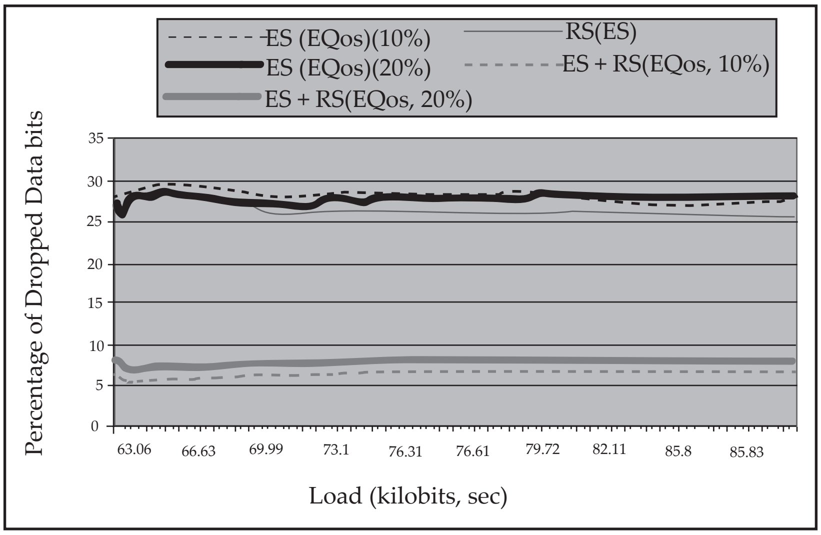
Figure 10 shows the average dropped data bits (kilobits) for the telemedicine stations and the regular stations vs. the average load for a station. Our proposed scheme is compared with the baseline scheme, which is the IEEE 802.11 standard in the PCF mode without priority given to any station. We used this scheme to form a benchmark for the performance of a regular station. Therefore, in the baseline scheme, all the stations are considered as regular stations as opposed to our proposed scheme, in which stations are divided among telemedicine stations and regular stations. *ES (EQoS) (10%)* denotes Enhanced Telemedicine Stations in our proposed telemedicine QoS scheme, and they are 10% of the total stations in the simulated WLAN network. Similarly, RS (BS) denotes Regular Stations in the Baseline Scheme. ES+RS (EQoS, 10%) denotes the overall performance of all telemedicine and regular stations in our proposed EQoS scheme when there are 10% telemedicine stations in the simulated WLAN networks. Conversely, when there are 10% telemedicine stations, then there will be 90% regular stations, and when there are 20% telemedicine stations, there will be 80% regular stations. We can see that the percentage of the dropped data bits are considerably less for the telemedicine station in our proposed scheme, as expected.

It is also shown in Figure 10 that although the *percentage of the dropped data bits* for a regular station in our scheme is greater than that in the baseline scheme, this difference is not much larger as compared to that in the baseline scheme. Hence, even though in our proposed scheme we concentrate on the telemedicine stations, the performance degradation for a regular station is not that large. The graph also shows that there is a slight increase in the percentage of the dropped data bits for the telemedicine stations when their number is increased from 10% to 20%. However, for overall performance of all regular and telemedicine station, this increase is negligible. This may be due to less contention experienced by regular stations as the number of regular stations contending for the same channel has decreased.

Table 1. Simulation parameters and their values

Parameter	Values used
Grid size	100*100 meters
Transmission range	30 meters
Traffic	Bursty
Network Scale	Office
Simulation Time	900 seconds
No. of stations	10
No. of stations equipped w/ emergency channel	2

Figure 10. Percentage of dropped data vs. average load



We can also see that there is a steady increase in the *percentage of the dropped data bits* with the increased load for the telemedicine stations. This is due to the fact that EAMs reach the AP through a time division multiplexed channel. Hence, when one telemedicine station gains the channel access, the other telemedicine station has to wait until the first one completes its transmission. Thus, with an increasing load, more data bits will be dropped as the waiting time will increase.

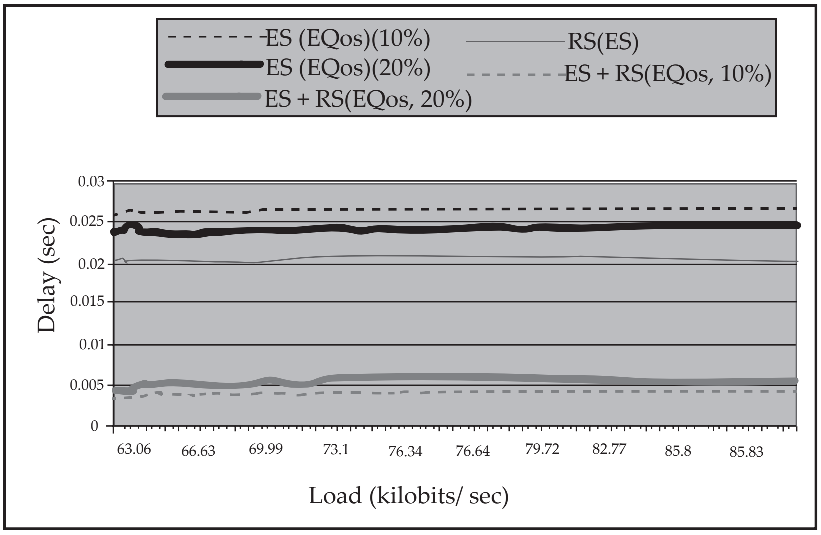
Figure 11 shows the *average delay of the end-to-end transmission* for the telemedicine stations and the regular stations vs. the average load for the station. As the load for the station increases, the average delay experienced by both the telemedicine and the regular station increases. However, the delay experienced by the telemedicine station is much less than the delay experienced by the regular station in our scheme. This is due to the fact that whenever a telemedicine station needs to send data to the AP, it can send an EAM over the emergency channel and get the channel access scheduled in a deterministic and negligible time period. However, regular stations have to contend with other regular applications (which results in nondeterministic delay) or wait to be polled by the AP before they can start sending their data.

Again, even though in our scheme we concentrate on improving the performance of the telemedicine stations, the performance degradation for a regular station is not much as compared to the regular station in the baseline scheme. This can be inferred from the curve showing the overall average delay experienced by all the telemedicine and the regular stations, which is slightly higher for our scheme as compared to the baseline scheme. The average delay experienced by the telemedicine stations increases when their number is increased from 10% to 20%. This is again due to the fact that at higher loads a telemedicine station will have to wait for a longer period until the telemedicine station, which has gained channel access earlier, has finished its data transmission.

CONCLUSION AND FUTURE WORK

Due to the highly erratic nature of the telemedicine emergency events, designing mechanisms to provide QoS based on traditional methods is not trivial, if not impossible. This is mainly because the traffic pattern based traditional scheduling QoS solutions cannot be used for telemedicine application. If resources are prereserved, it will

Figure 11. Average delay vs. average load



result in a highly inefficient solution. On the other hand, the traditional on-demand QoS approaches are contention-based and may result in unbounded *maximum delay*, and therefore cannot ensure the QoS requirement of the delay intolerant telemedicine applications either. In this article, we proposed a novel mechanism to provide QoS for telemedicine applications. Our proposed dual channel-based QoS approach, where the slim express secondary channel is dedicated for transmitting short Emergency Alert Message (EAM), is an effective and simple method of providing QoS in ubiquitous telemedicine applications. The proposed solution uses the IEEE 802.11e standard as its baseline mechanism (Deng & Haas, 1998). The simulation results show that not only is this mechanism simple and efficient, but also it results in bounded maximum delay for the erratic emergency data transmission in telemedicine applications.

In the future, we will simulate and compare our proposed mechanism with the traditional QoS methods to estimate the overall performance improvements. We will also carry out an analysis on the maximum number of devices for telemedicine and general applications that an AP can accommodate simultaneously, given specific QoS requirements (e.g., maximum tolerable delay) of various telemedicine applications.

APPENDIX A.

OVERVIEW OF IEEE 802.11E MAC

IEEE 802.11e (IEEE Std 802.1 WD3.3., 2002) has been proposed specifically to support QoS requirements. It introduces the concept of a Hybrid Coordination Function (HCF), which basically consists of two access schemes:

- The Enhanced Distributed Coordination Function (EDCF), which is an extension to the DCF in 802.11 to provide service differentiation via priorities, and
- The Hybrid Coordinator (HC), which is a modification to the existing Point Coordinator (PC) for more efficient polling schemes.

When using EDCF, multiple Access Categories (ACs) have been defined to provide QoS. Each AC uses the DCF; however with different values of the contention parameters DIFS, now called Arbitration IFS (AIFS). ACs with lower parameter values will experience lower mean waiting and backoff times and thus will have a relatively higher access priority to the medium. A station or a node which has multiple ACs in parallel will have internal contention between its own ACs in addition to the access contention with other stations.

According to the draft standard (IEEE Std 802.1 WD3.3., 2002), four different types of services, voice, video, video probe, and best effort, are considered with each of them having their own AC. Table 2 lists the parameter values which have been assigned to each of the four ACs. The values are chosen in such a way that the highest access probability is given to the “voice” AC and the lowest one to the AC supporting the best effort data traffic.

Table 2. Contention parameter values for different ACs

AC	AIFS	CW_{min}	CW_{max}	Service
0	2	15	1023	Best effort
1	1	15	1023	Video probe
2	1	7	15	Video
3	1	3	7	voice

In addition to the EDCF contention mechanism providing service differentiation, a polling-based access mechanism similar to the IEEE 802.11 PCF is also included in the 802.11e draft standard (IEEE Std 802.1 WD3.3., 2002). This polling scheme is controlled by a centralized hybrid coordinator (HC) located at the access point (AP). The HC can start a controlled access period (CAP) whenever needed, in order to poll traffic from the stations.

An important new attribute of the IEEE 802.11e MAC is that the station that obtains the medium access cannot utilize it longer than the duration greater than a specified limit. This attribute is known as a transmission opportunity (TXOP). A TXOP is defined by its starting time and duration. TXOPs obtained via contention-based medium access are referred to as EDCA-TXOPs, and TXOPs obtained by the HC via controlled medium access is referred to as HCCA-TXOP or polled TXOP. The duration of an EDCA-TXOP is limited by a TXOP-limit. This TXOP-limit is distributed regularly by the HC within an information field of the beacon.

Another enhancement is that no station can transmit across the target beacon transmission time (TBTT). This means that a station can send its frame only if it can be completed before the upcoming TBTT. This reduces the expected beacon delay, which gives the HC better control over the medium, especially if the optional contention free period (CFP) is used after beacon transmission.

Chapter 2.15
Designing Clinical Decision Support Systems in Health Care:
A Systemic View

Wullianallur Raghupathi
Fordham University, USA

ABSTRACT

Clinical decision support systems have historically focused on formal clinical reasoning. Most of the systems are rule-based and very few have become fully functional prototypes or commercially viable systems that can be deployed in real situations. The attempts to build large-scale systems without examining the intrinsic systemic nature of the clinical process have resulted in limited operational success and acceptance. The clinical function, another area of medical activity, has emerged rapidly offering potential for clinical decision support systems. This article discusses the systemic differences between clinical reasoning and clinical function and suggests that different design methodologies be used in the two domains. Clinical reasoning requires a holistic approach, such as an intelligent multiagent, incorporating the properties of softness, openness, complexity, flexibility, and generality of clinical decision support systems, while traditional rule-based approaches are sufficient for clinical function applications.

INTRODUCTION

Clinical decision support applications development in the field of medicine historically has been constrained by two factors. First, the design concept was limited to formal clinical reasoning based on expert physicians' rules of thumb. Second, design appears to have been technology driven, for nearly all of the current systems are rule-based, wherein rules in clinical reasoning (e.g., in diagnosis and treatment) are represented as rules in the clinical system. None of the clinical reasoning applications have yet to become fully functional prototypes or commercially viable (Bates, Kuperman, Wang, Gandhi, Kittler, Volk, & et al., 2003; Kaushal, Shojania, & Bates, 2003; Sim, Gorman, Greens, Haynes, Kaplan, Lehmann, & et al., 2001). The limited operational success of these large-scale systems (Kaplan, 2001) is due in large part to the failure to reflect more fully in the design the diverse systemic features of the clinical process. Newer sociotechnical approaches to design, for example, a multiagent approach, and more flexible representational methods are needed to produce viable clinical decision support systems (CDSSs).

A second area of medical activity, which we term here the clinical function, has emerged rapidly as health care participants (e.g., physicians, nurses, HMOs, hospitals, diagnostic labs) increasingly perform their clinical applications work using advanced information technology (IT), such as artificial intelligence-based (AI) systems (Wyatt & Spiegelhalter, 1991) and in-house medical staff. These new AI-based clinical function systems present design issues that differ from those of clinical reasoning systems. For example, these systems typically concern much smaller domains (e.g., alerting to drug interaction, monitoring patient vital signs, reminding to medicate patient) involving structured applications in medicine (Bates et al., 2003; Delaney, Fitzmaurice, Riaz, & Hobbs, 1999; Kaplan, 2001; Kawamoto, Houlihan, Balas, & Lobach, 2005; Ramnarayan & Britto, 2002).

The application of AI (e.g., expert systems) and other computational intelligence techniques (e.g., neural networks) to the field of medicine (Catley, Petriu, & Frize, 2004) has resulted in the attempts to develop CDSSs. Wyatt and Spiegelhalter (1991) have defined medical aids as "active knowledge systems which use two or more items of patient data to generate case-specific advice." CDSSs have the potential to analyze, synthesize and integrate patient-related information to perform complex evaluations and provide that information to clinicians in real time. Over time, as they evolve in sophistication, they offer the prospect of improving the effectiveness and efficiency of patient care by preventing medical errors and enhancing quality (Johnston, Langton, Haynes, & Mathieu, 1994).

Further, the systems can improve preventive care services and help in adhering to recommended care standards (Kawamoto et al., 2005). The overall goal is to improve clinical decision making by focusing on individual patient characteristics and mapping them to a computerized knowledge base of characteristics of similar patients (Garg et al., 2005). They provide a range of levels of decision support, from simple alerts to complex diagnosis. For example, a CDSS can aid a physician in processing complex information to improve prescription writing practices in electronically delivered recommendations (Durieux, Nizard, Ravaud, Mounier, & Lepage, 2000). These types of systems are differentiated from operational decision support systems (DSSs), which are defined as enterprise repositories of clinical and financial information for utilization review, cost evaluation, and performance evaluation (Classen, 1998). In contrast, CDSSs focus on medical decisions (both on making decisions and assisting in making decisions). The key is to use patient specific information that transforms protocols into customized, real-time clinical advice (Kawamoto et al., 2005; Teich, Osheroff, Pifer, Sittig, & Jenders, 2005).

This paper discusses the clinical decision support applications design issues arising from the systemic differences (Churchman, 1971; Van Gigch, 1978, 1991) between clinical reasoning and clinical function systems, and it proposes that different design methodologies be used in the two domains. The paper is organized as follows. First, design issues in clinical reasoning and clinical function are discussed. Second, knowledge representation issues are highlighted. Third, the systemic properties of softness, openness, complexity, generality and purpose are discussed in the context of the two domains. Fourth, domain issues are identified. Next, operational examples of clinical reasoning and clinical function applications are described. Finally, conclusions are offered.

DESIGN ISSUES IN CLINICAL REASONING AND CLINICAL FUNCTION

Clinical reasoning is concerned with the decision processes of medical experts, such as physicians and surgeons, the interpretation of clinical information, and medical diagnostic rules. The outcome of clinical reasoning is some kind of clinical decision (diagnosis). On the other hand, the clinical function has emerged as a differentiated organizational entity. It is defined here as the set of activities that involves the routine and procedural application of medical rules and protocols to the operational needs of the medical care delivery organization. Differences between clinical reasoning and the clinical function are distinguished in terms of several system concepts. First, we discuss clinical knowledge representation and system design.

Clinical Knowledge Representation and System Design

Despite the domain complexity, most expert systems in clinical reasoning have involved the one-to-one mapping of rules of medicine onto rules in the system. This type of representational approach does not provide the flexible basis necessary to develop a sociotechnical clinical reasoning system that affords the openness, softness, complexity, and generality to deal with the dynamics of sociomedical aspects of clinical reasoning. Purely rule-based representation and problem solving are suitable for many clinical function applications that often involve narrow, structured well-designed domains. Knowledge representation for clinical reasoning, however, must include objects, frames, semantic nets, rules, and combinations of these to adequately represent different levels of knowledge, in combination with abstract medical concepts at higher levels and clinical rules at lower primitive levels. Combined with a multiagent systems model for complex problem solving, these representational modes enable interaction between multiple sources and levels of medical knowledge and different types of clinical reasoning, which comprise the problem-solving methodologies. The use of multiagent models will be a major departure from the current limited, rule-based approaches for implementation of AI clinical decision support systems.

Softness and Openness

Natural systems have been characterized as being somewhat hard, mechanistic, and rigid (Van Gigch, 1978). While clinical reasoning does involve some rigidity in terms of medical rules/procedures, the application of clinical reasoning reflects the relatively soft nature of the sociomedical aspects of medicine (e.g., consideration of gender, ethnicity, culture, religion, individual patient customized protocol). Softness considers subjectivity and value as important considerations in the design of clinical reasoning applications. Applications in the clinical function, on the other hand, usually involve specific routine procedures or repetitive tasks. Design models for the clinical function, therefore, should be more rigid and mechanistic in view of the procedural nature of this applied medical work.

Clinical reasoning involves open system properties (Hewitt, 1985), for, as an integral part of society and health care organizations, the medical system continually processes inputs and feedback from the environment, including changes in medical practice, new/modified protocols, new drugs, effect of clinical trials, societal values, replacement of medical experts, organizational perspectives (e.g., hospital mission), and others. The medical systems, as a model at the cusp of hard (pure science) and soft (social science) sciences, exhibits its negentropic nature as clinical reasoning adapts to changing goals (e.g., prevention vs. treatment), new research findings and advances in medicine, different sources of knowledge, and learning from experience. The clinical reasoning system must be capable of arriving at similar decisions equifinally by accepting inputs from multiple experts and applying alternate reasoning paths and different approaches to problem solving (Hewitt, 1985).

While the medical literature emphasizes the open-textured nature of medicine, openness is a feature of the entire medical system. Openness in the design of clinical reasoning systems provides for the flexibility to include several interacting domains in clinical reasoning, accepting inputs from multiple external sources of information and expertise, and accommodating the various reasoning mechanisms that are part of clinical decision processes.

In contrast, applications in the clinical function are essentially closed-system models requiring minimum feedback. Dynamic interaction and flexibility are limited because of the structured nature of clinical function tasks.

Complexity in DSSs

Complexity in CDSSs results from interaction internally between subsystems and externally with various systems in the environment, such as the economic (insurance) and primary care systems, as well as government entities, such as Medicare and Medicaid. Within an organizational health care delivery system (e.g., a hospital), there is also interaction and interdependence with the legislative bodies, the judiciary, the National Institutes of Health, the American Medical Association, medical experts, ethicists, managers, and the general public. The design of expert clinical reasoning systems must include provisions for the various modes of inquiry (Churchman, 1971) and complex interactions among various sources of clinical knowledge, such as medical facts, protocols, judgmental experience of medical experts and health care managers (e.g., nurse managers, discharge planners), customs, and medical precedents. Since societal values also impinge on outcomes, holism in design is essential to deal with the sociomedical complexity.

In the design of CDSSs for clinical reasoning, the trade off has historically been in formulating a computer model that is well structured and rigid in specification as opposed to one that provides for flexibility and adaptability. Strictly reductionaistic, rationalistic approaches to the design of clinical decision-making applications effectively eliminate these essential features. Mutiagent models hold considerable promise for assimilating the variety of inputs for complex clinical reasoning. The clinical function has emerged in health organizations because of increased organizational complexity and environmental uncertainty (e.g., hospitals). The growth of the clinical function was part of a general pattern of organizational elaboration and differentiation of specialized functions. While clinical reasoning is complex by nature, the clinical function is relatively simplistic, and interaction with the environment is minimal. Because of the procedural nature of most clinical function activities, rule-based (procedural) system approaches to application design are adequate and most often used.

Generality and Purpose in CDSSs

Research in AI frequently has emphasized the need for generality in the problem-solving methods. This is an important issue, for clinical reasoning applications should be capable of handling a wide range of medical problems.

Current design efforts for AI-based systems in clinical reasoning, however, tend to be limited to a single domain of medicine or reasoning. Generality in clinical reasoning suggests that the system cannot be limited to a single domain or a particular type of reasoning mechanism. For purposes of design, more general problem-solving models for the clinical reasoning domain have to be investigated. Again the multiagent model (e.g., the blackboard approach) possesses the characteristic of generality, and being conceptual, also can accommodate features that are unique to particular domains. In contrast, clinical function tasks are situation specific and do not require the generality needed by clinical reasoning systems.

Clinical reasoning applications are typically designed to arrive at a clinical decision. Examples of such systems include diagnosis of the cause of patient's chest pain (Hunt, Haynes, Hanna, & Smith, 1998); treatment of infertility (Garg et al., 2005); implementation of clinical guidelines on venous thromboembolism prophylaxis in an orthopedic surgery department (Durieux et al., 2000); analysis of outcome of patient cardiovascular risk (Montgomery, Hahey, Peters, MacIntosh, & Sharp, 2000); interpretation of blood work results (Classen, 1998); and others. Clinical reasoning culminates in decisions (e.g., outcomes—diagnosis of a disease, treatment selection) as the result of the interaction among various sources of knowledge and types of reasoning. The goals for clinical reasoning applications are relatively vague and ill defined. Clearly, a holistic and integrative view of design is needed, rather than the current focus on segmentized, disparate approaches that compartmentalize types of clinical reasoning, including analysis, critiquing, diagnosis, pattern recognition, and treatment recommendation, to name a few (Ramnarayan & Britto, 2002).

Clinical function applications are designed to execute programmed decisions involving narrowly defined medical tasks to achieve specific goals in the health care delivery organization. Some generic examples of such clinical function applications include detection of drug overdose (Hunt et al., 1998); selection of appropriate drug dosage, providing immunization reminders (Garg et al., 2005); alerting to drug interaction and monitoring patient vital signs (Classen, 1998); and others. Typically, the clinical function activities include alerting, recognition, alerting, and monitoring (Kawamoto et al., 2005; Ramnarayan & Britto, 2002).

Domain Issues

The variety of issues faced by clinical decision processes poses significant problems for domain definition in design. Historically, the boundary identification problem in design has been addressed by limiting the system domain to a particular specialty of medicine (e.g., disease), type of reasoning (e.g., rule-based, case-based), or problem-solving approach. Such design limitations have led to the problems with clinical reasoning systems discussed previously. The design of clinical function applications, while not trivial, is less challenging, for the boundaries of individual systems are limited to specific tasks. It is becoming more common for these tasks to be performed by nurse practitioners, nurses, and clinical technicians, who have gained expertise in routine and repetitious tasks in narrow medical domains and who are being increasingly supported by clinical function systems. Examples of clinical function applications include nurse practitioner functions. By and large these are the most readily developed for rule-based applications. Nurse practitioners carry out routine repetitive tasks and develop expertise in such domains as alerting, monitoring, and reminding and, therefore, provide input for clinical decision processes at higher levels. A number of generic applications are currently available to support nurse practitioner tasks. Most of the applications are fairly simple and implemented as rule-based systems. However, they lack the sophistication necessary to support clinical reasoning tasks.

Examples of clinical reasoning tasks include diagnosis, interpretation, and planning. All these high-level clinical decisions are characterized by complexity, ill-structuredness, and uncertainty. Typically, such decisions are collectively made by a group of medical experts. Table 1 summarizes the example of clinical reasoning and clinical function tasks in health organizations. As seen in Table 1, most programmed tasks are performed at lower and middle levels. Rule-based approaches are suitable for (expert system) applications development for these tasks. The higher-level tasks are typically nonprogrammed, ill-structured, and complex. Multiagent models are more appropriate for applications supporting these activities.

Table 1. CDSSs

Health Organization Level	Problem Type	Tasks
Top		
Physicians Surgeons Medical directors Residents Specialists	Ill-structured, complex Nonprogrammed (multiagent model)	Diagnosis Causal analysis Clinical reasoning Recommendation Interpretation Prediction
Middle		
Physician assistants Nurse practitioners Nurses	Semistructured, somewhat Comples, nonprogrammed (single to multiagent)	Alerting Monitoring Clinical reasoning Clinical function Reminding
Lower		
Nurses Clinical assistants Discharge planners	Structured, routine, Programmed (single angent)	Alerting Reminder

Other Issues

The identification of users and experts in the clinical function is straightforward, while deciding whether the physician is the only user or the expert in clinical reasoning is not always so clear. Clinical reasoning involves deeper epistemological and ontological considerations; the development time for a clinical reasoning application is lengthy; the cost is very high; the design and implementation effort is extensive; risks are considerable (e.g., misdiagnosis); and the payoffs are uncertain. In contrast, clinical function applications involve shorter development time, low costs, and considerably less effort. A clinical function application can be built using available technology, such as shells (rule-based expert system). Unlike clinical reasoning applications, these systems do not require extensive medical knowledge on the part of the knowledge engineer. Knowledge acquisition is easier and application validation is more readily achieved. User acceptance of clinical function applications is higher, especially for systems that act as "intelligent clinical assistants" for medical task performance (e.g., drug dosage tracking, monitoring patient vital signs), leading to increased potential for use and commercial viability. Table 2 summarizes the systemic differences between clinical function and clinical reasoning.

Operational Examples of Clinical Reasoning and Clinical Function Systems

With regard to clinical reasoning systems, St. Mary's Medical Center in West Palm Beach, FL, maintains statistics about infants (e.g., vital signs) in an electronic documentation system. This data is analyzed and mined, for example, to identify potential risks and side effects from commonly used medications (Landro, 2006). At Partners Health in Boston, expert systems provide information on medication dosing for specific types of patients, taking into account several factors.

Table 2. Clinical reasoning versus clinical function

Concept	Clinical reasoning	Clinical function
Nature of model	**Open** **Soft** **Flexible** **Dynamic** **Holistic**	**Closed** **Hard** **Inflexible** **Axiomatic** **Sequential**
Solution	**Satisficing**	**Optimal**
Reasoning	**Opportunistic** **Mulitagent**	**Rule-based**
Knoweledge Representation	**Accommodates rules** **Frames, objects, and others** **Modular**	**If-then rules** **Chain of rules**
Control	**Mostly explicit**	**Mostly implicit**
Domain Characteristics	**Ill-structured** **Multiple sources of knowledge** **Multiple reasoning mechanisms** **Nonprogrammed**	**Structured** **Single source** **Single line of reasoning (typically rule-based)** **Programmed**
Decision tasks	**Planning** **Diagnosis** **Interpretation**	**Alerting** **Monitoring** **Reminder**
Knowledge Acquisition	**Modular, Multiple**	**Data intensive** **Integrated**

Also, iLog, a decision support software, enables the sharing of clinical best practices to gather and analyze new or yet untapped data (Mcgee, 2006). IBM and Sloan-Kettering Cancer Center are working with systems to extract lab-result details from text intensive pathology reports to discover correlations by analyzing patterns, for example, of how specific kinds of tumors respond to various therapies (Mcgee, 2006). At West Mead Hospital, Sydney, Australia, Brain Resource in collaboration with IBM is building DSS software that can help analyze data from millions of sources of brain data (Mcgee, 2006). Mayo Clinic and IBM are applying pattern recognition and data-mining techniques to the electronic records of millions of patients to customize medical treatments to individual patients, such as selecting the best chemotherapy for a cancer patient with a particular genetic marker (Mcgee, 2004). In surgery, New York-Presbyterian Hospital is testing Penelope, a robot arm, that uses voice and visual recognition techniques to provide nursing assistance in the operating room (Santora, 2005). A system to analyze lab, pharmacy, patient, and other data, using inference engine software (infection control system), is being used at New York-Presbyterian Hospital. The purpose of this is to study data patterns to alert infectious disease nurses when a situation within the hospital could lead to an outbreak (Havenstein, 2005; Mcgee, 2005). Additionally, AI software is used to create treatment plans for patients in the cardiac intensive care units (using case-based approaches). Furthermore, the Cleveland Clinic and IBM are developing a translational medical platform and infrastructure to apply data-mining techniques to support clinical decision making. In another example, Kaiser Permanente's comprehensive medical database was used (via analysis and pattern recognition) to demonstrate that the arthritis drug Vioxx could cause heart problems (Eweek, 2006). In terms of clinical function applications, Aurora St. Luke's Medical Center, Milwaukee, uses the eICU system, which monitors patients electronically, helping a team of doctors and nurses to keep constant watch on more than 10 ICUs in four different hospitals across eastern Wisconsin (Fischman, 2005). A prototype wristwatch that monitors recovering cardiac patients' vital signs and sends them to their doctors via the cell phone network is being scheduled to be launched in 2006. The system called MDKeeper is being developed by Tadiran Spectralink of Israel (New Scientist, 2005). In Canada, the Global Public Health Intelligence Network (GPHIN) functions as a secure Internet-based early warning system assessing and cross referencing patients to track the length of time spent in a hospital or in quarantine. This type of information assists in providing a big-picture view of the operations of pandemics over large regions (Songini, 2006). Kranhold (2005) reports about a physician-alert system that alerts physicians if they are prescribing a medication that may react with another medication that the patient is taking—the system tracks patients' allergies and warns physicians if a medication might interact badly with the allergy. At University of Pittsburgh Medical Center (UPMC) in western Pennsylvania, a clinical information system delivers treatment information to doctors and nurses at the bedside, providing fast access to lab tests and X-rays, so they do not have to be repeated. The data also can be analyzed for possible outbreaks (Landro, 2005a). Also, another computer-order entry system at the UPMC Children's Hospital automatically calculates appropriate drug doses, based on a child's age and weight, and flags possible allergies or drug interactions (Landro, 2005b). Another application allows doctors to type in a patient's symptoms, and, in response, the system outputs a list of possible causes is reported in Leonhardt (2006). At St. Joseph's Hospital Health Center, Syracuse, NY, a picture archiving and communications system enables physicians and lab technicians to search and access patient information, data, and X-Rays via a Web portal (Mearian, 2005). Children's Memorial Hospital of Chicago is using a new system that confirms that the right medication is being administered at the right time to the right patient by scanning bar codes on the medication bags and sending it to a central computer that performs the matching (Pettis, 2006). The New York City is using a system for early warning of disease patterns called the Syndronic Surveillance System. It uses statistical analysis to calculate risk probabilities for possible disease outbreaks (Perez-Pena, 2003).

CONCLUSIONS

Distinguishing the systemic differences between clinical reasoning and the clinical function can enhance the design of CDSSs by assisting in the selection of the appropriate problem-solving architecture. The automation of clinical reasoning required a holistic approach that incorporates the properties of softness, openness, complexity, flexibility, and generality of medical systems. The trend toward distributed systems, multiagent models, parallel open-system architectures, and general models of intelligence for complex problem solving indicates that these alternatives must be explored in the design of automated clinical reasoning systems. Decision support applications development in medicine is in a primitive stage compared to other domains, but the use of system constructs in design can accelerate its maturing process.

Chapter 2.16
Nonparametric Decision Support Systems in Medical Diagnosis:
Modeling Pulmonary Embolism

Steven Walczak

Bradley B. Brimhall
University of Colorado School of Medicine, USA

Jerry B. Lefkowitz
University of Colorado at Denver and Health Sciences Center, USA

ABSTRACT

Patients face a multitude of diseases, trauma, and related medical problems that are difficult to diagnose and have large treatment and diagnostic direct costs, including pulmonary embolism (PE), which has mortality rates as high as 10%. Advanced decision-making tools, such as nonparametric neural networks (NN), may improve diagnostic capabilities for these problematic medical conditions. The research develops a backpropagation trained neural network diagnostic model to predict the occurrence of PE. Laboratory database values for 292 patients who were determined to be at risk for PE, with almost 15% suffering a confirmed PE, were collected and used to evaluate various NN models' performances. Results indicate that using NN diagnostic models enables the leveraging of knowledge gained from standard clinical laboratory tests, specifically the d-dimer assay and reactive glucose, significantly improving overall positive predictive value, compared to using either test in isolation, and also increasing negative predictive performance.

INTRODUCTION

Medical and surgical patients today face a variety of conditions that are both difficult and costly to diagnose and to treat. With ever skyrocketing medical costs (Benko, 2004), the use of information technology is seen as a much-needed means to help control and potentially to reduce medical direct costs (Intille, 2004). Deep vein thrombosis (DVT) and pulmonary embolism (PE) are medical conditions that are particularly difficult to diagnose in the acute setting (Mountain, 2003). Frequent usage of costly clinical laboratory tests to screen patients for further treatment is commonplace. All too commonly, hospitals provide treatment to patients without PE as a preventative measure (Mountain, 2003). Furthermore, patient mortality, morbidity, and both direct and indirect costs for delayed diagnosis of these conditions also may be substantial. Recent studies show that 40% to 80% of patients that die from PE are undiagnosed as having a potential PE (Mesquita et al., 1999; Morpurgo, Schmid, & Mandelli, 1998).

DVT may occur as the result of patient genetic and environmental factors or as a side effect of lower extremity immobility (e.g., following surgery). When a blood clot in the veins of a lower extremity breaks away, it may travel to the lungs and lodge in the pulmonary arterial circulation causing PE. If the clot is large enough, it may wedge itself into the large pulmonary arteries, leading to an acute medical emergency with a significant mortality rate. Approximately 2 million people annually experience DVT, with approximately 600,000 developing PE and approximately 10% of those PE episodes resulting in mortality (Labarere et al., 2004, Mesquita et al., 1999). Documented occurrence of DVT in postoperative surgical populations ranges from 10% (Hardwick & Colwell, 2004) to 28% (Blattler, Martinez, & Blattler, 2004).

Direct costs associated with DVT and PE come from the expensive diagnostic and even more expensive treatment protocols. It may be possible to lower these direct costs, especially when additional testing or treatment may be ruled out due to available knowledge. Nonparametric neural network (NN) systems enable the economic examination (Walczak, 2001) and nonlinear combination of various readily available clinical laboratory tests. Laboratory tests typically performed on surgical patients (e.g., blood chemistry) form the foundation for analysis and diagnostic model development.

One such test is the D-dimer assay that measures patient plasma for the concentration of one molecular product released from blood clots. When blood vessels are injured or when the movement of blood is too slow through veins of lower extremities, blood may begin to clot by initiating a series of steps in which fibrin molecules are cross-linked by thrombin to form a structure that entraps platelets and other coagulation molecules —a blood clot. As healing begins to occur, plasmin begins to break down the clot and releases, among other things, D-dimer molecules. D-dimers are actually small fragments of cross-linked fibrin and provide the basis for assessing blood-clotting activity. Patients with DVT and PE frequently have elevated levels of D-dimer in their plasma. Consequently, many hospitals now employ the D-dimer assay as a first test in the diagnostic pathway for these conditions. Usage of the results of a D-dimer assay effectively reduces the direct costs of DVT by reducing the requirement for downstream testing and treatment, specifically Doppler ultrasound tests (Wells et al., 2003). The use of nonparametric models enables the analysis of laboratory tests without regard to the population distribution, which may be a problematic factor when combining more than one laboratory test for the diagnostic prediction. Additionally, NNs provide nonlinear modeling capabilities that may be beneficial in combining pathology tests.

The research reported in this article will examine the efficacy of using NN models to predict the likelihood of a PE in surgical patient populations. A corollary research question is whether less invasive and less costly diagnostic methods are both available and reliable in predicting PE. The benefit of the reported research is twofold. First, the reported research examines new combinations of laboratory tests in order to determine if a combined model may be more reliable than currently used single variable medical models. Second, the research evaluates the viability of utilizing an NN model to predict PE (and potentially DVT). The NN provides improved positive predictive performance of the combined laboratory test model over the more traditional stepwise logistic regression models that currently are employed in medical modeling (León, 1994; Tran, VanOnselen, Wensink, & Cuesta, 1994; Walczak & Scharf, 2000). The cost effectiveness of utilizing the described neural network pathology tool is determined by examining the direct costs to patients, where direct costs represent the costs of diagnostic workups and the costs of any goods, services, and other resources utilized in any subsequent intervention (Patwardhan et al., 2005; Wildner, 2003). Implementing the described NN-based PE predictive model is capable of reducing patient evaluation direct costs by well over $1,200 per patient suspected of having a potentially life-threatening PE as well as reducing medical risks associated with some of the more advanced diagnostic methods.

The organization of the remainder of this article follows. The next section gives background on some of the issues associated with diagnosing and treating PE and DVT as well as examining the utilization of NN systems in medicine and issues surrounding the design of NN systems. The methodology section describes the patient population and development of the neural network models for predicting PE occurrence. The next section performs an analysis of the NN system's performance and consequent savings in direct costs. The last section concludes with a summary of the research findings and directions for future research.

BACKGROUND AND LITERATURE REVIEW

Diagnostic Difficulties of PE

Various tests exist for attempting to detect the presence of DVT or PE and commonly are administered to patients viewed as being at risk, based on medical history as well as patient signs and symptoms. For example, leg pain or swelling may indicate a patient with DVT; however, such symptoms are far from specific. Venography (x-ray with injected intravenous radioactive contrast dye) of the legs, Doppler ultrasound scans, plethysmography (measuring differential blood pressure between arms and legs), and the D-dimer assay blood test are some of the tests that may be employed in the evaluation of DVT (see http://www.nlm.nih.gov/medlineplus/ ency/article/000156.htm). Venography is the gold standard for diagnosing DVT, which commonly is treated with anticoagulant therapy such as intravenous heparin, requiring hospitalization, or injected low molecular weight heparin combined with oral warfarin medication, which may be continued for six months.

Patients with a sudden onset of chest pain or tachycardia or rapid shallow breathing may have PE, but these are also general signs of a wide variety of medical conditions (Mesquita et al., 1999; Mobley et al., 2005). PEs often are evaluated first using ventilation perfusion scanning (cost is $300 to $500 and involves the injection of radioactive tagged material) and chest x-rays that may be followed by pulmonary angiography (see http://www.nlm.nih.gov/medlineplus/ency/article/000132.htm). If the diagnosis of PE is made, the patient requires emergency treatment, typically thrombolytic therapy in order to dissolve the clot, and hospitalization.

While the pulmonary angiogram is considered the gold standard for determining PE presence (Evander et al., 2003; Mountain, 2003), it has a direct cost between $800 and $1,200 and involves injecting radio contrast die through a catheter that has been threaded into major coronary blood vessels with associated morbidity and mortality risks. If use of the D-dimer assay can determine better the likelihood or absence of PE, then a significant reduction in risks to the patient and costs ensues. The D-dimer assay has a direct cost of less than $7. Another factor that encourages the use of the D-dimer and other blood tests is the timeliness of the test, which averages approximately 30 minutes total time, including acquisition of the sample, transportation, analysis, and delivery of results. Improved detection of PE and early management will decrease the mortality and morbidity associated with PE (Stein, Kayali, et al., 2004).

Currently, the D-dimer assay has strong negative predictive reliability that excludes DVT or PE patients who are exceedingly unlikely to benefit from further invasive testing (e.g., angiography) or very few false negatives. Unfortunately, the test does not appear to have reliable positive predictability (Stein, Hull, et al., 2004), leaving the diagnostic role of the D-dimer uncertain. A potential cause of the lack of positive predictability is that, due to the potential life-threatening outcome of PE, the screening threshold for the D-dimer result is set very low (e.g., 400 or 450) in order to avoid false negative tests. As a result, many patients who do not have PE must undergo a pulmonary angiogram or other expensive testing procedures to determine if PE exists. Additionally, no standard for the D-dimer result threshold has been established, allowing for a wide range of cutoff values between hospitals (Stein, Hull, et al., 2004) and subsequent variation, though usually high, of patient population percentages undergoing unnecessary treatment.

Neural Networks in Medicine

The issues related to the use of D-dimer assay results—lack of standardized cutoff value, lack of positive predictive capability, and other influencing factors—pose a modeling problem. NNs provide strong modeling capabilities when population dynamics of the independent variables are unknown or nonlinear (Smith, 1993; Walczak & Cerpa, 2002), as would happen when using multiple laboratory test results to perform a diagnosis.

Before examining the factors that affect NN development (in the next section), a brief review of NN applications in medical domains is provided in this section. Neural networks or artificial neural networks applied to solve or provide decision support for a variety of medical domain problems started nearly two decades ago (Leese, 1986).

Many physicians are reluctant to utilize artificial intelligence technologies, including NN, especially neural networks that attempt to perform diagnosis or treatment in other than a decision support role (Baxt, 1995; Baxt & Skora, 1996; Hassoun, Wang, & Spitzer, 1994; Hu, Chau, Sheng, & Tam, 1999; Kleinmuntz, 1992; Walczak, 2003). The reluctance of physicians to adopt neural networks has led to the usage of neural networks as primarily image processing and laboratory test analysis tools. Table 1 provides a brief overview of historic and more recent neural network applications in medicine. A full review of all neural network applications in medicine is beyond the scope of this article,[1] and as such, Table 1 only provides a representative sample of research over the past decade.

Although representative and not comprehensive, Table 1 indicates that NN applications in medical domains tend to be used either in imaging or in laboratory settings (Walczak & Scharf, 2000), with diagnostic neural networks occurring rarely. Of interest from Table 1 for the research presented in this article are the three PE-related NN applications. Each of these NN research applications (Evander et al., 2003; Fisher, Scott, & Palmer, 1996; Serpen, Iyer, Elsamaloty, & Parsai, 2003) examines the improvement in identification or validation of PE from chest x-ray images or pulmonary angiogram data. Thus, each of these existing methods still requires the usage of and

Table 1. Types of neural network applications in medicine

Classification	NN applications research
Imaging (detect indicators in images)	Breast disease (Khuwaja & Abu-Rezq 2004, Papadopoulos et al. 2005), Coronary artery disease (Baxt 1991, Baxt & Skora 1996, Dorffner & Porenta 1994, Lapuerta et al. 1995, Scott et al. 2004), Electromyography (Hassoun 1994), Lung disease (Lin et al. 2005, Suzuki et al. 2004), Pulmonary embolism (Evander et al. 2003, Fisher et al. 1996, Serpen et al. 2003), Tomography (Bruyndonckx et al. 2004, Tourassi & Floyd 1995)
Laboratory (produce test results)	Breast disease (Mattfeldt et al. 2004), EEG (Güler et al. 2005b, Nowack et al., 2002, Walczak & Nowack 2001), General blood test pathology (Liparini et al. 2005) Head injury (Erol et al. 2005), Heart disease (Andrisevic et al. 2005, Haraldsson et al. 2004, Mobley et al. 2005), Hematology (Zini 2005), Lung disease (Güler et al. 2005a, Folland et al. 2004),
Resource Planning	Blood transfusions (Covin et al. 2003, Pereira 2004, Ruggeri et al. 2000, Walczak 2005, Walczak & Scharf 2000), Pharmacology (Gaweda et al. 2005, Polak et al. 2004)
Diagnostic	Breast cancer (Übeyli 2005)
Other	Medical cost estimation (Crawford et al. 2005, Goss & Vozikis 2002, Polak et al. 2004), Medical data mining (Petrovsky & Brusic 2004) Patient Outcomes Assessment (Buchman et al. 1994, Frye et al. 1996, Izenberg et al. 1997, Orunesu et al. 2004, Walczak et al. 2003, Yeong et al. 2005)

incurrence of the direct costs associated with these more costly diagnostic methods.

While NNs previously performed image analysis in order to confirm a diagnosis of PE, the use of NNs to predict a PE from standard low direct-cost blood tests is a novel application of this nonparametric modeling paradigm. The next section examines factors impacting the development of NN models, with an emphasis on the medical domain application of predicting PE.

Neural Network Design Issues

Patient treatment information necessarily must be of high quality (Silverman, 1998), since the consequences of prediction error can lead to increased morbidity and even mortality. NNs have been shown to outperform various statistical modeling methods in medical domains with respect to the accuracy of results (Baxt & Skora, 1996; Buchman, Kubos, Seidler, & Siegforth, 1994; Dybowski & Gant, 1995; Lapuerta, Azen, & LaBree, 1995; León, 1994; Stair & Howell, 1995; Walczak, 2005; Walczak & Scharf, 2000; White, 1992). NN design can be problematic and should account for the following influencing design factors (Walczak & Cerpa, 1999, 2002): training algorithm selection, input variable selection, and hidden layer architecture.

Various NN training algorithms exist; however, Alpsan, Towsey, Ozdamar, Ah, & Ghista (1995) have claimed that the backpropagation training algorithm produces classification and prediction models that generalize (on out of sample data) as well as or better than most other NN training algorithms, at least for their specific medical domain problem. Backpropagation-trained NN, in particular have been proven to be robust models of arbitrary complex equations (Hornik, 1991; Hornik, Stinchcombe, & White, 1989; White, 1990). Backpropagation-trained NNs are used commonly to provide solutions to business and engineering problems and also are the most common NN type for medical domain applications, which facilitates cross-research comparison of methodologies (Alpsan et al., 1995; Baxt, 1995; Cherkassky & Lari-Najafi, 1992; Dorffner & Porenta, 1994; Dybowski & Gant, 1995; Montague & Morris, 1994; Rodvold, McLeod, Brandt, Snow, & Murphy, 2001).

A reason for selecting another training algorithm besides backpropagation, such as the radial basis function, is to overcome problems with very noisy input data in the training sets (Barnard & Wessels, 1992; Carpenter, Grossberg, & Reynolds, 1995). Since the proposed NN prediction model utilizes the results of laboratory tests, many that already are controlled by computers and robotics, the resultant error rate in the input data is minimal and should not require a training algorithm that may not generalize well in order to alleviate error-prone data problems. Generally considered the best and most robust training method for NN classification and prediction models, backpropagation works well when low noise input data exist (Walczak & Cerpa, 2002). The backpropagation algorithm has been discussed widely in literature, and readers should see Fu (1994), Hertz, Krogh, and Palmer (1991), Jain, Mao, and Mohiuddin (1996), and Rodvold et al. (2001) for further details on the function of the backpropagation NN training methodology.

A critical step in the design of any NN model and especially in medical applications is the selection of high-quality predictive input (independent) variables that are not highly correlated with each other (Pakath & Zaveri, 1995; Smith, 1993; Tahai, Walczak, & Rigsby, 1998; Walczak & Cerpa, 1999). Domain expert physicians identify all available data that are related to the PE diagnosis problem.

The final influencing factor from the previous in developing NN models is the determination of the hidden node architecture (Smith, 1993; Walczak & Cerpa, 1999). The quantity of hidden nodes has a direct effect on generalization performance (Hung, Hu, Shanker, & Patuwo, 1996) with both too few and too many hidden nodes decreasing performance. The number of hidden layers also affects the smoothness and closeness of fit of the solution surface (Barnard & Wessels, 1992). A common heuristic method to determine the optimal number of hidden nodes is to start with a small quantity of hidden nodes (commonly one-fourth to one-half of the quantity of input nodes) and increment the hidden node quantity by one, until generalization performance begins to deteriorate. This method will safeguard against underfitting and overfitting the model (Walczak & Cerpa, 1999).

The research reported next will evaluate the efficacy of utilizing an NN methodology for developing a diagnostic model of PE that utilizes tests with a lower direct cost.

METHODOLOGY: A NEURAL NETWORK DIAGNOSTIC MODEL FOR PE BASED ON THE D-DIMER

As stated previously, the evaluation mechanisms for determining if a patient has a PE and requires treatment currently have high direct costs (e.g., ventilation perfusion scan that costs from $300 to $500, and pulmonary angiogram that costs from $800 to $1,200). In addition to other demographic and medical risk factors, the purpose of this research is to determine if less costly evaluation mechanisms for PE are available, especially using the D-dimer assay results, which have a direct cost of less than $7 and is used commonly to negatively screen out patients for PE (Stein, Hull, et al., 2004).

Research Population Description

The patient population in this research was 292 surgical patients admitted to a large Midwest teaching hospital during a nine-and-a-half-month period. All patients during the period of the study diagnosed by physicians as being at risk either for DVT or for PE were included in the study with no exclusions. Database records maintained by the hospital clinical laboratory as well as clinical information provided from radiology and chart records provide the data used in the NN input vector (independent variables). Patient records used in this study only come from patients clinically identified as being at risk for a DVT or possible PE by attending physicians based on signs (e.g., swelling in legs or irregular breathing) and symptoms (e.g., report of pain in legs for DVT or chest for PE). Just over 15% of this patient population, 44 out of 292, suffered a confirmed PE, which is consistent with other findings on the rate of DVT occurrence in surgical populations and consequent occurrence of PE (Hardwick & Colwell, 2004; Blattler et al., 2004). A pulmonary angiogram confirmed or negated the presence of PE.

The at-risk population of surgical patients for DVT and a possible PE has some basic statistical measures that are displayed in Table 2. From Table 2, it can be seen that the D-dimer results alone are not significantly different between patients with PE and patients without PE, although the PE patients have a much larger average D-dimer result and also a wider distribution. High D-dimer values may result from a variety of causes in addition to DVT or PE, which further confuses the application of the D-dimer for diagnosing PE.

NN Design of a PE Diagnosis Model

The focus of this study is on the use of the D-dimer assay results in possible combination with other values to improve the overall positive predictive performance to reduce false positives, which leads to unnecessary PE evaluation direct costs. As discussed in the "Neural Network Design Issues" section, the small error associated with laboratory tests and the reported robustness of the backpropagation training algorithm implied selection of backpropagation as the training algorithm for implementing the NN-based PE diagnosis model. Radial basis function (RBF) neural networks and stepwise logistic regression (LR) models also were implemented simultaneously in order to produce multiple models for comparison and to evaluate if a backpropagation-trained neural network would produce the optimal model. Using the model selection perspective (Swanson & White, 1995), comparison of each of the independent model types yielded the backpropagation NN model as the optimal model. The backpropagation models, with regard to overall accuracy (the sum of true positives and true negatives divided by all cases) outperformed both of the other model types ($p <$ .01 against the RBF-trained NN and $p < 0.10$ for the LR models).

Domain expert physicians identified blood test results with minimal direct costs that would be available for suspected DVT and PE patients prior to the performance of an angiogram. Since the research question of trying to determine if one or more of these test results could improve the PE diagnosis accuracy, a correlation matrix of all blood chemistry and other blood test results is performed to determine those variables that appear to be correlated with a positive diagnosis of PE. The variables include D-dimer, reactive glucose (Glu-R), blood urea nitrogen, serum creatinine, serum sodium, serum potassium, serum chloride,

Table 2. Typical d-dimer surgical population values

	D-dimer minimum	D-dimer maximum	D-dimer μ (average)	D-Dimer σ (std dev)	Age μ Age σ	Gender
Patients w/ confirmed PE	145	35450	4218.7	5862.75	48.45 22.38	47.5 % male
Patients w/o PE	124	22375	1782.63	1264.16	53 16.64	38.34 % male

serum carbon dioxide level, serum calcium, white blood cell count, red blood cell count, hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, red cell distribution width, and platelet count. Other values, including mean platelet volume, absolute neutrophil count (and percent), absolute lymphocyte count (and percent), absolute monocyte count (and percent), absolute eosinophil count (and percent), and absolute basophile count (and percent), were considered for use but eliminated due to missing data for many of the patients (i.e., the tests had not been ordered by their attending physician). The predictive correlation of different blood test results measured by a Pearson's correlation matrix indicated that the D-dimer had the highest correlation with a validated PE for those test results included in the matrix and that randomized glucose (Glu-R) and CO_2 also both had significant ($p < 0.05$) predictive correlations with the PE-dependent variable. The age and sex of the patient also are included as independent variables to determine if these may be predictive when combined with blood test results.[2] Different backpropagation-trained NN models use various combinations of these five variables: age, sex, D-dimer, Glu-R, and CO_2 as the input vector of independent variables, producing 23 different sets of input variables and corresponding diagnosis models.

NN models for each of the 23 different input vectors start with a single hidden processing node. Both one- and two-hidden-layer architectures are evaluated, since the complexity of the diagnosis solution surface is unknown (Fu, 1994). When a second hidden layer is implemented, it also is started with a single hidden processing node. The quantity of processing nodes in each layer is incremented independently of the other layer and by a quantity of one. Reinitialization of each new larger model produces random interconnection weights before training occurs. Hidden node expansion stops, once the generalization performance begins to deteriorate and the model with the best generalization performance is kept.

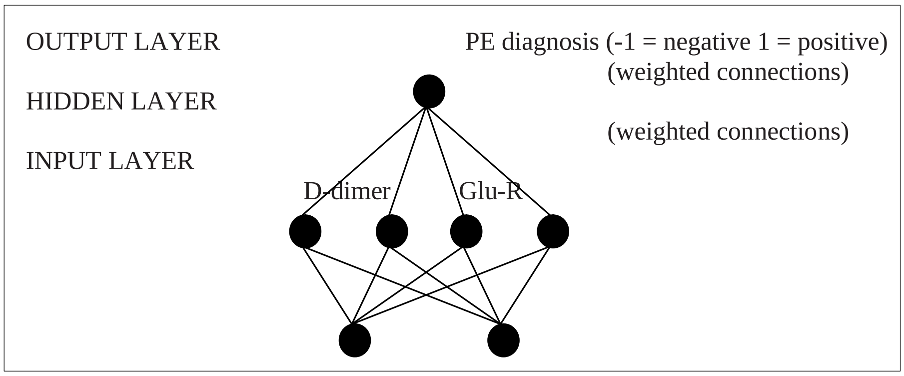
Training of each NN model uses one sample of data, and then validation uses a separate holdout sample. Due to the relatively small size of the population data, we use an eightfold cross validation technique in order to increase the quantity of holdout samples analyzed in the results to the full population of 292. The majority of the NNs evaluated performed similarly to just using the D-dimer result alone, meaning they had very good specificity (identifying positive PE cases) but very poor sensitivity (identifying negative PE cases). The finding that the sex-independent variable did not influence the performance of the various neural supports the findings of Stein et al. (2003b), who found that sex was not a factor in the diagnosis of PE.

The best performing NN model utilized both the D-Dimer and the GLU-R result for each patient. The name of the NN PE diagnosis model is PEDimeNet, since it utilizes the D-dimer laboratory test in combination with another test in order to maximize positive PE-predictive performance. The hidden node architecture for this backpropagation-trained NN is two input nodes representing the D-dimer and Glu-R results, four hidden nodes, and one output node, as shown in Figure 1. This NN is the one discussed in the next section.

RESULTS AND DISCUSSION

Backpropagation-trained NNs provide a real number output between -1 and 1 (though some NN shell tools allow this range to be extended) and not a true or false result for predicting the occurrence of a PE in a patient. These real-number output values require interpretation in order to determine the optimal cutoff point for partitioning the solution space into the two desired groups: probable PE and unlikely PE. An ROC (Receiver Operating Characteristic) curve analysis is performed commonly by those involved in medical diagnostics in order to determine the optimal threshold cutoff value for maximizing positive predictive performance

Figure 1. PEDimeNet NN architecture



on the generalization sample (Kamierczak, 1999; Obuschowsk, Lieber, & Wians, 2004), and this technique is used with the NN training sample output values in order to determine the optimal real number threshold value for performing the classifications. A similar and independent ROC curve analysis for the RBF and LR models reported in the previous section determines each model's cutoff value. The area under the ROC curve for the training data was 0.79. Once the ROC threshold value is determined, it is then applied universally to all out-of-sample output values produced by the NN in order to determine the NN's PE diagnosis for the corresponding patient.

Table 3 displays the prediction results of the resulting NN model. Similar to increasing the D-dimer cutoff value to include more of the patient population in the group that undergoes further evaluation via an angiogram or other PE verification method, a tradeoff exists between the positive predictive accuracy and the negative predictive accuracy using the NN model. Lowering the PE cutoff point causes the positive predictive accuracy to increase and creates a corresponding decrease in the negative predictive accuracy. Due to the possible outcome of mortality for PE patients, a positive predictive performance of 90% sensitivity is desired, as specified by the domain expert physicians (where the TP rate in Table 3 is the sensitivity, and the TN rate is the specificity). The overall diagnosis accuracy ([TP+TN]/Total) performance of the PEDimeNet NN model is 62.33% with almost 91% of all PE patients identified as well as nearly 57% of patients that do not have a PE and, therefore, do not require any additional testing for PE with subsequent reduction in direct costs.

Recall that traditional usage of the D-dimer with a relatively low threshold value produces a false negative (FN) rate very close to 0%. As a result, a negative PE result usually means that the patient truly will not have a PE. The false positive rate for the standard D-dimer test is very high, which leads to increased medical costs through unnecessary costly procedures for follow-up evaluation (e.g., pulmonary angiogram).

Table 3. NN diagnostic prediction results for PE

	NN positive PE	NN negative PE
Actual PE (positive)	TP = 40 (90.91%)	FN = 4 (9.09%)
No PE (negative)	FP = 107 (43.15%)	TN = 141 (56.85%)

(TP = True Positive, FN = False Negative, FP = False Positive, and TN = True Negative)

For the test population used in the research reported in this article, a simulation of adjusting the D-dimer cutoff value to produce a false negative rate identical to the proposed NN model produced a false positive rate of 91.53% (227 patients that require unnecessary evaluation tests), meaning that only 21 of 248 patients did not have further costly PE evaluation procedures recommended. Whereas, the PEDimeNet NN was able to save additional laboratory testing for 141 patients, as opposed to just 21 when using the traditional D-dimer only diagnosis. Therefore, an NN model of PE that utilizes both D-dimer and Glu-R test results provides a high-quality positive predictor. The NN PE prediction model exceeds using a non-NN D-dimer-based evaluation mechanism with respect to true negatives (patients without PE) by well over 600%, resulting in significant cost savings for the patients. Direct cost savings would be approximately $96,000 to $144,000 for the nine-and-a-half-month period of the research study, which translates to a $121,000 to $182,000 direct-cost annualized savings.

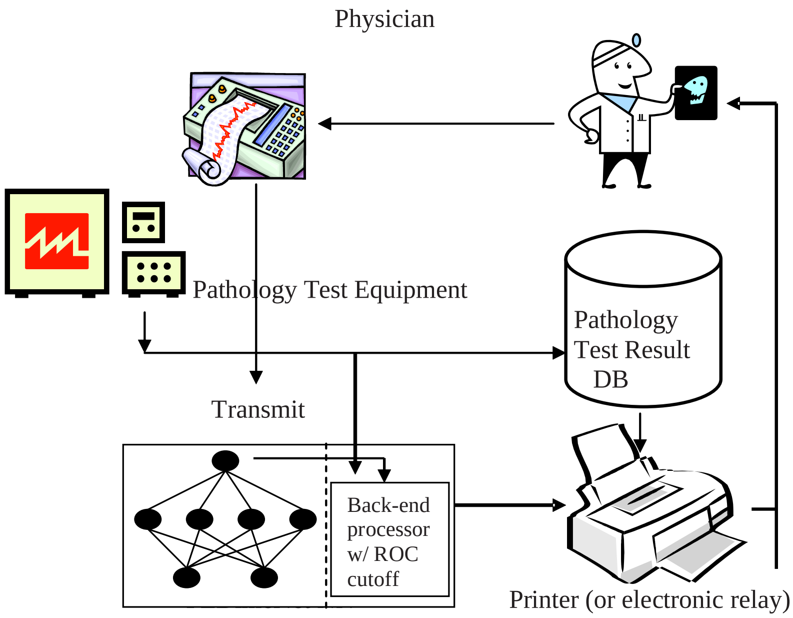
A limitation of the reported research is that the NN diagnosis model only models the population at a single hospital. While this hospital is one of the larger providers in a major metropolitan area and, as such, has a demographically diverse population, differences in the correspondence between the D-dimer and Glu-R values with an actual PE may exist in different geographic populations (Stein, Kayali, et al., 2004). As such, the methodology described would require each hospital to independently train their own NN model and to establish their own ROC cutoff threshold value for interpreting the generalization (out-of-sample) diagnosis values of the NN.

Utilizing the proposed NN system would require only very minor workflow changes in the emergency department and clinical laboratory of the studied hospital and would integrate similarly at most hospitals that follow similar diagnostic methodologies. Medical user acceptance of new decision support technology is highly dependent on two factors: (1) that the decision support technology not be perceived as attempting to make diagnosis (Baxt, 1995; Baxt & Skora, 1996; Walczak & Scharf, 2000) and (2) that the new information technologies not disrupt normal workflows (Kirkley & Stein, 2004; Walczak, 2003). Physicians receive laboratory results at most hospitals either electronically or on paper after encoding and storing the results in a pathology database. The PEDimeNet NN-based decision support system would be positioned architecturally in the pathology departments' IT framework, as displayed in Figure 2. This integration of the PEDimeNet NN diagnostic tool then would appear seamless to physicians, integrating with their existing workflow simply by adding the analysis to the pathology report already received by the physician.

The PEDimeNet PE diagnosis decision support tool is composed of the PEDimeNET NN, an interface that allows the entry of D-dimer and Glu-R laboratory test results (which may be handled electronically through an EDI interface or performed manually at a keyboard), a backend program that contains the ROC curve analysis-based decision cutoff value (which also may be read from a database to allow for movement in the cutoff value over time, perhaps due to new pathology equipment sensitivity) and produces the go/no-go diagnostic recommendation for probable PE in a patient. Future enhancements would include a database or agent-oriented Web browser to recommend additional tests, if necessary, and treatment protocols.

The following scenario presents an illustration of the functioning of the proposed PEDimeNet system within a hospital setting. A physician would request a diagnostic workup, including a patient blood draw. The clinical laboratory receives the patient's blood sample. Laboratory tests are completed using the existing laboratory equipment. The results are delivered to the physician either electronically (with EDI requiring a small hardware modification to interface with

Figure 2. PEDimeNet relative to other pathology IT systems



the existing pathology instrumentation) or on paper (after entering the results into the laboratory database with a simultaneous transmission to the PEDimeNet). A software interface to the database or other peripheral devices (in C# or Java) encodes the received value into the format required by the NN. The PEDimeNet diagnostic decision support system then would interpret the NN's results, based on a cutoff value established by applying the ROC curve analysis determined threshold. The backend analysis of the NN output provides a report of the interpreted NN prediction in either electronic or printed format for the attending physician, who then would determine if any further evaluation was required. Other than the step in the lab necessary to transmit the results to the PEDimeNet decision support system, the automated process is similar to standard decision-making processes for evaluating the need to screen for a PE. From the physician's perspective, there is no change in workflow from the traditional receipt of the original noninterpreted D-dimer assay results.

CONCLUSION

The research presented in this article demonstrates the efficacy of utilizing NNs for predicting the occurrence of PE in patients presenting to the emergency department and those at risk of PE following surgery. The reported results were able to match the very low false negative rate of a more traditional test that relied on the D-dimer alone. Although the usage of a D-dimer screening test is questioned in cases of PE (Stein, Hull, et al., 2004), it has proved reliable for evaluating the presence of DVT (Wells et al., 2003), a leading cause of PE. Furthermore, over a 600% increase in true negative predictions with a corresponding decrease in associated medical risks to patients and decreased medical costs of hundreds of thousands of dollars per hospital per year demonstrates the benefits of using a nonlinear and nonparametric modeling technique such as the backpropagation train NN.

Another benefit derived from this research is the identification of the superior positive predictive performance for PE when using the combination of the D-dimer result value in combination with the Glu-R result value. The D-dimer individually was not able to distinguish reliably between positive PE cases and negative ones, creating a high corresponding false positive assessment rate so that only a very small number of actual PEs would be misdiagnosed. The utilization of an NN as the statistical analysis component of the PEDimeNet NN decision support system enabled the rapid combination of input values in nonlinear ways without regard to population distribution characteristics. A potential drawback of using NNs as a model determination mechanism in order to evaluate the contribution of various independent variables is the need to determine the ideal architecture. While the current research utilized a brute force incremental process to analyze both single- and two-hidden-layer networks, new neural network shell tools are able to automate some or all of the NN node architecture optimization process.

While the research reported in this article focused on the prediction of PE, the relationship between PE and DVT and previous research has indicated a strong positive correlation between the D-dimer assay results and accurate DVT diagnosis (Wells et al., 2003), which indicates that a similar NN model would be able to accurately predict DVT. This would permit the operation of two side-by-side (or possibly one) NNs in the PEDimeNet decision support system in order to evaluate both PE and DVT simultaneously, which is a topic of future research.

In addition to the specific research benefits just described, generalizing the research method and results provides implications for both researchers and practitioners. Future research efforts will benefit by realizing that nonparametric modeling techniques in general and neural networks specifically are a viable method for analyzing complex and potentially ill-defined (unknown population and error distributions) problems. Researchers should embrace the most advanced modeling techniques available, especially since neural networks repeatedly have demonstrated increased performance over more traditional parametric statistical methods. The data set for the presented NN PE diagnosis application is relatively error-free. Researchers should note that designing optimal neural network models has many implementation factors, and careful attention in selecting input variables, selecting the training algorithm, and determining the hidden-layer and hidden-node architecture will help to produce the optimal NN model (Smith, 1993; Walczak & Cerpa, 1999, 2002).

An implication for practice is to challenge existing protocols and heuristics. The addition of a low direct-cost variable to the PE diagnosis model significantly increases the accuracy and reduces direct costs. Other medical diagnostic and assessment problems may derive benefit from examining new sets of variables. The NN modeling method provides an inexpensive and reliable way to rapidly assess the impact of adding new variables or removing existing decision variables (Walczak, 2001). Previous research (Walczak et al., 2003) demonstrates this by showing that a commonly used variable for determining acute pancreatitis patient outcomes, RANSON score, detracts from the predictive performance of other readily available variables.

The research reported in this article demonstrates the impact of NN diagnosis models through the reduction of direct costs. Future research is needed to realize the overall benefit gained from NN diagnosis models by examining the impact on indirect costs, such as reduced patient healing times and overall quality of care received.

ENDNOTES

1. A database inquiry on EBSCO using the terms *neural network* AND (medicine OR medical) produced 997 articles. A similar query on PubMed, the NIH article database, produced 6,120 articles.
2. The occurrence of PE between blacks and whites has been found to be comparable (Stein et al., 2003a) and, as such, is not included in the variables considered for the NN input vector. Additionally, this variable is subjective, being either self-reported by patients or reported as an observation by the admitting nurse in the studied hospital and, as such, may have a higher than acceptable error rate for use in a backpropagation-trained NN.

This work was previously published in International Journal of Healthcare Information Systems and Informatics, Vol. 1, Issue 2, edited by J. Tan, pp. 65-82, copyright 2006 by IGI Publishing, formerly known as Idea Group Publishing (an imprint of IGI Global).

Chapter 2.17
A Cross-Cultural Framework for Evaluation

Pekka Turunen
Shiftec, Finland

ABSTRACT

The evaluation of information systems (ISs), especially in the healthcare field, is a complex task. Evidently, there is a need for better understanding of the different aspects evaluation. While in the general IS science field there have been several attempts to build frameworks and models to better understand the evaluation of ISs, in healthcare similar frameworks have been almost nonexistent. Unfortunately, general frameworks cannot be exactly applied for the cross-cultural evaluation of healthcare ISs, because they do not recognise the specific nature of the medicine. Based on works in different areas, this chapter represents an attempt at to combine them to conceptual frameworks for the evaluation of healthcare ISs.

INTRODUCTION

The evaluation of health information systems (ISs) has proved to be an especially difficult task. Evaluation projects are often interdisciplinary by nature and designed by both information technology people and medical professionals (Heathfield, Pitty, & Hanka, 1998; Turunen & Talmon, 2000). Different parties have difficulties in understanding each other because, for example, a lack of common tools (Nykänen, 2000).

Among others, one problem is the lack of framework for conceptual understanding of IS impacts and their evaluation. Frameworks and models, used for that purpose, are mainly drawn from different research areas and, unfortunately, are inadequate for this specific field. The frameworks for the evaluation of information systems are not able to describe the specific nature of the area (e.g., golden standards). At the same time, the frameworks for evaluation in the healthcare field do not usually recognise the difficulties of measuring impacts of ISs, the need for external validity or they are too general for the evaluation of ISs. Yet, it has been suggested that a new evaluation paradigm is needed (Shaw, 2002).

This chapter presents well-known models from those different areas and combines them into an appropriate framework for the evaluation of health ISs. The framework is based directly on the previous works and is a logical extension of the historical development of such models and frameworks.

The purpose of the frameworks is to formulate a conceptual guide of evaluation and emphasise the connection (noncausal by nature) between the different impacts of healthcare ISs. Thus, the framework may be useful in identifying relationships among the success variables of ISs. It assists in taxonomising existing evaluation results of ISs and, therefore, in comparing different evaluations. Equally, the framework should aid in making an overall judgment based on different evaluation methods and results of the healthcare IS. Furthermore, the frameworks may give some hints for the measurement of different impacts.

The article presents frameworks at two levels. A general framework describes healthcare IS evaluation at a general level. In addition, a specific framework has been developed for diagnostic ISs. A procedure to minimise evaluation is also presented.

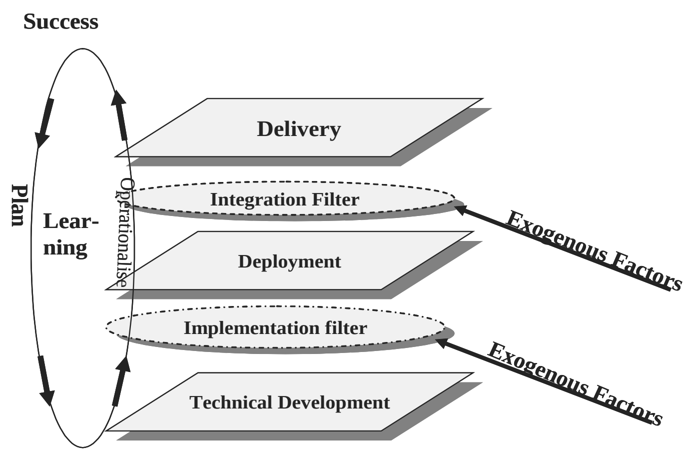
FRAMEWORKS FOR THE EVALUATION OF INFORMATION SYSTEMS

The best known and most widely used framework for the evaluation of ISs is probably DeLone and McLean's (1992) IS success model (Iivari & Ervasti, 1994; Jurison 1996). This model has brought about a good amount of fair and unfair criticism and, therefore, has encouraged further development in the area (Ballantine et al., 1996; Bonner, 1995; Grover, Jeong, & Segars, 1996; Kangas & Manwani, 1998; Manwani & Kangas, 1998; Pitt, & Watson, 1994; Seddon, 1997; Seddon, Staples, Patnayakuni, & Bowtell, 1998). One of the most important further developments is the 3-D model of IS's success (Balantine et al., 1996).

The 3-D model has been divided into three main elements: a) development, b) deployment, and c) delivery (see Figure 1). The development element includes such things as technology, system type, quality of data, IS-professional skills, and so forth. The second element contains variables such as user satisfaction, task impact, personal impact, and so on (e.g., alignment of individual business objectives, resources, and use of the output are included in the delivery element). In addition to these three elements researchers also refer to a *fourth element* of political, social, and economic impacts. The meaning of these aspects will be increased while implementing wide Internet-based ISs. However, private-sector focus of evaluation is still often at the organisational level.

Filters among elements try to illustrate that an impact at one level does not automatically cause

Figure 1. The simplified version of 3-D model for information systems success. (Source: Balantine et al, 1996)



an impact at the next level. One of the most important new features that Ballantine et al. (1996) have added to the original idea is the learning loop. Learning addresses that the evaluation is always a two-way process.

There are three main features common to almost all the models, guidelines, taxonomies, or frameworks, which try to grasp the principal idea of information flow and evaluation of that process as a whole. All significant aspects can be seen, for example, in the 3-D model (see Figure 1 and the previous text).

First, the division of ISs into three basic constructs or elements are typically a) technology, b) user, and c) organisation (Balantine et al., 1996; Cronk, 2000; DeLone & McLean, 1992; Enning et al., 1997; Friedman & Cornford, 1989; Hamilton & Chervany, 1981; Rowley, 1998; Salmela, 1997; Scott, 1994). In different studies slightly different terms, such as *individual* instead of *user*, are used for the same elements. Some of the studies and schools have concentrated in making more accurate analyses of the main elements (e.g., Chismar & Wiley-Patton, 2003; Venkatesh & Morris, 2000).

Second, the frameworks cover a wide range of different kinds of both subjective and objective evaluation methods (e.g., Ballantine et al., 1996; Cronk, 2000; DeLone & McLean 1992). Third, most frameworks are based on the premise that an impact on one level leads most likely, but not always, to an impact on the next level.

According to Nykänen's (2000) longitudinal research of several evaluation cases, ISs' evaluation models do not take into account healthcare environmental variables. Medicine, for example, tends to focus on patients, medical evaluation methods considered "golden standards" and attention is also given for physicians.

FRAMEWORKS IN THE FIELD OF HEALTHCARE

A Framework for Assessing Quality of Care

Donabedian's (1980) framework is aimed at assessing quality of care. Quality assessment is built on the concept of three elements: a structure followed by a process and an outcome (see Figure 2).

In Donabedian's (1980) framework, the *structure* can mean human, physical, and financial resources. For example, medical tools are a typical example of the structure. The *process* is a set of activities (e.g., treatment plans that go on within and between practitioners and patients). The *outcome* is the change in a patient's health status that can be attributed to given care. The health status is defined broadly to include, for example, patient satisfaction, a patient's knowledge of health-related issues, and health-related behavioural change. In such a chain, each element is, to some extent, a cause of the element that follows. The structure of the framework and the content of the three elements are very much the same as in frameworks that are used in the IS science (Hebert, 2001).

A Framework for Evaluation of Telehealth

The framework for telehealth evaluation has been based on DeLone and McLean's (1992) IS success

Figure 2. The functional relationship among three elements in Donabedian's (1980) framework for assessing the quality of care

model and Donabedian's (1980) framework for assessing quality of care (Hebert, 2001; see also Figure 3). The framework for telehealth evaluation is one rare attempt to combine different aspects of the cross-cultural research area.

In the framework, individual and organisational elements have been innovatively divided into structures and outcomes, a taxonomy that the other researchers have not used. According to Hebert (2001), Donabedian's (1980) structure is equal DeLone and McLean's (1992) first element, "information and system quality." Nevertheless, in the telehealth framework the structure has been connected with DeLone and McLean's "individual and organisational impact," which actually should mean Donabedian's outcome, not structure (Hebert, 2001). Probably as a result of these, we use only three basic elements (structure, process, and outcome) for categorising two case studies. However, the telehealth framework is a first proper framework to cover the whole picture of the evaluation of telehealth.

Models for Evaluation of Medical Technology

Fineberg, Bauan, and Sosman (1977) first presented the idea of modeling efficacy of clinical diagnostic technology (see Figure 4). Their model greatly influenced physicians' thinking (e.g., Chizeck & Katona, 1985; Cook, Brun-Buisson, Guyatt, & Sibbald, 1994; Maisey, 1996; Sailly et al., 1985; Szczepura & Stilwell, 1988; Ure, Spangenberger, Lefering, Dietrich, & Troidl, 1992) and it has been used for the evaluation of telehealth systems (Ohinmaa & Reponen, 1997). This model emphasises the clinical-care process, medical technology, and the significance of physicians (making diagnoses). Even though the clinical efficacy model is narrower than models in the IS science, the principal idea of the model is very similar to that of IS models, because they all present a Western scientific way of thinking.

Guyatt, Tugwell, Feeny, Drummond, and Haynes (1986) have developed the clinical ef-

Figure 3. A framework for evaluation of telehealth (Source: Hebert, 2001)

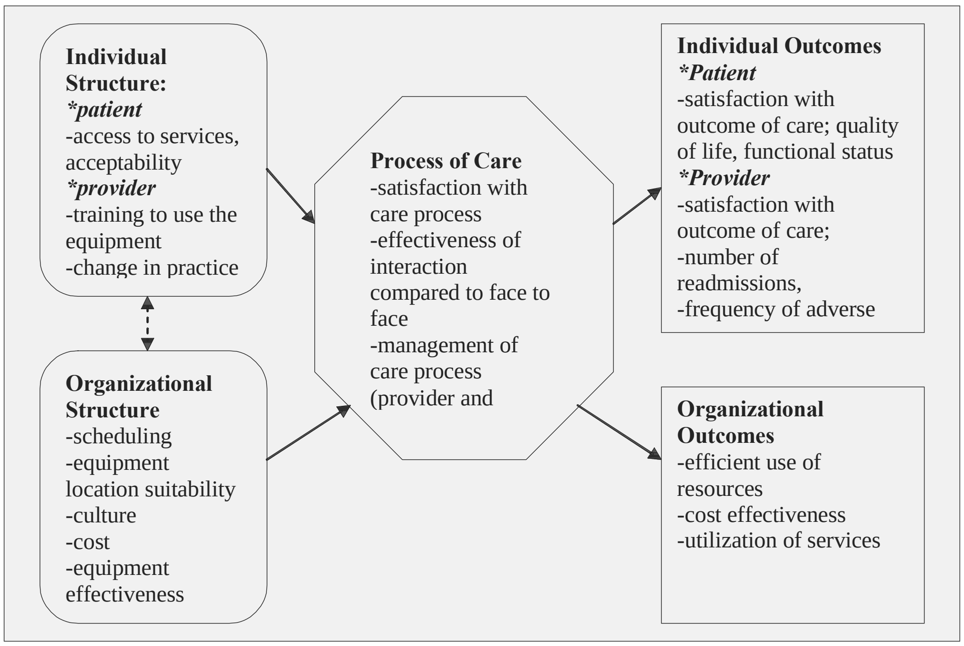


Figure 4. Clinical efficacy model (Source: Fineberg, et al., 1977)

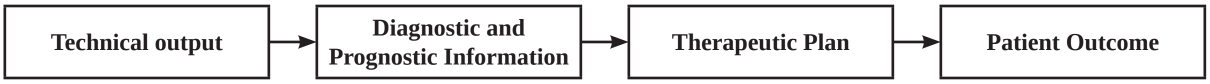

ficacy model in two ways. They have extended the evaluation of patient outcome to include the economic evaluation. They have also added the therapeutic process as a new process parallel to the diagnostic process. Their framework also emphasises randomised controlled trial (RCT) in the evaluation of medical technology. The new features are welcome extensions in the direction of a framework that covers all the impacts and evaluation methods of medical technology.

Normally, stakeholders with a strict medical background approach the evaluation of health ISs through Fineberg et al.'s (1977) or Guyatt et al.'s (1986) pattern. The problem is that patterns can address only a minority of effects that medical technologies are causing and only a small minority that healthcare ISs are causing. Evaluation methods, such as the RCT, can hardly evaluate complex ISs in the real-life situation in which effects of the system may be indirect, intangible, or nonquantified (Davey, 1994; Feinstein, 1983; Heathfield et al., 1998; Hebert, 2001; Kaplan, 2001; Shaw, 2002).

Traditional medicine has also favoured validation of outcome. However, the development of ISs is usually also a main issue in the evaluation of ISs. Unfortunately, a summative evaluation does not incorporate a development perspective (Hamilton & Chervany, 1981).

A CONCLUSION OF PRIOR RESEARCH: FRAMEWORKS FOR EVALUATION OF HEALTHCARE INFORMATION SYSTEMS

The idea of evaluation frameworks is to combine the key elements of both research areas in such a way that frameworks are able to cover the healthcare information area and can possibly be accepted by the different stakeholders. Another significant issue is to present nonmedical evaluation methods to stakeholders with a medical background. It is important try to use a language that looks familiar to stakeholders (Nykänen, 2000). The frameworks may provide new measurements for the evaluation of healthcare ISs, when it is not possible or reasonable to use traditional clinical measurements.

Three basic elements familiar from the general IS area can be combined equally with elements of medical technology. The main combined elements are a) technical quality, b) user impact, and c) organisational and patient impact (see Figure 5). One has to take into consideration the role of societal impacts while increasing the amount of Internet applications and integration process in nationwide ISs. However, evaluating the impacts is still impossible or at least extremely difficult.

In Figure 5, the arrows showing effects of the IS and evaluation (they could also be called a learning loop) are shown above the figure. The use of a broken line is designed to emphasise the noncausal nature of ISs and the evaluation of their impact.

According to Nykänen (2000), IS people are not able to consider the environmental variables of healthcare. For them the specific subframework emphasises, and hopefully, crystallise, the core process of medical treatment and the importance of evaluating it (see Figure 6). The specific framework is especially designed for diagnostic ISs or clinical decision support systems and can also be seen as a model for physicians.

Figure 5. A general framework for the evaluation of impacts of health information systems

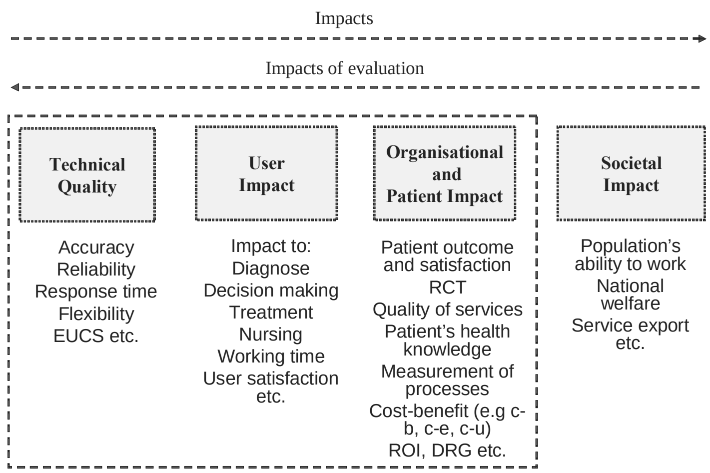

Figure 6. A framework for the evaluation of diagnostic information systems

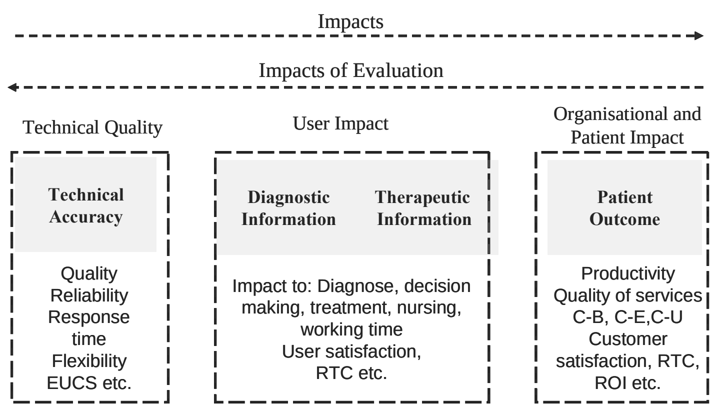

The Use of Frameworks to Minimise Evaluation Set

Resources are rarely available to enable the launching of massive evaluation programs (Friedman & Wyatt, 1997). Following aspects may ease formulating evaluation plans in order to minimise the evaluation set:

1. What are the expected relationships between the different elements or variables (Fineberg et al., 1977; Hebert, 2001)?
2. How does use of new IS compare to the process of traditional care or previous IS (Hebert, 2001)?

This procedure may help to formulate a minimum amount of evaluation trials to prove an impact of a system or to find the potential cases that may affect the outcome (e.g., improved medical data to lead better decision making and better outcome).

The framework may help to classify evaluation results and thus, to compare evaluation studies. Because classification of evaluation studies seems to be in some sense a subjective task (see Figure 5), this framework is offered rather as a conceptual guide for classifying, not as a straightjacket.

BACIIS:
Biological and Chemical Information Integration System

ABSTRACT

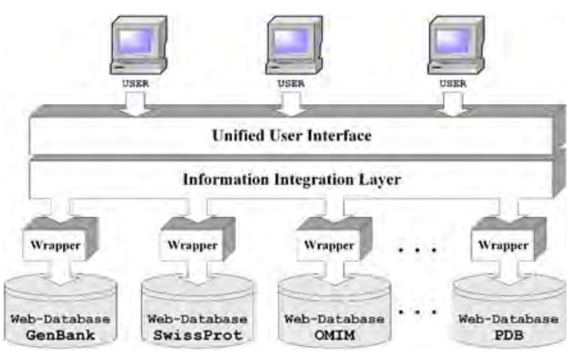
Life science Web databases are becoming increasingly essential in conducting everyday biological research. With more than 300 life science Web databases and the growing size of the life science data, searching and managing these complex data requires technology beyond that of traditional database systems. The open research issues include the interoperability of geographically distributed autonomous databases, which are generally only Web-accessible, and the seamless semantic-based integration of these databases with total transparency to the user. In this paper, the implementation of a Biological and Chemical Information Integration System (BACIIS) is presented. BACIIS supports the integration of multiple heterogeneous life science Web databases and allows the execution of global applications that extend beyond the boundaries of individual databases. This paper discusses the architecture of BACIIS. It also discusses the techniques used to extract and integrate data from the various life science Web databases.

INTRODUCTION

The confederation of geographically distributed life science databases is a critical challenge facing biological and biomedical research. Databases are the intermediaries between experimental observation and the ability to extract biological knowledge. The challenge in managing life science data is due to the large volume of data, the rate at which the data are increasing in size, and the heterogeneity and complexity of the data format. There are currently more than 300 life science Web databases (Baxevanis, 2002) providing access to scientific data and literature via the Web. These databases use different nomenclatures, file formats, and data access interfaces. Furthermore, they may include redundant and conflicting data.

This paper presents a system (BACIIS) that uses the mediator-wrapper approach to support the integration of life science Web databases. BACIIS constructs a tightly coupled federation of databases and uses ontology as a global schema. Currently, BACIIS (Figure 1) integrates seven life science Web databases: GenBank (Benson, 1998), SWISS-PROT (Bairoch, 1998), PIR (Baker, 1998), PROSITE (Sigrist, 2002), ENZYME (Bairoch, 2002), PDB (Berman, 2000), and OMIM (McKusick, 1998). GenBank is an annotated collection of all publicly available DNA sequences, which includes approximately 20 million DNA sequences. SWISS-PROT is an annotated, non-redundant protein sequence database that includes high-quality annotation of proteins, such as the description of the function of a protein, its domain structure, post-translational modifications, and variants. PIR is a protein sequence and structure database. ENZYME is a database that contains information relative to the nomenclature of enzymes. PROSITE is a database of protein families and domains. It consists of biologically significant sites, patterns, and profiles that help to identify to which known protein family a new sequence belongs. PDB is a database of 3-D biological macromolecular structure data. The OMIM database is a catalog of human genes and genetic disorders, which contains textual information, pictures, and reference information.

Figure 1. Information integration for life science Web database



This paper specifically shows how a mediator-wrapper approach can be successfully used to integrate Web databases in the context of the restrictions imposed by the life science domain. These restrictions include:

- The databases are autonomous and only Web accessible. Therefore, data extraction has to be performed following the data presentation protocol that is adopted by the component databases.
- Access to the databases can change often; different databases return their result in a different format, and there is a large number of life science databases. Therefore, any data extraction mechanism needs to take these aspects into consideration in such a way that it easily can adapt to changes in the databases, and databases can be added to the integration system easily.
- Resolving heterogeneity is an important aspect in the integration of life science databases and has to be addressed with minimal user intervention in order for the integration system to be useful to the scientists.

BACIIS is a tightly coupled federation of life science Web databases. Its architecture, shown in Figure 2, is a three-tier software architecture (Kossmann, 2000) that consists of a mediator, wrappers (Ambite, 1998; Levy, 1998; Wiederhold, 1992), and an ontology that is used as a global schema. The mediator transforms data from its format in the component database to the internal format used by the integration system (Ambite, 1998). A wrapper extracts information from the component database (Levy, 1998). Each component database is described by using domain ontology terms. This information is stored in a data source schema file, and each life science Web database is associated with a data source schema file. The ontology and the data source schema files for the component databases make up the domain knowledge base of BACIIS.

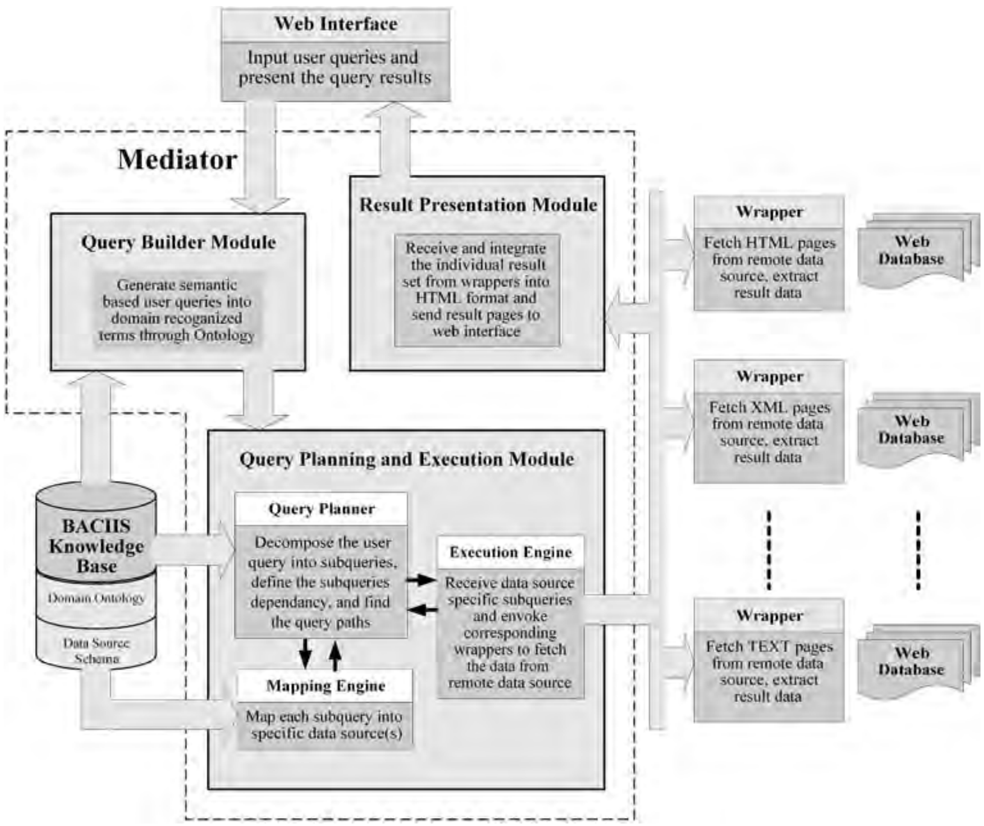
In the remainder of the paper, the approaches that we developed and the design decisions that we adopted to integrate life science Web databases, while respecting the above-mentioned restrictions, are discussed. The three tiers of the BACIIS software architecture are presented in the following sections. The last three sections of the paper present an example execution of a query in BACIIS, discuss related work, and summarize the major contributions of this paper.

MEDIATOR

The mediator in BACIIS identifies the relations between the query input and output data types by using the domain knowledge. Based on these relations, it generates a query execution plan, using the appropriate Web databases. After the wrapper fetches the results from the Web databases, the mediator needs to integrate the results returned from the Web databases according to the object relations defined in the ontology.

The mediator (Figure 2) includes three modules: (1) a query builder module, (2) a query-planning module, and (3) a result presentation module. The query builder module translates a multi-database query entered by the user into domain-recognized terms from the ontology. Queries translated by the query builder module are forwarded to the query-planning module.

Figure 2. BACIIS architecture



This module consists of the query planner, the mapping engine, and the execution engine. The query planner receives a multi-database query and decomposes it into subqueries. The mapping engine uses the data source schema to find the appropriate Web database, which can accept the set of input data types and generate the set of output data types for a given subquery. Using the list of Web databases established by the mapping engine, the query planner constructs an execution path for the entire multi-database query, according to the dependencies among the subqueries. The execution engine receives the query execution path from the query planner and invokes the wrapper associated with each Web database that corresponds to a given subquery.

This mediator behaves like a traditional mediator (Kossmann, 2000). The novelty introduced in BACIIS is the ability to identify the Web databases that can answer the subquery without user intervention by matching the query input and output types of the query to the input and output types recorded in the data source schema files of the component databases. This departs from previously proposed systems (Decker, 2001) that require the user to specify the query execution plan and the desired semantic mapping.

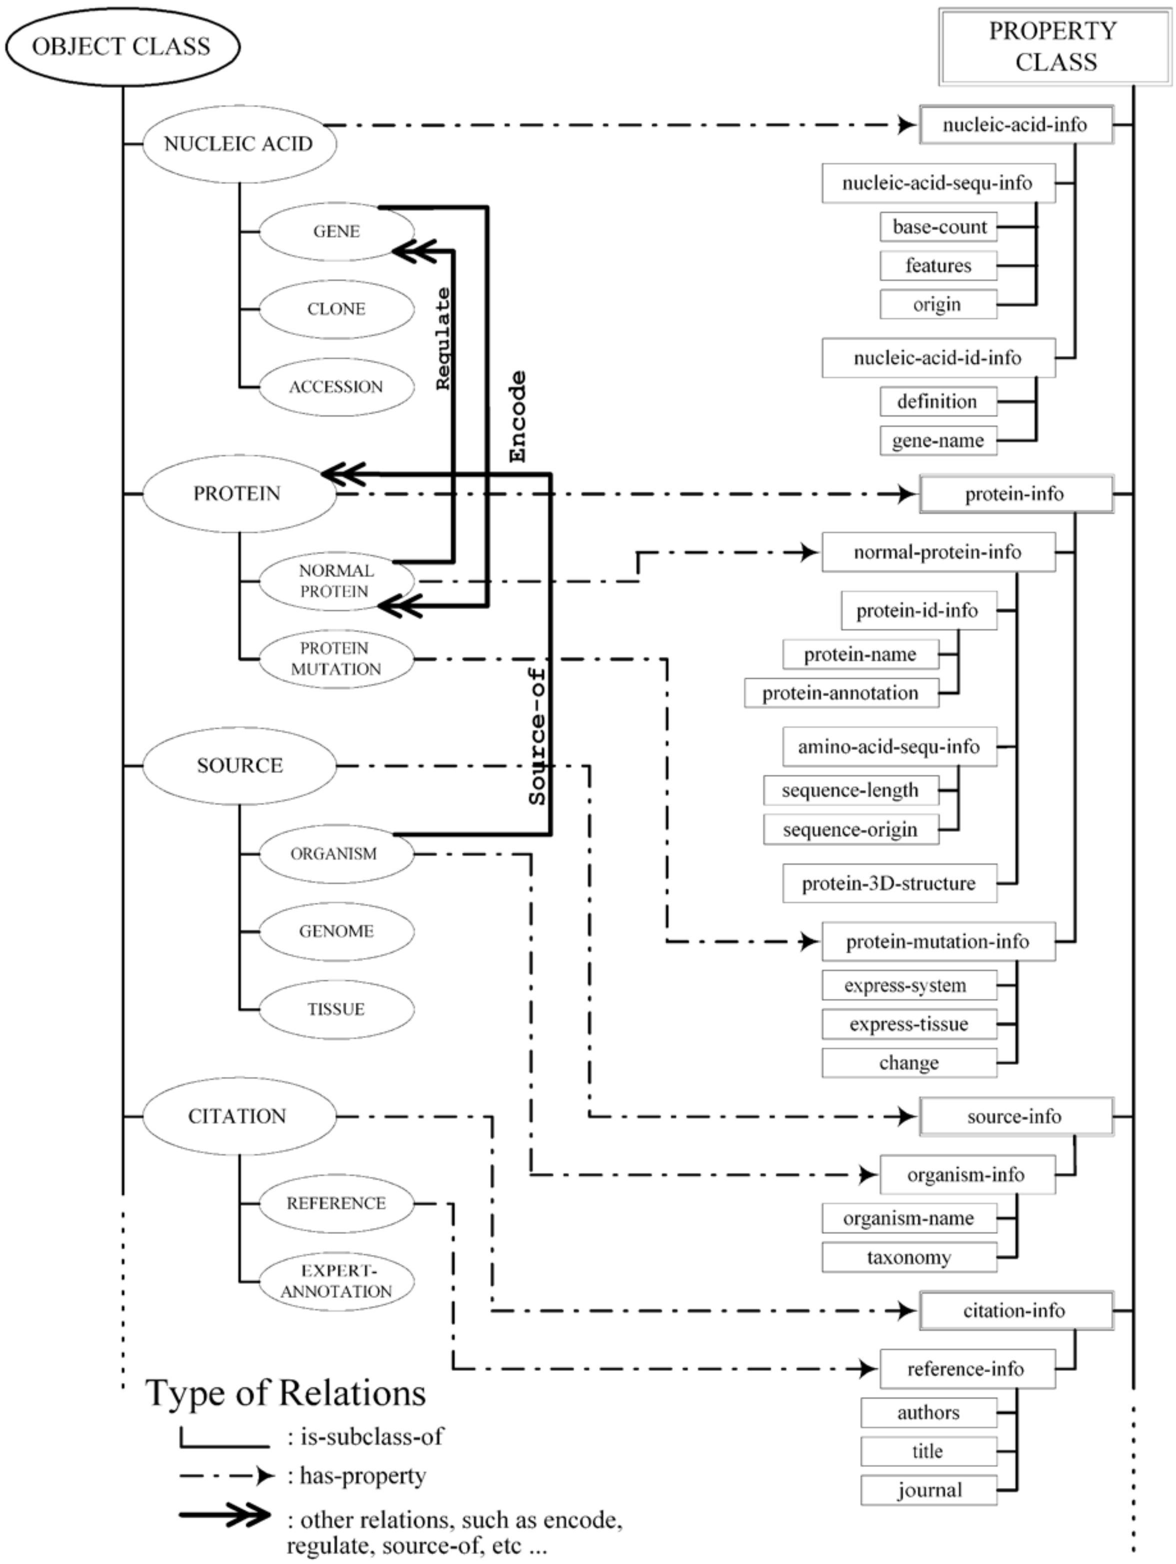
DOMAIN ONTOLOGY

As stated in Lakshmanan (1996), when integrating heterogeneous databases, three issues have to be addressed: semantic, syntactic, and system variability. Resolving semantic variability consists of adequately interpreting and cross relating information stored in different databases (Lakshmanan, 1996). In general, syntactic variability arises from the heterogeneity of the database schema, data models, and query processing approaches. System heterogeneity refers to the use of different operating systems and communication protocols (Lakshmanan, 1996). In BACIIS, the databases are accessed via their Web interfaces. Therefore, system heterogeneity is not critical. However, both semantic and syntactic variability are critical and have to be addressed before the integration system is of any use to the scientists.

Domain ontologies (Bouguettaya, 1999; Gruber, 1993; Ouzzani, 2000) have been used successfully as domain models in several general-purpose information integration systems, such as the Information Manifold (Levy, 1998), Observer (Mena, 1998), Ontobroker (Decker, 1999), and SIMS (Arene, 1996). The domain ontology in BACIIS serves as a global schema and plays a major role in resolving both semantic and syntactic variability. It is used for the reconciliation of synonyms across the various databases. For example, to refer to the literature reference, the database GenBank uses “reference,” and the databases PDB (Protein Data Bank) and PIR (Protein Information Resource) use “citation” and “bibliography,” respectively. The ontology is used to map all the different terms used by the remote databases to a single term. In addition, the ontology in BACIIS provides the domain knowledge necessary for resolving syntactic heterogeneities. For example, the reference information in the database SWISS-PROT is a single attribute. In the database GenBank, reference information consists of multiple attributes including author, title, journal, and so forth. By using the ontology and the data source schema, these heterogeneous data types are all mapped into appropriate domain concepts. The data extracted from the Web databases is internally reformatted to adhere to the unified data representation specified by the ontology.

Different from the traditional two-dimensional approach, the ontology developed in BACIIS has three dimensions: object, property, and relation. A portion of this three-dimensional ontology structure is shown in Figure 3. For example, *nucleic acid* and *protein* in Figure 3 are object classes. In the same figure, *nucleic-acid-sequ-info* and *amino-acid-sequ-info* are property classes. In the ontology of BACIIS, the properties of an

Figure 3. Portion of the BACIIS domain ontology



object are defined as a property class, which occupies a position in the property hierarchy tree. In ontology, a relation refers to the association between two concepts. In BACIIS, classes under the object and property dimensions are arranged into a hierarchy tree, based on the relation "is-a-subclass-of." For example, GENE is a subclass of the class NUCLEIC ACID in the object hierarchy. Similarly, "base-count" is a subclass of "nucleic-acid-sequ-info" in the property hierarchy. Also, relations under the relation dimension link concepts between the two dimensions property and object as well as within each of these dimensions. For example, the relation "has property" indicated by "—·→" in Figure 3 is between the object classes and property classes, as in the case of the class NUCLEIC ACID in the object hierarchy and the class "nucleic-acid-info" in the property hierarchy. The relation "is-a-subset-of" is used for property classes or object classes with parent-descendant relationships. It is indicated by "|—" in Figure 3. The relations "regulate" and "source-of" indicated by "→>" are used for object classes that are neither parents nor descendants of each other.

The three-dimensional structure of the ontology makes it possible to differentiate between two relations without affecting the traditional definition of a relation. Relations between two classes from different dimensions, object and property, are object-property relations. Relations between two classes within the same dimension are either property-property relations in the case of the property dimension or object-object relations in the case of the object dimension. This design choice makes the ontology more flexible and extendible. For example, changes to a property class will not have an impact on the definition of the object classes.

In order to resolve semantic and syntactic heterogeneities, in particular for tightly-coupled federated databases, ontology has recently emerged as an efficient framework for capturing biological knowledge (Goble, 2001). Ontology is basically a formal description of the concepts and entities in a given domain. A core part of the ontology is a vocabulary of terms and their meanings (Schulze-Kremer, 2002). Therefore, it is ideally suited for resolving both syntactic and semantic variations in the biological domain. Semantic variations are resolved by expressing the concepts in ontology at different degrees of granularity (3rd Millennium Inc., 2002). Furthermore, by expressing the relationships among the various concepts, the ontology organizes the concepts in a structured way, thus reducing the number of possible interpretations of these concepts (Schulze-Kremer, 2002).

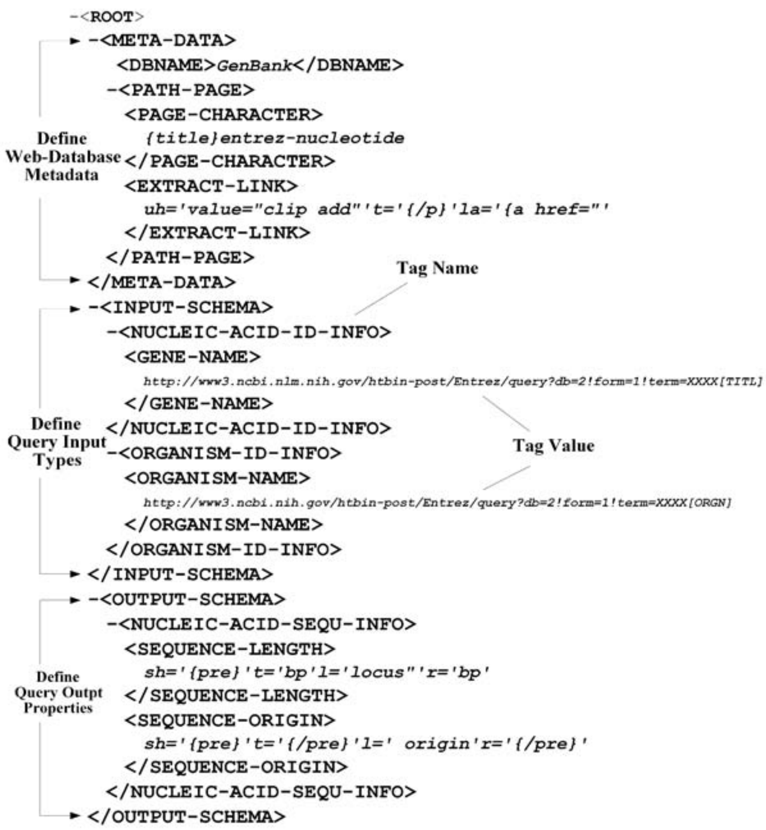
In BACIIS, we improve on this paradigm by making the ontology independent of the individual data schema of the component databases. Because of this independence, the ontology will change only when the biological domain evolves to include new discoveries and knowledge concepts rather than when a component database changes or a new component database is added. This independence is important in light of the fact that the life science databases change their Web interfaces often, and the fact that there is a large number of databases in the life science domain.

DATA SOURCE SCHEMA

The data source schema is used to describe each database participating in the integration. Each data source schema consists of the input data types accepted and the output data types generated by the corresponding Web database. These data types are expressed by using ontology terms and are used, as previously mentioned, to select the component databases that can answer a given subquery. Also, the expression of the input and output data types in terms of ontology terms facilitates synonym reconciliation and the resolution of presentation heterogeneity, since the schema of the different component databases are mapped to the same global schema.

Figure 4 shows a portion of the data source schema of the database GenBank. This schema consists of three sections: metadata, input data types, and output data types. The metadata section includes general information about the Web database, such as the database name. The input data types section includes all the input data types that are accepted by the Web database — in this case, GenBank. These input data types correspond to the property classes in the ontology, and they adhere to the same hierarchy established between the property classes in the ontology. For example, "nucleic-acid-id-info" corresponds to a property class in the ontology (Figure 3). This property class has the property subclass "gene-name." This parent-descendant relationship is preserved in the data source schema of Figure 4. The property classes in the ontology correspond to tag names in the data source schema. Some of the property classes also have tag values. These property classes correspond to input data types for the Web database, and they also correspond to property classes that are leaf nodes in the property dimension of the ontology. These leaf nodes have tag values that correspond to the URL that can be used to query the database by using the corresponding input data type (or tag name). For example, gene-name is a leaf node in the property hierarchy, and it is also an input data type for the database GenBank. Its tag value in the data source schema of GenBank is http://ww3.ncbi.nlm.nih.gov/htbin-post/Entrez/query?db=2!form=1!term=XXXX[TITL], which can be used to query GenBank, using gene name as input. A given database may not accept all the property classes defined in the ontology. Therefore, only the property subtree that is induced by the input data types accepted by the database is included in the

Figure 4. Example of data source schema defined in XML format



data source schema. The output data type section in the schema file has the same characteristics as the input data type section, with the exception that the tag names and the tag values correspond to output data types that can be retrieved from the Web database and the extraction rules needed to extract this data from the pages returned by the Web database, respectively.

By using the data source schema to describe each Web database and the ontology to describe the domain knowledge, the integration system can identify the content of each database, determine which database(s) can answer a given query or subquery, retrieve and extract the information from this database, and integrate it with data from other databases. All of these operations can be performed by using the proposed approach, while preserving the autonomy of the databases and without any user intervention.

WRAPPERS

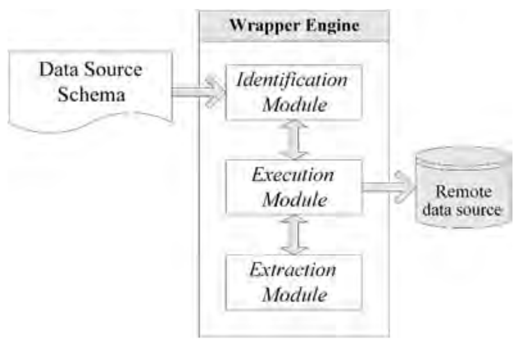
The wrappers are responsible for retrieving the data from remote databases. They have been used widely to extract information from Web databases (Decker, 2001; Lage, 2002). When integrating traditional databases, the wrapper usually resides on the server side. However, in the case of Web databases and because of their autonomy, the wrappers in BACIIS reside on the client side.

Because of the large number of databases and the fact that their Web interfaces change often, the wrapper approach used in BACIIS is different from a traditional one. The wrappers in BACIIS are constructed on the fly by using a generic wrapper engine and the data source schema of the target Web databases. Database-specific information, such as the URL addresses used to construct the subqueries for each input data type and the extraction rules needed to extract the required data from the returned result page for each output data type, are included in the data source schema.

The wrapper engine has three modules (Figure 5): the identification module, the execution module, and the extraction module. The identification module first constructs an empty result container for the result data for each query step. The result container is organized according to the relation hierarchy defined by the ontology. The execution module submits the database specific subquery to the remote database and fetches the return pages. The extraction module then parses the returned pages, extracts the desired data by using the proper extraction rules, and puts the extracted data into the result containers constructed by the identification module. The wrapper engine extracts all the database-specific information that it needs from the data source schema file. In a sense, the wrapper engine acts like a compiler that interprets the instructions included in the data source schema file. Since the wrapper engine does not include any database-specific information, adding a database requires only creating the corresponding data source schema. Furthermore, changes to the Web interfaces are only reflected in the data source schema. This is different from wrappers in other integration systems, which construct a wrapper for each database independently (Decker, 2001).

The data container is constructed by using a tree structure derived from the property hierarchy in the ontology, which includes all the descendants of the output data type. The mediator collects the

Figure 5. Wrapper



data containers from all the wrappers and organizes them according to the property hierarchy defined in the ontology. The query results are organized in a tree structure. The information belonging to the same property is stored in the same node. The hierarchy structure and concept definition imposed by the ontology allows data from different component databases to be combined semantically.

EXAMPLE QUERY

This section illustrates the execution of the following query in BACIIS: "Find all the literature references and DNA sequences for the mouse gene RAS and also return the amino acid sequences and protein 3-D structures for the proteins that are encoded by this gene." The query will be expressed as follows: "select *nucleic-acid-sequ-info*, *references*, *amino-acid-sequ-info*, *protein-3D-structure*, where *organism-name*=mouse and *gene-name*=RAS." The user expresses the multi-database query by using query input data types and query output data types from the ontology. In this example, the output data types *nucleic-acid-sequ-info*, *references*, *amino-acid-sequ-info*, *protein-3D-structure* and the input data types *organism-name* and *gene-name* are all ontology terms.

From the Web interface, the user can compose this query by specifying the input and output data types and values. The input and output data types displayed to the user are obtained directly from the ontology. The user specifies only the top-level property classes as output data types. The subclasses or descendants of these property classes are retrieved from the ontology during query processing. The property classes "reference," "nucleic-acid-sequ-info," and "amino-acid-sequ-info" are all top-level property classes. Figures 6 and 7 show how the user selects the query input data types and query output data types from the ontology in order to compose this query.

Figure 6. Compose query input

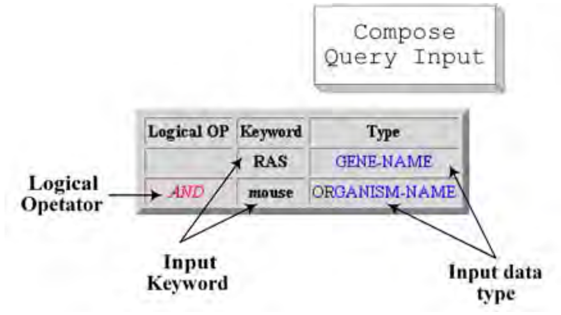


Figure 7. Select query output types

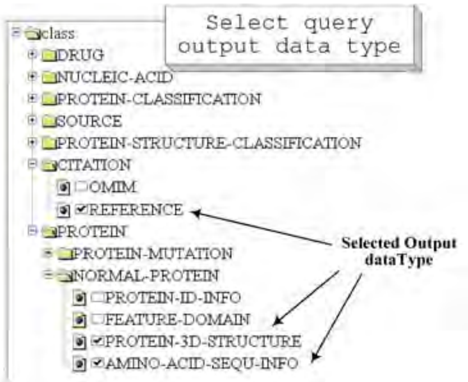

More specifically, in order to build the query input part, the user enters "RAS" as a keyword and selects "gene-name" as the input data type. The user then adds the second input by entering "mouse" as a keyword and selecting "organism-name" as the input data type. For the output part, the user can select the object class "PROTEIN" from the ontology. When the user selects "NORMAL-PROTEIN," which is an object subclass of the object class "PROTEIN," the property classes that are associated with this object subclass will be automatically retrieved from the ontology. For example, the object class "NORMAL-PROTEIN" is linked to the property class "normal-protein-info" by the relation "has-property" (shown by "—·→" in Figure 3). Thus, when "NORMAL-PROTEIN" is selected, the ontology property subtree rooted at "normal-protein-info" will be displayed to the user. The user then can select the output data types "amino-acid-sequ-info" and "protein-3D-structure," which are top-level property classes of this property subtree. The top-level property class "amino-acid-sequ-info," for example, has multiple descendants, including "origin," "base-count," "version-no," and so forth, as shown in Figure 3. In order to complete the query, the user can add the other output data types first by selecting the object "nucleic-acid," and then by choosing the property "nucleic-acid-sequ-info" from the property list returned by the ontology for the object "nucleic-acid." In order to specify reference information for the gene "RAS," the user needs to choose one more property, "reference," from the property list of the "citation" object in the ontology. The result of the example query is shown in Figure 8.

RELATED WORK

One of the main advantages of federated databases is that they do not require that component databases be physically combined into one database (Karp, 1995). Database federation is used to integrate autonomous, heterogeneous, and distributed databases (Busse, 1999). This class of integration systems can be divided further into two subclasses: tightly coupled and loosely coupled.

In a tightly coupled federated database system, a global data schema is constructed, and the queries are expressed on this unified schema (Yu, 1998). The global schema integrates all the component schemas. Therefore, the component databases are transparent to the user. TAMBIS (Goble, 2001; Paton, 1999) is an example of tightly coupled federated databases. It uses ontology as a conceptual model to integrate multiple biological Web databases.

In a loosely coupled federated database system, there is no global schema, and the user needs to specify the component databases in the query by using a multi-database query language (Busse, 1999). One of the disadvantages of loosely coupled federated databases is that the component databases and any heterogeneity that may be present among their schema are not transparent to the user. This approach is used by BioKleisli (Davidson, 1997).

As previously mentioned, both BACIIS and TAMBIS use the tightly coupled federated databases approach with an ontology-based global schema. However, they differ in the way the

wrappers are generated. In TAMBIS, wrappers are database-specific and are constructed by using functions from the CPL language. A similar approach is used by BioKleisli.

CONCLUSION AND FUTURE WORK

The contribution of the BACIIS system is that it integrates geographically distributed heterogeneous Web databases with total transparency, while preserving the autonomy of the databases. The life science domain is unique in the sense that it counts Web databases in the hundreds. Furthermore, these databases are not accessible via their DBMSs, and they do not adhere to a common standard interface or data model. The BACIIS system overcomes these limitations through a scalable design with an ontology-centric approach. Most of the previously developed life science integration systems do not hide the heterogeneity of the databases from the users.

The use of an ontology-centric approach of a three-dimensional ontology and of independent data source schema that contain database specific information reduces the overhead associated with adding new databases or changing the existing databases, while addressing the heterogeneity of the component databases.

While the current BACIIS successfully integrates multiple life science Web databases, the implementation of BACIIS has one limitation that needs to be addressed: The extraction rules used stored in the data source schema files are constructed manually. These extraction rules need to be modified every time the interfaces of the Web databases change. Although this is an improvement on traditional wrappers, which are entirely hand-coded, the manual update of the data source schema files is still tedious. The development of an inductive wrapper algorithm that will generate the extraction rules automatically is being considered. We are currently designing a method similar to the one proposed by Lage (2002) for simple Web interfaces. However, in the case of BACIIS, the wrapper induction approach has to be able to handle complex Web interfaces.

BACIIS is available at http://baciis.engr.iupui.edu/

Chapter 2.19
Macroscopic Modeling of Information Flow in an Agent-Based Electronic Health Record System

Ben Tse
University of Regina, Canada

Raman Paranjape
University of Regina, Canada

ABSTRACT

This chapter presents an architecture, or general framework, for an agent-based electronic health record system (ABEHRS) to provide health information access and retrieval among different medical services facilities. The agent system's behaviors are analyzed using the simulation approach and the mathematical modeling approach. The key concept promoted by ABEHRS is to allow patient health records to autonomously move through the computer network uniting scattered and distributed data into one consistent and complete data set or patient health record. ABEHRS is an example of multi-agent swarm system, which is composed of many simple agents and a system that is able to self-organize. The ultimate goal is that the reader should appreciate the benefits of using mobile agents and the importance of studying agent behaviors at the system level and at the individual level.

INTRODUCTION

Health information is the heart of any electronic health record (EHR) application, and the management of this growing and complex information has become a huge and complicated task for every health care organization. Moreover, much of this health information is fragmented and scattered among different medical service facilities, mainly because a patient is usually seen by many different health care providers in many different medical service facilities. So, the patient is likely to have at least one relevant health document or record in each medical facility he/she visits. Over time, the patient's medical record becomes fragmented, inaccurate, and inconsistent. This is the complex environment in which EHR management must operate.

Fortunately, a large part of today's health information is already available in electronic form, and the primary task of the EHR system is to communicate this information electronically anywhere in the world. Based on this vision, the need to move the patient's health information among different health care facilities grows in parallel with the need to centralized health information across numerous EHR systems within the health care domain (Silverman, Andonyadis, & Morales, 1998). Therefore, in order to allow rapid and accurate access of patients' health record, the creation of a digital health information network is essential to our modern health care system.

Mobile agent technology can be an essential tool in creating this system, because of fundamental mobile agent attributes including: autonomy, mobility, independence, pro-activity, reactivity, communicability, swarm, and group intelligence. Because of these attributes, mobile agents can provide solutions to address the challenges of health information systems in the health care domain, as suggested in Nealon and Moreno (2003) and Crow and Shadbolt (2003). Later section in the chapter, we will present an architecture or general framework for ABEHRS to provide health information access and retrieval among different medical services facilities.

As shown in Lerman and Galstyan (2001), a swarm agent system (simple agents with a distributed controller) that exhibits collective behaviors has demonstrated advantages in robustness, scalability, and cost, over a traditional agent system (intelligent agents with a centralized controller) that exhibits individualized behaviors. Moreover, self-organization is one of the interesting collective behaviors that appears in a swarm system. This concept of self-organization manifests itself in our ABEHRS, which allows the patient's health record to self-organize. In the background section, basic definitions of swarm and intelligence will be presented, and the definition of self-organization will also be presented. Later sections in the chapter will present the reasons why the swarm paradigm is chosen over the traditional paradigm and the process of self-organization used in our ABEHRS.

In order for our ABEHRS to be useful, a study of the system-level behavior must be performed. This allows a greater understanding of the system dynamics, so that if such a system was actually implemented, the dangers of unexpected system behavior could be limited. Smith, Paranjape, and Benedicenti (2001) show that the full potential of individual agents is not obtained during unexpected/unwanted agent-group behaviors (for example, oscillation of agents between hosts). Therefore, we believe that the behavior of agents in a multi-agent system must be completely understood before the completion of actually system design, so as to minimize the chances of system failure and to achieve superior system and individual agent performance. In the proceeding sections, we present a study of agent behaviors in ABEHRS using simulation and mathematical models, as well as the comparison between the simulation and numerical results.

BACKGROUND

The Electronic Health Record

As defined in Grimson, Grimson, and Hasselbring (2000) and the Web site of the Healthcare Information and Management Systems Society (http://www.himss.org), an electronic health record is an electronic version of patient's health record, which includes prescriptions, lab results, evaluations by doctors, and so forth. Since the EHR is in an electronic format, so it can be easily accessed by a health information system within an electronic health network. Around the world, people are recognizing the value of EHR systems. Their advantages include increasing effectiveness and efficiency of clinical staff and health practitioner, providing seamless care for patients with timely, appropriate, and secure access to the right information whenever and wherever they are, and increasing the profitability of the practice or facility.

Although EHR appears to hold great promise, there are many challenges that need to be addressed before they can be fully integrated in a health care system. As described in Nealon & Moreno (2003), Huston (2001), and Walczak (2003), these challenges include scattered and fragmented health information, security and confidentiality, delay in availability of information, complexity of medical data, heterogeneous health information system, and network bandwidth consumption.

Mobile Agent Technology

A mobile agent (MA) is a software object that can migrate to different computers over an Internet protocol (IP) network, or the Internet, to perform user-assigned and self-initiated tasks in heterogeneous computing environments (Gray, Kotz, Nog, Rus & Cybenko, 1997). An MA is a representation of its owner, and it inherits the owner's authority and acts on behalf of the owner. By adding artificial intelligence modules to a MA, it can have the ability to select the best set of activities to perform until it reaches the goal specified by the owner, or the ability of reacting to specific events in its surrounding environment to provide flexible, dynamic, and intelligent solutions. Mobile agents exhibit a number of characteristics, and they include:

- **Modularity:** Mobile agents are diverse in nature; different services can be distributed among a set of agents or encapsulated into a single complex agent. In this way, the required algorithms can be embedded into the agent system to perform the service
- **Mobility:** Agents can migrate to the resource they need instead of accessing these resources remotely, which reduces network bandwidth usage tremendously
- **Interactivity:** Agents can communicate to other agents using a specified message format
- **Autonomy:** Agents are typically independent entities and have the ability to choose the best actions to perform to achieve specific goals

Mobile agents do not operate independently; they required extensive supporting infrastructure to provide communication services, mobility services, management services, security, and monitoring services. This infrastructure is commonly called an agent execution environment, or AEE. The AEE must be installed and running on a host computer before the mobile agent program can run. TEEMA (TRLabs execution environment for mobile agents) is an AEE that was developed by the faculty, staff, and graduate students at TRLabs Regina and Electronic Systems Engineering at the University of Regina. More information related to TEEMA can be found in Gibbs (2000) and Martens (2001). TEEMA is the experimental platform used in this work.

There are various software applications that are uniquely suited for development using mobile agent technology. Typically, these applications take advantages of the intrinsic characteristics of mobile agents, including autonomy, re/proactivity, modularity, interaction, and/or mobility. And our ABEHRS is one of the applications that take advantage of these intrinsic characteristics of agent to facilitate the process of retrieving/accessing fragmented and scattered patient health information across different medical service sites. So, each mobile agent has the ability to "move" around different medical service facilities across

IP networks, the ability to "automate" tasks on behalf of the patient, the ability to act in a "re/pro-active" bases to respond to the patients or medical providers, the ability to "interact" with other agents, and the ability to "embed" partial or whole patient information as a function. After the health information is encapsulated by the agent, it can be moved to different medical sites within our ABEHRS, we can define these behaviors/actions as information flow within ABEHRS.

Swarm and Its Intelligence

The idea of an intelligent agent swarm takes its inspiration from insect societies in biology and nature. Swarm consists of a large group of small insects (such as bees or ants), and each insect has a simple role, with limited capability (for example, moving around). The swarm as a whole (such as a colony of ants or a hive of bees), however, is able to do many complex and sophisticated tasks (such as finding the shortest distance between the nest and the food source). Furthermore, each insect works autonomously, and essentially their teamwork is self-organized. Coordination and cooperation between individual insects arises from the interactions between insects, or the interactions between insects and the environment. Through these interactions (such as stigmergy), collective behavior emerges, and efficient and effective outcomes are generated.

As defined in Bonabeau, Dorigo and Theraulaz (1999), swarm intelligence is the concept of using the collective behavior arising from a group of relatively simple objects in a decentralized and self-organized system to solve complex and distributed problems. Artificial swarm intelligence can be demonstrated using relatively simple and autonomous agents. The agents are distributed, self-organized, and there is no central controller to direct how each agent should behave. Agents may be dynamically added or removed, making the system highly flexible and scalable. Examples of agent swarm systems are Truszkowski, Hinchey, Rash, and Rouff (2004), Wu (2003), and Charles, Menezes, and Tolksdorf (2004).

Self-Organization Definition

According to Camazine et al. (2001), self-organization is a key feature in a swarm system. It refers to the process that describes a system as it moves from a chaotic state to a well-ordered state by using the interactions at the lowest-level components of the system. Camazine et al. also pointed out the four characteristics of self-organization in a swarm system, and they are: positive feedback, amplification of fluctuations, multiple interactions, and negative feedback. When the system is in the chaotic state, the positive feedback signals will influence certain properties of the system, and these properties will be amplified by the many random interactions between the individual components. These interactions can be seen as a combination of exploitation and exploration of new solutions from the components. The negative feedback serves as a regulatory control mechanism of the system's properties, and is used to direct the system back to a well-ordered state. In fact, the self-organization of a system can be seen as a formulated feedback control loops between the individual components in the system. An example of a self-organized swarm system is Kadrovach and Lamont (2002).

By combing the concept of self-organization with agent technology, we are able to allow individual health record to self-organize themselves in our ABEHRS.

Agent Behaviours Modeling

In order to ensure that a useful and effective mobile agent system is constructed, it is important to study, examine, and analyze the system-level behaviors, as well as the agent-level behaviors. There are several approaches used to study behavior in multi-agent systems; most include simulation and mathematical modeling. Using the simulation approach to evaluate agent behaviours in multi-agent systems is a traditional approach for agent designers and researchers. In this approach, the simulation consists of a set of agents that encapsulate the behaviours (for example, rules of movement, strategies) of various individuals that interacted with the local environment and with other individuals. Usually, these behaviours, as well as external forces (for example, resource fluctuation), are represented using different stochastic processes, and so, by executing these behaviours during the simulation, a global dynamic model of the system and of the agents can be created. The simulation model provides reasonable design ideas to the agent designers when developing a real multi-agent system. Simulations of agent behaviour in multi-agent system are shown in Tecchia, Loscos, Conroy, and Chrysanthou (2001), Smith et al. (2001), and Heine, Herrier and Kirn (2005).

The mathematical modeling approach is an alternate way of evaluating agent behaviours. The mathematical model usually consists of a set of equations that describe the process of the behaviours being modeled, and these behaviours are represented by a set of stochastic probabilities that are used in the equations. In order for the mathematical model to be useful and realistic, relevant details of the process must be accounted for. Generally, two different levels of mathematical modeling are used to describe a multi-agent system, and the levels are microscopic and macroscopic. In general, a microscopic model describes the agent-level behaviours in a multi-agent system, for example, interactions between two agents. On the other hand, a macroscopic model describes the system level behaviours in a multi-agent system, for example, collective or global behaviour emerged from the agent's interactions. Studies of agent behaviours using microscopic or macroscopic mathematical models are shown in Agassounon and Martinoli (2002), Lerman and Galstyan (2001), Lerman and Shehory (2000), Sugawara and Sano (1997), and Wang, Liu, and Jin (2003).

In this work, we choose the approach of agent system evaluation using simulation and mathematical modeling. For the simulation, a prototype of ABEHRS model was developed using TEEMA platforms, and simulation results were obtained. For the mathematical modeling, we choose a macroscopic model to analyze system behavior in ABEHRS. The reasons to use a macroscopic model are that global dynamic behaviors of the system can be readily observed, and macroscopic modeling is computationally more efficient than microscopic model, since only a few parameters are used. Moreover, among the mathematical modeling approaches mentioned above, Lerman and Galstyan (2001) have presented a general mathematical macroscopic approach to analyze the global dynamic behaviors of multi-agent swarm system. In our mathematical model, a set of differential equations based on the Lerman and Galstyan (2001) model are determined and numerical results are obtained by solving these equations. We can compare and contrast these results in the context of our ABEHRS. It is our belief that a simple multi-agent swarm system will exhibit complex and unexpected behaviors, and unless we model these behaviors using a macroscopic mathematical model and simulation, unpredictable system behavior will result.

THE AGENT-BASED ELECTRONIC HEALTH RECORD SYSTEM

Our main objective in this work is to propose a general framework or architecture that incorporates the use of mobile agent technology to facilitate the flow of health records among various medical service facilities, and combines all scattered and fragmented health records into one consistent and complete data set.

To accomplish the system objective, agents must exhibit the following characteristics: autonomy, re/pro-activity, mobility, modularity, and interaction. With the presence of autonomy and re/pro-activity, agents can monitor any changes in the patient's electronic health record. Whenever a change is identified to the patient's electronic record, the agent will automatically perform necessary tasks to ensure the electronic record of the patient is up-to date and is consistent. Thus the ABEHRS agents are highly autonomous. Another important characteristic of agents is mobility. With this characteristic, agents are able to migrate to different medical service facilities to perform necessary data collection tasks. Interaction between agents is mandatory in our system, and it is used in identity verification of patients and agents at different medical service facilities. It is also used in the co-ordination of other agents' activities. Agents can encapsulate health information, communication protocols, or medical data en/decoding formats as embedded functions. By using mobile agents and their fundamental and intrinsic characteristics, many of the challenges of the EHR systems can be overcome. In the subsequent sections, we will present system concepts, design concept, and the system components for the ABEHRS.

System Concepts

By using mobile agent technology, we add mobility and autonomy to the health record, which allows the record to automatically move anywhere within the health information network. This system can be colloquially described as "putting a mobile agent wrapper" around an electronic health record and instructing the agent to move to other medical facilities for its owner (the patient).

There are two important aspects of the system, which are shown below:

1. A complete health record is defined as every pieces of information in a patient's health record (which may be generated by different medical facilities within the health care system) united into one consistent and complete set of information. The health record may include doctor's evaluations, test results, prescriptions, and so forth.
2. The ABEHR system is described as self-completing, self-regulating, and self-organizing. We define these capabilities for the system as the mechanism by which it automatically (without any supervision or guidance) makes each patient health record complete.

Therefore, we wish to apply the idea of self-organization through agents to facilitate the concept of self-completing patient's health records. The following subsections will provide an overview of how self-organized health record is achieved, and how agent cloning is used in ABEHRS.

Self-Organized Health Record

As defined above, self-organization refers to the process of a system moving from a chaotic state to a well-ordered state by using the interactions between the lowest-level components of the system. From the perspective of the individual patient's health record, an individual health record is in a well-ordered state, when the record is complete and consistent. If the health record is not complete and consistent (for example, newly created record), then the record is in a chaotic state. Mobile agents are effectively the lowest-level component, which autonomously interact with other agents in the system to move a chaotic health record into a well-ordered state (for example, update health record in HRC and in patient's health storage device). Once initiated, agents perform the necessary actions to have the health records system self-organize. All the actions and interactions related to self-organized health record performed by the agents are presented in the section of Typical Actions of Patient Agent in Different Medical Sites.

Agent Cloning

In order to facilitate the process of self-organization and to provide needed information in a timely fashion, agent cloning is used in our ABEHRS. By using the agent-cloning approach, the agents are able to perform parallel tasks at different medical sites. Also, when inheriting sensitive information (for example, health card number, access control permissions) from the initiator (the agent who initiates the cloning process), more secure control of data may be achieved than passing the information to other agents using messaging. Therefore, cloning of mobile agents is the process typically used in the ABEHRS. The events that trigger the cloning process depend on the medical services required by the patient. Medical services could be record update/retrieval services, prescription-filling services, lab test services, and so forth. Using this agent-cloning approach, a group of agents can be easily generated, and their direct and group actions work, to keep the health record complete and consistent for the individual patient.

Design Concepts

As previously stated, multi-agent systems are either developed using the traditional paradigm with centralized control and deliberative agents or the swarm paradigm with distributed control and simple agents. There are various factors that influence the decisions as to which design paradigm to adopt for the development of ABEHRS, and Lerman and Galstyan (2001) had shown us that the swarm paradigm is a more suitable approach than the traditional paradigm for the development of our ABEHRS. Reasons supporting this decision are the following:

- Health information systems are diverse in nature. This diversity makes it almost impossible to develop a centralized controller for a large group of health information systems.
- Deliberative agents are smarter, autonomous, and more individualized than swarm agents. Deliberative agents contain deeper knowledge about the system and have higher capabilities to perform more complicated tasks. In order to get the full potential out of the deliberative agents, agent designers must have detailed coordination and complete plans of actions for the agents. These robust mechanisms simply do not exist. Conversely, agents in the swarm are simple and task-oriented, so agent designers can easily develop mechanisms to coordinate and plan the actions of agents. Also, swarm agents require only the knowledge necessary to perform the specified task. Thus, designing and coding swarm agents is more simple and less error prone than deliberative agents.
- In general, health information organizing is conceptually simple but it requires collective effort from a large group of agents to accomplish. When the task is performed in a collective way, the operation is more effective and efficient than if an individual complex agent attempts to perform it. Coalition formation of deliberative complex agents is not easily achieved, while for swarm agents, coalition forming can scale up to thousands of agents easily.
