# CONTENTS

**PART VI. ECONOMIC ANALYSES OF ISSUES AND MARKETS**

# Preface

As I write this preface in mid-January 2009, interest in economics is at an all-time high. Among the challenges facing the nation is an economy with unemployment rates not experienced since the Great Depression, failures of major businesses and industries, and continued dependence on oil with its wildly fluctuating price. Americans are debating the proper role of the government in company bailouts, the effectiveness of tax cuts versus increased government spending to stimulate the economy, and potential effects of deflation. These are questions that economists have dealt with for generations but that have taken on new meaning and significance.

At the same time, economists' recent innovative approaches to analyzing issues and behavior and the expansion of economic analysis to nontraditional topics and arenas of activity have attracted new interest and attention from citizens and scholars. Economists are working with sociologists and psychologists in areas such as neuroeconomics, the economics of happiness, and experimental economics. They have applied economic analysis to sports, the arts, wildlife protection, and sexual orientation, in the process demonstrating the value of economic methods in understanding and predicting behavior in a wide range of human activities and in development of policies aimed at many social issues.

Economics is generally described as the study of resource allocation; or of production, distribution, and consumption of wealth; or of decision making—descriptions that sacrifice much for the sake of brevity. Within these relatively vague definitions lie fascinating questions and critical policy implications. Traditional economic analysis has been used to explain why people who are overweight tend to have lower incomes than those who are thin as well as why some nations grow faster than others. Economists have explored why people gamble even though they are likely to lose money as well as why stock markets respond in predictable or unpredictable ways to external events. They develop models to analyze how tax policies affect philanthropy and how managers of baseball teams can determine which players are worth their salary demands. The range of questions that falls within the domain of economic analysis is much broader (and more interesting) than those suggested by the traditional definition of the discipline.

The value of economic analysis in development of policies to address social issues is also much broader than generally perceived. Economists have played a critical role in the development of policies aimed at protecting endangered species and addressing global warming and climate change. They contribute to development of policies that will curb smoking, promote entrepreneurship, reduce crime, and promote educational quality and equality. And they also provide the theory and evidence that is applied in policy arenas more traditionally thought of as being in the purview of the discipline—managing unemployment, economic growth, and inflation; regulating industries to promote competition, innovation, and efficient outcomes; and developing tax policies and rates that achieve a range of possible objectives.

Encompassing analysis of traditional economic theory and topics as well as those that economists have only more recently addressed, this handbook will meet the needs of several types of readers. Undergraduate students preparing for exams will find summaries of theory and models in key areas of micro- and macroeconomics. Readers interested in learning about economic analysis of a topic or issue as well as students developing research papers will find introductions to relevant theory and empirical evidence. And economists seeking to learn about extensions of analysis into new areas or about new approaches will benefit from chapters that introduce cutting-edge topics.

Authors of chapters in this handbook come from universities and policy institutes around the world. They represent well-known, distinguished scholars as well as doctoral students working in areas that have only recently gained the attention of economists. Perhaps most important, they reflect the full range of ideological, methodological, and political orientations and perspectives present in the discipline. Authors were selected based on their ability to accurately, succinctly, and clearly address the chapter topic and to present a balanced approach to the analysis, but while some of the authors represent the orthodox approach to economics, others reflect one that is more radical. The willingness of economists from various schools of thought and with diverse orientations and perspectives to contribute chapters has certainly been of benefit to this book.

For most authors, the biggest challenge in writing their chapter will have been the need to avoid using calculus and to limit the level of technical and quantitative detail. Calculus is like shorthand for economists; it provides them

with a quick and efficient means of analyzing and explaining relationships between economic variables. It is the language economists are comfortable using; it is the language they were trained in. Furthermore, economists are accustomed to discussing empirical evidence in terms of results of complex statistical tests and econometric methods. But to make the book accessible to undergraduate students and to nonacademic readers, it was essential that models be presented only in graphical format, or with minimal calculus, and that empirical evidence be summarized in a way that does not require much background in statistics or econometrics. The authors have been remarkably successful in achieving this goal, which for most will have required very careful thought and many revisions. To help readers understand some of the empirical parts of the chapters, there is a separate chapter that reviews basic concepts in econometrics. Readers challenged by more difficult models and applications may find it helpful to read some of the earlier chapters that review basic theories and models. For those readers who want more technical detail or empirical evidence, each chapter includes a list of related readings. The chapters in this book provide a good place to begin researching or studying a topic in economics, and they also provide direction for where to go next.

To the extent possible, the chapters in the book follow a common format. They begin with a review of theory and then examine applications of the theory, relevant empirical evidence, policy implications, and future directions. This format reflects the typical approach of economists to a topic. They begin by asking what theory or models exist to help in understanding the behavior of the participants in decisions related to the topic. Participants may be consumers, producers, resource owners, agents of government bodies, or third parties who are affected by but not in control of the decisions made by other participants. Often, existing models will be sufficient for understanding the decision-making process, but if not, existing models will be modified or expanded or, occasionally, entirely new models may be developed.

The theoretical base is then applied to the decisions and behavior of participants relevant to the topic being explored. For example, an economist examining the decisions of owners of professional baseball teams may find that traditional models of profit maximization provide a good base but that they have to be modified to take into account motives that include status or pleasure in addition to profit. Whether existing or modified models are used, the economist's objective is to ask whether the theory or model can take into account the unique considerations critical to the topic.

Once the theory or model is developed, empirical evidence is explored, usually using statistical and econometric tools, to evaluate the ability of the model to predict outcomes. If the data lend support to the model, the model can then be used to predict outcomes. It is at this point that economic analysis leads to policy implications. Once economists have models that explain decision making and predict outcomes, policy makers have the basis for altering incentives to lead economic agents to make desirable choices. For example, once economists have identified the key variables influencing consumers' decisions about how much sugary soda to drink or whether or not to recycle soda cans, policy makers can establish or modify incentives for consumers to change their soda consumption and to recycle their cans instead of putting them in the trash.

The format of most chapters—theory, applications, empirical evidence, policy implications—is consistent with this common approach to economic analysis. Following the section on policy implications, most chapters discuss future directions—what are the new but related questions that are likely to be explored by economists; what new methods are being developed to analyze data on the topic; what insights from other disciplines are likely to be applied to this topic; what policies are likely to be developed related to the topic? Chapters in the book generally reflect this approach and the resulting format, but given the wide range of topics addressed, the format is not appropriate in every chapter. Some of the initial theory chapters, methodology chapters, and history chapters more logically follow a different structure, and common format has been sacrificed in favor of following the logic.

Identifying 100 economists to write chapters in their areas of expertise has been made easier by the assistance of the members of the editorial board. Jeff Ankrom from Wittenburg University, Robin Bartlett from Denison College, Karl Case from Wellesley College, and Wendy Stock from Montana State University provided contacts with economists from a wide range of universities and perspectives. In some cases, a potential author could not work this chapter into his or her writing schedule but provided information about young colleagues who were working in the same area. Some of the chapters dealing with more cutting-edge topics were written by economists identified in this roundabout way.

The members of the editorial board were also very helpful in identifying the list of topics that are represented in the 92 chapters of the handbook. And again, many good suggestions were made by authors who were contacted about writing on one topic but felt that the book would benefit from a new area of their research or from the work of a colleague. In a field as expansive as economics, these suggestions were invaluable.

Members of the editorial board also made valuable contributions to the book by reviewing many of the chapters and providing insights and suggestions for authors who, invariably, accepted recommendations with enthusiasm. The comments of other economists and policy makers who reviewed chapters have also contributed to ensuring that the book is correct, current, and balanced.

Jim Brace-Thompson, Acquisitions Editor, was an inspiring and reassuring voice from the inception of this project. Sanford Robinson, Developmental Editor, provided

needed advice, prompting, and encouragement throughout the writing process. I am very grateful to both of them.

Laura Notton and Leticia Gutierrez, SAGE Reference Systems Coordinators, are surely some of the most patient people I've worked with. They promptly answered innumerable questions and resolved the never-ending stream of technical problems associated with publishing a book with 100 authors.

Of course, the greatest thanks are owed to the authors of these chapters, many of whom struggled through multiple revisions to find just the right level of detail and depth of analysis. Explaining economics without calculus was a challenge for many of them, but they all succeeded in providing explanations that will be accessible to college students and other readers. Authors were also diligent about finding the most recent evidence and most interesting applications, writing right up to deadlines so that they could incorporate the latest government figures, conference proceedings, and journal articles. For senior economists whose contributions to this handbook reflect many years of work on a topic, I hope that it has been gratifying to write a chapter that is likely to provide crucial information and inspiration for many undergraduates as they embark on research projects. For younger contributors for whom this may be the first publication, I hope that this is just the first of many valuable contributions that will made to the discipline.

Working with 100 authors around the world meant that for the last few years I have been e-mailing, editing entries, and managing reviews during vacations, on holidays, and on weekends at all hours of the day and night. I am grateful to my children, Lindsey and Graham, who continued to be patient and understanding when I worked at times when I should not have and when I did not pay attention to the most important things in life.

# About the Editor

**Rhona C. Free** (PhD, University of Notre Dame) is Vice President of Academic Affairs and a professor of economics at Eastern Connecticut State University. She was honored in 2004 as a Professor of the Year National Winner from The Carnegie Foundation for the Advancement of Teaching and the Council for Advancement and Support of Education. She was a founding member of the Connecticut Consortium for Learning and Teaching and of the Connecticut Campus Compact. In 2001, Free received ECSU's Distinguished Faculty Member Award.

Free is the author of many textbook supplements and has consulted frequently in the development of principles of economics textbooks. She has written on a range of topics, including teaching with technology and accommodating students with learning disabilities. Free's research interests focus on earnings differences by race and gender. Her current research analyzes effects of college major choice on differences by race and gender in expected starting salaries.

# About the Contributors

**Christopher Ross Bell** is an associate professor of economics at the University of North Carolina at Asheville. He received his BA from the University of California, Berkeley and his PhD in economics from the University of Pennsylvania. His main research areas are transaction cost economics, especially its intersection with political economy, and teaching economics as a laboratory science. He is also interested in Web programming and Web design and is taking advantage of those interests to create a Web application that will allow economics professors to display automatically updated economic data on their class Web sites.

**Nathan Berg** is an associate professor of economics in the School of Economic, Political, and Policy Sciences (EPPS) at University of Texas–Dallas. He has published more than 40 articles and chapters in behavioral economics since 2001 in journals such as *Journal of Economic Behavior and Organization, Social Choice and Welfare,* and *Contemporary Economic Policy.* Berg was a Fulbright Scholar in 2003, and his research has been cited in *BusinessWeek,* Canada's *National Post, The Village Voice, The Advocate,* and *Atlantic Monthly.* Berg spent 2005 at the Max Planck Institute–Berlin, Center for Adaptive Behavior and Cognition. In 2006, Berg was appointed to the editorial board of *Journal of Socio-Economics* and elected to the Board of the Society for the Advancement of Behavioral Economics. He sings and writes for the acoustic rock band Halliburton(s), and links to his work as a movie actor can be found at www.nathanberg.net.

**Mahadev Ganapati Bhat** is an associate professor of natural resource economics in the departments of earth and environment and economics at Florida International University. His current research focuses on the economics of coastal and marine resources, ecosystem restoration, water resources, and payment for environmental services. He is specialized in applying quantitative techniques—namely, spatiotemporal dynamic models, game-theoretic models, economic input-output models, and economic valuation techniques—to environmental problem solving. His research projects have been funded by the Everglades National Park, U.S. Department of Agriculture, U.S. Agency for International Development, the World Bank, the Government of India, and Ford Foundation. He has more than 150 publications, including refereed articles (30), conference publications, research reports, and book chapters. Dr. Bhat is a Berg Fellow of the Soil and Water Conservation Society. He routinely serves as a referee for several professional journals and is on the editorial board of the *Journal of Sustainable Agriculture*. Dr. Bhat received his PhD in agricultural economics (with specialization in natural resource economics) from the University of Tennessee in 1991 and a master's degree in the same area from the University of Agricultural Sciences, Dharwad, India, in 1983.

**Lyda S. Bigelow** is an assistant professor of strategy at the David Eccles School of Business, University of Utah. She received her PhD from the University of California, Berkeley. Her research focuses on using transaction cost economics to assess the impact of efficient boundary of the firm decisions (e.g., make-or-buy decisions, strategic alliances) on firm performance. Her most recent work has investigated the trade-offs of managing efficient sourcing arrangements under conditions of rapid technological innovation. Her work has appeared in the *Strategic Management Journal, Management Science,* and the *Journal of Economic and Organizational Behavior,* and she has won Best Paper awards from both the Entrepreneurship and Business Policy and Strategy Divisions of the Academy of Management. She is a member of the editorial board of the *Strategic Management Journal.* Prior to joining the faculty of the David Eccles School of Business at the University of Utah, she was a strategy professor at the John M. Olin School of Business, Washington University in St. Louis.

**Peter J. Boettke** is the BB&T Professor for the Study of Capitalism and University Professor of Economics at George Mason University (GMU). He received his PhD in economics from GMU in 1989. Prior to returning to GMU in 1998, Boettke held faculty positions at New York University and the Hoover Institution at Stanford University. Boettke's research is in the areas of comparative political and economic systems and their consequences with regard to material progress and political freedom, as well as twentieth-century economic thought and the methodology of the social sciences.

**Robert A. Boland** is a clinical assistant professor of sports management at New York University. He received his JD from Samford University's Cumberland School of Law and his AB degree from Columbia University. An admitted attorney and certified sports agent, his research interests

include collective bargaining, labor law, player compensation and antitrust law issues, and the history and social implication of sports.

**Michael E. Bradley** is a professor of economics at University of Maryland, Baltimore County. He received his AB degree from Albion College and his MS and PhD degrees from Cornell University. He has taught at Pennsylvania State University, Cornell University, the Paul H. Nitzke School of International Studies of the Johns Hopkins University, the U.S. Department of State Foreign Service Institute, and Colgate University. He has published articles and book chapters in the areas of comparative economics, international economics, and history of economic thought. He is the author of a two-volume text, *Microeconomics* (2nd ed.) and *Macroeconomics* (2nd ed.). His current teaching and research is in intermediate and graduate microeconomics, history of economics, and economic history of Russia and the USSR.

**Jennifer L. Brown** is an assistant professor in the department of economics at Eastern Connecticut State University. She earned her PhD in economics from the University of California, Santa Barbara. Her research focuses on environmental economics, energy economics, and industrial organization. Her most recent work evaluates the impact that environmental regulations have historically had on the petroleum industry. Additional work has focused on analyzing the impact that global climate change is expected to have on the economies of least developed countries.

**James D. Burnell** is a professor of economics and currently the chair of the urban studies program at the College of Wooster. He received his PhD from the University of Illinois in 1978. His research has recently focused on land use issues with particular consideration of the strategic interaction of the zoning decisions of suburban communities. His current research is on the neighborhood spillovers associated with housing tenure decisions and the availability of mortgage funds.

**Peter T. Calcagno** is an associate professor of economics in the department of economics and finance and director of the Initiative for Public Choice & Market Process at the College of Charleston. He received his PhD in economics from Auburn University. His research focuses on public choice and the political economy of voting institutions. He has published a number of articles in academic journals, including *Public Choice, Economics of Governance, Public Finance Review,* and the *Journal of Public Finance and Public Choice.*

**Neil Canaday** is currently a visiting assistant professor at Wesleyan University. His areas of interest include economic history, public finance, and labor economics. Related to public finance, he has publications examining tax assessment policy and discrimination in school resources during segregation.

**Ping Ching Winnie Chan** is a research economist in the analysis branch of Statistics Canada. She received her PhD from the University of Toronto in 2009. Her dissertation is on school choice and public school performance, and her research focuses on the economics of education, public economics, and labor economics.

**Carmel U. Chiswick** is a professor of economics (emeritus) at the University of Illinois at Chicago. She earned her PhD in economics from Columbia University in 1972, specializing in economic development, labor economics, and economic history. Her recent research focuses on the economics of religion, and she is a founding member of the Association for the Study of Religion, Economics and Culture (ASREC). A selection of her articles on Judaism from various journals and reports is now available in *The Economics of American Judaism* (2008).

**Victor V. Claar** is an associate professor of economics at Henderson State University, the public liberal arts college of Arkansas. He earned his PhD in economics at West Virginia University, where he wrote his doctoral dissertation under the guidance of Ronald Balvers. Prior to Henderson he held the rank of associate professor of economics (with tenure) at Hope College in Michigan, where he taught from 2000 to 2009. He spent a recent year as a Fulbright Scholar in Armenia giving graduate lectures and conducting research at the American University of Armenia. Claar is coauthor, with Robin J. Klay, of *Economics in Christian Perspective: Theory, Policy and Life Choices* (2007), and his scholarly articles have appeared in several peer-reviewed outlets, including *Applied Economics, Public Finance Review, and the Journal of Markets & Morality*. He recently completed work on a short book about fair trade, scheduled to be published by the Acton Institute in 2010.

**Paul F. Clark** is a professor and head of the department of labor studies and employment relations at Pennsylvania State University. He received his PhD in public policy and administration from the University of Pittsburgh. His research has focused on the structure and government of American unions and on collective bargaining in the coal, steel, and health care industries.

**Richard D. Coe** is an associate professor of economics at New College of Florida in Sarasota. He received a PhD in economics (1979) and a JD (1978) from the University of Michigan. His research has included issues in welfare use, the definition of poverty, and the legal requirements for a land tax.

**Richard R. Cornwall** is a professor emeritus of economics at Middlebury College in Middlebury, Vermont. He received a PhD in economics in 1968 from the University of California, Berkeley. His work has been in mathematical microeconomics and queer theory. Since 1998, he has been retired from teaching and living in San Francisco, devoting full time to research on the interaction between markets and social identities.

**Kenneth A. Couch** is an associate professor in the department of economics at the University of Connecticut and director of the Center for Population Research. He received his PhD and a master's degree from the University of Wisconsin and holds a master's degree from the University of Glasgow. His research interests include wage determination, disadvantaged groups in the labor market, and policy evaluation.

**Rosemary Thomas Cunningham** is the Hal and Julia T. Smith Professor of Free Enterprise in the department of economics at Agnes Scott College. Cunningham received her BA in mathematics/economics, MA in economics, and PhD in economics at Fordham University. Prior to coming to Agnes Scott College in 1985, she was an assistant professor at Fairfield University.

**Christopher S. Decker** is an associate professor of economics at the University of Nebraska at Omaha (UNO). He received his PhD in business economics from Indiana University's Kelley School of Business in 2000 and currently teaches managerial economics in UNO's MBA program. Decker has published numerous journal articles in the fields of environmental regulation, energy economics, and industrial organization. Recent work has focused on the market structure and workplace accident rates.

**George F. DeMartino** is an economist at the Josef Korbel School of International Studies, University of Denver. He has written extensively on economics and ethics, particularly in the context of international economic integration. He is the author of *Global Economy, Global Justice: Theoretical Objections and Policy Alternatives to Neoliberalism* (2000) and *The Economist's Oath: On the Need for and Content of Professional Economic Ethics* (in press).

**Gillian Doyle** (BA, Trinity College Dublin; PhD, University of Stirling) is the director of the Masters Programme in Media Management at the Centre for Cultural Policy Research at the University of Glasgow and is a visiting professor at the Institute of Media and Communications, University of Oslo. Her research interests are media economics and media and cultural policy, and she is currently President of the Association for Cultural Economics International (ACEI).

**Patricia A. Duffy** is Alumni Professor of Agricultural Economics and assistant provost for Undergraduate Studies at Auburn University. She received her PhD from Texas A&M University. She is the coauthor of *Farm Management* (6th ed.) and has authored or coauthored numerous journal articles in the areas of farm management and applied policy analysis. Her current research interests concern problems in farm management as well as the effect of nutrition programs on food security, diet quality, and obesity.

**Isaac Ehrlich** is State University of New York and University of Buffalo Distinguished Professor of Economics, Melvin H. Baker professor of American Enterprise, chair of the department of economics, and director of the Center of Excellence on Human Capital at the State University of New York at Buffalo. He is also a research associate at the National Bureau of Economic Research and editor-in-chief of the *Journal of Human Capital,* published by the University of Chicago Press. Ehrlich received his PhD from Columbia University and served as assistant and associate professor of business economics at the University of Chicago before joining SUNY Buffalo. He is one of the founders and leaders of the literature on the economics of crime and justice and has published extensively on other topics in leading journals of economics. He has been listed among the top 100 economists in published citations and has been included in all issues of *Who's Who in Economics: A Biographical Dictionary of Major Economists 1700–1980,* as well all of its later editions.

**Seda Ertaç** received her PhD in economics from the University of California, Los Angeles in 2006. She then joined the economics department of the University of Chicago as a postdoctoral scholar and is currently an assistant professor of economics at Koç University. Dr. Ertaç's fields of research are applied microeconomic theory and experimental economics. Her research agenda includes theoretically and experimentally studying the links between imperfect information and incentive systems in the context of effort and motivation in organizations, as well as the effects of gender and personality on economic behavior. Dr. Ertaç's experimental work to date has been supported by the U.S. National Science Foundation, Russell Sage Foundation, and the European Union.

**Erick Eschker** is a professor and chair of the department of economics at Humboldt State University, Arcata, California. He earned his PhD in economics from the University of California, Davis in 1997 and his bachelor's degree in economics from the University of Illinois, Urbana-Champaign. He was a research economist with the American Medical Association and is currently the director of the Humboldt Economic Index, which collects and analyzes data on the regional economy.

**Viktar Fedaseyeu** is currently a doctoral candidate in finance at Boston College. His primary research interests include bounded rationality, behavioral finance, corporate social responsibility, and the way financial markets react to uncertain information. He holds a degree in economics from Belarus State Economic University and was a student at Eastern Connecticut State University.

**Ann Harper Fender** is a professor of economics (emeritus) at Gettysburg College, Gettysburg, Pennsylvania. She received her PhD from Johns Hopkins University. Her research involves studies of the economics of the fur trade and contemporary issues relating to the structure of the telecommunications industry.

**Aju Fenn** is the John L. Knight Professor of Free Enterprise and chair of the department of economics and

business at Colorado College in Colorado Springs, Colorado. Past honors include the Lloyd E. Worner Teacher of the Year award and the John D. and Catherine T. MacArthur professorship. He teaches the economics of sports, mathematical economics, intermediate microeconomic theory, research methods and econometrics. He also specializes in the economics of addiction. His work in sports economics focuses on the measurement of competitive balance in sports and the determinants of competitive balance. He has also published work on the value of a sports team to an area. He has served as a referee for journals such as *Economics Letters, Southern Economic Journal, Contemporary Economic Policy, International Journal of Sport Finance,* and *Journal of Sports Economics.*

**Satyananda J. Gabriel** is a professor and chair in the department of economics at Mount Holyoke College in South Hadley, Massachusetts, and academic coordinator of the Rural Development Leadership Conference Summer Institute at the University of California, Davis. He received his PhD from the University of Massachusetts at Amherst. Gabriel is the author of *Chinese Capitalism and the Modernist Vision* (2006) and *Rising Technomass: The Political Economy of Social Transformation in Cyberspace* (2010). His current research interests include Chinese and East Asian economic development, corporate finance, and comparative economic systems.

**Thomas Gall** is an assistant professor of economics at the University of Bonn in Germany. He obtained his diploma in 2001 after his undergraduate studies in economics at the University of Munich, Germany, and Pompeu Fabra University in Barcelona, Spain. In 2005, he completed a PhD in economics after graduate studies at Mannheim University, Germany, and University College London, UK. His research interests lie in microeconomic theory, and he has published on imperfect matching markets, occupational choice, and development economics.

**Lawrence D. Gwinn** is an associate professor of Economics and Chair of the department of economics at Wittenberg University, Springfield, Ohio. He received his PhD from the University of Kansas. His research interests include the international transmission of economic disturbances and monetary policy effectiveness under alternate exchange rate systems.

**Thomas W. Harvey,** DBA, is an associate professor of finance and the director of the Institute for Contemporary Financial Studies at Ashland (Ohio) University, where he is responsible for the asset management track of the finance curriculum and for directing various student research initiatives. Dr. Harvey received his doctorate in management strategy and international business from Cleveland State University. His MBA is in finance from Case Western Reserve University, with his BA in English from Hillsdale College. Dr. Harvey's research interest is behavioral finance and the changing nature of investor behavior. He is also a student of the financial markets in the United States and has published two books that focus on the commercial banking industry: *Quality Value Banking*, with Janet L. Gray, and *The Banking Revolution*. Prior to joining the faculty at Ashland, Dr. Harvey's career was spent in the commercial banking industry.

**Sue Headlee** is an associate professor of economics at American University, Washington, D.C., where she teaches the Washington Semester Program in Economic Policy. She received her PhD in economics at American University. She is the author of three books: *The Political Economy of the Family Farm: The Agrarian Roots of American Capitalism; The Cost of Being Female,* coauthored with Margery Elfin; and *A Year Inside the Beltway: Making Economic Policy in Washington.* She is the author of two articles: "Income and Wealth Transfer Effects of Discrimination in Employment: The Case of African Americans, 1972–1990," in *The Review of Black Political Economy,* and "Economic History, Western Europe," in the *Elgar Companion to Feminist Economics.*

**Gillian Hewitson** is in the political economy department at the University of Sydney. She received her PhD in economics and women's studies from La Trobe University in Melbourne, Australia. She is the author of *Feminist Economics* (1999) and journal articles and book chapters in the areas of feminist economics and monetary theory. Her current research interests include gender, race, and class in the history of economic thought, particularly in relation to Australia, and the political economy of the food supply.

**Michael Hillard** is a professor of economics at the University of Southern Maine. He has published widely in the fields of labor relations, labor history, and the political economy of labor in academic journals, including *Labor: Studies in the Working Class Histories of the Americas, Labor History, Review of Radical Political Economics, Advances in Industrial and Labor Relations, Journal of Economic Issues, Historical Studies in Industrial Relations,* and *Rethinking Marxism.* He has coauthored many articles on a Marxian analysis of industrial relations with Richard McIntyre, professor of economics at the University of Rhode Island. His essay titled "Labor at Mother Warren" won Labor History's "Best Essay, U.S. Topic" prize for 2004.

**Steven Horwitz** is the Charles A. Dana Professor of Economics at St. Lawrence University in Canton, New York. His PhD is from George Mason University, and he has written extensively on the Austrian School of Economics, macroeconomics, and political economy, as well as recent work on the economics and social theory of the family. He is currently completing a book manuscript on classical liberalism and the evolution of the western family.

**David Hudgins,** lecturing professor of economics at the University of Oklahoma, received his PhD in 1993 from the University of Illinois at Urbana-Champaign. He is also

a Certified Financial Manager and has served as a financial adviser for Merrill Lynch. His recent publications include articles in *Computational Economics* and *Review of Applied Economics.*

**Shawn Humphrey** is an assistant professor of economics at the University of Mary Washington in Fredericksburg, Virginia. He earned his PhD from Washington University in Saint Louis. His research is concerned with uncovering the political-military foundations of economic prosperity.

**Steven L. Husted** is a professor of economics at the University of Pittsburgh. Professor Husted has published widely in the areas of international trade, international finance, and monetary economics and is coauthor with Michael Melvin of a popular textbook on international economics. In 1986–1987, he spent a year as a senior staff economist specializing on trade policy issues on the President's Council of Economic Advisers. He has had wide-ranging international experience, including visiting appointments to the Australian National University, the University of Glasgow, and the University of Strathclyde. His current research interests include studies of the growth and geographic extent of Chinese exports, financial capital flows to developed economies, and long-run exchange rate behavior.

**Lee H. Igel** is a clinical assistant professor of sports management at New York University. He received his PhD in industrial/organizational psychology from Capella University and holds degrees in both counseling and clinical exercise physiology from Boston University. A frequent writer and speaker on human affairs, his areas of study are in management and organizations.

**Elizabeth J. Jensen** is a professor of economics at Hamilton College in Clinton, New York, where she has taught since 1983. Professor Jensen received a BA in economics from Swarthmore College and a PhD in economics from the Massachusetts Institute of Technology. Before coming to Hamilton, she worked at the Council of Economic Advisers. Professor Jensen has been honored for her teaching, receiving a prestigious award for outstanding teaching from Hamilton College. Jensen is coauthor of *Industrial Organization: Theory and Practice,* a leading industrial organization textbook developed in part from experiences teaching students at Hamilton College. Her recent work investigates the predictors of academic success in college, student course choice, and the determinants of students' interest in economics. Jensen teaches courses in industrial organization, antitrust and regulation, American economic history, and microeconomic theory.

**Shirley Johnson-Lans** is a professor and the chair of the department of economics, Vassar College. A labor economist who teaches and does research in the areas of health economics, economics of education, and gender studies, she is the author of *A Health Economics Primer* (2006) and of numerous articles and working papers. She is a member of the City University of New York/Columbia University faculty seminar on demography and health economics and of the New York Health Policy Group. She holds a PhD in economics from Columbia University; an MA in political economy from Edinburgh University, where she was a Marshall Scholar; and a BA magna cum laude in philosophy from Harvard.

**Nicholas A. Jolly** is a visiting assistant professor in the department of economics at Central Michigan University. He received his master's and PhD in economics from the University of Connecticut. Prior to joining the faculty at Central Michigan University, he worked as an economist at the Connecticut Department of Labor. His research interests include wage determination, job displacement, applied microeconomics, and policy analysis.

**Rebecca P. Judge** is an associate professor of economics and environmental studies at St. Olaf College in Northfield, Minnesota. After receiving her MS in biology from the University of Minnesota, Duluth, and her PhD in economics from Duke University, she has spent her career engaged in questions relating to the intersection of economics and the environment. Her publications include a study exploring least-cost methods for implementing an endangered species preservation constraint on public lands, an analysis of household response to alternative incentives to engage in recycling, and an exploration of the property regimes influencing John Locke in the development of his theory of property.

**Fadhel Kaboub** is an assistant professor of economics at Denison University (Granville, Ohio) and research associate at the Levy Economics Institute of Bard College (New York), the Center for Full Employment and Price Stability (Missouri), and the International Economic Policy Institute (Ontario, Canada). He taught at Drew University, where he was also co-director of the Wall Street Semester Program; the University of Missouri–Kansas City (UMKC); and Bard College at Simon's Rock. Kaboub's research is in the post-Keynesian and institutionalist tradition in the fields of macroeconomic theory and policy, monetary theory and policy, and economic development. His work has been published in the *Journal of Economic Issues, Review of Radical Political Economics, Review of Social Economy, International Journal of Political Economy,* and *International Labour Review*. He has been a member of the editorial board of the *Review of Radical Political Economics* since 2006 and has been the book review editor of the *Heterodox Economics Newsletter* since 2007. He holds a PhD in economics from UMKC.

**Bradley P. Kamp** is an associate professor of economics at the University of South Florida. His areas of interest include product quality, predatory pricing, and signaling models. His work has appeared in journals such as *International Journal of Industrial Organization, Southern Economic Journal, Economic Inquiry,* and *Review of Law and Economics.* He earned a BA from the University of Illinois and a PhD from the University of California, San Diego.

**Pavel S. Kapinos** is an assistant professor of economics at Carleton College in Minnesota. He received his PhD in economics from the University of Illinois at Urbana-Champaign. His research focuses on the optimal design of monetary policy.

**Stephen H. Karlson** is an associate professor of economics at Northern Illinois University. He completed a PhD in economics from the University of Wisconsin at Madison in 1980. His research interests have included regulation of electric utilities, technology adoption in steelmaking, and irreversible investments. He is currently an Environmental and Energy Policy Scientist with Argonne National Laboratories on a temporary basis.

**Peter Kennedy** is professor emeritus at Simon Fraser University, Canada. He received his BA from Queen's and his PhD from Wisconsin. He has published widely in economic education and in econometrics and is best known for his book *A Guide to Econometrics,* perhaps the best single source on the full range of econometric topics.

**Markus Kitzmueller** is an Erb Postdoctoral Research Fellow at the S. M. Ross School of Business/SNRE of the University of Michigan (Ann Arbor). Currently, he is expecting his PhD in economics as a Researcher of the European University Institute (EUI) in Florence (Italy). He has graduated magna cum laude with an MA in European Economic Studies from the College of Europe in Bruges (Belgium) and has worked for the European Commission (DG ECFIN) in 2004–2005. His research focus is on applied microeconomics, especially information economics, contract and organization theory, industrial organization, as well as public economics. Current interests center on the interaction between strategic firm behavior and public policy in light of corporate social responsibility.

**Kevin C. Klein** is a professor of economics at Illinois College in Jacksonville, Illinois. Dr. Klein earned a Doctorate of Arts in Economic Education at Illinois State University. His teaching focus is economics at the principles and intermediate undergraduate levels with special interest in environmental economics. He has authored or coauthored several teaching manuals, test banks, and study guides. He is also a coauthor of a survey of economics textbook.

**Agneta Kruse** is a senior lecturer in economics at Lund University in Sweden. Her research focuses on economics of social insurance and pension systems. She served as an expert to the parliamentary Commission on Pensions preceding the Swedish pension reform. She analyzes, among other things, pay-as-you-go pension systems and their sustainability encountering demographic and economic changes as well as the political economy of pension reforms. She has published articles in journals and contributed chapters to a number of books. Lately, she has also been working on globalization and social insurance.

**Roy Love** obtained his PhD at the University of Leeds (UK). He has lectured in economics at the universities of Botswana, Lesotho, and Addis Ababa and at Sheffield Hallam University, England. He has publications on the subject of HIV/AIDS and is currently an independent researcher and consultant with experience of economic evaluation for major international donors on HIV/AIDS and health projects in Africa.

**Yahya M. Madra** teaches political economy and history of economics at Gettysburg College. He is also an associate editor of *Rethinking Marxism: A Journal of Society, Economics and Culture.* He has published on the methodology and philosophy of economics, as well as the intersection between Marxian political economy and Lacanian psychoanalysis. His writings have appeared in the *Journal of Economic Issues, Rethinking Marxism, Psychoanalysis, Society and Culture,* and edited volumes. Currently, he is working on the intellectual genealogy of neoliberalism and its variants.

**Leah Greden Mathews** earned her PhD in agricultural and applied economics from the University of Minnesota and is associate professor of Economics at the University of North Carolina at Asheville. Her research as an environmental economist has focused on nonmarket valuation and the links between economics and policy. Dr. Mathews's current research, The Farmland Values Project, estimates the values that communities in western North Carolina have for farmland, with particular attention to those values that are not typically exchanged in markets such as scenic beauty and cultural heritage.

**Sandra Maximiano** is an assistant professor of economics at Krannert School of Management, Purdue University. After receiving her PhD from the University of Amsterdam, in 2007 she started as a postdoctoral scholar in the economics department of the University of Chicago. Dr. Maximiano's research interests lie in the fields of behavioral and experimental economics, labor economics, economics of education, and organizational economics. Her projects span various issues and are built on both laboratory and field experiments and microeconometric tools to investigate questions related to social preferences and reciprocity, education and training, incentive systems, and gender and culture differences in economic decisions.

**Ken McCormick** is a professor of economics at the University of Northern Iowa. He was an early critic of the AD/AS model. McCormick has published numerous papers on a variety of topics, including the AD/AS model. His book *Veblen in Plain English* (2006) has been well received and led to an appearance on the *Bob Edwards Show.*

**Rachel McCulloch** is the Rosen Family Professor of International Finance at Brandeis University. Prior to her appointment at Brandeis, she was a faculty member at the University of Chicago, Harvard University, and the University of Wisconsin–Madison. She received her PhD in economics from the University of Chicago in 1973. Her current research focuses on international economic policy.

**John D. Messier** is an assistant professor of economics at the University of Maine at Farmington. He earned his PhD from American University and studies international development issues. Dr. Messier spent 5 months in Ecuador working with informal workers on credit issues and the impact of financial shocks on well-being. Currently, Dr. Messier is working on the impact of fair trade on income and nutrition for coffee producers in Nicaragua.

**Laurence Miners** is the director of the Center for Academic Excellence and a professor of economics at Fairfield University in Fairfield, Connecticut. He earned his doctorate in economics at the University of North Carolina at Chapel Hill. His research interests focus primarily on economic pedagogy and course design. He has led faculty development workshops at other colleges and universities and made presentations at regional and national conferences focusing on both economics and pedagogy.

**Michael R. Montgomery** is an associate professor of economics at the University of Maine. He received his PhD from the University of Florida. He works in macroeconomics, monetary theory, and public economics. He has done work on the history of macroeconomics as well as applied work on the macroeconomic implications of time-intensive capital production periods and complementarity between types of capital goods.

**Mehdi Mostaghimi** is a faculty member in the school of business at Southern Connecticut State University. He is the author of many journal articles, book chapters, and technical reports on economic turning point forecasting, combining forecasts, consensus and group decision making, and strategic decision making.

**Shannon Mudd** has ventured between academics and nonacademics in his career as an economist. While completing a PhD in economics at the University of Chicago, he spent 2 years working as an analyst for the Federal Reserve Bank of Atlanta and taught for another year at Comenius University in Bratislava, Slovakia. After finishing his degree, he spent 4 years working on a USAID project in Moscow on taxation and intergovernmental relations. He has taught at the MA, MBA, and undergraduate levels and is currently an assistant professor at Ursinus College. His research has most recently focused on issues of access to finance for small- and medium-sized enterprises and the effect of banking crises on future expectations of banking crises.

**Sean E. Mulholland** is an associate professor of economics at Stonehill College. He received his BS and MA in economics from Clemson University in 1997 and 2001, respectively. He earned his PhD in applied economics from Clemson University in 2004. His research interests include the long-run economic growth within the United States, the economics of race and religion, and private and public land conservation.

**Kathryn Nantz** is an associate professor of economics at Fairfield University in Fairfield, Connecticut. She earned her PhD from Purdue University. Her teaching and research work is primarily at the intersections of the fields of labor economics and comparative economic systems. She is interested in how various incentive structures affect the behavior of workers in their jobs and in how political and cultural norms can create widely varying labor market outcomes in different settings.

**Lena Nekby** received her PhD from Stockholm University and is now an assistant professor at the department of economics, Stockholm University, and affiliated with the Stockholm University Linnaeus Center for Integration Studies (SULCIS). She is also an IZA Research Fellow. Her research is focused primarily on labor market issues relating to ethnicity, migration, and gender.

**Christopher J. Niggle** received his BA from Arizona State University (1967), MA from New School University (1970), and PhD in economics from the University of California, Riverside (1984). Since 1983, he has taught at the University of Redlands in Southern California, where his teaching responsibilities include courses in macroeconomics, money and banking, history of economic thought, and comparative economic systems. His research and publications have primarily been in the areas of money and macroeconomics. Current interests include comparisons of institutionalist and post-Keynesian macroeconomics with New Keynesian macroeconomics.

**Peter Nyberg** is an assistant professor at the Helsinki School of Economics. He obtained his PhD from the Hanken School of Economics in Helsinki. His research interests include asset pricing and financial econometrics.

**Lindsay Oldenski** is assistant professor of economics at the School of Foreign Service at Georgetown University. She received her PhD in economics from the University of California at San Diego, master's degree in public policy from the Kennedy School of Government at Harvard University, and BA from Guilford College. She has taught international trade and microeconomics at the Johns Hopkins University School of Advanced International Studies and at California State University, San Marcos. Her research interests include international trade in services and the organization of multinational activities.

**Anita Alves Pena** is an assistant professor of economics at Colorado State University. She received her PhD in economics from Stanford University in 2007, her MA in economics from Stanford University in 2004, and her BA in economics from the Johns Hopkins University in 2001. Her research interests are in public sector economics, economic development, and labor economics, and her current research relates to undocumented and documented immigration, public policy, poverty, and agricultural labor markets.

**Dante Monique Pirouz** is an assistant professor at the Ivey School of Business at the University of Western Ontario. She earned her PhD at the Paul Merage School of Business at the University of California, Irvine. Her

research interests include neuroeconomics and consumer decision making. Her current work focuses on the neural response of addictive product users such as cigarette smokers to marketing cues. She is a trained researcher in functional magnetic resonance imaging (fMRI) and has received the Athinoula A. Martinos Center for Biomedical Imaging Functional MRI Visiting Fellowship at Harvard Medical School and Massachusetts General Hospital. She also has an MBA from the Wharton School of Business and an MA from the Lauder Institute at the University of Pennsylvania, and she graduated cum laude with a BA from the University of California, Los Angeles.

**Clifford S. Poirot Jr.** is currently an associate professor of economics in the department of social sciences at Shawnee State University, where he teaches both standard economics courses as well as courses that focus on sociocultural evolution. He has also been the director of the Shawnee State University Honors Program and is currently president of the Faculty Senate. He completed his BS in economics and political science in 1984 at Guilford College, Greensboro, North Carolina, where he wrote an undergraduate thesis on the evolution of political violence in Guatemala. He received his PhD in economics in 1991 from the University of Utah, where he wrote his dissertation on the evolution of the open field system in late medieval and early modern England. He has also taught at Eastern Washington University in Spokane, Washington; the University of Timisoara in Timisoara, Romania, under the auspices of the Civic Education Project; the American University in Bulgaria, in Blagoevgrad; and Mary Washington College in Fredericksburg, Virginia. He is the author of multiple articles on sociocultural evolution and related topics and has published in the *Journal of Economic Issues, Journal of Post-Keynesian Economics,* and *The Forum for Social Economics.*

**Indrajit Ray** is a chaired professor in the department of economics, University of Birmingham, and currently leads the economic theory group in his department. His area of academic research is game theory, general equilibrium theory, experimental economics, and environmental economics. He was trained in premier institutions such as the Indian Statistical Institute, India, and CORE, Belgium. He has taught at University of York and Brown University. Professor Ray has published numerous research articles in international journals, including in premier journals in his field such as: *Games and Economic Behavior*, *Economic Theory*, *Journal of Mathematical Economics*, *Social Choice and Welfare*. He has served as an editor of the journal *Bulletin of Economic Research* during 2000–2005 and currently is the associate editor of the electronic open-access journal *Quantitative and Qualitative Analysis in Social Sciences*. He has visited different universities in several countries to present his research in workshops and seminars. Professor Ray is also an active educationist and the chairman of a trust called *Vidyapith* that supports education in India.

**Marta Reynal-Querol** is an ICREA Research Professor at the department of economics and business at Pompeu Fabra University. She is also an affiliated professor at the Barcelona Graduate School of Economics. She is a member of the editorial board of the *Journal of Conflict Resolution* and the *European Journal of Political Economy* and is associate editor of the *Spanish Economic Review*. She is an award holder of the ERC-starting grant, awarded by the European Research Council. She holds a PhD in economics from the London School of Economics and Political Science (2001) and Master with Honors from Pompeu Fabra University. Reynal-Querol worked at the World Bank between 2001 and 2005. Her research has been concentrated on the causes of civil wars and genocides, conflict resolution and the aftermath of conflict, aid effectiveness, and the economics of institutions. She has published in *American Economic Review, Review of Economics and Statistics, Economic Journal, Journal of Economic Growth, Journal of Development Economics, European Journal of Political Economy, Journal of Conflict Resolution, Journal of Comparative Economics, Defence and Peace Economics,* and *Economic Letters,* among others.

**Anthony M. Rufolo** is a professor of urban studies and planning at Portland State University, where he specializes in state and local finance, transportation, urban economics, and regional economic development. He has a BS in economics from the Massachusetts Institute of Technolocy and a PhD in economics from the University of California, Los Angeles. Prior to joining the faculty at Portland State in 1980, he spent 6 years as Economist and Senior Economist with the Federal Reserve Bank of Philadelphia. Dr. Rufolo has extensive experience in transportation research and policy, including analyses of articulated buses, weight-mile taxes for heavy vehicles, the effect of road capacity on the time distribution of travel, the effect of access to light rail on home values, and the effects of pricing on miles driven. Dr. Rufolo has served on the Economics Committee of the Transportation Research Board and has served as a Visiting Scholar at the U.S. Department of Transportation.

**Benjamin Russo** teaches economics at the University of North Carolina at Charlotte. He received a PhD in economics from the University of Iowa. His recent research studies the effects of taxation on economic growth and state and local taxes. Russo has served on a number of state tax study commissions and as a tax consultant to Department of Finance Canada.

**Julie Sadler** is an assistant professor, department of labor studies and employment relations, Penn State University. She earned her doctorate and master's degree from the School of Industrial and Labor Relations at Cornell University. Her research focuses on the internal dynamics of labor unions in the United States, with a particular emphasis on leadership development and member engagement labor unions and nonprofits.

**Steven J. Shulman** is a professor of economics at Colorado State University. He received his PhD, MA, and BA from the University of Massachusetts at Amherst. He is the editor of *The Impact of Immigration on African Americans* (2004) and the author of numerous scholarly articles on the economics of racial inequality, low-wage work, and immigration.

**Brian Snowdon** is currently a senior teaching fellow (part-time) at the department of economics and finance at Durham University, UK. Previously, before retiring, he was professor of economics at Newcastle Business School, Northumbria University. He received his undergraduate and postgraduate degrees in economics from Leicester University. His main research interests are in the areas of macroeconomics and international growth and development. As well as numerous articles in academic journals, he has authored/coauthored/coedited 10 books in the area of economics, including *Conversations on Growth, Stability and Trade* (2002), and *Modern Macroeconomics: Its Origins, Development and Current State* (with H. R. Vane, 2002). His most recent book, *Globalisation, Growth and Development: Conversations With Eminent Economists,* was published in 2007.

**Maritza Sotomayor** is a lecturer at Weber State University, Utah. She received her master's degree in economics in 1990 from Centro de Investigación y Docencias Económicas (CIDE), Mexico City, and her PhD in applied economics in 2008 from Universidad Autónoma de Barcelona, Spain. She has published chapters in books and coauthored journal articles. Her research interest includes intra-industry trade, *maquiladoras,* and Latin America's external trade.

**Lawrence M. Spizman** is professor of economics at the State University of New York at Oswego. He received his PhD in economics in 1977 from the State University of New York at Albany. He has been a practicing forensic economist since 1985. He has published 27 articles, with many of them in the field of forensic economics. Dr. Spizman has coauthored the seminal work on estimating the damages to a minor child, "Loss of Future Income in the Case of a Personal Injury to a Child: Parental Influence on a Child's Future Earnings." He is called to consult throughout the United States.

**Mikael Svensson** is an associate senior lecturer in economics at the Swedish Business School, Örebro University, Sweden. He is also an affiliated researcher at the Centre for Research on Child and Adolescent Mental Health at Karlstad University, Sweden. He received his PhD from the Swedish Business School at Örebro University in 2007. His current research interests include health economics and economic evaluation.

**Leila Simona Talani** joined the department of European studies of King's College London in 2009 as lecturer in International and European Political Economy. She was previously a lecturer in European Politics at the University of Bath and a research fellow and then lecturer at the European Research Institute of the London School of Economics. In 2001 she spent a year as associate expert on migration issues at the United Nations Office for Drug Control and Crime Prevention in Cairo. She gained a PhD with Distinction from the European University Institute in Florence in 1998. Her thesis has been published as Betting for and Against *EMU: Who Wins and Who Loses in Italy and the UK From the Process of European Monetary Integration* (2000). She is also author of *European Political Economy: Political Science Perspectives* (2004), *Between Growth and Stability: The Demise and Reform of the Stability and Growth Pact* (2008), *Back to Maastricht* (2008), *EU and the Balkans: Policy of Integration and Disintegration* (2008), *The Future of EMU* (2010), *From Egypt to Europe* (2010), and *The Global Crash* (in press). Her current research interests focus on the political economy of migration flows from southern Mediterranean countries to the EU and on the credibility of exchange rate commitments and economic agreements.

**Troy L. Tassier** is an associate professor of economics at Fordham University in New York City. Prior to his position at Fordham, he was a postdoctoral research fellow at the Center for the Study of Complex Systems at the University of Michigan. He received a PhD in economics from the University of Iowa in 2002. Dr. Tassier's research focuses on complex systems research in economics and particularly diffusion processes in social networks. He has published papers on the effects of referral hiring and social network structure on labor market inequality and segregation, the evolution of social networks to optimize job information flows, and how the structure of social networks influences the spread of fads and fashions. His current research continues the study of job information networks as well as additional topics such as the spread of infectious diseases across social networks, how the structure of firms and other organizations influences problem-solving capabilities, and mechanisms of public goods provision.

**Peter Skogman Thoursie** received his PhD from Stockholm University and is now an associate professor at the Institute for Labour Market Policy Evaluation (IFAU), Uppsala in Sweden. His research deals primarily with empirical labor economics.

**Frederick G. Tiffany** is an associate professor of economics at Wittenberg University in Springfield, Ohio. He received his BA in economics from Kenyon College (1977) and PhD in economics from the University of Pennsylvania (1988). He teaches intermediate microeconomic theory, game theory, industrial organization, managerial economics, mathematics for economists, and public finance. His current research interest is the market for college education, especially the use of price discrimination by monopolistically competitive colleges.

**Kiril Tochkov** holds an MA in Chinese studies from the University of Heidelberg, Germany, and an MA and PhD in economics from the State University of New York at

Binghamton. He has studied at the Beijing Foreign Studies University in China and has worked as assistant manager in the marketing division of Volkswagen Automotive Co. Ltd. in Shanghai. He is currently an assistant professor of economics at Texas Christian University in Fort Worth, Texas, where he regularly teaches a class in Asian economics. His research focuses on regional growth, convergence, and efficiency in China.

**Paola Tubaro** earned a PhD in economics at the University of Paris-Ouest and the University of Frankfurt. She is currently a lecturer at the University of Greenwich, Business School in London and an associate member of Centre Maurice Halbwachs in Paris. Among her research interests are the history of economic thought and the philosophy and methodology of economics, with focus on the history of mathematical modeling and the methodology of experimental and computational economics.

**John Vahaly** is chair of the department of economics at the University of Louisville. He attended Vanderbilt University as a graduate student. He has authored teaching materials for principles texts in macroeconomics and has published articles about the macroeconomics of emerging market economies. His approach to teaching macroeconomics is primarily historical, showing how macroeconomics has changed over time. This presents students with a better understanding of current problems and what new challenges they present.

**Carlos Vargas-Silva** is an assistant professor of economics at Sam Houston State University. His research interests are workers' remittances, exchange rates, monetary policy, and time-series econometrics. He holds a PhD in applied economics from Western Michigan University.

**Douglas M. Walker** is an associate professor of economics at the College of Charleston, in Charleston, South Carolina. He received his PhD in economics from Auburn University. His research focuses on the economic and social effects of legalized gambling, especially casinos. Walker has published a number of articles in academic journals, and his book, *The Economics of Casino Gambling,* was published in 2007.

**Douglas O. Walker** is professor of economics in the Robertson School of Government at Regent University. He holds a PhD from the University of Southern California. Before joining Regent, Dr. Walker was a senior economist with the United Nations Secretariat, where he drafted studies of trends and prospects for the world economy and served as chief of quantitative research, secretary of the United Nations systemwide committee on technical research, and speechwriter to the Under-Secretary-General. While with the secretariat, Dr. Walker was adjunct professor of economics at Baruch College of the City University of New York and a member of the New York Academy of Sciences.

**Quan Wen** is a professor of economics at Vanderbilt University. He received his PhD in economics from the University of Western Ontario in Canada. Wen has authored and coauthored numerous journal articles on game theory and applied game theory in economics. His current research interests include repeated game, bargaining theory, mechanism design, and industrial origination.

**Sarah E. West** is an associate professor of economics at Macalester College in St. Paul, Minnesota. She received a PhD in economics from the University of Texas at Austin. Her research analyzes optimal tax policy, focusing on behavioral responses to policies for the control of vehicle pollution, including taxes on gasoline, subsidies to clean vehicles, and Corporate Average Fuel Economy standards. From 2002 to 2007, she was a member of the National Bureau of Economic Research's Working Group in Environmental Economics. Her work has been published in *American Economic Review, Journal of Environmental Economics and Management, Journal of Public Economics, Journal of Transport Economics and Policy, National Tax Journal,* and *Regional Science and Urban Economics.*

**David Wiczer** is a doctoral candidate at the University of Minnesota and research assistant at the Federal Reserve Bank of Minneapolis. He received his master's from the University of Illinois, Urbana-Champaign. He studies macroeconomics, with work ranging from optimal control in growth models to currency depreciation in sovereign default. His current focus is on computational methods and using micro-level data to estimate macroeconomic models.

**Amy M. Wolaver** is an associate professor of economics at Bucknell University. She received her PhD from the University of Wisconsin–Madison in 1998. Her research areas focus on the impact of public provision of family planning coverage on contraceptive use, pregnancies, pregnancy outcomes, substance use, and labor market effects of internal migration. She teaches courses in introductory economics, microeconomic theory, and health economics, as well as a team-taught course on HIV/AIDS.

**Timothy A. Wunder** received his PhD from Colorado State University in the fall of 2003. His dissertation was a history of thought on the origins of economic sociology, emphasizing the contributions from both Thorstein Veblen and Joseph Schumpeter. Since receiving his PhD, he has written several pieces on the history of economic thought and on economic education. Dr. Wunder currently is Senior Lecturer in the department of Economics at the University of Texas at Arlington.

# PART I

## Scope and Methodology of Economics

# 1

# History of Economic Thought

Paola Tubaro

*University of Greenwich; Centre Maurice Halbwachs*

Like economic history, the history of economic thought (HET) investigates economic issues in long-run perspective. Yet the two fields are distinct and should not be confounded: HET does not study economic *facts* such as the 1929 financial crisis but rather economic *theories* and economic *literature.* It focuses on the historical roots of economic ideas and takes into account a wide array of schools of thought; in conjunction with pure theory and the history of facts, it constitutes part of a comprehensive approach to the study of the economic bases of modern societies. Examples of research questions in HET include how economic issues (say, unemployment or growth) have been dealt with at different points in time, what intellectual debates they have stimulated, and what solutions have been concocted; how the meaning and interpretation of economic concepts such as involuntary unemployment or market equilibrium may have changed over time and how they have affected policy debates; and whether and how exchanges with neighboring disciplines or with currents of thought in philosophy have exerted an impact on the development of economics.

A variety of approaches to the study of HET coexist, but it is possible to identify two broad tendencies into which most of them would fit: one more "theory oriented," the other more "history oriented." The theory-oriented approach, often referred to as *history of analysis,* emphasizes *continuity* between present and past reflection, so that earlier writers are seen as a source of inspiration that may assist today's researchers in devising new solutions to current theoretical questions. Because economics is an approach to the study of society that endeavors to look beneath context-specific factors to discover underlying regularities in the behavior of individuals and communities, older economists who have already identified some of these regularities can provide useful insight despite the time distance that separates them from us. Earlier ideas have remained partly underdeveloped, and getting back to them can potentially suggest new directions for research. For some scholars, this means reviving alternative explanations and interpretations of economic phenomena, in a critical perspective with respect to any consensus that might exist today. In line with this methodological stance, historians of analysis primarily rely on the conceptual tools of contemporary economic theory.

In contrast, the history-oriented approach emphasizes *discontinuity* between different stages of development in economics and the specificities of each of them. The idea is that an economic theory is embedded in its historical, sociopolitical, and institutional environment and constitutes a response to the problems of the day, so that it is incorrect to understand it in abstraction from them. Specifically, a "retrospective" interpretation of past economic theories in light of the knowledge that has been subsequently acquired is impoverishing because it tends to present them all as imperfect, preliminary drafts of today's supposedly superior models. Instead, it is essential to detail the context in which an older theory emerged, and useful insight may come from historical techniques such as archival work, biographies, and oral history. This approach emphasizes the relative character of economic theories and their connections to politics and society at large. Among scholars who work along these lines, a large group has developed a close association with, and adopted methods of, science studies, in some cases with a critical perspective toward economics.

While the two above-outlined approaches are the object of recurrent and sometimes lively controversies within the HET community, many scholars are in fact aware that each has both strengths and weaknesses and try to combine the two in their research. Still other approaches may be occasionally present, particularly in the case of research at the crossroads between HET and the philosophy or methodology of economics.[1]

What follows is a brief overview of the main areas of research in HET that also correspond to a classic division of phases of development of the economics discipline from its origins to its present state. Following the *Journal of Economic Literature* classification, the evolution of economics has been subdivided into two phases—namely, HET through 1925 and HET since 1925; a shorter third part on recent developments has been added to this basic scheme.

There is obviously insufficient room to cover *all* aspects of the intellectual reflection in economics over such a long time span. For this reason, the presentation is limited to a sketch of what each period contributed to the study of three foundational issues in economics—namely, the theory of individual economic behavior, the market mechanism as a coordinating device, and the respective roles of markets and governments in the regulation of economic systems. Reflection on these issues has progressively formed economists' understanding of society and presently allows applications to a broad range of social phenomena, from monetary and financial matters to health and the environment. Furthermore, these very issues have been the object of major controversies that have divided economists into different schools and have ultimately shaped the history of the discipline. While a long tradition of thought has contributed to developing economic models of individual behavior, dissenting groups have recurrently pointed to its neglect of other important motives of human action; while most economists since a very early stage have promoted a conception of the market as a self-adjusting social mechanism capable of coordinating individual actions at best, critics have often raised doubts on its merits; and while a majority has often supported pro–free market arguments against government intervention, the opposite position has sometimes prevailed. In outlining these developments, similarities and differences between past and present theories will be emphasized whenever possible, with the help of HET literature and in an effort to stress the insight that may come from both of the above-outlined approaches.

Further readings include classic works such as Robert Heilbroner's (1999) *The Worldly Philosophers,* Joseph Schumpeter's (1954) *History of Economic Analysis,* and Mark Blaug's (1997) *Economic Theory in Retrospect,* together with recent reference books such as *A Companion to the History of Economic Thought* (Samuels, Biddle, & Davis, 2006) and *The History of Economic Thought: A Reader* (Medema & Samuels, 2003). The main scholarly journals in the field are *History of Political Economy, European Journal of the History of Economic Thought,* and *Journal of the History of Economic Thought.* The Web site of the History of Economics Society (http://historyofeconomics.org) and the HET page of the New School for Social Research (http://cepa.newschool.edu/het) also offer information. Finally, Liberty Fund has republished at affordable prices many of the great books that have made the history of the discipline, providing some of them online at its Library of Economics and Liberty (http://www.econlib.org).

## HET Through 1925

Scholars in Antiquity and the Middle Ages thought a great deal about trade, money, prices, and interest rates, but an autonomous discipline developed only toward the late seventeenth to early eighteenth centuries. The early designation of *political economy,* proposed by Antoine de Montchrestien in 1615, was later replaced by *economics* and refers today to a specific subfield only, but it has the merit of stressing a persisting feature of the discipline as a whole—namely, its linkages with public policy and the role of the economist as an adviser to the policy maker. This specificity still matters and distinguishes economics from other social sciences.

Despite the interest of the early literature (see, e.g., Hutchison, 1988), a detailed account of it would be beyond the scope of this chapter, and the more traditional convention of starting from the late eighteenth century will be followed. Focus will be on Adam Smith (1723–1790), who is widely regarded as one founder of the discipline; the remainder of this section will outline the development of economic thought in the nineteenth and early twentieth centuries, with the emergence of the so-called classical and then the neoclassical schools.

### Adam Smith

In his 1776 *Wealth of Nations,* Smith laid the foundations of what would become basic principles of economists' understanding of individual behavior, the market mechanism, and the role of markets vis-à-vis governments. Smith was the first to explicitly characterize individual economic behavior as *self-interested behavior,* admitting that it is people's desire for a gain that explains work, production, and ultimately the existence of an economic system:

> It is not from the benevolence of the butcher, the brewer, or the baker that we expect our dinner, but from their regard to their own interest. We address ourselves, not to their humanity but to their self-love, and never talk to them of our own necessities but of their advantages. (Smith, 1776/1981, pp. 26–27)

Self-interest was initially thought to be at odds with another principle that Smith had developed in his *Theory of Moral Sentiments* (1759/1982)—namely, sympathy between

human beings who, by putting themselves imaginatively in the place of others, understand their feelings and expectations and are moved to act accordingly (e.g., to give to those who are in need). This apparent contradiction, known in the literature as *Das Adam Smith Problem,* has been largely resolved by recent scholarship that has rather stressed how self-interest and sympathy emphasize different aspects of human nature, whose relative importance varies depending on the situation. They constitute two instances of a unique framework for thinking about human behavior, in which the individually centered, self-interested component is accompanied by an interpersonal dimension, so that it becomes possible to account for various forms of behavior, from trade and profit-seeking actions to philanthropy. Reconciliation of these two aspects of Smith's thought makes him the father of economics in a broad, comprehensive sense: Although the discipline was long viewed as the systematic analysis of the behavior of self-interested individuals, today's research (especially in behavioral economics) tends to integrate forms of prosocial behavior into economic analysis.

Smith's work also contributed to shaping economists' view of the market as a coordinating device in a world in which private property and freedom enable individuals to make self-interested decisions autonomously, without ex ante coordination by some outside (political) authority: The market is a social mechanism that ensures, ex post, that individual decisions are consistent with one another and generate an orderly result. Smith's "invisible hand" metaphor has often been recognized as an effective representation of this mechanism:

> by directing [ . . . ] industry in such a manner as its produce may be of the greatest value, he [man] intends only his own gain, and he is in this, as in many other cases, led by an invisible hand to promote an end which was no part of his intention. By pursuing his own interest he frequently promotes that of the society more effectually than when he really intends to promote it. (Smith, 1776/1981, p. 456)

Because individuals are not isolated but part of a larger human community, their actions have unexpected or *unintended consequences* at the system level. Individuals take into account only their self-interest, yet their choices affect others and trigger a chain of interactions that eventually affect society as a whole, well beyond their original intentions. Strikingly enough, Smith argues that this spontaneous process does not lead to chaos but to harmony: Self-interest may not seem a noble motivation, yet it triggers consequences that benefit society even more than those arising from benevolence. Thus, there is no need for a strong state power that would impose social order from above, as argued by Thomas Hobbes (1651/1996). The idea of unintended consequences and the possible reconciliation of individual self-interest and social good, first articulated by Smith, have been at the core of subsequent economic reflection—which is another reason why Smith is credited as a founder of the discipline.

While acknowledging the merits of the market, Smith did not deny the need for a solid government. In particular, he insisted that government should ensure the basic conditions that allow markets to function properly, primarily protection of private property and enforcement of contracts (Smith, 1776/1981, p. 910). The government should also be in charge of surveillance against what we would call today unfair competition and other abuses (Smith, 1776/1981, p. 145).

## The Smithian Heritage and the "Classical" School

Smith's seminal work stimulated much reflection. On individual behavior, the idea that individuals act to satisfy their self-interest gradually developed into the individual optimization principle that is at the basis of today's textbook microeconomics (see below). This principle has often been criticized as restrictive, not taking into account the multifaceted motivations that drive human behavior. Yet historians of economics have highlighted that in the nineteenth century, the economic model of individual behavior had the merit of supporting an egalitarian perspective that had great impact on political debates. If the same scheme holds for all individuals, they are all equal and have the *same capacity for decision making;* observed differences, if any, depend only on incentives, chance, and history. This egalitarian view was shared by most economists of the time and strongly contrasted the (then also widespread) hierarchical stance that regarded the lower classes of society and supposedly "inferior" ethnic/racial groups as less capable of making decisions and thus in need of guidance (Peart & Levy, 2005). Interestingly, the infamous "dismal science" designation of political economy was originally an accusation against economists' antislavery orientation, which resulted from their belief that all humans are equal (Levy, 2001).

On the coordinating mechanism, reflection was motivated by the questions that Smith had left open as well as by the socioeconomic transformation brought by the Industrial Revolution. David Ricardo (1772–1823) provided one of the finest analyses of the relationship between prices and quantities; although he did not use mathematics, his compelling arguments raised the level of rigor in the subject and set basic standards for later modeling. His *On the Principles of Political Economy and Taxation* (1817/2004) offers an in-depth analysis of the effects of scarcity on price formation. Suppose some quantity of produce (say, a ton of corn) can be obtained with a given amount of labor and other inputs (seeds, water, fertilizers) on fertile land. Production of a ton of corn on less productive terrain requires larger amounts of inputs, so production costs are higher. Hence, self-interested producers will exploit fertile lands first and will extend production to lower quality lands only when demand is so strong that there are no spare high-quality lands to satisfy it. In such cases, high consumer demand

pushes up the market price of corn until it covers production costs on the worst fields; consequently, price exceeds the cost of producing corn on the best fields and earns a "rent" for their landlords. While this description is highly simplified and does not take into account potentially relevant factors such as technological progress, it still allows applications to present-day natural resource economics. An example is oil, whose extraction costs differ in different areas, so the worst oil fields are profitable only when global demand is strong and prices rise.

Prices and quantities also vary depending on the competitive conditions that prevail in a market. It was already known that in monopoly situations, prices are higher and quantities are lower than in cases in which several firms compete, but no rigorous explanation of this phenomenon was available until Augustin Cournot (1801–1877) with his *Researches Into the Mathematical Principles of the Theory of Wealth* (1838/1927). A pioneer of the use of mathematics to guide economic reasoning in times when few did so, he illustrated how the sole seller of a good is able to control the entire market and hence extract a monopoly rent. In the case of two or more sellers, Cournot highlighted the importance of strategic interactions, so that each seller's decision depends on other sellers. The market is in equilibrium when each firm's output maximizes its profits given the output of other firms—a notion of equilibrium that has been acknowledged to prefigure that of (pure-strategy) Nash equilibrium in game theory. The author also thought that the weight of strategic interactions declines as the number of sellers increases, so when many of them compete, no one is capable of exerting any influence on market prices. Cournot was the first to prove that under competitive conditions, the quantity produced is such that its market price equals (what we would call today) its marginal cost.

Economists of this time period are often referred to as "classical" economists. Other prominent classical writers include Thomas Malthus (1766–1834) and John Stuart Mill (1806–1873). There have been controversies on the definition of the classical school, its timeframe, and scope: Smith and Ricardo are considered among its main contributors, while Cournot is less frequently included, although there are similarities and differences between all three. On the whole, these writers were mainly interested in production/supply forces, working conditions, and the relationship between wages and profits, while they placed relatively less emphasis on utility, consumption, and demand. Although Ricardo's rent theory relied on demand to determine whether less productive resources could be profitably used, and Cournot went as far as to draw supply-and-demand diagrams, these writers did not derive demand from utility; even Cournot with all his mathematics regarded it only as an aggregate relationship calculable from expenditure data. Arguably, it is not that their arguments were underdeveloped but that the classical school primarily pointed to the influence of the whole economic system on individual behavior, rather than the other way round, and focused on the differential impact of conditions of production on individuals according to their position as workers, capitalists, or landowners. This viewpoint had the merit of calling attention to problems related to income distribution and the possible tension between wages and profits.

Early nineteenth-century policy debates focused on free-market principles and the role of the state in countering potential negative effects of markets. One key controversy concerned unemployment, of which external trade was one perceived cause, to the extent that increased low-cost imports might have resulted in national workers being displaced by cheaper foreign workers; similarly, technological innovation could be conducive to displacement of workers by machines. Would the market mechanism self-adjust to reabsorb the workers left idle by an opening of the country to external trade and/or a technological shock? These questions are important for the well-being of a country and, since then, have recurred several times in the history of economics. A prominent contributor was Ricardo, who first claimed that market adjustments would be sufficient and then admitted that consequences for the working classes were likely to be hard, at least for some time—although he still believed that restraining technical progress and free trade would have been detrimental to the country.

Like Ricardo, many supported free trade despite its possible inconveniencies and the need for government to intervene in some cases. However, this time period also saw the development of socialist ideas in reaction to the conditions of workers in the new industrial age and the classical economic thought that accompanied it. Influenced by classical authors but at the same time critical of them, Karl Marx (1818–1883) highlighted the internal contradictions of the current social relationships of production, the conflict between labor and capital, and the historical tendencies that brought about the modern economic system but also generated tensions that eventually led to its collapse. Marx's *Capital* (1867) attracted many followers in economics and also inspired political action directed at radical social, economic, and political change.

## The Late Nineteenth Century and the "Neoclassical" (Marginalist) School

From the second half of the nineteenth century onward, increased emphasis was put on consumption rather than production only, with the introduction of a notion of utility as a measure of individual satisfaction from the consumption of goods or services. Some reflections on utility had already appeared, with the idea that the problem of political economy and the ultimate purpose of all productive activities is to satisfy human wants at best. Yet it was long before utility could be fully integrated within economic models, not least because at first glance, it may have appeared as a subjective, qualitative notion devoid of any objective, let alone quantifiable, attribute. The solution came from reinterpreting utility not as an absolute but as a *relative* magnitude, varying from one individual to another and for each

individual, depending on the available quantity of a good. One could thus distinguish the total amount of utility from "marginal" utility—namely, the change in the level of utility that results from a given increase in the quantity of the good. Marginal utility was thought to diminish with the quantity consumed, reflecting the capacity of individuals to order the possible uses of successively acquired units: For instance, one would reserve the first gallons of water for drinking and the successive ones for personal hygiene, for housekeeping, and finally for watering plants. In passing, this assumption solved what earlier thinkers considered a paradox—the fact that useful goods such as water or air have low market value: The reason is their abundance, which means that the last increment in quantity generates an extremely small increase in utility. These results suggested an interpretation of self-interested behavior in terms of attempts to raise one's utility to its highest possible level and were obtained independently, in 1871–1874, by William S. Jevons (1835–1882) in Britain, Carl Menger (1840–1921) in Austria, and Léon Walras (1834–1910) in Switzerland.

The importance of thinking in terms of marginal variations rather than total magnitudes proved so useful to account for utility and demand that it was subsequently extended to supply. In fact, notions of marginal productivity and marginal cost of production, as opposed to total productivity/cost, had already been introduced (e.g., by Cournot) but were refined and generalized in the 1890s by, among others, John B. Clark (1847–1938), Philip H. Wicksteed (1844–1927), and Knut Wicksell (1851–1926). Marginal reasoning seemed so important that the economic thought of this time period is often referred to as *marginalism.*

Accounts of the market mechanism of this time period place emphasis on the *symmetry* of supply-and-demand factors and on the resulting equilibrium. Individual demand and supply are derived, respectively, from agents' calculations of utility (for consumers) and profit/cost (for firms), and market supply and demand are obtained by aggregating all individual values. When market supply equals demand, the market is in equilibrium—that is, the decisions of all households and all firms are consistent with one another. These common traits can be combined with different assumptions to give rise to various models of the market. Alfred Marshall (1842–1924) is renowned for developing a "partial equilibrium" approach, focusing on the study of a single competitive market and illustrated with the help of price-quantity diagrams in which demand decreases and supply increases with price. The intersection of the supply-and-demand schedules identifies equilibrium—a price at which supply equals demand and the market clears (Marshall, 1920). The partial equilibrium approach provides a tractable framework to study the relationship between price and quantity; however, it is based on the restrictive assumption that changes in the price of a good have repercussions on the quantity of that good only, ruling out the possibility that a variation in the price of a good will have an impact on the demand and supply of substitutes and/or complements. Hence, it can be taken at most as an approximation, not as a rigorous analytical device. In contrast, interdependencies among markets were a key concern for Walras (1874/1977), who tried to model agents who allocate their budgets to the purchase of multiple goods so that changes in the market price and/or quantity of one good are likely to have repercussions on the markets for other goods. His notion of "general equilibrium" is directly derived from this view and corresponds to a situation in which supply equals demand *on each market,* so that all clear simultaneously.

A closely related, though distinct, question is whether and how actual trade practices will drive prices and quantities toward equilibrium. Again, Marshall and Walras provided different answers. Walras (1874/1977) proposed a model of auctions in which at given prices, all traders declare the quantity of each good that they wish to buy or sell at those prices; if with these quantities, supply equals demand on each market, then this is the general equilibrium and trade takes place; if not, prices are adjusted in such a way that they diminish where supply exceeds demand and increase in the opposite case; at the new set of prices, traders announce again the quantities that they wish to buy or sell, and the process (which he labeled *tâtonnement,* a term still used in the literature) starts again, until equilibrium is reached. In short, transactions take place simultaneously, at equilibrium only, so that the same prices apply to all traders. Instead, Marshall (1920) had in mind a sequence of bilateral transactions on a single market, in which each pair of traders negotiates a price and each transaction withdraws some units from the market so that lesser quantities are available for later trades—in other words, the conditions under which traders negotiate are altered at every step. Such changes gradually dampen price adjustments until they reach the level that corresponds to the intersection of supply and demand. Here, transactions occur sequentially, in disequilibrium, at prices that may differ from one pair of traders to the other.

Is there continuity or rupture between the classical school of thought and the marginalist—also known as "neoclassical"? The emergence of the latter current of thought used to be referred to in HET as a "revolution," thus suggesting a major change, which some argue is primarily due to the postulated symmetry between supply-and-demand conditions rather than to the use of marginal concepts, yet important features of neoclassical thought and elements of reflection on utility and demand were anticipated by earlier authors. Today's HET scholars mostly believe that there was no such thing as a sudden transformation of the discipline but a long, slow transition; key marginalist concepts appeared early, but it took long before they were systematized into a coherent, comprehensive framework. In turn, neoclassical economics does not constitute a single theory but rather a family of approaches: The market models of Marshall and Walras are examples of such differences.

Openness to more rigorous thinking and increased use of mathematics have been often thought to characterize neoclassical theories; an indication of this tendency is the renaming of the discipline in the late nineteenth century from *political economy* to *economics,* primarily at the initiative of Marshall. However, qualifications should be introduced to the extent that some earlier writers such as Cournot had already used some mathematical tools in their analysis (Theocharis, 1993); conversely, late nineteenth-century economists were not unanimous on the desirability of using mathematics, and Marshall himself limited his quantitative expressions to a minimum. It took long before the use of mathematics became standard in the profession, and debates on the legitimacy of using mathematical tools in the study of human behavior and society have been recurrent since then.

## HET Since 1925

This section outlines the development of neoclassical economics in the twentieth century, with focus on its two hallmarks of individual optimization and market equilibrium. The section also includes an overview of the emergence of macroeconomics and how it gradually came to incorporate the principles of optimization and equilibrium.

### Neoclassical Economics: Individual Optimization and Market Equilibrium

The neoclassical concept of utility was refined over time, and mathematical models of utility maximization under a budget constraint saw the light. Progressively, the constrained maximization model was extended to the study of all individual decision units, on both the demand and the supply side of the market, and became the basis of all analyses of individual economic behavior. It gradually came to be understood as rational behavior—choosing the best possible means to achieve one's ends. This opened the way to a conception of economics based on two pillars: optimizing behavior of agents (both consumers and firms with, respectively, utility and profit as objective functions) and equilibrium of markets. The contribution of Paul Samuelson (1915–2009) was essential to these developments and mainly consisted in rewriting many problems of economics as maximization problems, with extensive use of mathematics. From the 1940s onward, Samuelson's effort to show that apparently diverse subjects have the same underlying structure and can be treated with the same mathematical tools gave unprecedented unity and coherence to the discipline.

The optimization model has not been beyond dispute, though: At least since the 1950s, Herbert Simon (1916–2001) and others contended that actual decision makers lack the cognitive capacities to solve maximization problems and rather content themselves with "satisficing" behavior, choosing options that are not optimal but make them happy enough. Along these lines, they developed a "bounded rationality" approach as an alternative to the seemingly strong rationality requirements of the individual maximization model.

Regarding market models, Marshall's partial equilibrium approach continued to be used in applied economic studies, but it was the general equilibrium model that most attracted the attention of economic theorists during this time period. Its extraordinary development after World War II was largely due to the introduction into economics of highly advanced mathematical tools and of a new way of thinking about mathematics (Weintraub, 2002a). The new tools allowed for a sophisticated refinement of Walras's approach, named the Arrow-Debreu-McKenzie model after its main contributors. A major achievement in the 1950s was a formal proof of existence of equilibrium. The difficulty was that it was not enough to show that the system of simultaneous equations representing equality between supply and demand in all markets has a solution: For this solution to be meaningful economically and not only mathematically, it was also necessary to prove that equilibrium prices and quantities are nonnegative. By demonstrating that it is indeed the case, it was established that the notion of a set of prices that clear all markets is consistent (i.e., that the notion of equilibrium of a system of interrelated competitive markets is not void).

Another success for general equilibrium theory was the mathematical proof of the so-called two theorems of welfare economics—a modern reinterpretation of Smith's "invisible hand." The first theorem states that a general equilibrium corresponds to a socially optimal allocation of resources, and the second states that, under some conditions, any socially optimal allocation of resources can be sustainable by a general equilibrium. These results shaped policy discussions for long: They amounted to rigorously establishing the properties of the free-market mechanism that earlier economists had put forward intuitively—namely, the idea that a market-based solution to the problem of allocating scarce resources produces a desirable outcome for all and cannot be superseded by any other alternative. The two theorems made a strong case for the free market but also enabled clear identification of cases where government intervention is legitimate: Whenever the assumptions that support the two theorems (e.g., competitive conditions) are not met, the market may fail to yield efficient outcomes ("market failures"), and the government should step in.

In the 1950s and 1960s, such progresses put the Arrow-Debreu-McKenzie model at the center of the stage and increased confidence in its potential to provide the whole of economics with rigorous mathematical foundations. However, problems started with attempts at proving two other key properties of equilibrium—namely, stability and uniqueness. The question of stability was meant to ensure that after an exogenous shock, the market mechanism is capable of generating endogenous forces that bring it back to equilibrium; if equilibrium exists but the market cannot find it, then arguments for free markets are harder to make. In addition, if uniqueness is not guaranteed, it is unclear where an adjustment process might drive the system after a

shock; besides, some equilibriums may be unstable. It became soon clear, though, that formal proofs of stability and uniqueness could be obtained only under very restrictive, unrealistic assumptions. Critics stressed that these results reveal that with all its mathematical underpinnings, general equilibrium theory did not truly succeed in improving knowledge of how the market mechanism works and how prices adjust in response to variations of supply-and-demand conditions (Ingrao & Israel, 1990). Today the theory is still part of economists' education, but research in this field has entered a phase of relative decline.

## Keynes and the Emergence of Macroeconomics

In the aftermath of the Great Depression, macroeconomics also entered the scene. John Maynard Keynes (1883–1946), one of the fathers of the new approach, is among the most influential economists of the twentieth century. His *General Theory of Employment, Interest and Money* (1936/1997) proposed a new way to look at economic systems, one that placed emphasis on quantity adjustments at given prices, rather than on the supposed capacity of price adjustments to equilibrate markets, and focused on aggregate relationships rather than on individual behavior. The new approach was rooted in the belief that the macrolevel of analysis differs in nature from the microlevel and contented itself with the use of simple behavioral assumptions that do not require optimization: Consumers spend a fraction of their income and save the remaining part, and firms' investment decisions depend inversely on the interest rate. In this way, it hoped to tackle the question of unemployment that was crucial at the time. The neoclassical conception was ill-suited to explain why some people could be involuntarily unemployed for long: It regarded labor as hardly different from any other good, so that market price adjustments should in principle bring the system back to its full-employment equilibrium after a temporary shock. In contrast, Keynes stressed the specificity of labor relative to other goods and suggested that the level of employment may depend less on prices than on aggregate demand (i.e., the total expenses of an economic system). In this perspective, an economy may be unable to deliver full employment, even if all markets for goods clear in the long run: Underemployment may be its normal state. In this sense, the book challenged the idea that markets are capable of self-regulation and built a theoretical framework that legitimated increased government intervention to stimulate the economy. Policy measures could take various forms, ranging from increased public spending to lower interest rates to encourage investments and thus raise demand for labor.

The book had enormous success and changed the way economists and policy makers looked at the role of governments in a market economy: Not only did it inspire a significant amount of research work, but it was also at the basis of economic policies in Western countries after World War II, so it is sometimes referred to as a Keynesian "revolution." Policies of demand stimulation along Keynesian lines were enhanced by the parallel development of macroeconometric techniques that made it possible to assess the state of an economic system and to estimate the impact of government interventions.

However, the neoclassical approach was not completely abandoned, and in particular, a group of economists tried to reconcile it with Keynes's view. A hallmark of this tendency is the model known as IS/LM, designed in 1937 by John Hicks (1904–1989) to represent key principles of the *General Theory* in the form of a system of simultaneous equations reminiscent of those of general equilibrium theory. Indeed, the model succeeded in capturing some major aspects of Keynes's thought, but at the same time, its partly neoclassical roots made it less suited to account for the possible existence of unemployment in an economy that is otherwise in equilibrium. Later, the IS/LM model was enlarged to take into account international transactions (the so-called Mundell-Fleming model) and was accompanied by a Phillips curve that explained the behavior of prices on the basis of an inverse relationship between inflation and the level of employment. Starting in the mid-1950s, a consensus emerged around this approach at least in the United States, where it constituted a basis for descriptive economic analysis and for policy advice. It coexisted with neoclassical microeconomics and became known as the *neoclassical synthesis,* a designation commonly attributed to Samuelson.

Keynesianism came under attack after the 1973 oil crisis and the ensuing nasty combination of inflation and unemployment for which it seemed to have no remedies: Demand policies would reduce unemployment but would lead to higher inflation, while public expense cuts would tame inflation but would raise unemployment. This period saw the rise of an alternative approach, known as *monetarism* and primarily associated with Milton Friedman (1912–2006). Monetarism revived the pre-Keynesian belief that market economies can regulate themselves without any need for government intervention and brought to light a strong relationship between money creation and inflation, so that an economy may be destabilized if the authorities print too much money: It followed that the focus of economic policies should be solely on keeping the quantity of money under control and that active demand policies are useless, if not in fact damaging. Monetarism spread widely in the early 1980s and had a strong influence on policy making. Keynesian ideas did not completely vacate the scene, though: Many became convinced that government policies can still have a temporary effect and that the Keynesian framework of analysis holds in the short run, while the monetarist framework holds in the long run.

This compromise was challenged by Robert Lucas (born 1937), who made a strong case for unifying the foundations of economic theory through an extension to macroeconomics of the microeconomic assumptions of the rational behavior of individuals and of the self-equilibrating capacity of markets. Agents make optimal choices: In particular, they form expectations about the state of the economy by taking into account all available information and by processing it in the best possible way, so that they can be

called "rational expectations." More precisely, agents make consumption or investment decisions that take into account the model of the economy as well as government policies, so that they reach equilibrium immediately and their expectations are validated. If all agents behave in this way, the economy is always in equilibrium. A major implication of this view is that economic policies are ineffective even in the short run because they are anticipated by agents and are accounted for in their decisions. Only unexpected policies that take individuals by surprise can move the economy from one state to the other—but this means that to be effective, policies must be occasional and unsystematic or else they will be detected, so the scope for governments to steer the economy becomes extremely limited. A consequence of this view is the invalidity of macroeconometric models that purported to evaluate the effects of public policies with the help of aggregate data: If agents take into account policies in their decision making, their behavior is not policy invariant so that existing observations may not predict future choices well. Only a sophisticated model of how individuals make optimal decisions based on their expectations can offer reliable predictions.

The rational expectations school of thought tried to give greater coherence to the discipline by basing both micro- and macrotheories on the two main pillars of individual optimization and market equilibrium. This choice responded to a widespread demand for more rigorous economic theorizing but also reflected renewed confidence in the functioning of the free-market mechanism and skepticism with regard to government intervention; in this sense, it represents a comeback for pre-Keynesian attitudes. Since then, most developments of macroeconomics have reflected this tendency—with the development, among other things, of the real business cycles approach by Finn E. Kydland and Edward Prescott in the 1980s.

Although the great majority of macroeconomists have now recognized the need to firmly ground macroeconomic theorizing on sound microeconomic foundations, many disagree with the pro–free market orientation of these currents and have tried to develop alternative approaches that would still be based on rigorous microfoundations but would lead to Keynesian results, most prominently by showing the possibility for unemployment to persist in an equilibrium economy. These approaches, commonly referred to as *New Keynesian,* have brought to light characteristics of the economy that might lead to this result, ranging from implicit contracts, efficiency wages, and coordination failures to imperfect competition. An overview and an appreciation of their contributions are provided in De Vroey (2004).

Over time, a consensus gradually has been established around general equilibrium theory and macroeconomics with rigorous microfoundations, which have come to be identified as the core of the discipline—what some now call "mainstream" economics. They are now at the basis of economics education and constitute a reference for the profession as a whole. Since their introduction, training in these fields has contributed to raise the level of rigor in economics reasoning and to spread the use of mathematical and quantitative tools.

## History of Recent Economics

Research in mainstream economics is still active, even if there has been a relative decline in recent years. This has paralleled a tendency to increasing diversification of approaches, methods, and topics, which has seemingly reversed the twentieth-century trend toward unification of the different parts of the discipline. Still, economists tend to have in common an enduring emphasis on mathematical tools and formal reasoning.

A detailed account of the different emerging approaches to economics would be beyond the scope of this brief account of HET, but more information can be found in other chapters in this handbook. This section instead will provide an overview of some significant developments and how they are challenging established knowledge in economics.

Models of rational behavior have put the accent on the *strategic dimension* of rationality in situations where agents make decisions whose success depends on the choices of others. This shift in emphasis results from the rise of game theory as a challenger to established microeconomics, which has been spectacular in recent years even though the origins of the theory date back to (at least) the 1940s. Applications of game theory include bargaining, imperfect competition, and questions at the interface between economics and other sciences, such as social network formation, the emergence of social norms, and voting systems.

Assumptions of individual rationality do not go unquestioned, though. The stream of research that is known as "behavioral economics" has provided substantial evidence that humans often violate some implications of optimization models and has tried to develop more realistic psychological approaches to the study of individual behavior. Some researchers, in particular, have focused on how happiness and individual satisfaction, as well as prosocial and cooperative attitudes, may be important determinants of individual behavior that were not fully accounted for in older maximization models. To do so, new sources of information have been exploited, notably experimentation and analysis of survey data with the help of increasingly sophisticated microeconometric techniques. While these fields remained marginal for a while, they are now recognized parts of the discipline and attract an increasing number of young economists.

Models of the market have been greatly enriched by a detailed study of auctions and other mechanisms of allocating goods. Part of the motivation for these studies in the 1990s and early 2000s was the need to design trading mechanisms that would help governments to privatize companies, infrastructures, and other facilities that they

previously owned. To some extent, economists' work in this area resembles that of engineers at the service of the government—a new role that, nevertheless, renews the time-honored image of the political economist as an adviser to the policy maker. These studies depart from the general equilibrium tradition in a double sense: First, they highlight the importance of trading institutions to yield socially desirable outcomes, instead of abstracting them away, and second, they signal a tendency to focus less on interdependencies and rather concentrate on single markets—what Marshall modeled in a "partial equilibrium" perspective.

At the macrolevel, greater emphasis has been placed on economic governance. The conditions under which governments can ensure protection of property rights and enforcement of contracts, already emphasized by Smith as key requirements for market economies to function properly, have been studied in greater depth from the 1990s onward. Focus on governance and institutions sometimes accompanies criticisms of pro–free market principles but sometimes supports the free-market tradition of thought by providing a more precise definition of how the government can create conditions for markets to function properly.

## Conclusion

To conclude, it can be said that the discipline advances over time with the progressive introduction of new tools, new approaches, and an improved understanding of key concepts. Yet some questions are recurrent and constitute some of the great, unresolved dilemmas of contemporary society. This chapter has emphasized the problems of individual economic behavior, the functioning of the market mechanisms, and the place of the market vis-à-vis the government. The answers provided at different epochs, though based on different arguments and different sources of evidence, often have elements in common—partly because these are issues that have major philosophical and political implications. By accounting for the circumstances in which a variety of responses have emerged in the past, HET can contribute to today's reflection on these issues. As Keynes (1936) once wrote,

> The ideas of economists and political philosophers, both when they are right and when they are wrong, are more powerful than is commonly understood. Indeed, the world is ruled by little else. Practical men, who believe themselves to be quite exempt from any intellectual influences, are usually the slaves of some defunct economist. (p. 383)

# Economic History

Sue Headlee
*American University*

Economic history is the series of social arrangements and physical processes by which human societies produced the material conditions of human life since the emergence of the human species. The discipline of economic history is the study of this series of arrangements and processes, although much of the discipline is devoted to the study of the development of modern economic growth. The reason for this is that modern economic growth brought with it sustained and accumulating increases in the per capita wealth of human societies. Before modern economic growth, any improvement in productivity led to an increase in the population, not an increase in the standard of living.

In this chapter, human economic history will be examined through the lens of the discipline of economic history. First, theory is analyzed, and then empirical evidence. The theory and evidence sections are followed by policy implications, future directions for research, and a conclusion.

## Theory

Neoclassical economic theory was largely developed in the nineteenth and twentieth centuries at the time of industrialization of the West. It is able to explain the increase of total output and the output per capita for societies with market economies experiencing modern economic growth. Simon Kuznets (1968) defined modern economic growth as sustained and faster growth of output per capita than the rate of growth in earlier periods of history. Neoclassical economic theory does not explain long-term growth or growth of societies where the market is not the predominant mechanism to allocate resources.

Economic growth is caused by an increase in the amount or quality of capital or labor used in production, an increase in the ratio of capital to labor, and technological innovation, according to Robert Solow's (1970) theory of economic growth. Douglass North (1981) added a theory of institutions to the theory to make it possible to analyze longer term growth, starting before markets and aiming to understand how societies came to have markets allocate resources. North thus theorized about how humans advanced from hunting and gathering to the discovery of agriculture and the subsequent rise of ancient civilizations such as ancient Greece and Rome, the rise and fall of feudalism in Europe, and finally the era of early modern Europe. With a theory of institutions, North could explain the distribution of the costs and benefits of economic growth.

As a field of economics, the discipline of economic history has focused on the causes and effects of modern economic growth in the West. This is important because in fact modern economic growth arose in the West and then transformed the world, creating the industrial civilization that we live in today. What follows is a survey of the factors most widely thought to cause modern economic growth.

### Causes of Modern Economic Growth

*Expansion of Markets and Trade*

Adam Smith (1776/1976) wrote that the greater the extent of the market and the greater the development of the division of labor and specialization, the greater the wealth of nations. Since Smith, neoclassical economists have focused on markets, the market system, and the price mechanism as the foundations of modern economic growth.

Neoclassical economic theory states that when output and inputs to production are allocated by markets efficiently, this stimulates growth. In addition, relative prices guide economic agents to make production and distribution decisions efficiently. David Ricardo (1819) put forth the comparative advantage theory of why countries trade. This theory held that it was to the advantage of all countries to trade by specializing in the production of a good in which they had a comparative, even if not absolute, advantage. Increasing international trade causes economic growth.

*Evolution of Institutions*

North won the Nobel Prize in Economics for adding the causal factor of the evolution of institutions to the neoclassical growth model. A key institution is the regime of property rights, which gives economic agents incentive to save and invest in physical, financial, and human capital. Political institutions evolve that specify and enforce these property rights. Institutions, like markets, provide incentives. Economists believe that when there are positive incentives to do so, people will respond with behavior that leads to growth. If property rights are secure, farmers will invest in improving their farms.

*Rise of the Modern State*

Among the institutions conducive to modern economic growth, of great importance is the modern state. Premodern states are a drag on progress because they favor the elite, aristocrats, and landowners, giving them rent (income from power and owning land) rather than gains from investment in production. Modern states, more representative of the middle classes, can implement economic policy to favor domestic markets. This leads to an increase in the standard of living of the population. Government policies that help economic growth include the investment in infrastructure, such as railroads and ports, and in human capital, such as literacy training for adults and the spread of primary education for children.

*Accelerated Technological Change*

Thomas Malthus (1798/1993) held that incomes do not rise when there is an increase in productivity. He argued that populations tend to grow beyond the capacity of resources and that societies use an increase in production to support more people, rather than to increase the standard of living. Historically, much of the world has stayed in a static economic condition or has gone through waves of expansion followed by decline because of this Malthusian trap. Malthus lived before the great acceleration of technology that made modern economic growth possible.

Joel Mokyr (1990, 2002) has written that the important characteristic of the Industrial Revolution was its accelerating and unprecedented technological change. Technological innovation increases the productivity of labor, making an increase in income per capita possible. Technological change has developed slowly throughout history, but in the late eighteenth century, there was a dramatic speedup in the pace and the ability to sustain it. The Industrial Revolution was a pivotal event in human history. Technological change revolutionized manufacturing, agriculture, and transportation in the nineteenth and twentieth centuries.

*Human Capital and the Stock of Knowledge*

Gary Becker (1975) stressed the role of human capital in causing economic growth. Human capital is what economists call the result of investing in education and training, just as investing in productive equipment is called capital formation. Solow's (1970) growth model shows that this investing in education improves the quality of the labor input and thus adds to the productive capacity of the economy. Mokyr (1990, 2002) provides a history of the development of the stock of knowledge in the West that enabled the elites of societies to advance the mastery of nature for the benefits of the masses of the population.

*Demographic Changes*

Becker (1975) found that under certain circumstances, people reduce the number of children they have. They may do this because they no longer need the labor of children on the farm or for security in old age. They may do it to have a higher standard of living for themselves and/or to have "higher" quality children. This makes it possible for the economy's output to grow faster than the population. There is a feedback loop here in that as income per capita grows, people reduce family size further. In some societies, the demographic transition from women having many children to having fewer children comes before economic growth, and in some it comes after that growth. North (1981) speaks of this process as lining up individual and social costs and benefits of having children.

*Evolution of Capitalism and Industrialization*

Under capitalism, profit maximization by the capitalist firm induces competition and that induces technical innovation, as firms look for ways to increase productivity and reduce costs. That in turn increases the productivity of labor, further propelling industrialization. The factory system evolved to capture economies of scale by using the steam engine and organizing large groups of hired labor. Factories replaced artisan shops, home production, and the cottage industry. Thus, it was not just the application of science and technology to production that created modern economic growth but also a new way of organizing production: capitalism. Capitalism uses a market economy based on private ownership by individuals or corporations and private investment. The role of the state is to protect property rights and contracts. The first Industrial Revolution consisted of the mechanization of production

and the use of inanimate power. Joseph Schumpeter (1961) stressed waves of technological innovation financed by the extension of credit as characteristic of capitalism. "Industrial capitalism" was the initial path out of the Malthusian trap in the West.

*Expansion of Agriculture*

W. W. Rostow (1960) wrote that an increase in agricultural output beyond what is required for subsistence is needed to free up agricultural workers for industrial jobs, to supply food, for markets and for capital. Commercialized agriculture tends to produce this increase and thus replaces subsistence farming. One structural change accompanying modern economic growth is the reduction of the percentage of the labor force that is working in agriculture.

*External Causes: Shocks and Substitutions*

Neoclassical economics has had success in explaining the economic growth of countries such as the United Kingdom and the United States. But not all countries were so fortunate as to evolve by market mechanisms. Some countries were awakened by external shocks, from the commercial or military power of those early industrialized states. When a nation is shocked, it can respond to this challenge by adopting the industrial capitalism of its conquerors as Japan did in the nineteenth century, or it can submit and be dominated, as China did. Alexander Gershenkron (1962) wrote that, in backward countries, the state could make substitutions for one of the missing prerequisites for industrial development, such as taking the place of entrepreneurs if none were available in the private sector. He theorized that the more backward the country, the more the state focused efforts on developing heavy industries and large-scale production. This path to modern economic growth is more than usually uneven and dualistic, with the modern sector developing independently of the traditional sector, and often with no increase in the standard of living of the common people, as can be seen in Germany and Russia in the nineteenth century.

*External Causes: International Trade and Investment, Colonialism, Imperialism*

Neoclassical economists argue that the colonial powers broke down the barriers to growth in non-European countries, freeing them up for potential modernization. Furthermore, foreign-promoted export expansion—by means such as developing plantations and mines—enabled non-European countries to grow. Some European colonial powers left additional positive legacies, such as the rule of law, secure property rights, modern transportation, and communication systems. On the other hand, Andre Gunder Frank (1966) argued that in the nineteenth and twentieth centuries, foreign capitalist penetration of countries such as Argentina and India led them to be dependent on the European powers, resulting in underdevelopment at home. This is called dependency theory. On this view, at the time of independence, after draining off the surplus production for decades, the colonial powers left their former colonies in the hands of a local elite uninterested in pursuing economic development, and they left a transportation system designed to facilitate export from the colony to the mother country, rather than for internal development within the country or region. The railroads led from the interior of Africa and Latin America to the ports but not between places within each continent. Technological change brought by the colonial powers did lead to an increase in productivity, but it did not lead to an increase in the standard of living of the larger population, which stagnated during the colonial period.

## Effects of Modern Economic Growth

The increasing productivity of labor achieved under modern economic growth causes the cost of basic goods to fall and enables the real wage to rise. There is also a huge decrease in the drudgery of labor, and life in general becomes more comfortable. A large middle class develops between the old groups of rich and poor of premodern days. Medical advances and improved sanitation lead to declining mortality and morbidity rates (Riley, 2001). All these signify great increases in material well-being of the bulk of the population. North (1981) and Lindert and Williamson (1983) take this view of the consequences of modern economic growth.

Not all economic historians agree on the positive effect of modern economic growth on the working class and on the poor. Frederick Engels (1845/1974) and Eric Hobsbawm (1968) saw this effect as negative. Cynthia Taft Morris and Irma Adelman (1988) argue that the nature of this effect depends on the timing and pace of industrialization, developments in agriculture, and the growth of population. They theorize that, in the early stages of modern economic development, per capita income and the average wage in agriculture and in industry do fall somewhat, and the proportion of the population in extreme poverty does rise. This happens where change was rapid and new employment was not available to replace the traditional jobs that were lost due to economic change. However, Morris and Adelman maintain that in the long run, poverty was reduced by the continued growth in the productivity of labor.

Due to contemporary concerns over climate change, Angus Maddison (2007) has projected trends in the future relationships between economic growth, energy consumption, carbon emissions, and global warming. This theorizing sheds light on pollution as a major effect of the Industrial Revolution. Starting with the use of coal, the first fossil fuel, and later petroleum, the second fossil fuel, the energy sources for industrialization produced the negative externality of pollution. On the other hand, Indur

Goklany (2007) presents arguments and evidence that we are living on a cleaner planet due to technological innovation and economic development.

Modern economic growth gave wealth and power to the West, and that economic power led to political and military power and the ability to dominate much of the world. Some find this course of events to be negative and label it *Western imperialism.* Others interpret it as merely a matter of increased trade and investment of the West in the rest of the world with positive effects for all.

## The Historical Record

### Europe

The economic history of Europe is studied because Europe was the first region of the world to develop modern economic growth and because of its successful offspring: the United States, Canada, Australia, and New Zealand.

To discuss the economic history of Europe as far back as the Roman Empire, we must leave the realm of modern economic growth and enter the realm of long-term economic development. North (1981) stressed the importance to continental Europe of inheriting Roman law, the codification of property rights. The Roman Empire lasted for a thousand years, with a high point in 200 CE. The Roman Empire conquered what today are the European nation-states of Italy, France, Spain, the United Kingdom, and Romania. The Roman Empire collapsed in the fifth century CE. In the Dark Ages that followed, there is little empirical evidence of economic activity in Europe. It is known that the rise of Islam caused the Mediterranean to become a Muslim lake in this period.

Economic historians have analyzed the rise and fall of the European feudal system, with a labor system of serfdom and a political system of decentralized control by lords. Eventually, long-distance trade was revived and cities evolved in previously rural economies. Manufacturing advances such as in the production of woolen yarn and woolen garments took place in northern Italy and Flanders.

Robert Brenner (1987) ignited a debate by arguing that in the fourteenth century, there was a great divide between Western and Eastern Europe. In the West, the feudal system evolved from a labor system of dependent serfs to a labor system of independent peasants, and thus forward economic developments could occur. In the East, the feudal system was confirmed in the form of serfdom and thus doomed to backwardness. This was also the era of the Black Death, in which so many Europeans died that there was a fundamental change in the labor-to-land ratio. In Western Europe, that enabled serfs to become free peasants.

Jan de Vries (1976) wrote a general history of Europe from 1600 to 1750. This is a crucial period because it was a period of crisis in Europe's traditional economy after the great expansion of the sixteenth century and before the great expansion that came with the Industrial Revolution. Countries and regions responded differently as they reached the limits of earlier forms of economic growth. Economic activity and political power shifted from the Mediterranean and the exhausted empire of Spain to the northwestern edge of Europe and its Atlantic coast. Parts of northern Europe achieved highly commercialized agriculture; southern areas struggled to achieve subsistence. Industry moved to the countryside and was restructured as the "putting-out system," also referred to as proto-industrialization. The Dutch added dynamism to trade with ships that could carry great bulk, creating a new high-volume, low-value trade. The British were creating an Atlantic economy with their colonies in North America. Europe was urbanizing with a few cities growing rapidly. In northwestern Europe, governments invested in canals, roads, and coastal shipping. Markets in land, labor, and even some capital markets were developing. All these activities were creating the preconditions for industrialization and huge economic growth to come in northwestern areas of Europe.

Brenner (1987) argued that in the seventeenth century, the United Kingdom pulled ahead as the strongest economy in Europe by developing capitalist farming using commercialized land, capitalist farmers, and wage laborers. This is in contrast to France, which by and large kept a semi-feudal system of peasants and sharecropping—a less progressive form of agriculture.

A large literature has been created on the economic history of the United Kingdom, the Netherlands, France, Germany, and Russia. I present the main outlines of these stories.

#### *The United Kingdom*

In the hundred years from 1760 to 1860, the economy of the United Kingdom was transformed by the Industrial Revolution. This spread to the European continent a generation later. Under the hegemony of the United Kingdom between 1850 and 1914, there was a dramatic spread of modern economic growth throughout much of the world, in individual countries, in some colonies, and in an international economy with global capital markets, railroad construction, and a global cotton textile market. The discipline of economic history has sought to explain why the Industrial Revolution took place in Western Europe and why it began on the small islands of the United Kingdom.

David Landes (1969) documented the leading sectors of the Industrial Revolution in the United Kingdom: cotton textiles and the coal-steam-iron complex. In the cotton sector, technological innovations included the mechanization of cotton spinning and weaving and the use of machine tools to produce textile machinery. In the coal-steam-iron sector, there was the use of coal, the first fossil fuel, which replaced wood (a renewable energy source). New ways of making iron with coke enlarged the capacity to produce iron. The newly invented steam engine replaced watermills, animal and human power, and sailing ships.

Economic historians have advanced many theories of why the United Kingdom was the home of the first Industrial Revolution. First, it had a modern state dating from the seventeenth-century Civil War, which established a constitutional monarchy. Second, the United Kingdom had an agricultural revolution that freed up labor and capital for the industrial sector. Third, it expanded overseas, created an empire, and dominated international trade and finance. The crown jewel of the Empire was India. At first, the United Kingdom imported Indian textiles and tea, but in time, the United Kingdom forced India to import cheap cotton textiles from the United Kingdom, as well as iron. The British used their superior military power to get the Chinese to import opium in exchange for tea. The United Kingdom established an informal empire in Latin America after these nations gained independence from Spain and Portugal. The United Kingdom was a winner in the "Scramble for Africa," thereby gaining a market for its cotton textiles, iron, and railroad building.

There was a highly charged debate in British economic history between the pessimists and optimists on the standard of living of English workers during the Industrial Revolution. The pessimists argue that the impact was negative and that the workers were impoverished. E. P. Thompson (1963) analyzed the making of the English working class, a process that took more than a generation. Engels (1845/1974) described the hard conditions of the working class in England during its second generation. Riley (2001) documented a decline in life expectancy in some industrial cities. Hobsbawm (1968) stressed the terrible insecurity due to cyclical and severe unemployment experienced by three generations of workers. C. T. Morris and Adelman (1988) added the focus on the course of poverty during the Industrial Revolution and demonstrated that in the United Kingdom, poverty increased painfully in early stages, though in time it decreased. The impoverishment of the handloom weavers caused by the introduction of the mechanical loom is an example of how economic development can worsen the condition of parts of the working class, at least temporarily.

The optimists such as T. S. Ashton (1948) argued that the impact was positive and that the standard of living of British workers increased. Lindert and Williamson (1983), mining new sources of accumulating data, demonstrated that from 1820 to 1850, the level of real wages doubled. Gregory Clark's (2007) study led him to conclude that the real wages of urban unskilled workers began to rise by 1815.

Looking back on the debate now, it appears that both sides were right. The first generation of English factory workers was impoverished, but their grandsons reaped the rewards of their sacrifices, achieving a much higher standard of living. Above all, the debate appears to have been about value judgments. The pessimists took the harm to the first and second generations of workers to be important enough to count the effect of industrialization as negative. The optimists took the long-term improvement of living conditions for the majority of workers to count the effect of industrialization as positive, despite the suffering endured by the early generations.

Niall Ferguson (2002) argued that the British Empire was a dynamic force for the good in spreading private enterprise around the world. In addition, he claims that the export of British capital and institutions, such as the common law, a secure land tenure system, and other forms of property rights, was of benefit to the world. The United Kingdom led a world boom of trade and investment from 1899 to 1913, the first era of globalization.

The British Empire had been the largest and most powerful empire in the West since the ancient Roman Empire. However, the world economy eventually found more efficient ways to trade, invest, and grow than by colonizing the non-European world. After World War II, decolonization was accelerated as the peoples of the colonies demanded independence and took action.

### *The Dutch Republic*

In the seventeenth century, before the Industrial Revolution in the United Kingdom, the Dutch Republic was the global power. The Dutch were competitive in international trade because of the sailing vessels they designed that were able to carry large volumes of cargo on transoceanic voyages. They were especially active in the spice trade in the East Indies. In addition, the Dutch Republic was the site of a powerful financial revolution with the founding of a central bank, a national public debt, permanent joint-stock companies, and the Amsterdam Stock Exchange. After 4 years of war between England and the Dutch, the governments of the two great powers divided the East Indies between them, with the Dutch East Indies Company controlling the spice trade in what is today Indonesia and the English East Indies Company controlling the Indian textile trade.

### *France*

The French Revolution got rid of the rent-seeking, landowning feudal class and began the development of democracy in Europe. Yet, the movement of labor from agriculture to industry was much slower in France than in England. French farmers had lower literacy rates and paid a higher percentage of output to direct taxes to the French state. The Industrial Revolution in the United Kingdom was an external shock to the French economy. French industry could not compete with British industry in continental European markets. Challenged by the United Kingdom's development of industrial capitalism, the French took the political route to modernity. In the Second Empire, Louis Napoleon Bonaparte oversaw state-led industrialization, as did the leaders of the Third Republic, established in 1870. The French developed a banking system in Paris to finance the building of railroads in France and Russia. By the late nineteenth century, France was a major industrialized power. The French participated in international trade and

investment in the world economy in the nineteenth century and colonized North and West Africa and Indochina.

*Germany*

Economic history of modern Germany began with Napoleon's defeat of Prussian forces at Jena and the capture of Berlin in 1806. This external shock led to the beginning of the process of unifying the German state. In 1834, a Customs Union, the *Zollverein,* was formed under the leadership of Prussia with most of the other German states. In 1862, Prime Minister Bismarck used the state to industrialize Prussia. The German states were united in 1870 to form Germany. From 1870 to 1914, Germany (along with the United States) created the Second Industrial Revolution based on new technology in heavy industry: chemical, electricity, petroleum, and steel. The Second Industrial Revolution used science-based technological innovation and required the financing and building of fixed capital in the form of plants, machinery, and infrastructure. Large German banks financed the creation of large-scale enterprises with the latest technology. By 1914, Germany was a major industrial power and exporter of capital. Its national output, output per person, and share of world manufacturing were greater than the United Kingdom's. German modern economic growth began later than British and French and was more uneven than is usual in industrial capitalism. The agricultural east of Germany was backward, whereas in the west there had been manufacturing continuously from the Middle Ages, and there was much coal and iron for modern industry. Some economic historians claim that it was the Second Industrial Revolution that created the unparalleled prosperity of the West.

*Russia*

The economic history of modern Russia also began with an external shock, Napoleon's invasion of Russia in 1812. It was not until 1861 that serfdom was abolished in Russia. The freed serfs had to pay for the land they worked, thus keeping them in poverty. Consequently, agriculture was a drag on economic growth, not a handmaiden to it. Russia is a strong case of Gershenkron's (1962) theory that the state can substitute for private entrepreneurs, when they are lacking, and lead an industrialization effort. In 1905, Prime Minister Witte oversaw state-led industrialization. From 1906 to 1914, Prime Minister Stolypin led reform in the agricultural sector, creating private property rights and consolidating small plots into large capitalist farms. More economic progress might have prevented the Russian Revolution in 1917. Central planning with 5-year plans was the strategy of the Soviet communists. In the 1930s, Stalin forced the fastest industrialization of an economy in history, taking 10 years compared to the hundred years it took to industrialize the United Kingdom. This increased the standard of living of industrial workers, but the agrarian workers whose farms were collectivized to feed the industrial workers suffered greatly. The Soviet Union was a case of brutally uneven economic development of late, state-led industrialization.

## Asia, Africa, and Latin America

In Asia, ancient civilizations arose in the river valleys of Mesopotamia, Egypt, India, and China. Human capital development was limited to the spread of literacy in written language among the elites. Physical capital development took the form of irrigation for these agrarian societies. In the medieval era, the rise of Islam from the Arabian Peninsula led to the development of another civilization that spread west along North Africa and east to India and Indonesia. It was spread by Arab warriors and traders. It was a flourishing civilization during the long epoch of the Dark Ages in Europe. The Arabs kept alive the knowledge of the ancient world, which they translated into Arabic. In addition, they translated knowledge from China and India into Arabic. The Islamic Empire covered an area greater than the Roman Empire. Later, Turkish Ottoman invaders from central Asia shocked and then reorganized much of the Middle East. The Ottomans took control from the Arabs but adopted their religion of Islam.

Civilizations also developed beyond the Eurasian land mass: in the New World, the Aztecs and Mayans in Mexico and the Incas in Peru. In sub-Saharan Africa, there arose empires on the plains of Ghana, kingdoms of central Africa, and the states of southern Africa, such as the Great Zimbabwe.

During the "Age of Discovery," from the early fifteenth century to the early seventeenth century, Europeans explored the non-European world, crossing the seas in search of gold, silver, and spices. The Europeans were blocked in the East by Islamic empires and thus could not use the ancient overland "silk road," or the sea route through the Red Sea or the Persian Gulf, to obtain the luxury goods of the East. Facing this challenge, the Portuguese invented the carrack and the caravel, ships that could sail on the open Atlantic. Portuguese explorers rounded the cape of Africa and sailed to India. The Spanish sent Columbus to find Asia by sailing west. In time, the Spanish conquered the ancient empires of the Aztecs in Mexico and the Incas in Peru, stealing their gold and silver. In 1493, the pope divided the world in half along meridians of longitude in the Atlantic and the Pacific, giving Portugal Brazil and all non-European lands to the east of the Atlantic meridian and Spain all the land to the west, including Central and South America and the Philippines. The Spanish sent Portuguese explorer Magellan to sail west to find the Spice Islands (today Indonesia). His ship was the first to circumnavigate the earth. His sailors found the Strait of Malacca, which connects the China Sea with the Indian Ocean. The Portuguese were the first Westerners to reach and trade with Japan. In time, the Spanish and

Portuguese were overtaken by the Dutch, French, and English who ignored the pope's division of the world. Here, then, world economic history begins.

The "Age of Imperialism" saw great rivalry among the industrial nations of Europe, much of which played out in conquering or dominating non-European lands with guns, trade, and investment. The Ottoman Empire (1299–1922 CE) controlled the Middle East, blocking European penetration there until World War I.

Economic historians have tried to explain why Europe pulled ahead of the rest of the world in the modern era. Mokyr (2002) argued that the Industrial Revolution occurred in Europe because of the scientific revolution in the seventeenth century and the Enlightenment in the eighteenth century. He contends that it was the resulting superior technological creativity and knowledge of the British, Germans, and French that enabled them to industrialize first (Mokyr, 1990). Eric Jones (2003) argues that Europe in the early modern era (1400–1800) was developing technology and markets, discovering new lands, and developing a system of nation-states that propelled it to worldwide power and prosperity. He writes that China was a huge empire and controlled from above, and thus it lacked the system of nation-state competition which propelled the great breakthroughs of the Industrial Revolution in Europe. Another disadvantage that China had, according to Jones, was that in the fifteenth century, it closed itself off from maritime exploration and trade, great engines of growth for Europe. Jones also contends that Europe had the advantage of being far from the nomadic raiders from Central Asia that interrupted the trajectory of development in the Islamic Middle East (the Ottomans), India (the Mughals), and China (the Manchus). Recently, Kenneth Pomeranz (2000) has argued that the two causes of Europe escaping the Malthusian trap, led by the United Kingdom, were the colonization of land in the New World and the lucky geographical accident of having coal.

Centuries of commercial capitalism in Europe prior to the Industrial Revolution were part of the advance of Europe over Asia. Thus, the dating of the diverging paths of Europe and Asia becomes an issue. Pomeranz (2000) has claimed and presented some evidence that Europe did not pull ahead of China economically until 1800. This is highly debated. Many economic historians stand by Landes (1969), who demonstrated that from 1500 to 1700, Europe was pulling ahead of Asia in economic growth, and by Maddison (2007), the great constructor of premodern economic statistics of the world, whose statistics showed Western Europe growing twice as fast as the rest of the world from 1000 to 1500 and that Western hegemony was established between 1820 and 1870.

Brief sketches of five major non-European countries and regions are presented below, plus what economic historians had achieved so far in the explaining the economic growth in the non-European world.

### *Japan*

Japan was the first non-Western nation to achieve modern economic growth. Like the British Isles, the Japanese archipelago lies off the Eurasian land mass. This was a time of the crucial importance of water transportation. The external shock that woke up Japan was the gunboat diplomacy of Admiral Perry, who with four U.S. warships demanded that Japan open up to trade. Prior to this shock, Tokugawa Japan (1603–1868) was an isolated, preindustrial feudal society. However, it was not stagnant. The city of Edo (modern-day Tokyo), the seat of the Shogun (secular rulers), in the eighteenth century, was perhaps the largest city in the world. Financing and marketing rice production and coastal shipping developed slowly. To cope with the Western challenge from Perry, the rulers of Japan led a campaign to industrialize and modernize Japan. Feudalism was abolished and a Western-style legal system put into place. These were called the Meiji Reforms. The Meiji Restoration (1860s) gave Japan an emperor but a constitutional monarchy. With a favorable international economic environment, modern businesses arose in the 1880s, and there was a take-off in the 1890s to sustained modern economic growth. Japanese leadership was open to and borrowed methods and ideas from abroad. C. T. Morris and Adelman (1988) describe the growth of productivity in Japanese agriculture from the sixteenth century, leading to market-oriented farmers who emerged from the disintegration of medieval farming in the nineteenth century. They contend that the slow commercialization during the Tokugawa period produced less extreme poverty in Japan than in Russia, India, or China. In the later nineteenth century, the Japanese government had a policy of locating industry in rural areas to absorb underemployed labor, thus reducing poverty. After World War II, Japan rose to become the second largest economy in the world, after the United States.

### *China*

China had a large population on the east end of the Eurasian landmass, just as Europe had on the west end. China manufactured much, invented new technologies, had high levels of literacy, administered exams for civil servants, and had a national market. China had a single government controlling a huge territory for two thousand years. The Chinese invented many important tools but did not apply them economically, such as gun powder. Mokyr (1990) argues that in 1300, China was the site of dramatic technological creativity and yet lost that creativity after this.

In the nineteenth century, European traders forced the Quin Dynasty (Manchu China, 1644–1911) to open to trade, forcing them to take European imports, especially opium. European merchants forced their way into ports such as Shanghai, which became an international city. The British took control of Hong Kong. Chinese economic growth

stagnated in the nineteenth century. The Chinese did not react to the European challenge as the Japanese did; they did not adopt European technology. They exported tea and silk and imported British cotton goods, providing a market second in size only to British India.

The Republic of China, formed in 1912, ended two thousand years of imperial rule and started the early stages of industrialization. This was interrupted by the Japanese invasion in the 1930s and the Chinese Communist takeover in 1949. Communist central planning with 5-year plans led to disasters in agriculture and to forced attempts at industrialization. However, through public investment in health and education, there was an impressive increase in the life expectancy of the Chinese people, a rise in literacy rates, and a decline of the proportion of the population in absolute poverty.

Since 1978, China has been taking off into sustained modern economic growth by opening up to global economic forces and allowing economic competition internally. The world has seen unprecedented economic growth rates in China, raising standards of living and lifting hundreds of millions of people out of poverty.

R. Bin Wong (1997) challenged Western economic historians by documenting "Smithian" economic growth (from trade, not technology) in China up to the nineteenth century. He argues that the West did not overtake China until the Industrial Revolution and its use of inanimate energy. The causes were more political than economic—while China was a huge empire, Europe was a system of competing nation-states propelling modern economic growth.

### *India*

K. N. Chaudhuri (1990) presented the Indian subcontinent as lying at the center of a huge sea trade system with Western Asia, across the Arabian Sea and along the Persian Gulf and the Red Sea, and with Eastern Asia via the Bay of Bengal and through the Straits of Malacca to the China Sea. Indian and other Asian merchants such as the Arabs were the leading economic agents in Asian development for a thousand years before the arrival of the Europeans.

Jones (2003) argues that the economic development of India was interrupted by the invasion of the Mughals from Central Asia in the sixteenth century. In the nineteenth century, India faced a second shock with the invasion of European merchants and in time European governments. British India (1857–1947) has been analyzed by British economic historians. Morris D. Morris (1960) argued that economic growth in India in the nineteenth century was constrained by lack of productive capacity, not by the politics of colonialism. Under the 90 years of British colonialism, India was open to trade and investment from the world economy, connected to it by the Suez Canal, railroads, and telegraph. The British developed land markets and established secure property rights. They commercialized agriculture and developed export crops of cotton and tea. Much of this was accomplished by coercion and violence. Tirthankar Roy (2002) argued that, in the first 60 years of British colonialism, there was economic growth in India and an increase in the standard of living. But after World War I, conditions worsened for the whole world economy and thus for India, which was connected to that world economy.

For the postcolonial period, Indian scholars tended to focus on the negative consequences of a century of British rule in India. The British certainly did leave India with low life expectancy, low literacy, stalled industrialization, and trouble feeding itself. It is not known whether this was worse than they found it in terms of the masses of the Indian population. From 1947 to 1990, the leaders of independent and democratic India closed the economy off from the West. Progress was made domestically using central planning with 5-year plans focused on agriculture. With the help of Western science and philanthropy, the Green Revolution of using high-yielding hybrids of rice and wheat after 1965 enabled India to feed its growing population. Indian central planners practiced import-substitution (protecting infant industries and producing at home what was previously imported) and used subsidies to support industrialization as well as maintain the cottage industry. Their goal was equity as much as efficiency.

Since the 1990s, the Indian government has been liberalizing the economy and opening it to the world. Currently, India is experiencing modern economic growth due to the expansion of the information technology sector and other business services and, to a lesser extent, labor-intensive manufacturing. Economists are studying the transformation from the lower "Hindu" rate of growth under central planning to the accelerated rate under economic reforms. India still lags behind China in educating its people and in investment in infrastructure.

### *Latin America*

While there are many histories of the Aztec, Mayan, and Incan civilizations, there have been few studies of their economic histories. In English, there are some economic histories of colonial Latin America. Most of the countries in Latin America gained their independence from European powers by the early nineteenth century: Brazil from Portugal and Argentina and the rest of Latin America from Spain. The empirical research of C. T. Morris and Adelman (1988) on the role of foreign economic dependence in the nineteenth century found that while Argentina was politically independent, an alliance of indigenous landlords and the British investors favored exports (beef and wheat) over domestic development. Argentina became heavily dependent: Domestic growth was dominated by their exports at the expense of developing a domestic market, foreigners dominated trade and banking, and investment was financed by foreigners, mainly the British. Morris and Adelman found Brazil to be moderately dependent on foreigners, first for the exportation of sugar and later coffee. Also, slavery was practiced in Brazil until

1888, which was not favorable to modern economic growth. Slavery generates no incentives for technological innovation because the cheap labor of slaves is available. Slavery did produce wealth for the slave owners, but it did not create households that had effective demand for consumer goods because slaves were kept at a low standard of living. Perhaps even more important for economic development, slave owners did not have demand for producer goods because they could not trust their slaves with more than rudimentary tools.

Enrique Cardenas and his colleagues published three volumes on the economic history of Latin America (Cardenas, Ocampo, & Thorp, 2002), in which they challenged the views of dependency theorists (Cardoso & Faletto, 1979; Frank, 1966) on the negative effects of European colonization and imperialism. They present evidence that, from 1870 to 1930, in addition to the expansion of foreign-promoted exports from Latin America, there was also development of domestic markets and manufacturing capacity. They cite the technological advance of the steel-hulled steamship, which reduced international transportation costs and thereby enabled Latin American countries to export their mineral and agricultural raw materials. It is true that foreigners invested in these sectors, as well as financed and built the railroad system needed for export, but in this view, that dependence was not negative but helpful. There is evidence of a domestic market made up of wage workers from the ranches, plantations, mines, railroads, and ports who wanted locally produced cotton clothing, beer, and cigarettes. During the Great Depression, industries in Latin America were able to grow domestically as world trade collapsed. Unlike the Washington consensus view that export-led growth is the best strategy for development, Cardenas et al. (2002) argue that import-substitution industrialization made sense in the 1940s to the 1960s for the development of national economies. In this strategy, a nation imported capital goods and then produced consumer goods for the domestic market that otherwise would have had to have been imported.

### *Africa*

There were many complex African empires and civilizations before the Europeans came to Africa. There are some histories of European colonization of Africa. But the development of the economic history of Africa as a discipline is just beginning.

From the sixteenth to the nineteenth centuries, about 9 to 12 million enslaved Africans were brought to the New World, mostly to Brazil. Seventy percent of all slaves were used on sugar plantations. European competition drove the process, starting with the Portuguese, the Spanish, and, later, the slave and sugar merchants of France, England, and Holland. By the eighteenth century, the British were the leading slave traders. The triangular trade consisted of Europeans taking copper, cloth, guns, ammunition, and alcoholic beverages to West Africa, exchanging them for African slaves, who were taken via the Middle Passage to the West Indies, where the slaves were traded for sugar, rum, molasses, and tobacco, which were then sent to European markets.

Eric Williams (1966) set off a debate that has continued for over a half century on the role of profits on the slave trade, as well as on slave production in the New World, for the economic development of Europe. He argued that Europe could not have taken off into modern economic growth without those ill-gained profits. Pomeranz (2000) presented empirical evidence showing that the amount exploited from this brutal activity was not as large as the profits made in the United Kingdom and Europe from their own domestic production of farms, workshops, and factories. The implication is that Europe could have advanced without the profits of the slave trade and slave production. In 1807, the United Kingdom abolished the slave trade, and in the 1880s, Brazil abolished slavery, the last country in the Western Hemisphere to do so. Thomas Pakenham (1991) has documented the "Scramble for Africa," when, from 1876 to 1912, the European nations divided sub-Saharan Africa among themselves for needed raw materials and for markets for their manufactured goods.

## Policy Implications

Economic history of the developed world can be used by development economists searching for the path to modern economic growth for those nations not yet on their way. Development economists are interested in poverty alleviation in addition to the goal of modern economic growth. One lesson for poverty reduction seems to be that agriculture and the rural sector need to be developed. Another implication is that the role of the state is complex in promoting modern economic growth. There is a role—to provide public infrastructure and human capital—but there is the danger of too much government intervention blocking market forces for change. National leadership and political will are needed to lead the drive for modern economic growth. The historical record is mixed on whether a nation should use an export-led growth strategy or an import-substitution industrialization. The case of Japan shows how policy can prevent an aggravation of poverty during industrialization. The cases of China and India suggest that nations need to be open to the world economy.

## Future Directions

Each generation has to write its own history, its own interpretation of past events, because it is faced with new problems that need different lessons from history. The twentieth century is now history. One possible agenda for finding out how to promote modern economic growth in the poor nations of the world would be to compare the Industrial Revolutions of the United Kingdom and continental Europe with that of the Soviet Union in the 1930s and with

China in the last quarter of the twentieth century. The continuing power of European and American banks and industrial firms in Africa needs to be analyzed and compared with the internal constraints on modern economic growth of the intrusive governments of many of the nations of Africa. Globalization now under the United States should be compared to globalization in the nineteenth century under the United Kingdom. Just as economic historians have tried to explain the rise of the West, now the rise of the East should be analyzed. In addition, economic historians should benefit from researching the economic history of the Middle East.

## Conclusion

The neoclassical model of growth explains the rise of the United Kingdom, France, and the United States in the nineteenth century, but heterodox models are needed to explain the underdevelopment of nations such as Argentina and India in the nineteenth and twentieth centuries. Dependency theory is still relevant but must be balanced with the neoclassical economic historians' view that imperialism (international trade and investment) was the pioneer of capitalism in the non-European world. The benefits of capitalism and imperialism are an increase in the material standard of living and an increase in life expectancy for many people. The costs seem to be a widening divergence in the fate of rich and poor countries and the pollution of the planet.

# Economic Methodology

Timothy A. Wunder
*University of Texas at Arlington*

Undergraduate students are often introduced to economic concepts using graphical expressions, and the expressions become the defining method of explaining and exploring the economic realm. The graphs become what the students perceive as "economics," and this is what is meant as "methodology." If you ask the students, "How do you do economics?" the answer would be based on the graphical examples offered in the classes. Methodology is a complicated way of saying, "These are the tools economists use to explain the economy." Beginning students are offered very simple tools to explain the concepts of supply, demand, and equilibrium, but the ideas, as well as the graphs, are all part of the methodology.

In most undergraduate economics classes, theory is offered to the student as a body of cohesive ideas set within a structure that seems internally consistent and mutually reinforcing. Such a monolithic view of theory may offer simplicity to a student who is just learning the basics, but this monolithic vision of methodology offers a false level of certainty based on an oversimplified version of ideas. Methodology used by economists today is very different from what was used 30 years ago, and what was used 30 years ago was very different from the methodology used by such great economists as Adam Smith and David Ricardo. The economic methodology that is taught in undergraduate courses today is the result of centuries of intellectual debate, and the origin of this body has been filled with differing thinkers often in violent disagreement with each other. It is in this history of methodology that the origins of undergraduate theory can be found, and an exploration of this history is both exciting and illuminating.

There are generally two standard bodies of theory that are offered in undergraduate economics classes. The microbody of theory offers a vision based on the individual behavior of consumers and firms. These actors operate under a theory of rational self-interest that leads to stable social outcomes referred to as equilibriums. The second body of theory is the macroexploration of economic activity. In this body, the economy as a whole is examined, and differing reasons are offered to explain why certain events occur the way they do. Undergraduate classes suggest that the microeconomy is ruled by the prevailing forces of supply and demand, and the macroeconomy is explained by aggregate supply and aggregate demand. This chapter's focus will be to explore where these theories and this methodology arose from.

## Present State of Economic Methodology

Trying to describe what is the present state of methodology in economics is a lot like trying to summarize modern culture. Whatever statements are made are going to be overgeneralizations with respect to differing groups. The methodology of undergraduate economics and that of professional economists is very different. The undergraduate will often learn about economic theory using graphs and some math, and even a little econometrics may be thrown in. This type of methodology was the prevailing form done by professional economists perhaps 30 years ago, but it is vastly different from what is done by professional economists today.

Professional economics is in a state of transition with respect to the methodology being used. The methodology

taught in undergraduate classes, however, does offer a reasonable, though simplified, vision of methodology that was used by most professional economists throughout the majority of the twentieth century. In the past, there were four major components to professional economic methodology. First was that economists agreed that the study of economics was based on the study of the individual, not of groups. Basing the study on the individual is known as methodological individualism, as opposed to methodological collectivism, in which individuals are studied within the context of the groups to which they belong. Second, economists held a mechanistic vision of the economy where economic laws were like physical laws seen in Newtonian physics. Equilibrium was the ultimate outcome that the economy would eventually revert back to. Third, mathematical rigor and deductive reasoning were used in place of empirical observations because there is an inability to conduct controlled economic experiments. Finally, internal consistency of theory was more important than empirical evidence, and evidence contradicting consistency was not highly valued.

As this chapter is being written, professional economists are questioning the appropriateness of all four methodologies. First, many within economics are now calling into question the appropriateness of studying economics based on solely individual action. Some economists, such as behavioral economists, are exploring how individuals behave within group economic settings, and the research is becoming popular. Readers interested in an introduction to this type of economics should read *Predictably Irrational* by Dan Ariely (2008). Second, the mechanistic concept of an economy headed toward an ultimate equilibrium is also being called into question, and this can be seen in books such as *The Origin of Wealth* by Eric D. Beinhocker (2006). Third, economists are not abandoning math, but deductive reasoning is giving way to more inductive methods. Under deductive reasoning, economists would state certain assumptions they believed to be true; by deductive logic, if the assumptions were true, then the conclusions would have to be true. Modern methodology is becoming much more inductive in that economists are testing theories using econometric techniques. This inductive method essentially starts by observing what is going on in the world and then hypothesizing why it is going on. The biggest unwritten rule in modern professional economics is that theory should be explored using data sets and econometric techniques, and this is far more inductive than methodology from even 30 years ago. Finally, the idea that internal consistency is more important than empirical verification is clearly falling by the wayside. The goal of many new economic studies is to use econometric techniques and data to either prove or disprove certain aspects of theory. For information on this issue, see Colander (2000, 2005, 2009); Colander, Holt, and Rosser (2007–2008); and Davis (2007). Modern methodology is in a state of flux, so this chapter will explore the origins of the methodology that was predominant 30 years ago and is still taught as "economics" in undergraduate classes today.

It should be noted that not everybody agrees with the above interpretation of the current state of methodology. Some historians of economic thought would disagree with this description of modern methodology and would disagree about the openness of economics to differing theories. In fact, many economists call themselves heterodox economists who would argue that the changes listed above are superficial at best. Readers interested in examining some materials from these heterodox thinkers can find many online resources at www.heterodoxnews.com. The truth is that it is difficult to determine who is correct because gradual change is much harder to recognize than is radical change. Often, paradigm changes in a discipline are radical in nature, and two periods in time are readily identifiable. Thomas Kuhn (1970) advanced this idea in *The Structure of Scientific Revolutions,* and the idea has been readily adopted by many who study the history of economic thought. The changes occurring in the methodology of economics today seem transformative of the discipline, but they have not come as an abrupt disjuncture from the previous methods. With that note, the chapter now turns to the origins of modern economics starting more than 200 years ago.

## The Classical Paradigm

In 1776, Adam Smith wrote *An Inquiry Into the Nature and Causes of the Wealth of Nations,* and economics as a modern intellectual discipline began. Most of what Adam Smith wrote in *Wealth of Nations* had been written about previously, but Smith brought all of the disparate ideas together into one work. With the unification of these ideas into a single work, a new and unique way of analyzing economic activity had been created. Yet what Adam Smith wrote in 1776 and what students are taught in undergraduate classes today are very different. In fact, Smith created a new methodology for exploring economic topics, but that methodology is not the methodology used today. This section will first explain the accomplishments of Smith and then talk about the methodology known as classical economics.

### Smith's Work

Smith's major contribution was to summarize a large body of thought into a single work, but Smith also explained how an economic system could work when there was no central control to direct the system. Smith argued that an economic system could operate without any form of central guidance, and society could be very well off allowing such a system to operate. Smith recognized that wealth was based on the ownership, use, and construction of goods and services rather than the possession of money. Smith showed how an economic system

based on people acting in their own rational best interests could lead to a socially desirable outcome. Anyone taking a modern introductory economics class can recognize these ideas in modern theory.

Adam Smith wrote *Wealth of Nations* to refute some of the mercantilist ideas that were prevalent at the time. Mercantilist policies emphasized the accumulation of gold to sustain military strength. Smith recognized that the end goal was the production of the materials needed to support the military. It was not the gold that supported the military; rather, it was the ability to produce food, ships, guns, and other items that ultimately allowed for maintained military strength. Modern economists are still far more interested in the exploration of the production of real goods and services than they are interested in the issues of money. The exploration of money in the realm of modern economics is almost always associated with how money affects the production of goods and services.

This materialist vision of economics was a breakthrough, but the idea that an economy could operate without centralized control was an even bigger revolution. As far back as the ancient Greeks, there was a negative connotation to people operating in an economic sphere with the sole purpose of gain. Aristotle and Aquinas, as well as most other previous thinkers, suggested that trade for profit was somehow unnatural. Smith confronted this paradigm, and his arguments shifted social thought in a completely new direction. Smith argued that individuals took the actions they did because they were pursuing their own self-interest. The baker makes loaves of bread for others to use in sandwiches but not out of generosity. She bakes so that she can sell the bread and use that money to buy the objects she wants. It is true that the baker serves the sandwich eater, but she does not do so out of charity; rather, she does so in pursuing her own self-interest.

Smith (1776/1965) argued that self-interest would direct most people's activities toward ends that would benefit society as a whole. He argued that an individual working in pursuit of his own self-interest "intends only his own gain, and he is in this, as in many other cases, led by an invisible hand to promote an end which was no part of his intention" (p. 423). The pursuit of self-interest alone could lead to outcomes that would benefit society in general. This was unprecedented in previous economic thinking, and this idea would become a cornerstone of economic methodology from this point forward.

## Ricardo and Malthus

Smith's (1776/1965) work became a watershed moment in economic thinking. By offering a system of thought that demonstrated how a decentralized economy worked, he allowed others to explore some of the components of such an economy. There were many important thinkers involved in the classical period, but the two who take on the greatest significance with respect to shaping future methodology are Thomas Malthus and David Ricardo. It is interesting to note that these two thinkers were in dramatic disagreement about many of the important classical ideas.

Thomas Malthus was an Anglican curate who began his exploration of economic topics to demonstrate the futility of utopian experiments to improve the lives of the poor. Malthus is most famous for his population doctrine that stated food production increased at an arithmetic rate, whereas human population increased geometrically. Given these differing rates, human populations would be forced to subsistence living. Malthus believed that as food grew scarce, relative to population, only two options were available: Either human population had to control birth rates, or nature would increase death rates. Malthus did not discuss issues such as birth control, so the only method of population control was human abstinence, and he had little hope that human self-control would win out. The thinking behind this population doctrine still is influencing modern discussions and also influenced thinkers outside economics, including Charles Darwin.

Related to this population theory was a concept that became known as the wage fund doctrine. In this theory, Malthus proposed that the ability of capitalists to fund projects was based on the available food in the system controlled by the capitalist. In the end, the workers had to be paid enough so that they could feed themselves and perpetuate the next generation. Malthus argued that the behavior of workers was such that increasing the wages of the workers would lead to increased procreation. Increased procreation would lower the pay of workers in future generations. In the end, the only stable outcome was one in which the wages paid the workers were at a subsistence level. The overall outcome in any economy might show temporary improvements in the material condition of the population, but in the long run, the condition would revert to a steady-state subsistence level.

David Ricardo was born into a merchant family and was able to earn substantial wealth as a stock broker before writing on economics. In 1817, and republished in several editions, Ricardo published *The Principles of Political Economy and Taxation,* which replaced Smith's *Wealth of Nations* as the primary reference for economic thinking. In *Principles,* Ricardo moved away from the Smithian methodology of deductive reasoning with inductive analogies to demonstrate the ideas. Ricardo moved into a very formal method of economics that was strictly deductive in manner. In this method, referred to as deductive reductionism, abstractions became a cornerstone of theory, and simplifications allowed for the creation of a model from which generalizations could be drawn. Ricardo very rarely started out with observations in the real world; instead, he began with his theories and proscribed advice for real-world situations based on how the model predicted the real world would react.

Ricardo created these models because he was interested in exploring why income distributions changed in the manner they did. To explain how incomes were determined required an explanation of why certain items traded

for higher prices than others. Inevitably, any such exploration will eventually call into question what is the source of value in a system, and answering that question is much harder than it may seem. Ricardo offered up a theory of value that took into account rents going to landowners, profits going to capital owners, and wages going to workers. However, Ricardo's theory of value really emphasized the absolute importance of labor in the whole process. Most historians of thought agree that Ricardo's theory of value was very much based on labor's role in the productive process, and thus it became known as a labor theory of value. An example to explain this idea is simple. In a primitive society where it takes 4 hours to capture a deer and 2 hours to capture a beaver, two beavers will trade for one deer.

Ricardo and Malthus were contemporaries and were in correspondence with each other for an extended period of time. They influenced one another's work, and in some cases, they were also very much in opposition to each other's ideas and methods. One of the greatest conflicts between these two thinkers involved the work of French economist J. B. Say. Say argued that a decentralized economy, as described by Smith, would by its very nature always use the whole of the resources available. This idea has come to be known as Say's law and has been abbreviated to read "supply creates its own demand." Suppose a baker sells a cake for $30; the baker immediately has created $30 worth of purchasing power. The process of creating a product immediately creates the purchasing power in the system to buy goods of equal value. If the baker does not spend the purchasing power herself, then she will lend the money to someone who will. On an economy-wide basis, this suggests that although there might be an overabundance in one good, there cannot be a general overabundance (known as a recession).

Malthus and Ricardo found themselves on differing sides of this issue. Ricardo was a backer of Say's law, whereas Malthus argued that the law was flawed. Ricardo believed that the Say's law was deductively true and therefore should be believed, whereas Malthus simply pointed to the history of continuing recessions. Ricardo believed that any general underconsumption (i.e., recession) could only be temporary and therefore dismissed it as a topic. Malthus believed underconsumption could occur for an extended time period and thought that looking at the issues involved was important. In the end, Ricardo's views became dominant until the arrival of Keynes, who will be discussed below.

## J. S. Mill and the Decline of the Classical Paradigm

The classical paradigm started in 1776 with *Wealth of Nations* and came to an end somewhere in the late 1800s. Although a precise final date cannot be given, a final great thinker of the movement can. John Stuart Mill was the son of James Mill, who was also a classical economist. J. S. Mill had a rigorous childhood education, and it is probable that he was one of the finest minds of his time. He was able to bring together all of the pieces of the classical paradigm and polish them in a way that established the high watermark of that school of thought.

Mill both explained the classical school's thoughts and had within his works the seeds of the economic thinking that would come to replace the classical paradigm. Mill was a firm believer in Say's law and a follower of the Ricardian tradition of deductive reductionism as a substitute for the inability to perform experiments in economics. Mill was a proponent of the separation of positive economics from normative economics, and he argued that economists could separate explanations of how the economy works (positive economics) from the moral validity of the economic outcomes (normative economics). This positive–normative distinction is still highly influential in economic circles today. Most economic theory tries to explain the economy from a positive perspective, and most economists will try to make their normative opinions known. However, other economists, such as Joseph Schumpeter, have suggested that the normative and positive aspects of economic theory are not so easily separable. Mill believed by concentrating on positive economics, the discipline could become more scientific in method and economic understanding could be improved.

Probably the most important aspect of Mill's contribution was his ability to summarize and defend the classical position against the onslaught of opposing social thought at the time. The mid-1800s was a time of great social upheaval, and there was a large reactionary movement against the social changes imposed by the rise of industrialization. Because the classical paradigm was seen by many as a defense of the capitalist system, Mill's ability to maintain the school's prominence was noteworthy. He was able to do this partially because he sympathized with the beliefs of the system's critics. Mill was able to refine the classical theory of economic growth and argued that the stationary state, which was a major prediction of classical theory, was not necessarily a bad outcome. Mill believed that the arrival of the new stationary level of economic activity could be achieved within a context of a more just social distribution of income. Mill thought differently than Malthus, who argued the future stationary system would condemn the multitudes to subsistence. Mill disagreed with Ricardo, who argued that the wage fund was an unchangeable fact that demonstrated that any attempt to raise workers' wages was doomed to failure. Instead, Mill argued that a level of social justice was possible within any future stationary system.

In defending the classical system, Mill laid the foundations of many ideas that were to come to dominate postclassical economics. Within Mill's work can be found the seeds of a supply-and-demand explanation of value as a replacement for the labor theory of value. Mill had nascent discussions on general equilibrium economics in his writings. His separation of positive from normative explanations came to

play a major role in future economic thinking, as did his separation of production from distribution. In the end, Mill was the greatest classical thinker, but he also was the economist who began the end of the classical paradigm when he refuted the belief in the wage fund doctrine. In Mill's writings, the highest point of classical theory can be found. In these same works are the seeds of thought that would come to replace the classical school with a new paradigm known as the neoclassical school.

### Objections to Classical Thought

The history of economic methodology is a history of competing ideas. Although the classical school has been offered as the economic methodology of the period, it should be noted that there were competing thinkers who disagreed with the methodology of the classical school. It is important to mention some of the competing thinkers before moving on to the neoclassical paradigm.

### Non-British Thought

The classical theory of economics was heavily influenced by the work of British thinkers, and it should be noted that British philosophical tradition is very different from other traditions. The British tradition emphasizes the importance of individualism as the foundation of social organization, whereas thinkers on the European mainland had a far more social bent in their ideological perspective. In part, it is this difference in the importance of individualism that is a defining difference in methodology between the classicals and their detractors.

Some of the first intellectual criticisms of the classical perspective came from a group of thinkers who have been labeled utopian socialists. Utopian socialist thought differed greatly from the socialist thought of Karl Marx, who will be discussed below. The utopian socialists included individuals such as Claude Henri de Saint-Simon, Robert Owens, Charles Fourier, and many others. The works of these thinkers all emphasized the need for a more social view with respect to economic methodology. The classical perspective emphasized the importance of individual self-interest as a central component to an optimal organization within an economic system. The utopian socialists argued that the capitalist system created great disharmony between differing classes, and neglecting to recognize social disharmony was a major flaw in classical methodology. In their works, the utopians emphasized the importance of planned activities in the economic sphere.

A second group severely critical of the classical methodology was the historical school. The historical school argued that one of the primary premises of classical methodology, separating theory from social context, was flawed. Remember that it was Ricardo who first emphasized that economics could be put into a form of pure theory and then used to abstract out the essential relationships. The historical school argued that it was impossible to understand how any real economy worked outside of the context of the society in which it is situated. The historical methodology emphasized exploring the actual shape of the economy and explaining how that shape came to be.

### Karl Marx

Marx's writings were to have a major impact on the twentieth century. Most people associate Marx with the concepts of socialism and communism, but in fact these ideas take up very little space in Marx's work. Instead, Marx spent most of his energy in describing and explaining the system of capitalism. What many are not aware of is that Marx based his descriptions of the capitalist system on the best economics of the time. Marx used the classical system as described by Ricardo as his basis of analysis. Marx took the labor theory of value and showed how the capitalist system was inherently unstable. The mechanics Marx used were not his own but rather taken from classical methodology. Needless to say, his works became very well known.

## The Marginal/Marshalian Methodology and the Rise of the Neoclassical

One of the major predictions of the classical economists was the eventual rise of a "stationary state" within the economic system. Malthus, Ricardo, and Mill all argued this would happen. Malthus and Ricardo both predicted that labor conditions would revert to subsistence. By the late 1800s, classical predictions were not materializing, labor conditions were improving, and there was no sign of an imminent end to economic growth. These failures in prediction led to rising criticisms of the classical paradigm, and new ideas began to appear. Some of the new thinkers were dissatisfied with the explanation of value arising out of the classical labor theory of value. Others wanted to explore more fully the nature of a self-directing economy. Whatever the differing reasons, several thinkers began to form the heart of a new methodology based on marginal thinking.

### The Beginnings of Marginal Thinking

The arrival of the marginal methodology was revolutionary, but the economists writing during the period were not aware of the revolutionary nature of the changes. Mark Blaug (1996), who is recognized as an expert on the history of economic thought, argued that the revolutionary nature of these changes was not really recognized until the next generation of economists. Yet what were the changes that happened, and who wrote about them?

Marginal thinking was a great breakthrough in economic theory. Simply described, marginal thinking suggests decisions are made on each consecutive choice rather than on whole groups of choices. Adam Smith posed a

puzzle called the water–diamond paradox that clarifies marginal thinking well. If someone were to offer you the choice of a bag of diamonds or a bottle of water, you would probably choose the diamonds. However, if you were in a hot desert and had not had water for several days, you would clearly choose the water. Why? In the first case, you are comparing the value of perhaps the first unit of diamonds to perhaps the thousandth unit of water. In the desert case, you are comparing the first unit of water with the first unit of diamonds. Marginal thinking suggests that decision makers decide to compare the extra units, not the total units. When comparing the first unit of diamonds to the thousandth unit of water, the diamonds are clearly more valuable. However, comparing the first unit of water to the first unit of diamonds quickly shows the value of water. Put in this manner, most people can see how they make decisions on the margin all the time, but clarifying this idea was revolutionary for the economic discipline.

Three major names are associated with the rise of marginal theory: Carl Menger, William Stanley Jevons, and Leon Walras. These three thinkers each operated independently in differing parts of Europe with amazingly different influences. However, even though they had little influence on each other and had few common influences on their own thinking, they simultaneously published major works elaborating on the ideas that were to become the marginal method.

Several major alterations in economic methodology arose during this period. The founders of the marginal methodology placed greater emphasis on demand versus the classical emphasis on supply. Such an emphasis on demand given the marginal perspective described above made sense. Why would someone choose the water over the diamonds? This is a demand question and is very different from what was being asked under the classical paradigm. The marginal movement argued that the value of an object was not constant as it was under the classical labor theory of value; rather, the marginal movement began using a subjective theory of valuation. One person may value the water more than the diamonds or vice versa, and who is to say one valuation is more accurate than the other? Marginal thinkers, particularly Walras, also emphasized a general equilibrium nature of the economy wherein all markets and decisions would balance out in a market system. Under a general equilibrium system, a small change in one area could affect all areas of the economy, but the flexible nature of the economy would sort out all of these changes automatically. Finally, the marginal founders also emphasized the process of rational maximizing behavior as the cornerstone of individual economic activity. Many of today's introductory economics students lose sleep over the ideas that originated at this time.

Such an emphasis on maximizing decisions based on subjective valuation led some to look more toward math to explore these differing individual choices. To some, math became a prevalent part of economic methodology, yet there was disagreement about the appropriateness of math as a tool for modeling the behavior of individuals. Menger, who is considered a founder of the Austrian school of economics, was strongly against the use of math. This antimathematical tendency is still prevalent in the Austrian school and its adherents. Jevons and Walras, on the other hand, used math as a tool to help explain their ideas. In the end, the work of Jevons, Menger, and Walras was incomplete. Their emphasis on the demand side of value was as flawed as the classical's emphasis solely on supply. The two sides would finally be brought together by economist Alfred Marshall.

## The Marshalian Scissors and the Neoclassical Method

Alfred Marshall was able to synthesize the works of many previous economists into a consolidated piece titled *Principles of Economics,* which was first published in 1890. The limited space of this chapter does not allow a detailed overview of the many contributors to neoclassical theory, but there were many. Each contributed to the ideas that were formulated into a single schema under Marshall.

Marshall was a great thinker, and his most important accomplishment was to bring together the newer works of the marginals and combine them with the important ideas from the classical school. Marshall took what was accomplished under the classical school and was able to build a partial theory of value based on costs. Marshall added the role of marginal decision making to firm profit maximization and explained a theory of supply. Marshall also took the theories of utility-maximizing consumers from the marginals and derived a theory of economic demand. Marshall then combined supply and demand into a single theory of market-driven price where both supply and demand work to determine price much like both blades of the scissors cut paper. Marshall's theory of markets has sometimes been referred to as the Marshalian scissors and is still a big part of what is learned in economics classes today.

With the works of Marshall, the foundations of neoclassical methodology were complete and contained the four components that would be major parts of economic methodology up until the 1990s. The first component was a vision of the economy as a great self-correcting machine similar to the Newtonian vision of physics common at the time. The second component was an emphasis on methodological individualism. The third was the use of deductive reasoning as a replacement for the experiments that were impossible to conduct, and the final component was an emphasis on internal consistency rather than external evidence. As described in the first section of the chapter, these were the major tools of methodology used by economists throughout the twentieth century.

## Objections to Neoclassical Economics

The rise of neoclassical economics was paralleled by a rise in thinkers critical of the methodology being used in

neoclassical economics. In economics, the methodology that is used by the majority of economics is often called the orthodox method, whereas the methodologies used by minority groups (usually critical of the majority) are called heterodox economics. Throughout the twentieth century, there were many heterodox critics of orthodox neoclassical methodology.

The historical school of thought was a heterodox group that was critical of the classical methodology and also actively criticized the neoclassical methodology for many of the same reasons. A controversy arose between the historical school and advocates of free market thinking. Part of the conflict revolved around the ability of a nation to plan an economy. Individuals arguing that such centralized planning could never work included Menger, whereas the historical school was led by a thinker named Gustav von Schmoller. The conflict between these differing groups was called the *Methodenstreit,* which is German for the "battle of the methods."

Another group of critics of neoclassical methodology were called the institutionalists. Thorstein Veblen, John R. Commons, and Wesley Mitchell were three founding institutionalists. Like the historical school, the institutionalists believed that economies had to be studied within a social context. The institutionalists also believed that the deductive method based on limited observations was flawed and that other methods were needed. Institutionalists criticized the neoclassical emphasis on the individual as the basis of study and argued in favor of a more socially driven vision of the economy. Institutionalists based their methodology on an evolutionary vision of the economy rather than a mechanistic view and argued that the theory of value created by the neoclassical methodology was rather simply a theory of price.

The Austrians were a third major group of critics of the neoclassical methodology. As mentioned above, Menger is considered both a founder of the Austrians and a major discoverer of marginal economics. Although the Austrian school is now considered a separate heterodox school, it has been considered only since the latter half of the twentieth century. Prior to the 1950s, the differences between the Austrians and neoclassical economics were small enough that a separating distinction was too minor to create a subclassification. The Austrian school moved away from the neoclassical school on a couple of points of methodology. The Austrians could agree with the neoclassical ideas that the individual should be the basic unit of economic study, and they could also agree that deduction was the best tool of reasoning available. The Austrians, however, began to diverge dramatically from the neoclassical perspective with respect to the usefulness of math in modeling individual behavior. As formal mathematical modeling of economics became more prevalent, so did the Austrian objections.

Although differing groups objected to neoclassical theory, this does not mean the differing groups agreed with each other. In fact, the founders of the Austrian school were some of the loudest critics of the historical school during the *Methodenstreit.* The Austrians and the institutionalists have also had sharp arguments over methodology. These differing schools still have proponents writing today and have influenced political policy in the past and present. The institutional school had substantial political influence from the beginning of the twentieth century until World War II. The Austrian school had a much greater influence during the second half of the twentieth century. In particular, Austrians such as Friedrich A. Hayak were highly influential on important political leaders such as Margaret Thatcher and Ronald Reagan.

## Keynes, the Neoclassical Synthesis, and Monetarism

The arrival of the Great Depression served as a major disruption to the neoclassical methodology. Neoclassical thinking took on a greater level of formality during the first three decades of the twentieth century, but little discussion was given about macroeconomic issues. Leon Walras had offered a partial explanation of a neoclassical vision of the macroeconomy in his theory of a general equilibrium model, yet a solid description of the model had never been given, and general equilibrium theories had been left unexplored until the 1930s. The Great Depression made this omission very clear and gave rise to the works of John Meynard Keynes and then eventually led to the inclusion of Keynes's ideas into a new version of the neoclassical methodology that used Keynes's insights and combined them in a Walrasian general equilibrium model. The 1970s saw a collapse of support for the neoclassical/Keynesian synthesis and a rise in the popularity of the monetarists.

### John Maynard Keynes

John Maynard Keynes was the son of John Neville Keynes, who was himself a well-known economist. Keynes was well trained in neoclassical methodology, and his works in macroeconomic theory were timely. Keynes looked back on the classical thinkers who spent most of their energy discussing the economy as a whole rather than economic activity on the individual level. Keynes had a daunting task to perform because he had to explain how a prolonged downturn in the economy could happen when most of neoclassical theory suggested that the economy would self-adjust. Keynes emphasized aggregate measures of economic activity to make a general theory of the macroeconomy. He began by analyzing how the goods created in the economy would be dedicated to different uses. They could be consumed, used for investment, used by the government, or traded to foreign nations.

With these expenditures explained, Keynes assumed that production in the system would follow what was desired by the differing groups who were acquiring the output. If the expenditures were maintained by the differing groups at a high level, then the economy would be

prosperous. However, there was nothing in Keynes's models to suggest that a high level of expenditures would automatically occur. In fact, Keynes envisioned situations wherein low levels of expenditures could remain for prolonged periods. In particular, Keynes suggested that during a crisis, firms would desire to invest significantly less, and because investment was a major part of expenditures, this could exacerbate the economic downturn. Simply put, a recession would cause firms to lower investment, which would further lower expenditures, which could lead to a bigger downturn. Keynes argued that this downward spiral could be stopped through government actions that increased government spending.

### The Neoclassical Synthesis

What Keynes wrote did not fit in nicely with the methodology of neoclassical economics. Keynes's work was not based in individual behavior as was neoclassical economics, did not emphasize a self-correcting mechanical nature to the economy, and lacked a mathematical formalism that was being strived for in neoclassical economics. However, the followers of the neoclassical methodology recognized the failure of their theory to reflect what was happening during the Great Depression, and the incorporation of the Keynesian vision into a neoclassical structure was quick.

The beginning of the synthesis occurred in 1937, when John Hicks wrote "Mr. Keynes and the 'Classics': A Suggested Interpretation," published in the journal *Econometrica.* The work was the beginning of a formalization of Keynesian ideas. The ideas were more formalized by other thinkers in the 1940s. The result of these works was a series of theories backed up with mathematical equations that were purported to represent the ideas presented in Keynes's work. The synthesis worked to place the ideas of Keynes within the context of the general equilibrium model first suggested by Walras. The resulting theories fit well within a neoclassical methodology, and Paul Samuelson (1948) popularized this method when he published it in his textbook that became one of the most popular economics texts available. During the 1950s and 1960s, economic analysis, as well as economic policy, was dominated by this neoclassical synthesis.

In Samuelson's text, much of the general information currently taught in undergraduate courses took form. The macroeconomy, based in large part on Keynesian expenditure analysis, formed the heart of the macroportions, and the market-based analysis of neoclassical economics formed the microportions. The formalization and apparent certainty of the neoclassical synthesis led to policy advice that seemed simple and useful. However, beginning in the 1970s, this certainty broke down under new economic circumstances. It should be noted that the models created in this synthesis failed to demonstrate how a continued period of economic downturn could happen, which was the main point of Keynes's work. There are some economists who have taken the Keynesian perspective in a very different direction. This group has created a fairly detailed description of a market system wherein continuing economic instability is explained, something that is missing in synthesis analysis. This group is called the post-Keynesians, and some of the better known economists from this group were Hyman Minsky and Joan Robinson.

### Monetarism

In the 1950s and 1960s, economic theory seemed so formalized that many began to think that governmental actions to correct economic imperfections were simple and easily accomplished. During the 1970s, the economy suffered a period of extended unemployment and inflation, which was something that could not be explained by the neoclassical synthesis models. This gave room in economic theory for a new group of thinkers led by Milton Friedman. Friedman and the monetarists argued that economic cycles were caused by changes in the levels of money in the economic system.

To the monetarists, all economic fluctuations were caused by changes in the monetary system. Friedman went so far as to try to demonstrate that the Great Depression was the result of misguided monetary policy and not the Keynesian explanation of dropping investment. With the decreasing popularity of the Keynesian position in the 1970s, the monetarists began to call into question the assumptions of the Keynesian positions writ large. The monetarists began to argue that the causes of the business cycles were changes in governmental policy and that if left alone the capitalist system was generally stable. The best way to maintain economic stability was to get the government out of the economy.

The monetarist ideas were different from the ideas of the neoclassical synthesis; however, the general methods still remained relatively the same. Starting with the foundations of the neoclassical school, there have been consistently four major components to economic method. The economy is seen as a mechanistic system with general equilibrium being the outcome. The basic unit of economic analysis is the individual, not groups. Deductive reasoning based on only limited observations is the best way to create economic theories, and internal consistency is to be valued over external evidence. Although new ideas and theories were to arise and fall, these basic tenets of methodology remained in economics for most of the twentieth century. This methodology is still dominant in undergraduate classes; however, the methods themselves are changing in the economics profession as a whole.

## Conclusion

Modern economic methodology is in a state of flux and is diverging from some of the main components of methodology that have been used for the past century.

Those previous components were first laid down during the neoclassical period of economics. However, modern economics seems to be moving away from them. Few modern economists use deductive reasoning as the basis for their work; instead, a much greater role has arisen for empirically testing theory using econometric tools. The rational individual as a cornerstone of theory is being replaced by a much more nuanced vision of the individual situated within society. External evidence that contradicts theories is given much more weight than ever, even if the evidence suggests that economic models may not be consistent. The mechanistic vision of markets always adjusting to equilibrium is also being questioned. Why all of this is happening now is difficult to answer. Perhaps the arrival of cheap and powerful computers is changing how economics is done. Perhaps it is the influence of critics of neoclassical methodology, or perhaps it is something else.

What is clear, however, is that the general concepts being taught in most undergraduate economics classes are the result of centuries of research and conflict. The origins of the micro- and macrodivisions of economics can be seen by looking back to the history of economic thought, and in that history you can find why methodology is taught as it is. This methodology is the result of an evolutionary process where differing ideas compete for acceptance. Whereas the undergraduate is taught economic methodology as a set of tools, the profession is always striving to alter and refine these tools to better understand the economy. In this process, the tools themselves change and methodology evolves. Adam Smith began asking questions important to his society at the time, and the tools he used fit those questions. Those tools have been altered by great thinkers such as Ricardo, Mill, and Marshall. Those tools have been shaped by important economists such as Malthus and Keynes. The methodology we receive today exists because of the works of these people, and the methodology our descendents receive will be altered by the economists writing today. Economics is a living discipline, and continued exploration will inevitably result in the metamorphosis of method. This chapter is intended as an introduction to the process; much more remains to be explored.

# Twentieth-Century Economic Methodology

Peter J. Boettke

*George Mason University*

The birth of the discipline of political economy is often dated to the eighteenth-century Scottish Enlightenment philosophers such as David Hume and Adam Smith. Of course, there were recognized antecedents dating back to Aristotle, the Spanish Schoolmen of Salamanca, and the French Physiocrats. Even the core idea of how private interest can be reconciled with public benefit through competition had a predecessor in Bernard Mandeville. But it was the Scottish philosophers who provided the foundation of classical political economy in the eighteenth century.

The systematic study of political economy begins with the recognition of two seemingly contradictory observations about commercial life. The first observation is that individuals pursue their self-interest and do so as effectively as they are capable of doing. The second observation is that commercial society exhibits a strong tendency to produce outcomes that enhance the public welfare in terms of material progress and betterment of the human condition more generally. Squaring these two observations is how the discipline was born.

## The Methodology of Economics and Political Economy: An Overview

Before we go further, I think it wise to stop and reflect on something unique about this disciplinary origin. Political economy and economics began with a reflection on an already existing set of practices in the world. It was, in this sense, in the quest to gain philosophical insight into the mystery of the mundane life around them that led these thinkers to study the economic system. In other words, a human practice was in operation that needed explanation. Economists did not invent economic life—whether as evidenced by the organization of the household, the harvesting of crops, the rise of manufacturing, or the free trade of goods and services across borders. Economic life happens, philosophers try to understand the manifestations of it—the changes in prices, the life and death of enterprises, the complexity of the division of labor, and the wealth and poverty of nations.

From the beginning of the discipline there have been debates concerning the methods used by thinkers to gain philosophic insight into these matters. One way to reconstruct Adam Smith's critique of the mercantilists is as a methodological critique of their understanding of the wealth of nations. Following the twentieth-century economist Fritz Machlup, this chapter will make a distinction between methods and methodology, where methods refer to the various techniques that economists employ in thinking about a problem and offering an explanation, and methodology refers to the philosophic study of those methods and their epistemological status. Methods of analysis have constantly evolved throughout the history of the discipline, and methodology has shifted as well with changes in epistemology. In other words, the positivism of the Vienna Circle placed criteria on what constitutes science that were different from the criteria that were understood during the age of British empiricism. As the criteria shift, so does the understanding of what is a good question to ask as well as what would be a good answer. Methods

of analysis are adopted if they help the explanation meet the currently fashionable criteria and discarded as relics of an older unscientific age if not.

Beginning in the late nineteenth and continuing throughout the twentieth century, the discipline of political economy was transformed into the science of economics as the methods employed by economists to study the economy more closely approximated the methods employed by those in the hard sciences, such as physics. Whether the methods developed in the sciences of nature were appropriate for the sciences of man was hotly contested throughout the twentieth century and continues to be the subject of intense debate into the twenty-first century. But it must be stated that most work-a-day economists do not see this as a debatable issue. Science is measurement, and the tools employed must satisfy that goal if science is to be done. The philosophical reflection on contemporary practice, let alone the entire enterprise of economics and political economy, is found in a specialized community of academics in philosophy, intellectual history, and economics who study the history of economic thought and methodology, as well as sometimes among the elderly of elite economists as they reflect back on their careers. In the discipline of economics proper, it is the very rare case (and professionally ill-advised) that a younger scholar will venture into the field of method and methodology.

But this does not mean that the methods of economics are stagnant either in the past century or today. No, they are constantly evolving as the problems that attract the attention of economists shift. However, the central disciplinary puzzle remains of explaining how through the self-interested behavior of individuals a social order can result that serves the public interest. The assessment of the truth value of this statement shifts with the times, as well as the normative assessment of economic exchange and the market economy. But every economist who has practiced the discipline since the eighteenth century would recognize the proposition that the market economy was self-regulating as central whether they agreed with it or not.

Joseph Schumpeter (1945), in his *History of Economic Analysis,* makes a distinction between "vision" and "analysis" and argues that "vision" is a necessary component of the advancement of scientific analysis. The simple reason is that "vision" is a pre-analytic cognitive act that provides the raw material for the scientist to analyze. As a mere matter of description of the way the human sciences operate, the economist must have a "vision" (a set of eyeglasses) that helps to clarify the questions that are to be raised. Visions are not neutral, however, with respect to the methods one uses to analyze a problem in the social world. Science may indeed be measurement, but the scientist has to know first what it is that must be measured and possess the measuring devises required for that task. Without either an idea of what to measure or the means for measuring, the intellectual enterprise can devolve quickly into nonsense rather than science.

Vision and analysis are both important parts of the narrative on the evolution of economic method and methodology in the twentieth and twenty-first centuries. The historical experience of economic disruption due to technological change, the devastation of war and depression, and the consequences of ideologically inspired revolutions also shaped twentieth-century economics. Just as the experience of the collapse of socialist ideological aspirations of the twentieth century shaped economic thought, the tragedy of less development, the fear of manmade global disaster such as irreversible climate change, the tensions of globalization, the fear of terrorism and religious fanaticism, demographic trends toward aging populations and the unsustainable public economic obligations that were made in the past, and the global financial crisis are in the process of shaping twenty-first-century economics. So we must be mindful of how visions frame the questions asked, how ideas of what constitutes science frame both what is considered a good question and good answer, how methods chosen will be a function of the question asked and the form an acceptable answer is expected to take, and, finally, how all of this is subject to change due to shifting philosophies of science, empirical puzzles that are thrown up in the world, and innovations in techniques of calibration that appear to permit measurement where it was seemingly impossible to get measurement before.

The toolkit of general competitive equilibrium, for example, that was developed in the late nineteenth century (Walras) and throughout the twentieth century (culminating in the Arrow-Hahn-Debreu model of the 1960s–1970s) sought to provide mathematical rigor to Adam Smith's "invisible hand" proposition. Smith's proposition came to embody in the mind of the economist a claim about the self-regulating nature of markets through relative price adjustments; the complex interdependency of economic life as evidenced by the division of labor, specialization, and exchange; and the efficiency of the market economy in production (least cost technologies employed) and exchange (gains from trade realized) through the guiding function of relative prices and the lure of pure profit and the penalty of loss. The incentives and information provided by clearly defined and enforceable private property rights; free movement of prices to reflect changing circumstances of tastes, technology, and resource availability; and profit and loss accounting, which induces entry of promising enterprises and weeds out failed enterprise, are enough to ensure that the market economy will satisfy the welfare criteria established by the theory of general competitive equilibrium. At least that is what elementary economics taught in the first chapters of Marshall's (1890/1972) *Principles of Economics,* as well as in the first chapters of Stiglitz's (1993) *Economics,* and for the most part every major textbook in between.

From at least the time of John Stuart Mill's (1843/1976) *Principles of Political Economy,* economists always have admitted that there were ample situations where the

"invisible hand" of the market would be hindered in its operation. The problem of monopoly was mentioned throughout the classical literature (though the source of monopoly was not seen in the natural tendencies of the market by many). The problem of common-pool resources was also mentioned, as were examples of what later would be termed externalities, asymmetric information with certain commodities, inequalities in distribution, economy-wide business fluctuations (theory of general glut or economic crisis), and public goods. The laissez-faire presumption that Mill laid out nevertheless had grounds for exception from the laissez-faire principle that were quite large. Many economic debates about method were in fact debates about how persuasive that case for the exception from the laissez-faire principle was. As analytical tools evolved, the answer to that question changed. Pigou had one answer, Coase had another, and Buchanan had yet another. To be clear, it is important to remember that if the laissez-faire principle stands, then the role of the economist is limited to that of a scholar and teacher, perhaps social critic, and the role of the government is mainly seen as that of a referee in the economic game. But if there are grounds for rejecting the laissez-faire principle, then the economists' role in society is potentially transformed into that of a policy engineer, and the government's role is transformed from a referee to an active player in the economic game. The method and methodology of economics are not invariant with respect to the policy aspirations of economists and political decision makers. It has been argued that the intended audience of Adam Smith's (1776/1976) *An Inquiry Into the Nature and Causes of the Wealth of Nations* was the enlightened statesman, and one could just as easily argue that this was true for the major works of Mill, Marshall, Pigou, and Keynes as well.

The theory of market failure developed by Paul Samuelson in the middle years of the twentieth century attempted to show under what precise conditions Smith's "invisible hand" proposition broke down. Ideas such as positive and negative externalities, free riders, excludability, nonrivalry, and so on became part of the everyday language of economists due to Samuelson's efforts both as a theoretical economist and as the leading textbook author for at least two generations of college students of economics. Samuelson's impact was in providing the latest reasons to doubt the veracity of Smith's proposition, and the form of argument in economics that he championed transformed the way economists must present their work for assessment among their peers. To eliminate ambiguity in argument, Samuelson argued, the rigor of mathematical formalism must replace the literary vagueness of an earlier less scientific age of economic analysis. The casualty of this transformation in method, Samuelson insisted, would only be the loose thinking of previous generations—loose thinking that produced an unfounded "faith" in laissez-faire and the invisible hand of the market economy. Samuelson spearheaded the neo-Keynesian synthesis in macroeconomics and the transformation of the welfare properties in microeconomics. Every area of economics, circa 1950 and 1960, was touched by Paul Samuelson. After Samuelson, the method and methodology would be unrecognizable to the previous century and a half of economic and political economy thinkers since Smith in a way that was not the case for, say, the history of the discipline from Smith to Frank Knight.

The Keynesian revolution and the development of macroeconomics in general offered an alternative vision that argued that in the context of the modern money-using economy, the classic link between private interest and public benefit had been severed, and thus the market could not be relied on to self-correct. Rather than self-correcting, the capitalist economy was said to be inherently unstable. Both the original Keynesian income expenditure model and the later neo-Keynesian IS-LM model were developed to demonstrate how once the link between savings and investment was broken, the classical vision of a self-regulating market economy that steered the self-interested behavior of individuals in such a direction that the public benefit was served could no longer be sustained. This model, not without challenges from thinkers such as Milton Friedman, dominated economic thinking in the post–World War II era.

Simultaneously with the lost faith in the central proposition of classical economics, economists also developed models that demonstrated that the market economy was prone not only to macroeconomic instability but also to monopolistic abuse and other microeconomic inefficiencies caused by various market imperfections. The model of general competitive equilibrium could no longer be said to mimic the outcomes of a free-market economy, but the model could serve as a tool of policy. The new approach to economics promised that government correctives would ensure that the welfare properties of the competitive equilibrium model would in fact be achieved even though the market economy could not achieve them when left to its own devices. The irony of this should not be lost. A model that was developed to represent what the market economy achieved without any central direction ("invisible hand") was transformed in the writings of economists such as Abba Lerner and Oskar Lange into a guiding tool for state direction of the economy (the visible hand of government planning). Economics was transformed from a discipline of philosophic reflection on the empirical reality of commercial life to a tool of social control by enlightened policy makers. Abba Lerner's (1944) book has the appropriate title, *The Economics of Control;* Samuelson, along with others, introduced linear programming into economics; William Baumol further developed the applications of operations research into economics; and some of the top minds in the field of economics, such as Leonid Hurwicz, would devote themselves to a field titled "mechanism design." In the 1940s to 1970s, the entire discipline of economics was transformed into a tool for social control, and

the methods and methodology of economics of that age fit that new purpose. Methods and methodology that did not fit the purpose of prediction and control were rejected as relics of a bygone era—a past era that was less scientific than the modern age.

In the mid-1970s, amid an economic reality of high unemployment and high inflation, the classical proposition concerning the "invisible hand" was resurrected with the work of Thomas Sargent and Robert Lucas and the new classical economics. Added to the lexicon of macroeconomics were rational expectations, time inconsistency, and the invariance proposition in policy design. The basic idea was that economists could no longer continue to model economic actors as completely passive actors that are to be manipulated by public policy decisions (as they were during the Keynesian hegemony) but had to model them as capable of anticipating the consequences of policies and therefore behaving in a way to put themselves in the best situation to take advantage of the policy change. This response, unfortunately, will potentially dampen the effectiveness of the proposed policy. A classic illustration of this was the Keynesian proposition concerning the trade-off between inflation and unemployment. The Keynesian consensus argued that as unemployment ticked up during a downturn, policy makers could stem this by engaging in inflationary policies. The inflation would drive down real wages, without affecting the nominal wage. In effect, workers will experience a wage cut, but due to "monetary illusion," they do not realize this, and so policy makers can keep unemployment in check through inflation. But this Phillips curve relationship breaks down if the workers recognize that their real wages are being cut and thus demand pay increases. Rather than inflationary monetary policy keeping unemployment in check, we get instead both inflation and unemployment rising. By the mid-1970s, the empirical reality of "stagflation" was the exact opposite of what was predicted by the Keynesian model of macroeconomics. Keynesian theory was empirically questionable, and theoretically incoherent was the judgment because it lacked microfoundations, and new classical macroeconomics filled the intellectual void.

At the same time, classical market theory reasserted itself against the market failure theories of the previous decade, and ideas such as the efficient market hypothesis (Fama), competition for the field (Demsetz), and contestable markets (Baumol) were added to the lexicon of microeconomics. Ronald Coase and James Buchanan pointed out that traditional Pigouvian welfare economics was logically either redundant (actors within the economy would bargain away conflicts themselves) or nonoperational (if private actors cannot bargain away the conflict, then under the same assumptions neither could public actors accomplish the policy goal). Coase and Buchanan spearheaded a revolution in economics to do comparative institutional analysis in law, politics, and the market. The conceptual framework of economics changed in the 1960s to 1970s, but many of those changes represented the resurrection of many of the themes found in the classical writings of David Hume, Adam Smith, David Ricardo, J. B. Say, and John Stuart Mill.

But it is important to stress for our present purposes that the changes of the 1960s and 1970s were not accompanied by a change in the methodology, so the methods were not so much transformed but applied consistently and persistently and into areas that previously were deemed out of bounds. In fact, one way to understand the new classical revolution was as a response to a dual intellectual inconsistency evident in the preceding economics literature: (a) a conflict between what was taught in microeconomics and macroeconomics in terms of core economic theory, thus requiring a search for microfoundations and (b) cutting short the story of market adjustment in microeconomic and macroeconomic narratives of imperfection and instability, such that when the economists opened up the analysis to account for agent learning and allowed for all the accommodating changes to take place in the market economy, the claims to imperfection and instability faded away. In other words, while there may be macroeconomic questions (e.g., inflation, unemployment, growth), there are only microeconomic answers, and those answers are provided through the examination of relative price effects and their impact on the behavior of individuals as they adjust to changing circumstances through time.

The development in the last quarter of the twentieth century of property rights economics, law and economics, public choice, the new learning in industrial organization, the economics of organization and new institutionalism, new economic history, entrepreneurial studies and market process theory, and new classical economics all represented efforts of one sort or another to analyze beliefs, behaviors, institutions, and situations that previously had been treated as either beyond the scope of analysis or as part of an unexamined framework. But again it is important to stress that while economic theory evolved and applications were found in new areas, the fundamental practice of economic methodology did not change as a result. In fact, the new methods were judged against the methodological conventions of formalism and positivism (at least the understanding of positivism among economists), and to the extent that the new methods failed to fit into those self-understandings of economic *science,* they would be dismissed as potentially interesting questions that were not operational. Until the set of questions being raised by new thinking in economics could be represented in a formal model subject to empirical test via sophisticated statistical analysis, they would have little impact on the practice of economists.

## The Fracturing of the Neoclassical Hegemony

I have argued that Paul Samuelson initiated the formalistic revolution in economics in the 1940s and 1950s. Samuelson's justification for this was simple—ambiguity

in thought emerges whenever we use the same words to mean different things or different words to mean the same thing, but by forcing economic arguments to be stated in a common formal language, assumptions would have to be made explicit (not hidden) and ambiguity would be avoided. In the 1950s, Milton Friedman also persuasively stated for economists that assumptions in theory construction did not really matter provided the construction was subject to empirical test. It is the submission to falsification that demarcates science from nonsense—an economist's rendering of logical positivism, instrumentalism, or whatever balled into an operational appeal for a simple formula of economic hypotheses subject to empirical test using statistical techniques. A philosophical statement of the positivist position with respect to the development of economics was actually made in the 1930s by T. W. Hutchison, but while recognized as a classic in economic methodology, the work did not persuade practicing economists. And it was not as if economists never made explicit methodological pronouncements—both descriptive and prescriptive prior to Hutchison. Lionel Robbins and Ludwig Mises defended the a priori and deductive logic nature of economic theory in the 1920s and 1930s. Mises, in particular, was adamant in his presentation of the a priori (purely deductive) nature of economic theory and built his argument on the earlier methodological work of N. Senior, J. N. Keynes, and C. Menger. Despite how Mises's statements have been interpreted by critics ever since, Mises did not claim originality for his position but argued instead that this was in fact the way that classical and neoclassical theorists of economics had in fact always done economics: deduction from self-evident axioms, combined with subsidiary empirical assumptions and aided by imaginary constructions (including the "method of contrast," where a world without change is constructed so we may understand the implications of change). In addition, Mises (following Weber) insisted on the positive nature of economic science against claims of ideological bias. Positive analysis prior to the philosophical development of logical positivism consisted of an argumentative strategy and was linked with Mises's consistent subjectivist stance. Treating ends as given and limiting analysis strictly to means-ends examination, Mises argued (as did Weber), would ensure the value-free nature of economics. Robbins (1932) picked up on this argument in the first edition of *An Essay on the Nature and Significance of Economic Science.* From a more continental philosophical tradition, Mises's student Alfred Schutz (1932/1967) made a similar argument in *The Phenomenology of the Social World.* However, the arguments of Mises and others that attempted to justify both methodological dualism (i.e., that economics was a science, but a science whose epistemic procedures were wholly different from those of the natural sciences) and the positive nature of economic theory proved to be ineffective in the wake of the empirical events of the 1930s and 1940s. The Great Depression and the grand ideological debates that were played out in World War II simply demanded an economics that was technical and analogous to physics—a form of social physics or better yet engineering. The discipline bent to this demand as young economists, motivated by the momentous events of the day, pursued advanced study of economics and went to work to solve social problems. Economics had to become a discipline capable of prediction and control and not endless disputes in social philosophy if progress was to be made and the shortcomings of the laissez-faire system were to be overcome through judicious public policy.

The change in the way economists do things that took place in the 1940s and 1950s was not led by philosophers of economics but a group of economic superstars who communicated to the rising generation how you are supposed to engage in the science. In this sense, the practice of economics in the second half of the twentieth century was dictated by Samuelson and Friedman (despite their disagreements), not by the Vienna Circle, Karl Popper, or Imre Lakatos. The methodological statements of Mark Blaug or Lawrence Boland or Bruce Caldwell in the 1970s and 1980s did not dictate practice in the discipline, just as the biting criticisms of Frank Knight or Ludwig Mises or Phil Mirowski (from the 1940s into the 2000s) have not curtailed the advance of the economists' self-understanding of the discipline as both formalistic and positivistic.

Both formalism and positivism came under intellectual assault in the 1960s to 1980s in the philosophy of science literature. Formalism resulted in unrealistic and sterile presentations of human life that missed as much as they captured, and positivism worked on an assumption that empirical tests were unambiguous. Without the empirical grounding provided by clean and unambiguous statistical tests, formal abstractions were prone to become free floating. Critiques of the modernist vision of science of an analytical form in the hands of Willard Quine (whether the falsifying result addresses the main hypothesis or the network of statements that led to the main hypothesis) or of the sociological variety in the hands of Thomas Kuhn and Michael Polanyi (paradigms and the notion of progress in science) or the continental form found in Richard Rorty (that all knowledge is contextual and framed by perspective) were embraced by various heterodox thinkers in economics, such as institutionalists, post-Keynesians, Marxists, and Austrian school economists. In addition, as formalism and positivism dominated practice in economics, there were always leading thinkers in the field who admitted the difficulties of carrying out the official methodology and questioned the current practice as failing to live up to the standards set or that the standards set were unrealistic. Ed Leamer's "Let's Take the Con Out of Econometrics" (1983) was one such critique of practice, as was D. McCloskey's (1998) *The Rhetoric of Economics.* There was, parallel to this, philosophers who challenged the economists' scientific pretensions, such as Alexander Rosenberg, who argued that economics was either mathematical politics or the science of diminishing returns, but

it was not an enterprise experiencing scientific progress. Dan Hausman has even described economics as an inexact and separate science. James Buchanan argued repeatedly that while economics is indeed a science, it is a philosophical science—which actually was a position staked out by R. G. Collingwood in the first decades of the twentieth century and was influential on Mises. Positions were stated by prominent figures, but they did not change practice or self-understanding.

During the 1980s and 1990s, survey articles on economic methodology were published in high-profile professional outlets such as *Journal of Economic Literature* and *Journal of Economic Perspectives,* and books on the subject were reviewed and discussed in a variety of traditional outlets. New journals were established such as *Economics and Philosophy* and the *Journal of Economic Methodology*. The critiques of traditional economic methodology led to a rise in heterodoxy, or at least a more self-confident and vocal heterodoxy. But ultimately, the actual methodological practice of elite economists changed little. McCloskey was a major advocate of change, but the criticisms offered in works such as *The Rhetoric of Economics* and *The Cult of Statistical Significance,* while widely read, did not have the force to change practice. What occurred instead was that attempts to justify practice by appeals to philosophy stopped among economists. Demarcation efforts were not a philosophical exercise but a complete embracing of scientific conventionalism. Economic science is what economists do, not what philosophers claim is scientific. And to do economics, one must think in terms of simplified models (parsimonious yet elegant mathematical representations) that are subject to sophisticated statistical tests. Critiques of the ability of statistical tests to answer fundamental questions (e.g., Greg Mankiw's critique of economic growth statistics) did not lead to a broadening in the notion of the evidentiary burden that must be met by contributions in the field but instead to renewed interest in finding better statistical instruments. Methods evolved, but the underlying methodology remained.

But the heterodox critique did not go completely unheeded. Questions concerning the behavioral foundations of economics led to a renewed appreciation of psychology and even neuroscience. Similarly, the institutionalist critique of economics led to a renewed examination of the legal-political-social nexus and its impact on economic life. Scholars such as John Davis have pointed to these intellectual developments among economists as evidence of a breakdown in the hegemony of the neoclassical mainstream. But one should be careful here because while psychological and institutional factors are now prominent in economic research, and the evolution of methods has led to a rise in laboratory experiments, computer simulations, and natural experiments that in a previous generation may have been viewed with suspicion, the form in which an argument must be stated in the top research journals to be considered "scientific" has not changed all that much from the days of Samuelson and Friedman.

## The Absorptive Capacity of Formalism

It is important to realize that I am not making a normative assessment of these developments (and lack of change) but instead providing a description of the intellectual landscape in economics from 1950 to today. Methods are constantly evolving but guided by a methodology that more or less has been fixed by scientific convention mid-twentieth century. Methodology not only determines to a large extent the questions that can legitimately be asked by a discipline but perhaps more important limits what would be considered a good answer to those questions. During this period, there have always been slightly out-of-sync economists who have been more or less nonconformists. Think of Nobel Prize winners such as F. A. Hayek, James Buchanan, Ronald Coase, Douglass North, Vernon Smith, and Thomas Schelling. Or broad-ranging economic thinkers such as Kenneth Boulding and Albert Hirschman. Or even recognized masters of the craft of thinking like an economist such as Armen Alchian. The economics profession during the twentieth and into the twenty-first centuries has had significant dissenters with respect to the prevailing consensus on method and public policy, but to dissent methodologically with respect to formalism and positivism was the quickest way to be utterly dismissed. And this was true even after developments in the philosophy of science literature questioned the modernist understanding of science. As McCloskey has repeatedly stressed to readers, economics is the most modernistic of the human sciences. And when the philosophy of science literature no longer justified those modernist ambitions, rather than rethink those ambitions, economists simply appealed to conventional practice. Economics is, in this understanding, simply what economists do. While previous generations of students were at least required to read Samuelson and Friedman on the methodology of economics during their first term in graduate school, the current generation of graduate students is expected to practice economics as they are taught without any serious study of the philosophical justification of the conventional methodology of economics.

Formalism has proven to be amazingly absorptive of heterodox ideas, especially after techniques and methods were developed that broke the taboo of multiple equilibria. Once the demand for models with determinate equilibrium results (i.e., single exit models) was relaxed, different paths could be explicated in models and so many heterodox ideas could be incorporated. One must remember that economists in the 1970s and 1980s struggled to gain acceptance for game theory, computer simulations, and laboratory experiments among economists. But once it was demonstrated that these methods could be used in a way consistent with the underlying methodology of model

and measure, they found wide adoption among economists for addressing questions that more traditional methods proved to be wanting. As Paul Krugman has pointed out in his discussions of the evolution of ideas related to economic geography and economic development, many nontraditional thinkers raised questions of increasing returns and location economies, but they lacked the tools to communicate those ideas in a way that economists could find useful. The usefulness criteria, I should point out, are provided by the methodological presumptions that were enforced. Useful, in other words, not as a tool of understanding but rather as a vehicle for forming testable hypotheses.

What is true for economic geography is also true for numerous other fields in economics, such as the study of politics, law, family, extended relationships, and norms. Many of the ideas being heralded as revolutionary are in fact the restatement of ideas held by an earlier generation of economists and political economists but previously deemed relics of an unscientific age of economics. Hume and Smith, for example, did not have a myopic view of humanity but instead believed in a behavioral model that included not only self-love but other regarding as well. The past 50 years of economic research and education have seen the placing of "old wine" of the classical school and early neoclassical writers into the "new bottles" of formalistic modeling and statistical testing empiricism.

The reports of the breakdown of orthodox hegemony by David Colander and John Davis have looked only at the method and policy dimensions, whereas the significant margin to look at that ultimately determines the character of economics is the underlying methodology. And on that margin, despite all the philosophical shifts, the basic justification of the enterprise of economics as a formalistic and positivistic science has remained unchanged. Unless an idea can be absorbed under this rubric, it will meet intellectual death. Methodology is the ultimate judge, jury, and executioner in economics, although it often lurks in the background unstated. As McCloskey has put it, when one's intellectual range is limited to M–N, when you get up close and look, it seems as if a wide range of topics are on the table and that all those around the table are fair and open-minded contributors to the enterprise, but when you step back, you realize that the intellectual span from M–N is quite narrow and misses the entire range of issues from A–L and O–Z. This is the fate of economics in its high modernist form, and little has changed in practice except that economists no longer appeal to high modernist philosophy to justify what they do.

## Where Is Economics Going?

With what I have said about the relationship between method and methodology firmly in mind, let us look at developments in economics as we entered the twenty-first century. First, during the last decade of the twentieth century, two empirical realities became of overriding concern to economists—the collapse of communism and the transition from socialism, and the failure of development planning and foreign aid programs to lift the less developed world into a position of greater freedom and prosperity. Second, as we prepare to enter the second decade of the twenty-first century, two other empirical realities became overriding concerns to economists—the tensions of globalization, threat of international terrorism, the financial crisis, and threat of worldwide depression.

One way to think about this is to envision the discourse in economics as following the shape of an hourglass. In the eighteenth and nineteenth centuries, economics was part of a larger discourse in political economy and moral philosophy. As the discipline self-identified with a more technical (less philosophical) and scientific approach to economic questions in the twentieth century, the scope narrowed. By the 1950s, the discipline of economics was narrowed to the midpoint on the hourglass. Since the 1950s, we have seen the broadening of the discipline again to take into account questions that once preoccupied the minds of the "worldly philosophers." By the turn of the twenty-first century, economists were once again tackling questions that could be recognized by the likes of Adam Smith and John Stuart Mill, let alone Max Weber. Indeed, the "worldly philosophy" seemed to be back en vogue. Amartya Sen tried to explain this shift in intellectual focus using the language of modern economics rather than imagery such as an hourglass. To Sen, there is a production possibility frontier for economic research, with economics as engineering on one axis and economics as philosophy on the other. During the twentieth century, economics moved toward a corner solution of economics as engineering, but during the last quarter of the century, economics began to move along the frontier away from the corner solution to once again pursue economics in a more philosophical manner. In Sen's writings, this shift relates to questions of ethics that must be raised for welfare judgments to be passed.

What I have suggested, however, is that while the questions have broadened once again, they have done so only to the extent that they can be restated in a form that conforms to the methodology that actually led to the narrowing of the hourglass (or the move along the frontier to the corner solution). I will leave to another time the question of whether this form constraint distorts the substantive content of the conversation. For now, the point I want to make is that the methodological constraint that produced the transformation of economics in the twentieth century (Samuelson-Friedman) is still binding on disciplinary discourse. Economics is a model and measure discipline; it is a discipline that advances through journal articles, not books, and it is a discipline whose scientific status while constantly questioned by outsiders is never questioned by those who occupy the commanding heights of the profession.

That much said, one would be blind not to see the important changes in research focus and methods of analysis that have taken place. In one sense, the empirical puzzles of the collapse of communism, the transition to capitalism, and the failure of development planning led to a renewed appreciation for the underlying institutional context of economic life. Economics in this sense is conceived of as a science whose subject is exchange and the institutions within which exchange takes place. On the other hand, the transplanting of institutions from one environment to another has proven to be a very difficult policy task, and both the transition to capitalism and the elimination of squalor and poverty in the Third World have proven to be more difficult than imagined. The contemporary empirical puzzles of the tensions emerging from globalization and the threat of international terrorism have focused economists' attention on "mental models," including ideology, religious beliefs, and cultural value systems in general. Directed by these pressing issues, economists are reexamining the cognitive foundations and behavioral assumptions of the discipline. In other words, in the upper echelons of the professional hierarchy, both the institutional and behavioral assumptions of conventional models have come under examination and a required modification.

As a question of public policy, many economists saw the link between the puzzles of the 1990s that resulted in examining the institutional assumptions and the puzzles of the 2000s that resulted in examining the behavioral assumptions. Solving the problems of transition and of Third World poverty has captured the imagination of leading economic thinkers such as Douglass North, Bob Lucas, Joe Stiglitz, Jeff Sachs, Esther Duflo, Abhijit Banerjee, Andrei Shleifer, and Bill Easterly. Many of these economists rejected the traditional neoclassical depiction of individual decision making and the market economy, as well as the free-market policy recommendations associated with the "Washington Consensus." Others argued for a more sophisticated understanding of the traditional model and offered a more nuanced defense of the basic message of the "Washington Consensus." These debates will continue. But the basic message from the economics of the 1990s and 2000s is that institutions matter, and while individuals respond to incentives, they are also prone to suffer delusions and other error-inducing cognitive limitations in those responses. Learning is context dependent. Behavioral economics, in particular, argues that individuals often are mistaken in their beliefs and expectations.

Actors are not perfectly rational, information is imperfect, markets are not atomistic, and resources are not always channeled to their highest valued use. While these admissions of imperfection open the discipline to new areas of research, those new areas can be pursued only via the conventional methodology. That is the dilemma of economics in the twenty-first century. Kenneth Boulding once remarked that the problem of economics (circa 1970) was that the discipline was asked to address twentieth-century problems (depression, war, cold war) with the mathematical tools of seventeenth-century physics (Newton). Hayek made similar remarks at the time—which should not be that surprising because both Boulding and Hayek were early adherents of general systems theory and respectively influenced in their thinking by Ludwig Bertalanffy and the idea of complex systems analysis. One could argue that an analogous critique could be offered to today's economics and does in fact get voiced in the discussions of complexity theory and economics. While models of social complexity and both agent-based and complex adaptive systems are not uncommon in the literature, they have not affected practice to the extent expected by the adherents of these models. In other words, the core theory of neoclassical general equilibrium theory remains the foundation of economic analysis. In a different context, Frank Hahn once described the criticism of the edifice of neoclassical theory as a bombardment of so many soap bubbles. In other words, the critiques are offered, but they ultimately bounce off.

Still, several method shifts in economics must be reckoned with in any discussion of economics and political economy in the twenty-first century. First, there has been the rebirth of political economy independent of the Marxist tradition. This goes back to the point raised by my hourglass metaphor or Sen's discussion of the movement along the production possibility frontier of economic thinking away from engineering and more toward philosophy. Positive political economy and constitutional political economy are intellectual developments in both the disciplines of economics and politics that have brought back the serious discussion among social scientists of the structure of government, the role of rules (formal and informal) in political and economic interactions, and the political-economic and legal-economic nexus. In one respect, post-1960 political economy can be accurately described as asking the fundamental questions of political theory from Thomas Hobbes, John Locke, David Hume, and U.S. founding fathers such as James Madison with the analytical tools of modern economics. When James Buchanan was awarded the Nobel Prize in 1986 for his development of public choice theory, political economy was well established again in the curriculum on economists and political scientists, and this has only continued in the decades since that award.

Second, there have been changes in the conceptual perspective of economists. There seems to be a willingness among economists to challenge the core ideas of rationality, self-interest, and equilibrium. But this willingness should be viewed with some suspicion because as I have argued, this new openness has been purchased by abandoning a commitment to substantive propositions in economics while steadfastly affirming the commitment to the form in which arguments must be made to be considered contributions to the economics. The criticisms associated with heterodox traditions of neoclassical methodology

have not won the day, and thus the enthusiasm one reads in Colander and Davis for the fracturing of the mainstream is overstated. Instead, the criticisms must be stated in a manner that conforms to those older Samuelson-Friedman notions of formalism and positivism. Roger Koppl has argued that the cutting edge of the mainstream (he refers to it as heterodox mainstream) is now occupied by work that employs the methods of bounded rationality, rule following, institutions, cognition, and evolution. And Koppl is certainly accurate in his description, but the argument that often accompanies this description of the current state of play in the discipline and the emerging alliance between various heterodox schools of thought such as post-Keynesian, old institutionalist, new institutionalism, complexity economics, Austrian economics, and post-Walrasian economics that will effectively challenge the prevailing orthodoxy is overstated. Instead, as I have stated earlier, the orthodoxy has tremendous absorptive capacity, and the evolution of methods of analysis such as evolutionary game theory has aided absorption. Heterodox arguments that can be restated in formal terms and tested using conventional statistical techniques can get a hearing among the professional elite, but those arguments that cannot quite be presented in that form (however interesting) will not get that same hearing, let alone influence economic research. This is one possible explanation as to why leading representatives of heterodox schools of thought are rarely published in the highest impact professional journals and are often unable to obtain teaching positions in the most prestigious departments. This is not an argument about discrimination and unfair barriers to entry in the field of economics. Economics is actually a very fluid discipline, and the culture at the top departments (e.g., University of Chicago) is notorious for the ruthless commitment to argument and not established status of individuals. But the judgment of what constitutes a good argument is not invariant with respect to the prevailing methodology. Model and measure rhetoric was used by Samuelson and Friedman to dismiss opponents, and the same can be seen today as the challenges of heterodoxy are absorbed into the orthodoxy—whether those challenges come from the lab, magnetic resonance imaging machines, computer simulations, history, anthropology, or philosophy. Still, there can be little doubt that the methods economists are employing in their work are evolving, and this evolution enables them to tackle many questions about the dynamic nature of economic life and the complex interdependencies that previous economic thinkers were unable to ask in a way that would produce acceptable answers as judged by the methodological strictures of formalism and positivism. Consider the work in this regard of the most influential economic thinkers in the 1990s and 2000s: Andrei Shleifer, Ed Glaeser, and Daron Acemoglu. These three have explored legal origins, the nature of regulation, and colonial heritage and the origins of democratic government. The questions are broad and the methods are creative, but the form in which the argument is stated is very conventional.

Third, there have been significant changes in the empirical techniques that economists employ in testing hypotheses. Developments in econometrics, such as nonparametric estimations, as well as instrumental variable approaches, have enabled economists to pursue empirical research on topics that previously had appeared elusive. In addition, there has been an acceptance of experiments across the board as providing not only useful but essential empirical information. Economists such as John List engage in natural experiments and field experiments. Of course, laboratory experiments have long been used by economists such as Vernon Smith to advance economic knowledge in the fundamental theory of choice, market theory, public goods, voting, and booms and busts. Smith's Nobel address is one of the most profound statements of the nature of rationality in economics, the context-dependent nature of choice, and the contingency of social order. Smith and his colleagues have studied trust relationships, cooperation in anonymity, conflict, and market efficiency. Also, developments in programming have enabled economists to do computer simulations that illuminate important economic ideas, such as the work on the interaction of zero information traders still able to generate market clearing. The focus on institutions has led to a renewed appreciation for the field of economic history among economists and political economists. The analytic narrative approach to political-economic history enables the rational choice theorist to combine the argumentative structure of economics with the compelling narratives of historical case studies (or comparative case studies). The bottom line: As the analytical methods of economics have broadened, they have been matched by new methods of empirical examination of the world around us. But note again that while the methods have evolved, the scientific aspirations of the intellectual enterprise have not—that aspiration is to provide a parsimonious model that generates testable hypotheses that are then subjected to empirical refutation.

One final change to the landscape of economics in the twenty-first century that is notable is the renewed interest in both the application of economics to unusual topics in everyday life and the popularization of economics among the public not as part of policy discourse but simply as a way of thinking about the world. This movement can be captured under the label "freakonomics" and is mainly associated with Steven Levitt. Levitt employs a natural experiment method to tackle everyday economics and make sense of statistical anomalies that are found in an examination of the data. Tyler Cowen's forays into "freakonomics" are more conceptual than Levitt's and attempt to walk his readers through the logic of choice, whereas Peter Leeson's work is focused more on explicating the mechanisms of social organization and explaining the operation of these mechanisms in unusual social environments.

As we finish the first decade of the twenty-first century, there should be little doubt that economics is a vibrant and diverse discipline. The methods of economics are constantly evolving as the technology of analysis changes. As I have discussed, in the twenty-first century, it has become commonplace for economists and political economists to tackle questions concerning the cognitive limitations of man and the institutional contingencies of exchange relationships. Koppl is right: The cutting edge of the profession is now occupied by researchers working on questions that were previously viewed as the domain of heterodox thinkers. But the narrative provided here disagrees with the assessment provided by Colander, Davis, and Koppl that a heterodox mainstream is emerging within economics that represents a fracturing of the core scientific enterprise of orthodox economics. When we look closer, what we see is that while the methods are evolving and the policy disputes are ongoing, the fundamental question of methodology and the conception of economics as a science are unchanging (and unchallenged). Economists are stuck in a world where the discipline attempts to mimic the methodology of the natural sciences. The new methods introduced (often imported from disciplines perceived as more scientific than economics to begin with) are always judged against this formalistic and positivistic standard. As long as this self-understanding and its corresponding standards of acceptance and rejection remain intact, then frameworks of analysis that focus disciplinary efforts on understanding rather than prediction will continue to be dismissed as unscientific. The challenges of the interpretative turn in the human sciences, as summarized by philosopher Richard Bernstein, are completely ignored. But today so are the admonitions by philosophers such as Alexander Rosenberg that economists must more faithfully follow the methodological prescriptions of positivism ignored. The formalistic and positivistic nature of economics is the product of scientific conventionalism, which actually proves to be a more elusive target in methodological disputes than explicit references to the philosophy of science.

Economics is what economists do, and what they do is build models and test those models against data sets with statistical tools. There are always exceptions to the rule, but the exception proves the point. Michael Polanyi once described how new contributions to science in general have to balance scientific plausibility, intrinsic interest of the community, and originality of the contribution. Economics is no different from physics in this regard. Conservative forces are weighed against revolutionary innovations in the practice of science to provide discipline so that wishful conjectures in truth seeking are channeled in a productive direction. Research efforts overlap, and the work of one scientist becomes the productive input into the scientific production process of another to form a dynamic orthodoxy. There has not been a revolutionary shock to the methodology of economics since the mid-twentieth century. There has been a broadening of topics and even the emergence of new and exciting methods in contemporary economics, but the basic notion of what it means to be doing scientific economics has not changed much since Paul Samuelson set the standard for theory and Milton Friedman explained what it meant to do positive economics. Methods of analysis are constantly changing and policy disputes are ongoing, but the underlying methodology of formalism and positivism has not been effectively challenged since it came to define the self-understanding of economics in the post–World War II period. So far, nothing in the twenty-first century practice of economics suggests that change to this self-understanding of scientific economics will come anytime soon.

# ECONOMETRICS

PETER KENNEDY
*Simon Fraser University*

Several definitions of econometrics exist, a popular example being the following: "Econometrics is the study of the application of statistical methods to the analysis of economic phenomena." The variety of definitions is due to econometricians wearing many different hats. First and foremost, they are economists, capable of using economic theory to improve their empirical analyses of the problems they address. At times they are mathematicians, formulating economic theory in ways that make it appropriate for statistical testing. At times they are accountants, concerned with the problem of finding and collecting economic data and relating theoretical economic variables to observable ones. At times they are applied statisticians, spending hours with the computer trying to estimate economic relationships or predict economic events. And at times they are theoretical statisticians, applying their skills to the development of statistical techniques appropriate to the empirical problems characterizing the science of economics. It is to the last of these roles that the term *econometric theory* applies, and it is on this aspect of econometrics that most textbooks on the subject focus. This chapter is accordingly devoted to this "econometric theory" dimension of econometrics, discussing the empirical problems typical of economics and the statistical techniques used to overcome these problems.

There are two main differences between econometrics and statistics. The first is that econometricians believe that economic data reflect strategic behavior by the individuals and firms being observed, and so they employ models of human behavior to structure their data analyses. Statisticians are less willing to impose this kind of structure, mainly because doing so usually is not fully consistent with the data. Econometricians ignore such inconsistencies, so long as they are not gross, to enable them to address issues of interest. The second difference stems from the fact that most economic data come from the real world rather than from controlled experiments, forcing econometricians to develop special techniques to deal with the unique statistical problems that accompany such data. For example, when analyzing female wages, one needs to account for the fact that some women with children will appear in the labor market only if their wage is large enough to entice them away from being a homemaker; this means that a sample of female wage earners is not a random sample of potential female workers—other things equal, low-wage earners are underrepresented. Patching up statistical methods to deal with these kinds of problematic data has created a large battery of extremely sophisticated statistical techniques. In fact, econometricians are often accused of using sledgehammers to crack open peanuts while turning a blind eye to data deficiencies and the many questionable assumptions required for the successful application of these techniques.

Despite these and many other criticisms, Masten (2002) argues convincingly that econometricians have a crucial role to play in economics:

> In the main, empirical research is regarded as subordinate to theory. Theorists perform the difficult and innovative work of conceiving new and sometimes ingenious explanations for the world around us, leaving empiricists the relatively mundane task of gathering data and applying tools (supplied by theoretical econometricians) to support or reject hypotheses that emanate from the theory. To be sure, facts by themselves are worthless, "a mass of descriptive material waiting for a theory, or a fire," as Ronald Coase, in characteristic form, dismissed the contribution of the old-school institutionalists. But without diminishing in any way the creativity inherent in good theoretical work, it is worth remembering that theory without evidence is, in the end, just speculation. Two questions that

theory alone can never answer are: First, which of the logically possible explanations for observed phenomena is the most probable? And second, are the phenomena that constitute the object of our speculations important? (p. 428)

## Linear Regression

The three main applications of econometrics are *estimating* relationships describing economic behavior, *testing* hypotheses about economic behavior, and *predicting/forecasting* economic events. The main methodology employed for these purposes is regression analysis, the essence of which is that we are interested in estimating a relationship such as

$$\text{Wage} = \alpha + \beta*\text{Education} + \delta*\text{Male} + \varepsilon.$$

This is interpreted as saying that an individual's wage is determined as a linear function of his or her years of education, gender (a "dummy" variable equal to 1 for males and 0 for females), and a random error term ε. The unknown parameters in this relationship, α, β, and δ, are what we wish to estimate; econometricians typically use Greek letters for unknown parameters. Special values of these parameters, such as that δ is equal to zero (corresponding to no discrimination on the basis of gender), are what we wish to test. Finally, if we knew the gender and years of education of a new individual, we could use this estimated equation to forecast this individual's wage.

Students studying econometrics need to become comfortable with several facets of regression.

The equation above is called the *specification;* the specification denotes the set of variables appearing in that relationship and the functional form of the relationship—in this case, a linear functional form. The wage variable is called the *dependent variable* or the *regressand.* The education and male variables are called *independent variables, explanatory variables,* or *regressors.* The unknown parameter α (unknown parameters are usually denoted by Greek letters) is called the *intercept* or *constant* term. The β and δ parameters are called *slope coefficients.* When there is more than one explanatory variable, the regression is called a *multivariate* regression. We speak of running a regression of the dependent variable on the set of independent variables; unless explicitly stated to the contrary, this includes an intercept.

Although this equation is written in a way that suggests a causal relationship, it is important never to forget that regression analysis can only assess the strength and direction of a quantitative relationship involving these variables. *Any conclusions regarding causality must come from common sense and economic theory.*

The error term is the *random,* or *stochastic,* element of the equation. It is added on for several reasons. First, a million extra variables influencing wage have been omitted from this equation; the error term reflects the sum of the effects of all these omitted variables. Second, there usually is some measurement error associated with the dependent variable. Third, the functional form of the relationship is probably not linear. And fourth, human behavior typically has a purely random component—faced with the same set of circumstances, a person will not always do the same thing. The error term is assumed to have zero expected value; any nonzero expected element of the error is absorbed by the intercept term.

The nonstochastic part of this relationship—namely, the equation without the error term—is called the *conditional expectation* of wage. What this means is that given values for the explanatory variables, the expected value of wage is given by this equation.

The slope parameter of an explanatory variable is the amount by which the dependent variable changes when that explanatory variable increases by one unit, *holding all other explanatory variables constant.* The terminology *ceteris paribus* is often used to refer to holding all other variables constant.

Estimates of the coefficients α, β, and δ are usually called $\hat{\alpha}$, $\hat{\beta}$, and $\hat{\delta}$. The forecasted wage for a man with 12 years of education is $\hat{w} = \hat{\alpha} + 12\hat{\beta} + \hat{\delta}$. The forecasted wage for a woman with 15 years of education is $\hat{w} = \hat{\alpha} + 15\hat{\beta}$. In words, we set the unknown error term equal to its expected value (zero) and plug our explanatory variable values into the estimated specification to predict/forecast the dependent variable.

The error in predicting the *i*th value of the dependent variable, $w_i - \hat{w}_i$, is called the *i*th *residual* and is denoted $e_i$ or $\hat{\varepsilon}_i$ because it is an estimate of the *i*th error term, $\varepsilon_i$. The popular ordinary least squares (OLS) estimates of the unknown parameters are estimates that result from finding values of the parameters that minimize the sum of squared residuals (SSR). The terminology sum of squared errors is often used in its place and so is often denoted SSE.

Because it minimizes the sum of squared residuals, the OLS estimator automatically maximizes the "fit" of the estimated equation, as measured by $R^2$, the fraction of the "variation" in the dependent variable explained linearly by variation in the explanatory variables. Adding an explanatory variable helps the computer minimize the SSE, even if this explanatory variable is irrelevant; the *adjusted* $R^2$ (written $\bar{R}^2$) corrects for this. $\bar{R}^2$ is only one of many criteria relevant to the choice of specification, primary among which is economic reasoning.

Thanks to the power of modern computers, calculating the OLS estimator, as well as most of the other estimators that econometricians employ, can be done very quickly and easily with econometric software. The more prominent of these are EVIEWS, LIMDEP, PC-GIVE, RATS, SAS, STATA, and TSP. An illustration of regression output produced by econometric software appears later.

## Sampling Distributions

### Why Is OLS So Popular?

It is extremely important to realize that the fact that OLS minimizes the sum of squared residuals and so

"fits" the data best (has the highest $R^2$) is not the reason why OLS estimates are so popular. OLS is popular because in a classic estimating problem (the classical linear regression [CLR] model), it has a high probability of generating an estimate "close" to the true value of the parameter being estimated. But if the estimating problem at hand does not satisfy the assumptions of the CLR model, OLS could be a very bad estimator. The study of econometrics revolves around how to generate a "good" estimate in a given estimating situation. All this is formalized in the sampling distribution concept, the foundation on which the logic of classical statistics rests. If you get this logic, statistics/econometrics makes sense! Here are the main things that need to be understood about sampling distributions.

Loosely speaking, a sampling distribution tells us the relative frequency with which we would obtain different values of a statistic (such as $\hat{\beta}$, an estimate of the slope of education in the specification given earlier) if we were to calculate that statistic many times over, each time using data embodying a new set of randomly drawn error terms. The important implication here is that the value of the statistic that we actually obtained can be viewed as a single random drawing out of this hypothetical sampling distribution; it is determined by the unknown error terms in the actual data we used. Here is an example. Suppose each student in a class of size 200 interviews 10 randomly chosen students and averages their 10 ages to produce an estimate of the average age of all students on campus. Would these numbers all be the same? No. We could take these 200 numbers and use them to create a histogram. This histogram would picture the sampling distribution of the sample average statistic for sample size 10. So if we had only one sample (of size 10), it could be viewed as a random draw out of this distribution.

To illustrate this, suppose that the variable $y$ (wage?) is a linear function of the variable $x$ (education?) plus an error term $\varepsilon$ with mean zero, so that we have $y = \beta x + \varepsilon$, where for simplicity we have omitted the intercept. Given 25 observations on $y$ and $x$, there are several possible ways of using these data to estimate the unknown parameter $\beta$. One of the simplest is $\beta^* = \Sigma y/\Sigma x = \beta + \Sigma\varepsilon/\Sigma x$. This shows that the value for $\beta^*$ is equal to $\beta$ plus (or minus) an amount that depends on the random errors we drew when we obtained our data. The errors have mean zero, so summing them should involve a lot of canceling out as positive errors are offset by negative errors. This suggests that $\beta^*$ should be a pretty good estimate of $\beta$ because $\Sigma\varepsilon/\Sigma x$ will be small, resulting in $\beta^*$ being close to $\beta$. But $\Sigma\varepsilon/\Sigma x$ will not be zero except by a fluke; sometimes it will be a positive number and sometimes a negative number, depending on the particular unknown error terms inherent in our data. It will probably be a small positive number or a small negative number, but if we had a peculiar draw of error terms, it could, with low probability, turn out to be a large positive or a large negative number. It is these possibilities, with different probabilities of occurring, that give rise to the sampling distribution of estimating formula $\beta^*$.

## How Do We Know What the Sampling Distribution Looks Like?

The computer output from an estimation procedure (such as OLS) provides a coefficient estimate $\hat{\beta}$ along with an estimate of its standard error. $\hat{\beta}$ is a single draw from its sampling distribution, so this does not help much in identifying what the sampling distribution looks like. But $\hat{\beta}$'s standard error is an estimate of the standard error of the sampling distribution, so this does provide information about $\hat{\beta}$'s sampling distribution, particularly about its spread. Beyond this, there are three ways of discovering what the sampling distribution of a statistic looks like—in particular, what is its mean. One has to do some algebra to derive it theoretically. This can be done in simple cases, but in most cases, the algebra is too difficult. In these difficult cases, two alternative methods are available. One is to use *asymptotic* (assuming the sample size is extremely large) algebra, which simplifies the algebra immensely but forces us to assume that results that are true for very large sample sizes are at least approximately true for our actual sample size. The other is to use a Monte Carlo study, in which a computer simulation is used to estimate the sampling distribution.

## Why Are Sampling Distributions So Important?

In short, the answer is because any statistic we calculate can be considered a random draw from that statistic's sampling distribution. This in turn has two extremely important consequences, one for statistics being used to estimate an unknown parameter and the other for statistics being used to test null hypotheses.

Suppose we are trying to choose between two estimating formulas, $\beta^* = \Sigma y/\Sigma x$ and $\beta^{**} = \Sigma xy/\Sigma x^2$, to estimate an unknown parameter $\beta$. Our choice is really the following: Would we prefer to estimate $\beta$ by drawing randomly a number out of $\beta^*$'s sampling distribution or by drawing randomly a number out of $\beta^{**}$'s sampling distribution? So to choose our estimator, we look for an estimating formula that has the "best-looking" sampling distribution.

## What Are the Characteristics of a "Good-Looking" Sampling Distribution?

One characteristic is *unbiasedness:* The mean of the sampling distribution equals the unknown parameter value $\beta$. A second characteristic is *efficiency:* The variance of the sampling distribution is small. A third characteristic is minimum *mean square error* (MSE). MSE is the expected magnitude of the squared distance between an estimate and the parameter it is estimating. A *best unbiased* estimator is an unbiased estimator that has variance smaller than the variance of any other unbiased estimator. A minimum MSE estimator is used whenever it is not possible to find an unbiased estimator with a small variance; it accepts some bias to reduce variance. This trade-off comes from deriving that MSE is equal to the sum of variance and squared bias.

An estimator that has a good-looking sampling distribution for one problem may have a bad-looking sampling distribution for another problem. In an earlier example, $\beta^* = \Sigma y/\Sigma x$ had a good-looking sampling distribution. But if in that example the intercept were not zero, this estimator would have a bad-looking sampling distribution. (Redo this example with an intercept $\alpha$, obtaining $\beta^* = \Sigma y/\Sigma x = \beta + N\alpha/\Sigma x + \Sigma\varepsilon/\Sigma x$, where $N$ is the sample size. Now $\beta^*$ will be close to $\beta$ only if $\alpha$ is close to zero!) A consequence of this is that a lot of what econometric theorists do can be characterized as follows: For a new estimating problem, find the estimating formula with the best-looking sampling distribution.

The second major use of the sampling distribution concept is in the context of hypothesis testing. Suppose we wish to test that $\beta = 1$, for example, and to that end, we calculate a test statistic $q$. Because $q$ is a statistic (i.e., it is a number calculated by putting the data into a formula), it has a sampling distribution. We ask ourselves the following: What would this sampling distribution look like if the null hypothesis were true? A lot of what econometric theorists do can be characterized as follows: For a testing problem, find a test statistic that, if the null hypothesis is true, has a sampling distribution described in one of the tables found at the back of statistics books.

The rationale behind hypothesis testing is intimately connected to the sampling distribution concept. A test statistic can be viewed as having been obtained by drawing randomly a single number out of that statistic's sampling distribution. Obtaining a number from the tail of the appropriate sampling distribution tabulated at the back of a statistics book (which assumes the null is true) poses the following dilemma: *Did we obtain this number by chance, or did it in fact come from a different sampling distribution, one that characterizes this test statistic when the null hypothesis is false?* The hypothesis testing procedure in common use results from setting up a rule to create an answer to this question.

### What Is This Rule?

If the number comes from the $\alpha$% tail of the null-is-true sampling distribution, conclude that the number came from a null-is-false sampling distribution and so reject the null hypothesis. In this case, $\alpha$% is the arbitrarily chosen Type I error; it is most commonly (without any good reason!) chosen to be 5%.

## The Classical Linear Regression Model

Introductory econometrics texts revolve around the CLR model, a set of assumptions about how the data were generated. If the data have been generated according to this model, the OLS estimator has very desirable sampling distribution properties, making it the first choice for estimation. Violation of one or more of the assumptions of the CLR model means that econometric theorists need to figure out what implications this has for the desirability of the OLS estimator and may lead to the choice of an alternative estimator. Chapters in textbooks typically examine violation of these assumptions one by one. There are five basic assumptions in the CLR model.

1. The first of these assumptions is that the linear specification is correct and that we have the right set of explanatory variables. Consider the specification used earlier:

$$\text{Wage} = \alpha + \beta^*\text{Education} + \delta^*\,\text{Male} + \varepsilon$$
or
$$w = \alpha + \beta\text{ED} + \delta\text{Male} + \varepsilon.$$

In this specification, wage is a linear function of years of education and gender, plus an error term. It also specifies that wage is determined only by education and gender, so that the influence of a million other variables is adequately captured by the error term. Probably some of these million other variables, such as experience and ability, are sufficiently important that, if possible, they should explicitly be included as explanatory variables in the specification.

The linearity assumption is not as restrictive as it appears. Here are some functional forms that reduce to linearity for estimation purposes.

a. *Polynomial:* $w = \alpha + \beta\text{ED} + \gamma\text{ED}^2 + \delta\text{Male} + \varepsilon$.

Here the square of years of education is included as an explanatory variable to allow the influence of education to die off as years of education becomes bigger and bigger. Note that this implies that the interpretation of $\beta$ changes. Although the functional form is quadratic, wage is a linear function of ED, $\text{ED}^2$, and Male, so that we can estimate via a linear regression of $w$ on ED, $\text{ED}^2$, and Male. What this means is that we create a new explanatory variable called $\text{ED}^2$, which has as observations the squares of the ED observations.

b. *Log-linear* or *semi-logarithmic:*
$\ln w = \alpha + \beta\text{ED} + \delta\text{Male} + \varepsilon$.

Here the dependent variable is the natural log of $w$, allowing the specification to represent a situation in which it is the percentage change in the dependent variable that is determined by changes in the explanatory variable. ($\beta$ is the percentage change in $w$ due to a unit change in ED.) This is in fact the most common way of modeling wage equations. Although the functional form is semi-logarithmic, $\ln wage$ is a linear function of the explanatory variables so that we can estimate via a linear regression of $\ln w$ on ED and Male.

c. *Log-log* or *double-logarithmic:*
$\ln w = \alpha + \beta\ \ln\text{ED} + \delta\text{Male} + \varepsilon$.

Here both the dependent variable and one or more of the explanatory variables are in log form. In this case, β is an elasticity—the percentage change in the dependent variable per percentage change in the explanatory variable. Estimation is via a linear regression of ln$w$ on lnED and Male. The classic example of this functional form is the Cobb-Douglas production function, in which output $y$ is a function of capital $K$ and labor $L$:

$$y = AK^{\alpha}L^{\beta}\varepsilon,$$

which upon taking logs becomes

$$\ln y = \ln A + \alpha \ln K + \beta \ln L + \ln \varepsilon.$$

In this functional form, α and β are elasticities, and α + β is the returns-to-scale parameter. A general rule for deciding when to use logged variables is to ask whether percentage changes or absolute changes are relevant for the context of your problem. For the wage specification, for example, people usually think in terms of percentage wage changes and the absolute number of years of education. In general, wages, income, price indices, and population figures are logged, and age, years of education, and rates of change such as interest rates are not logged.

2. The second assumption of the CLR model is that the expected value of the error is zero. In one respect, this is an innocuous assumption because the intercept in the specification gathers together the average influence of the million omitted explanatory variables, allowing the error term to have zero expected value. It is tempting to interpret the intercept in a linear functional form as the value of the dependent variable when all the explanatory variables are zero. This is a misinterpretation of the role of the intercept. The intention of all functional forms, linear or nonlinear, is that they approximate the "true" unknown functional form throughout the range of the data. The intercept merely serves to enhance this approximation.

3. The third assumption of the CLR model is that the error term variances are the same for all observations and that the error terms are all independent of one another. Violation of this assumption takes two common forms.

a. *Heteroskedasticity:* The variance of the error terms is not the same for all observations. A classic example of this is when the dependent variable is an average across all households in a town, with each town contributing one observation. Because the towns do not all have the same population, the averages will have different variances.

b. *Autocorrelated errors:* The error term for one observation is influenced by the error term for another observation. The most common case is in time-series data when the error in period $t$ is affected by the magnitude of the error in the preceding period $t - 1$. If an earthquake affects the dependent variable via a large negative error in time period $t$, the effect of the earthquake probably will not be fully overcome by the following period, so it is likely that the error in period $t + 1$ will also be negative.

4. The fourth assumption of the CLR model is that the explanatory variables are uncorrelated with the error. A classic example of this is simultaneity, a common economic phenomenon. Suppose we are estimating a demand function, regressing quantity on price. We know that quantity is determined by the intersection of the supply and demand curves. If the error term in the demand function bumps up, it shifts the demand curve, which through the simultaneous interaction with the supply curve changes price. Consequently, the error in the demand curve is correlated with price, the explanatory variable in the demand curve. Because when explaining changes in the dependent variable the OLS procedure gives as much credit as possible to the explanatory variables and as little credit as possible to the errors, the OLS procedure in this case lumps together the influence of the explanatory variable price and the influence of the error term and so creates a misleading (i.e., biased) estimate of the slope coefficient on price.

5. The fifth assumption of the CLR model is that there is no exact linear relationship among the explanatory variables. A classic example is the dummy variable trap. In our earlier example, we had a variable Male for gender, defined as 1 for males and 0 for females. Suppose we added an extra dummy variable Female, defined as 1 for females and 0 for males. Then Male plus Female equals 1, exactly equal to the intercept (the implicit 1 multiplying α). In this case, if you run a regression, the computer will rebel, complaining that you have attempted an impossible calculation such as trying to divide by zero. (More likely it will say "near singular matrix.") This problem is called *perfect multicollinearity;* it is impossible to run the regression. The case of an approximate linear relationship (which allows the regression to be run) among the explanatory variables is referred to as the *multicollinearity problem.* In this case, because the explanatory variables move together a lot, it is very difficult for the computer to figure out which explanatory variable is responsible for changes in the dependent variable. This causes the OLS estimates of the slope parameters to be unreliable: The variance of the OLS estimate is large.

6. An extra assumption that is sometimes added to the CLR model is that the errors are distributed normally. This creates the CNLR model, the classical *normal* linear regression model. The advantage of this assumption is that the normality of the errors allows use of the tables at the back of the book for hypothesis testing. Without normally distributed errors, the numbers in these tables are correct only in large samples. Fortunately, in most cases in samples of very modest size, these tables provide very good approximations to the numbers needed to perform hypothesis tests.

## Violating the CLR Model Assumptions

If the assumptions of the CLR model are met, the OLS estimator is unbiased and has the smallest variance among all linear estimators (a linear estimator is a linear function of the errors), and so it is called the *best linear unbiased estimator* (BLUE). The proof of this is called the *Gauss-Markov theorem.* But what happens to these desirable properties of the OLS estimator if the CLR model does not hold? Let us look at each of the CLR model assumptions in turn.

1. *Specification error.* The classic specification error dealt with in textbooks is omission of an important explanatory variable. In our wage example, suppose a measure of ability is omitted. Ability is likely correlated with education because people with more ability are likely to take more years of education. Because of this correlation, education will get credit for some of the influence of ability, biasing the education coefficient estimate. This could be a good thing if the estimated equation is to be used for forecasting because it compensates for the missing ability variable. But if the purpose of estimation is to produce a "good" coefficient estimate on education, the bias will not be welcome. Finding a wrong sign on a coefficient estimate is a warning that something is wrong with the specification. Because the specification is unknown, doing applied econometrics is much more difficult than doing econometric theory.

2. *Nonzero expected error.* If the expected value of the error term is a nonzero constant, no problem is created because its constant component is absorbed into the intercept.

3. *Heteroskedasticity or autorcorrelated errors.* There are two major consequences of errors that are heteroskedastic or autocorrelated. First, although OLS remains unbiased, it is not as efficient as an alternative estimator, the *generalized least squares* (GLS) estimator. This estimator minimizes a weighted sum of squared errors, where, for example, a lighter weight is put on errors with bigger variances because these observations are less reliable. But to some, a more important implication of violating this assumption is that the standard errors of the parameter estimates are biased, fouling up hypothesis testing. Whenever heteroskedasticity or autocorrelated errors are suspected, econometricians use OLS but employ "robust" standard error estimates that avoid this bias.

4. *Error correlated with an explanatory variable.* An instrumental variable (IV) estimator is usually employed to circumvent the bias caused by violation of this assumption. An IV is uncorrelated with the error but correlated, preferably highly so, with the delinquent explanatory variable. In our demand function example above, suppose that weather affects supply but not demand. Clearly, the weather is not correlated with the demand function error. And because it affects supply, it shifts the supply curve and so affects price, causing weather and price to be correlated. The part of price that is explained by weather (call it $\hat{p}$) is not correlated with the error, so by regressing quantity on $\hat{p}$, an (asymptotically) unbiased estimate of the price coefficient can be obtained. A drawback of the IV estimator is that its variance is bigger, sometimes dramatically so, than the variance of the OLS estimator; because of this, OLS may be better on the MSE criterion.

5. *Multicollinearity.* No bias is created, and OLS continues to be BLUE. The only problem is that the standard errors of the OLS estimator are large. There are only two solutions. First, do nothing because although the standard errors are large, they may not be so large as to compromise the purpose of the analysis. Second, find and use more information. More information means smaller standard errors. A classic example is to drop one of the explanatory variables that is highly correlated with another, adding the information that its coefficient is zero or nearly so. This eliminates the collinearity. It creates bias (deliberately!) because what you had believed was a relevant explanatory variable is omitted, but by eliminating the collinearity, standard errors shrink. On the MSE criterion, the resulting estimator may be superior.

## Beyond the Basics

What has been described above represents the basics of econometrics:

- the sampling distribution concept, upon which the logic of traditional econometrics rests;
- the CLR model, the workhorse of regression analysis; and
- the major violations of the CLR assumptions, the structure around which econometrics textbooks are built.

There is of course far more to econometrics. To provide a flavor of this, several major topics addressed in econometrics courses are briefly discussed.

### Nonlinear Regressions

Although as noted earlier, a lot of nonlinear functional forms can be estimated as linear regressions, many cannot. Here are some examples.

*Qualitative dependent variable.* If the dependent variable is a dummy variable—for example, taking the value 1 if an individual takes public transportation to work and 0 if not—a logit or probit model is used to estimate. These models have functional forms that produce dependent variable values lying between 0 and 1, with the estimated dependent variable values interpreted as the probability that the individual in question will take public transport. Multinomial logit/probit

models are extensions of this, with the dependent variable having more than two qualitative outcomes—for example, taking the bus to work, taking the subway to work, or using private transportation. If the dependent variable is qualitative with a specific order, such as bond ratings being AAA, AA, A, or B, an ordered logit or ordered probit can be used for estimation.

*Limited dependent variable.* If the dependent variable is limited in some way—for example, the number of tickets sold for a ballgame cannot exceed the capacity of the stadium—a tobit model may be used to estimate the demand function for tickets. Sample selection models are more sophisticated versions of this. For example, a female may enter the labor market only if the wage she is offered exceeds her reservation wage. The model thus contains two equations, one determining the reservation wage and the other determining the actual wage; estimation is complicated by having to recognize that only certain kinds of women make it into the sample of working females.

*Count data.* If the dependent variable is an integer representing the number of times something occurs, such as the number of cigarettes smoked in a day, a Poisson model may be used for estimation. The existence of nonsmokers complicates this because they all smoke zero cigarettes every day. The hurdle Poisson model adjusts for this by incorporating a separate (logit or probit) equation determining whether or not an individual smokes.

*Duration data.* If the dependent variable is how long it takes to have something occur, such as the number of weeks an unemployed person takes to find a job, a duration model is employed. Estimation is complicated because some of the observations are people who at the time the data were gathered had not yet found work, and so we do not know how long they will take to find work.

## Maximum Likelihood

OLS is a bad estimator for the models listed above (i.e., it has an unattractive sampling distribution). The most popular alternative is the *maximum likelihood estimator* (MLE). The maximum likelihood principle of estimation is based on the idea that the sample of data at hand is more likely to have come from a "real world" characterized by one particular set of parameter values than from a "real world" characterized by any other set of parameter values. The MLE is simply the set of parameter values that gives the greatest probability of obtaining the observed data. This is illustrated in Figure 5.1.

Suppose a random variable $x$ is distributed normally with mean $\mu$ and variance $\sigma^2$. You wish to use the $x$ observations, denoted by small circles on the horizontal axis in Figure 5.1, to estimate the two unknown parameters $\mu$ and

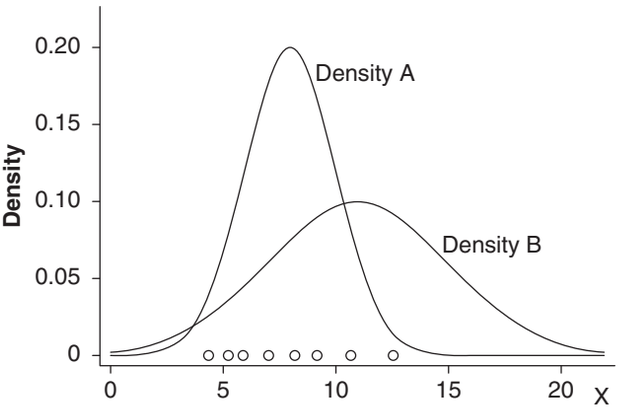

**Figure 5.1** Maximum Likelihood Estimation

$\sigma^2$. The distribution $A$ in Figure 5.1 corresponds to parameter values $\mu_A$ and $\sigma^2_A$. The distribution $B$ corresponds to parameter values $\mu_B$ and $\sigma^2_B$. From looking at Figure 5.1, distribution $A$ is clearly more likely to have produced the observations on $x$, so on the maximum likelihood criterion, we would prefer the parameter values $\mu_A$ and $\sigma^2_A$. By searching over all possible values of $\mu$ and $\sigma^2$, we can find the pair of $\mu$ and $\sigma^2$ values that are most preferred in this sense; these are the MLEs of $\mu$ and $\sigma^2$. In simple cases, an algebraic solution for the MLE can be found; in most cases, a computer search algorithm is used. The MLE has a very attractive sampling distribution, which explains its popularity. In large samples, it is unbiased, it has the smallest variance among all large-sample unbiased estimators, its sampling distribution takes the form of a normal distribution in large samples, and there is a universal formula (called the *Cramer-Rao lower bound*) that can be used to estimate its variance. Its only major drawback is that to calculate the MLE, the econometrician must assume a specific (e.g., normal) distribution for the stochastic component of the model.

## Panel Data

Thanks to the computer revolution, data sets in which we have observations on the same units in several different time periods have become common. These *panel* (or *longitudinal*) data have several attractive features. First, in any cross section, there is a myriad of unmeasured explanatory variables that affect the behavior of the people (firms, countries, etc.) being analyzed. (*Heterogeneity* means that these microunits are all different from one another in fundamental unmeasured ways.) Omitting these variables causes bias in estimation. Panel data enable correction of this problem. Second, panel data create more variability, through combining variation across microunits with variation over time, alleviating multicollinearity problems. With these more informative data, more efficient estimation is possible. And third, panel data can be used to examine

issues that cannot be studied using time-series or cross-sectional data alone. Consider the problem of separating economies of scale from technological change in the analysis of production functions. Cross-sectional data can be used to examine economies of scale by comparing the costs of small and large firms, but because all the data come from one time period, there is no way to estimate the effect of technological change. Things are worse with time-series data on a single firm; we cannot separate the two effects because we cannot tell whether a change in that firm's costs over time is due to technological change or due to a change in the size of the firm.

### Time-Series Data

Some time-series data behave like *random walks*—a variable's value is equal to its previous period's value plus an error term. Such variables are said to have *unit roots.* Because the error terms cumulate over time in this variable, rather than dying out, using such variables in regressions produces misleading results. Differencing the data can remove the unit root and allow regressions to be meaningful but at the cost of throwing away information in the data embodied in their levels—exactly the information economists can provide through characterizing equilibrium relationships. Great progress was made in econometrics by recognizing that this unit root problem could be resolved by combining such variables into equilibrium relationships and estimating a model using differenced data but in which the deviation from equilibrium affects the dynamics of the dependent variable. Such models are called *error correction models;* variables combining into an equilibrium relationship are said to be *cointegrated.*

### Robust Estimation

Econometric theory is very good at devising estimating procedures for special specifications about how the data were generated. But econometricians are seldom in a situation in which they can be confident about their model specification. What if some parts of the specification are wrong? Maybe the errors are more erratic than assumed, for example? *Robust* estimation procedures are designed to be insensitive to violations of the assumptions used to derive an efficient estimator. A simple example is minimizing the sum of absolute errors rather than minimizing the sum of squared errors. *Nonparametric* estimation is a more general form of this, in which estimation proceeds without any functional form constraining estimation.

### Diagnostic Testing

Associated with all topics in econometrics is a need to undertake tests designed to aid specification. Are explanatory variables missing? Is a linear functional form suitable? Are the error variances the same for all observations? Are the errors correlated? Is the error correlated with an explanatory variable? Are there outliers? A big part of studying econometrics is becoming familiar with a wide range of such tests.

## Illustrative Regression Results

Table 5.1 reports a set of OLS regression results representative of what econometric software packages produce. In this example, the logarithm of wage (LNWAGE) has been regressed on years of education (ED) and three dummies, with obvious nomenclature. Because the dependent variable is the log of wage, the estimated slope coefficients can be interpreted as percentages. The computer always prints out results to far more decimal places than is warranted, as illustrated here. The results in the coefficient column indicate that, other things equal, an extra year of education increases wage by about 6%, males earn about 34% more than females, non-Whites earn about 8% less than Whites, and union members earn about 26% more than non-union members. (Because of the nonlinearity here, these numbers are biased; better estimates can be computed as $e^{coeff}-1$. Doing this for the male/female difference, for example, increases the estimate of 34% to about 40%. This adjustment should always be done when the dependent variable is logged and we are estimating the percentage impact of a discrete explanatory variable.)

The *t* statistic column reports the *t* statistic for testing the null hypothesis that its associated coefficient is equal to zero, calculated by dividing the coefficient estimate by its standard error. The Prob. column reports the *p* value for the *t* statistic; this is the probability, if the null hypothesis is true (and assuming a normally distributed error), of obtaining a *t* value bigger in absolute value than the absolute value of the reported *t* value. With the exception of NONWHITE, these probabilities are essentially zero, leading us to reject these null hypotheses. In the case of NONWHITE, this probability is 11%; the decision to reject or not reject rests on what significance level (Type I error) we choose to use for the test. If we choose the popular 5% significance level, we would not reject the null that the coefficient of NONWHITE is zero.

Under the array of coefficient estimates are reported several secondary results of interest, explained briefly below.

- *R-squared* tells us that 28% of the variation in the dependent variable is explained linearly by these explanatory variables. Its adjusted value is only slightly smaller because the sample size (550) relative to the number of explanatory variables (4) is so large.
- *S.E. of regression* is the OLS estimate of the standard error of the error term in this relationship; its square is an estimate of the variance of the error term.

**Table 5.1** Illustrative Regression Results

| *Variable* | *Coefficient* | *Std. Error* | *t-Statistic* | *Prob.* |
|---|---|---|---|---|
| ED | 0.058655 | 0.006643 | 8.829840 | 0.0000 |
| MALE | 0.337946 | 0.037072 | 9.115928 | 0.0000 |
| NONWHITE | –0.077978 | 0.048717 | –1.600616 | 0.1100 |
| UNION | 0.261811 | 0.039135 | 6.689998 | 0.0000 |
| INTERCEPT | 0.668140 | 0.093488 | 7.146809 | 0.0000 |
| R-squared | 0.282894 | Mean dependent var | | 1.681002 |
| Adjusted R-squared | 0.277631 | S.D. dependent var | | 0.490157 |
| S.E. of regression | 0.416596 | Akaike info criterion | | 1.095649 |
| Sum squared resid | 94.58586 | Schwarz criterion | | 1.134830 |
| Log likelihood | –296.3034 | Durbin-Watson stat | | 1.955034 |
| F-statistic | 53.74976 | Prob(F-statistic) | | 0.000000 |

NOTES*:* Dependent Variable: LNWAGE. Method: Least Squares. Sample Size 550.

- *Sum squared resid* is the minimized value of the sum of squared residuals resulting from the OLS procedure.
- *Log likelihood.* If the error term is assumed to be distributed normally, the MLE, obtained by maximizing the likelihood of the sample (the probability of obtaining the sample), is the OLS estimator. In practice, the MLE is found by maximizing the log of the likelihood. *Log likelihood* is this maximized value.
- *F-statistic* reports the *F* statistic for testing the null hypothesis that the slope coefficients are jointly all equal to zero. Its numerator degrees of freedom is the number of individual hypotheses being jointly tested, in this case 4; its denominator degrees of freedom is the sample size less the number of coefficients being estimated, in this case 545.
- *Prob(F-statistic)* is the *p* value of this *F* statistic, the probability, if the null is true, of obtaining an *F* value bigger than the reported *F* value.
- *Durbin-Watson stat* is a test statistic used for testing for autocorrelated errors when using time-series data. If it is close to 2, the null of no autocorrelation is not rejected. Because the wage data are cross-sectional, this number is without meaning in this example.
- *Akaike info criterion* and *Schwarz criterion.* It is tempting to select the set of explanatory variables by maximizing adjusted $R^2$, implying that in essence one chooses the specification that minimizes the sum of squared errors plus a penalty for using extra regressors. The Akaike information criterion (AIC) and the Schwarz criterion (SC) are competing measures that employ "better" penalties for using extra regressors.
- *Mean dependent var* is the average of the observations on the dependent variable; *S.D. dependent var* is the standard deviation of these observations.

# Marxian and Institutional Industrial Relations in the United States

Michael Hillard

*University of Southern Maine*

This chapter presents industrial relations (IR)—the study of the capitalist employment relationship, with particular emphasis on employer/worker or "capital-labor" conflict. The field originated a century ago in the United States, maintaining an intellectual tradition and historical experience distinct from IR in other nations. The field was almost a purely American tradition until after World War II, when it was promoted and exported to Europe and developing countries, with U.S. cold war foreign policy an important impetus. The intellectual landscape and character of IR in other nations, with Britain a singular example with its heavy Marxist influence, is completely distinct and beyond the scope of this chapter. Kaufman (2004) provides a useful global history of IR.

Two IR schools of thought are summarized—the original, *institutional* tradition of industrial relations (or ILE/IR for institutional labor economics/industrial relations) and *Marxian-derived* modern political economy, which, drawing on the work of historians of U.S. labor and basic Marxian thought about class relations, has a competing interpretation of both the employment relationship and class conflict. Both schools provide an interpretation of U.S. labor relations' history and a policy agenda for solutions to employment relationship problems.

It is important to note that institutional and Marxian analyses share important conceptual ground. They are both *heterodox* theories (i.e., they are outside of the post-1950s Anglo-American neoclassical mainstream). Both emphasize the social determination of human beings' consciousness and norms of economic behavior (i.e., as opposed to seeing people as individual maximizing agents with preferences given and prior to any social influences), with institutions and power fundamentally shaping individual behavior and group economic outcomes. Most important, they share a belief that the default "market" situation in a "free" labor market is one of unequal bargaining power of capital over labor, an inequality that provokes conflict. They differ on understanding the nature and sources of power, especially in their interpretations of class conflict and of appropriate policy. This will all be explored in detail below.

Finally, this chapter presents IR's historical background. Class conflict is a historical phenomenon, with ebbs and flows and patterns of evolution and devolution. The origins of the field, the late coming of radical economic theory to the stage, and even a grasp of contemporary employment relations questions, in the view of the field, can be understood only historically. So, to situate our comparative analysis of institutional and Marxian schools of IR theory, we begin with the origins of IR in the industrial conflict that grew out of the American Industrial Revolution. Comparisons of the ILE/IR and Marxian views of the employment relationship, IR policy, understanding the decline of labor in the late twentieth century, and the future direction of the field follow this section.

## Capitalism and the Labor Question in the United States

It is widely understood by labor experts that industrial revolutions—the rise of a specifically capitalist system based on wage labor—create a brew of social and economic

conditions that provoke labor conflict (see Cowie, 1999; Dunlop, Kerr, Harbison, & Myers, 1960; Marx, 1977). The U.S. Industrial Revolution began in textiles in the early nineteenth century and gained full force after the Civil War when a new national railroad system sparked the rapid growth of a national market.

By the 1880s, the strongest force in the lives of the quickly growing U.S. industrial working class was their employer. Workers employed by large and small industrial employers who faced fierce competition in a national market—the world's largest—experienced harsh conditions, including low wages, long hours, management authoritarianism, and a lack of civil liberties in industrial communities. Early institutional thinkers such as Richard Ely and John R. Commons began to label these collectively as *labor problems* (Kaufman, 1993). As in all industrializing societies, American workers began rebelling, forming oppositional movements with both *militancy* (strikes, organized restriction of output, etc.) and *radicalism* (various ideologies of revolution within the labor movement) that were a threat to both the ability of capitalists to earn a profit and a potential long-run threat to capitalism itself. In turn, extreme hours, workplace exploitation, and chronic unemployment afflicted and provoked workers to organize and rebel.

As early as the 1870s, American workers created unions, joining in large numbers, in order to improve their chances of reducing hours (specifically the 8-hour day), gain fairness in the workplace and in their communities, and increase wages above meager levels. National railroad strikes in 1877 and 1894; nationwide marches and protests by workers on May 1, 1886, for the 8-hour day; and the famed Homestead steel strike in 1892 all seized the nation's attention. All were brutally repressed by state and federal troops. By the 1910s, the United States experienced an unprecedented, violence-filled strike wave that spread beyond "native" workers to include southern and eastern European immigrants, the growth of socialist politics and anarchist unionism, and acts of violence and terrorism that were seen as threatening prosperity and even social stability.

These phenomena, and the desire to bring about a progressive resolution to them, came to be known as *the labor question.* As President Woodrow Wilson framed it in 1919, the labor question was as follows:

> How are the men and women who do the daily labor of the world to obtain progressive improvement in the conditions of their labor, to be made happier, and to be better served by the communities and industries which their labor sustains and advances? (quoted in Lichtenstein, 2002, p. 4)

The labor question was highly political because of the degree of social conflict and strongly opposing ideologies associated with the different sides. The first choice of most employers was to use the government as an instrument of repression, along with spies and private militias. For instance, state militias were brought in to suppress strikes at least 495 times between 1880 and 1900, and by the 1930s, more than 100,000 were employed in union-busting "detective" agencies (Green, 1998; Laurie, 1989). This lasted until a sea change in government involvement and societal attitudes attenuated widespread use of overt repression of labor militancy roughly in 1940.

Political leaders, journalists, labor activists, and some business leaders responded to accelerating labor conflict in the 1910s by searching for labor problem solutions that addressed root causes and did not further inflame labor strife by breaking unions. Among experts, public leaders, and the union movement itself, the term *industrial democracy* became the term that described these alternatives to business repression and overt class warfare. Three visions of industrial democracy emerged during this era, becoming the contending models for IR policy for much of the twentieth century.

New employment relations experts defined two of these views—a "personnel management" (PM) tradition and the ILE/IR tradition (Jacoby, 1997; Kaufman, 1993; Kochan, Katz, & McKersie, 1986). These were clear and contending *professionally* driven visions and practices of how to bring about labor peace—an anti-union, PM tradition and the pro-union (though antiradical unionism) ILE/IR tradition. IR experts sought to enlist the state to support moderate "business unionism" (defined below) and create a regulatory role for IR experts themselves, while the PM group saw itself as a component of management. Personnel management was continually in direct competition with the authoritarian approach favored by most employers, while ILE/IR sought national government policies.

Within the labor movement itself, there was a split between proponents of business unionism and radicals. The American Federation of Labor (AFL) was the dominant national union institution. Founded in 1886, it was a federation composed of existing craft-based trade unions. The AFL's predominance was unchallenged until the formation of the Congress of Industrial Organizations (CIO) in the mid-1930s. The AFL advocated *business unionism,* which sought to have employees collectively bargain directly with employers for improvements (via compromises embodied in contracts) in wages and working conditions. The AFL did not seek a major role for government in industrial relations other than to stop employers and courts from repressing their rights to associate and bargain. The AFL position was consistent with and connected to the IR school's vision of employment relations. A third vision of industrial democracy came from a growing radical wing of the 1910s' labor movement that embraced both socialist politics and a more militant unionism favoring strikes and direct action.

While use of the phrase *industrial democracy* eroded in the coming decades, the basic categories of employment relations' policies continued throughout the rest of the

century, with some more ascendant in certain periods than others. Radical unionism/socialist politics persisted until its full repression in the 1940s, and the "non"-solution of employer autocracy remained the default practice for a majority of employers.

The U.S. federal government, needing employment stability during World War I, briefly instituted a version of the IR solution during 1917 and 1918. It was quickly dismantled after the war, and labor unions, which had grown rapidly, were just as quickly crushed. During the 1920s, large- and medium-sized U.S. employers hired PM experts widely to enact "corporate welfarism." Employers with as many as 3 million employees came under the aegis of "welfare" policies that included new disability and pension benefits, improved management practices, and "company" (i.e., employer created and dominated) unions (Brody, 1993; Jacoby, 1997).

The Great Depression brought about the ascendancy of the ILE/IR expert group, as the policies offered via the PM model collapsed in the economic crisis, leaving only employer autocracy, which worsened the depression by reducing wages and buying power. The IR model was embraced and sponsored by key congressional Democrats and the Roosevelt administration. They were its designers, rank-and-file bureaucrats, scholarly analysts, and public relations champions. ILE/IR members were both academics and political reformers devoted to a centrist solution to the problem of class conflict. In the 1930s, Democrats embraced ILE/IR proposals as a major component of liberal economic policy. IR policy came to the fore because of the peculiar and deep crisis of the 1930s (Kaufman, 1993; Lichtenstein, 2002). Crucially, IR policy offered a solution to the depression itself because it would lead to rising industrial wages and thus support greater mass consumption (i.e., effective aggregate demand) that would in turn revive the economy. It thus was a pillar of what came to be Keynesian macroeconomic policy. Also, IR policy offered an alternative to the twin "evils" of socialism and class warfare.

Two signal and roughly coterminous events marked the mid-1930s: the passage of the National Labor Relations Act (NLRA) in 1935 and the rise of the CIO, a federation of unions composed of populist and left-wing *industrial* unions. *Industrial* connotes a union composed of all workers in a workplace without regard to occupation or "trade." The AFL is a federation composed of *trade unions*—that is, with membership based principally on occupation (e.g., carpenters, machinists, typographers). The AFL bitterly fought industrial unionism from its inception through the 1930s (Dubofsky, 1996). CIO unions organized for the first time the preponderance of workers in twentieth-century mass production industries (steel, auto, rubber, electrical workers, etc.). The NLRA, designed by ILE/IR experts, legalized unions and created a government-sponsored election process to allow workers to elect for union representation, a requirement that capital and labor bargain collectively "in good faith," and, most important, proscription of traditional employer "unfair labor practices" (e.g., firing and blacklisting pro-union employees) that had previously blocked widespread unionization. New organization and the support of the federal government, combined with heavy pressure by government on recalcitrant industrial employers during World War II, sparked a fivefold expansion of union membership from 1933 to 1945. This ushered in the "New Deal IR system." After thriving for decades, the New Deal system went into an abrupt decline in the 1980s. The New Deal system provided dramatic increases in working-class living standards (however, with many groups left out—southern and some rural workers, African Americans, and women workers). Its end in the period around 1980 reversed this progress.

## The Institutional IR School: Peculiarities of the Labor Market, Unequal Bargaining Power, and Capital–Labor Conflict

IR began as a subset of the institutional economics field, focused on the question of capital–labor conflict and compromise solutions to that conflict. Institutional economists developing IR theory also studied the need for social insurance and sought to understand the institutional forces shaping the labor market.

Beginning with Richard Ely and especially with the work of John R. Commons and his students in the Wisconsin school in the late nineteenth and early twentieth centuries, an evolutionary line of descent can be traced through a second generation of scholar/policy makers from the 1930s to the 1990s, led by John Dunlop and Clark Kerr, Richard Lester, and Arthur Ross. This group was somewhat friendlier to orthodox (neoclassical) economics. A third generation is active and influential today (including Kate Bronfenbrenner, Michael Piore, Richard Freeman, Eileen Applebaum, Thomas Kochan, and Bruce Kaufman). Some in this third generation differed from the second in their greater concern for problems of urban poverty, racism, and sexism.

Richard Ely began with a view of labor markets that differed radically from the assumption of "free" labor markets found in neoclassical economics. Ely concluded that capitalist labor markets suffered three "peculiarities" that disadvantage workers vis-à-vis employers: a lack of bargaining power, management's authoritarian treatment of workers, and economic insecurity—that is, frequent unemployment (Kaufman, 1993, pp. 32–33). If labor in capitalism is "free" (i.e., free to quit a bad employer and find another, creating a competition among employers that should redress such problems), how could employers have such an upper hand? The premise is significant, chronic unemployment. Beatrice Webb (1901) provides a clear statement of the sources of this imbalance that defines why

capitalist labor markets were then and now are slanted in employers' favor:

> If the capitalist refuses to accept the workman's terms, he will, no doubt, suffer some inconvenience as an employer. . . . But, meanwhile, he goes on eating and drinking, his wife and family go on living, just as before. His physical comfort is not affected: he can afford to wait until the labourer comes back in a humble frame of mind. And this is just what the labourer must presently do. For he, meanwhile, has lost his day. His very subsistence depends on his promptly coming to an agreement. If he stands out, he has no money to meet his weekly rent, or to buy food for his family. If he is obstinate, consumption of his little hoard, or the pawning of his furniture, may put off the catastrophe; but sooner or later slow starvation forces him to come to terms. And since the success in the haggling of the market is largely determined by the relative eagerness of the parties to come to terms—especially if this eagerness cannot be hidden—it is now agreed, even on this ground alone, "that manual labourers as a class are at a disadvantage in bargaining." (pp. 8–9)

In turn, these resulted in labor *problems.* In distinction to the "labor question," *labor problems* included workers' low wages, insecure employment/income, and harsh treatment by supervisors. Employers faced the wake of workers' self-protective reactions, ranging from lost output due to workers' restriction of output and lost productivity from strikes. Society suffered because of lost production but mostly the disruption of violent strikes and nationwide strike waves (Kaufman, 1993).

Finally, conflict was inevitable in the face of such harsh conditions. The militancy and radicalism of industrial nations' workers seeking to redress exploitation and insecurity was well established by the late 1800s. As discussed below, this led to a policy vision focused on using the state and harnessing an invigorated, state-supported, conservative trade unionism to bring about labor peace through a government-supported process of compromise.

## Marxian IR: Marx and Capitalist Employment Relationship

Marx developed a theory of the inherent presence of class conflict in capitalist employment relations. Radical and Marxian analyses of the U.S. thrived until the early cold war period, when McCarthyist repression of radical intellectuals reduced radicalism to a marginal existence. The changed political environment of the 1960s permitted a revival. Scholars such as Samuel Bowles, James Crotty, Heidi Hartman, and Stephen Resnick and Richard Wolff led a rebirth around 1970. Marxian labor analysis grew out of the influential work of Harry Braverman (1974) and Gordon, Edwards, and Reich (1982).

Marx begins with what he sees as the historic fact of classes. Capitalism's class system is seen as the product of two related historic processes: "proletarianization" and primitive accumulation (Marx, 1977, pp. 873–930). Proletarians, capitalism's working class, are formed out of former serfs, independent "yeoman," or peasant agricultural workers who were forcibly separated from their access to land and dispossessed in European societies. Paupers moved to cities and sought waged employment. These proletarians were newly "free" to sell their labor time (for Marx, a person's "labor-power") and were "freed from" access to the land and resources needed to produce their means to survive. They are thus both "free" to participate in labor markets and, at the same time, utterly dependent on them. In turn, European aristocratic classes participated in global plunder and exploitation of slave-produced commodities such as sugar, as well as the slave trade, to produce a merchant class with the money to hire proletarians and begin the process of manufacturing for markets for a profit (Howe, 2002). Capitalists have exclusive control and access to physical capital (which Marx termed the "means of production") and money that can provide workers with a means of buying goods and services—thus being able to survive. Workers are compelled under these circumstances to work for a wage and accept giving over their time to the control of capitalists. The drive for profit by capital, as well as the control they have over workers' lives, results in exploitation and, in the absence of worker resistance or government limitations, tremendous excesses such as child labor and extremes of workdays (pushing physical limits of 14 to 18 hours per day) and working conditions that inevitably shortened life spans.

Marx published Volume I of *Capital* 20 years prior to Ely's founding of U.S. institutional economics, a history consistently ignored by IR scholars in the United States. Yet, Marx's analysis identified Ely's "three peculiarities of the labor market" and went beyond Ely to highlight workers' exploitation.

For Marx, the wage is set just like any other value, at the cost of the reproduction of the thing being sold. Thus, in Chapter 6 of *Capital,* Volume 1, Marx presumes that the labor market is fair in the precise sense that the wage is equal to what it costs to clothe, feed, house, and transport the worker and provide for the next generation at a socially and customarily determined standard of living. It is not in the labor market but *inside* the employment relationship that one must go to understand processes of conflict and cooperation.

What the capitalist wants to buy is labor (i.e., work), but what he or she can buy is labor time. For radical economists, this is Marx's famous "labor from labor-power" distinction. Capitalists buy from workers a commodity: the human ability to apply muscle and brain power. The cost of this commodity is set by its labor time necessary to produce (Marx used a "labor time" theory of commodities' value or price). Marx argued that a given capitalist society would have a socially determined

(i.e., by norms established historically and often through class struggle) combination of "wage goods." The labor time required to produce this "wage bundle" (i.e., what is necessary to socially reproduce the worker and the next generation of workers) would define the wage as the equivalent of "necessary labor time" (i.e., keeping a workforce alive and able to continue economic production). Capitalists earn a profit by getting more labor time from a worker than the wage. Labor, unlike the fixed cost of labor-power, is elastic and can be extended or intensified to increase labor time embodied in newly produced commodities beyond the cost of the wage, and this constitutes "surplus labor time." Surplus labor time is the source of profit (i.e., surplus value).

The labor from labor-power distinction causes two kinds of conflict. First is conflict over the length of the working day. If capitalists can lengthen the working day without increasing the (daily) wage, more of the output returns to them: that is, surplus labor time and the surplus product (i.e., the labor time and production above "necessary labor time"). Competition drives capitalists to push workers, in the extreme, to work arduous hours—up to and past 80 hours a week, to the point where workers' health is damaged and lives are shortened. Indeed, the beginning of the modern labor movement can be found in the struggle to limit the working day, first for women and children and then for all workers.

A second area of conflict is reduction in necessary labor time, or what Marx called *relative surplus value.* Here, the object is to reduce necessary labor time through increased productivity. Individual capitalists have an incentive to pursue this, in order to increase profits at the expense of competitors through cost advantages. Technical changes that increase the pace of production or allow skilled or high-status workers to be replaced by unskilled or low-status workers, production speedup that gets the worker to work harder, and moving production to regions with a lower standard of living all increase the relative part of the product that accrues to the capitalist. At the center of this strategy is intensification of the work pace beyond human limits and de-skilling of work that destroys the intrinsic value of skilled work. Both provoke worker resistance and rebellion.

While workers may struggle (sometimes successfully) against these two forms of exploitation, their success is limited by a number of factors, including the problem of coordinating individual action for mutual gain and the existence of the reserve armies of the unemployed who are ready to take employment under lower standards than incumbent workers.

Marx illustrated his ideas in a detailed case study of Britain's Industrial Revolution, with its struggle over the length of the working day, the rise of mass production, and the intense competition that makes capitalism both technically progressive but also intensely exploitative. British capitalists, seeking an advantage in competition, are shown pushing the working day past all physical and moral limits, including cruelties that dramatically shorten the lives of workers and rob children of a meaningful childhood. Marx (1977) argues that the incentive for every capitalist to use up labor-power without worrying about there being a tragedy of the commons can be limited only by society itself placing absolute constraints on the capitalist:

> *Apres moi le deluge!* is the watchword of every capitalist and of every capitalist nation. Capital therefore takes no account of the health and the length of life of the worker, unless society forces him to do so. (p. 381)

Workers, seeking to preserve their "property" (themselves) and their humanity, demand a working day that does not physically destroy them and leaves time for cultivation of their physical, intellectual, and cultural powers. Similarly, an inherent conflict exists over the *intensity* of labor, particularly once society establishes some norms on the extent of the working day. Capitalists divide the labor process, create single-task jobs (the "detail worker"), and generally impoverish the work process, increase its speed, and, by using specialized machinery (in what subsequently came to be known as "mass production"), create a super-productive work process that at the same time degrades work and the worker. As the "new" labor history and labor process theory has shown in recent decades, U.S. workers have indeed periodically and frequently rebelled over the length of the working day and over "control" in the labor process (see, e.g., Braverman, 1974; Montgomery, 1980; for a careful review of 30 years of "labor process" work provoked by Braverman's book, see Thompson & Newsome, 2004).

The institutional and Marxist traditions thus share the common assumption that class conflict under capitalism is to be expected. Where they depart ways is on what is the appropriate *resolution* of this conflict. For institutionalists, class conflict is seen as a threat to social order, a "primitive democracy" to be channeled and ultimately repressed (S. Webb & Webb, 1897). Marx proposed a different notion.

Marx infamously predicted in the *Communist Manifesto* (coauthored with F. Engels) a worker-led revolution that never materialized (Tucker, 1978, pp. 473–500). Marx also argued that the working class could, through waging class conflict, improve its position within an existing economic system *without* overthrowing it. He illustrated this idea by describing the British working class's victorious struggle to shorten the working day and reduce child labor:

> It will be easily understood that after the factory magnates had resigned themselves and submitted to the inevitable, capital's power of resistance gradually weakened, while at the same time the working class's power of attack grew with the number of its allies in those social layers not directly interested in the question. Hence the comparatively rapid progress since 1860. (Marx, 1977, pp. 408–409)

Marx (and Engels) stressed that even within the existing structure of capitalism, the state *could* be pressed by circumstance into opposition to the interests of capitalists. Friedrich Engels, Marx's collaborator, makes this point in his famous *Letter to Bloch,* citing the many occasions in which they made this point:

> If Barth therefore supposes that we deny any and every reaction of the political, etc., reflexes of the economic movement upon the movement itself, he is simply tilting at windmills. He has only got to look at Marx's *Eighteenth Brumaire,* which deals almost exclusively with the *particular* part played by political struggles and events; of course, within their *general* dependence upon economic conditions. Or *Capital,* the section on the working day, for instance, where legislation, which is surely a political act, has such a trenchant effect. (Tucker, 1978, p. 765)

A politically empowered working-class labor movement thus could and has shaped capitalist societies to improve treatment of the working class. Marx's conclusion about the struggle over the length of the working day is instructive on "reformist" possibilities within capitalism:

> For "protection" against the serpent of their agonies, the workers have to put their heads together and, *as a class,* compel the passing of a law, an all-powerful social barrier by which they can be prevented from selling themselves and their families into slavery and death by voluntary contract with capital. (Marx, 1977, p. 416)

The moments when the state leans against the interests—espoused and practical—of the capitalist class are restricted to those conjunctures when a combination of "pressure from below" and a host of other circumstances—political, economic, and ideological—combine to produce a change in the state that reacts back on the economy. Marx, despite his infamy as a predictor of the necessity and inevitability of the revolutionary demise of capitalism provoked by a combination of impoverishment of all workers and irresolvable economic crisis, had, with Engels, a specific vision of reform within capitalism that could better the fortunes of the working class.

## ILE/IR: A Program for Labor Peace and an End to Labor Problems

ILE/IR scholars defined a clear paradox: how to equalize the bargaining power of labor (thus curbing the "peculiarities of the labor market" and especially creating equal bargaining power between employer and worker) and *not,* as a consequence, provoke an empowered working class into more militancy and creating even more capital–labor conflict. ILE/IR offered a reform vision that, if implemented successfully, would resolve this paradox, bringing stability and steady economic growth. It called for "corporatism," a system where employer and worker representatives work together through a collective bargaining process to produce capital–labor stability by means of compromise. Just as important, the ILE/IR school promoted the nonrevolutionary business unionism of the AFL as the preferred mode of making corporatism work. The AFL and IR policy together provide *an alternative to radicalism,* defeating radicalism by making it irrelevant.

Kaufman (1993) summarizes this ethos in describing the ILE/IR corporatist view of "the efficacy of conflict in the employment relationship":

> From the point of view of the institutionalists, a certain amount of conflict is the normal by-product of the employment relationship and, indeed, frequently plays a constructive role to the extent that it vents repressed frustrations, resentments, and grievances. Good industrial relations, therefore, is not synonymous with an absence of conflict, for often this indicates complete domination of the relationship by the employer. Rather, good industrial relations requires equalizing the bargaining power of labor and capital both inside and outside the plant and letting them voluntarily negotiate a mutually satisfactory outcome. The watchword of the institutionalists is compromise. (p. 38)

Such compromise is imagined to be at least partly dependent on the work of state-supported mediation experts. Indeed, it is important to note how far this vision differs from a free-market view of the economy. Institutions—including unions and employers with bureaucratic representatives and working within parameters set, enforced, and often directly supported by the state—structure the process of striking a bargain, rather than "free," individual agents in a market.

More broadly, about the purpose and result of creating such a state machinery of IR experts, Commons famously said, "In dealing with the momentous conflict of 'capital and labor' . . . I was trying . . . to save Wisconsin and the nation from politics, socialism, or anarchy" (cited in Ramirez, 1978, p. 188). In other words, IR experts were to provide not just workplace stability but also political stability—making labor revolt and anticapitalist working-class political expressions less likely. In its place, Commons advocated for a system in which "neutral" experts provided technically determined compromises between the conflicting interests of capital and labor.

IR scholars have thus had as their goal the careful management of class struggle, with a fundamental aim of limiting (though not suppressing) conflict and encouraging nonsocialist political expression by workers through nonpartisan, nonmilitant unions. In turn, their role as experts has been to continuously study the underlying "problems" that might cause an unstable landscape—notably through case studies of industrial relations in specific industries—and get directly involved as mediators and experts, to ensure that the problems will not get out of hand and that compromises are struck. IR experts saw, for the New Deal

IR period, what Kaufman terms *institutionalization* in the creation of IR institutes with the creation of graduate programs at the top state universities throughout all regions in the United States except the South and also in federal and state mediation bodies.

It appeared that ILE/IR policy worked in the 1950s and 1960s. The mass strike activity of the 1930s/1940s abated. The U.S. economy experienced a combination of unparalleled income "compression" (i.e., greater equality) that saw industrial workers become middle class and enjoy steady and powerful income growth, as well as improvements, including fewer hours worked and an expanded private sector safety net provided through union contracts. The ILE/IR field itself appraised this as the success of expertise over a technical problem with capitalism and projected that the stability of the New Deal system would persist indefinitely. However, through the exercise of capitalist class power, this system came to an abrupt end in the 1980s.

## Marxian Political Economy: Class Strength and Workers' Improvement *Without* Revolution

Marxian analysis of U.S. employment relations employs a different analytical framework. It comes to several different conclusions that contrast and even contradict the ILR/IR school:

- Not only is class conflict inevitable, but it can be a good thing.
- A stronger labor movement tends to produce better social outcomes, including lower income inequality, less poverty, shorter weekly and annual work hours, and more comprehensive social insurance, without an overthrow of the capitalist system.
- Historical evidence supports these conclusions.

It has been the political quest of working-class parties in advanced capitalist countries to accomplish that very goal of improving the quality of life for workers and for society, seeking to humanize capitalism by minimizing economic insecurity and discrimination, reducing/eliminating poverty, implementing safety and health and labor standards (e.g., limiting hours worked, eliminating child labor), and providing public goods (e.g., education, child care, public space). The labor movements of various countries have also sought regulatory and union agreements that grant expanded workers' rights and decreased property rights, such as legal guarantees over right to job, workplace decision-making power, and having a significant stake in corporate governance.

Thus, Marx's emphasis on relative class strength as a predictor of social outcomes, as well as the possibility of a politically strong working class to enlist social allies (e.g., middle classes) and the state, has resonance with twentieth-century historical experience. Succinctly, the quality of economic and social life for a working class in a particular nation is a reflection of the strength and degree of past and current success of its labor movement. Child care, retirement, health care, social security, length of the working week, and weeks of paid vacations are better for workers in Sweden, Germany, or France than in the United States. Why? Because over the second half of the twentieth century, their labor movements succeeded economically and politically where the U.S. labor movement either failed or won only modest improvements (and, as noted, isolated only to certain regions) that a now far weaker labor movement has been unable to protect. There is of course no reason to believe that these improvements will lead to revolutionary change, but such improvements are, we would argue, good in and of themselves. Added to Marx's historical example of the 10-hour day, this offers compelling evidence that a politically and economically stronger working class, as well as class conflict emanating from it, produces positive outcomes for the working class. When two valid and opposite claims over the course of the employment relationship meet one another, as Marx put it, in the end, force decides.

To reiterate, a politically strong working class can, with allies and supportive historical circumstances, get the state to "lean against" the interests of the capitalist class. This happened in the United States in 1934–1937.

## The Case of 1934–1947

The Great Depression reignited working-class insurgency after more than a decade of dormancy. By 1934, workers, emboldened by Roosevelt's verbal support for unions, mobilized to form unions and conducted vigorous strikes, including three "general" (community-wide, multiemployer) strikes (Green, 1998; Lichtenstein, 2002; Lynd, 1996). Initially, Roosevelt's National Recovery Act implemented in 1933 and 1934 large businesses' proposal for solving the depression. This consisted of government-sponsored cartelization—businesses openly cooperating in setting prices and allocating markets. This approach did not address the underlying problem of inadequate aggregate spending and utterly failed. In combination with the public's already low esteem for big business—the American public held business responsible for causing the Great Depression in the first place—this failure left a political vacuum seized upon by two allied groups: the broad working-class insurgency played out in streets and factories across the country, and liberal political leaders who sought to impose ILE/IR policies such as the NLRA and a broad program of social security. This magnified the already existing loss of business legitimacy that the Great Depression created, opening the way for a coalition of congressional and executive branch leaders, representing the northern urban, working-class, union-based movement, to seize control of national policy making.

This permitted a onetime imposition of values and policies alien to U.S. capitalists. The loss of capital's credibility and power was unprecedented and short-lived, but it ushered in dramatic changes—an expanded welfare state and widespread unionization—that lived on for decades (Finegold & Skocpol, 1984; Lichtenstein, 2002). The results: a New Deal state that imposed state-sponsored support for an IR collective bargaining–based system (under the 1935 Wagner/NLRA Act), and a tax-supported national social welfare system, including Social Security and unemployment insurance, along with significant labor market regulation (especially the 1938 Fair Labor Standards Act). During this period, industrial unionism caught fire, gaining special momentum after Roosevelt's 1936 reelection; the new political environment contributed in part to high-profile union victories at General Motors and U.S. Steel in early 1937. While interrupted briefly by the late 1930s recession, the momentum toward rapid unionization resumed during World War II and continued into the 1950s.

In sum, this period illustrates a similar moment of dramatic, pro–working-class reform, supported and implemented to a significant degree by a state willing to act against capital's economic and political interests. Working-class political strength was unparalleled and briefly even unchallenged by capital. The result was long-lasting improvements for the working class.

This observation comes with an important qualification. Historical scholarship has a consensus view that African Americans, southern workers in general, and women were largely left out of this progress. At the level of policy (e.g., Social Security and unemployment coverage, as well as wages and benefits), this was most certainly true. Many in these groups were trapped in a "secondary" labor market of low wages and benefits with little opportunity for income security or advancement (Gordon et al., 1982). There are also notable exceptions to this partial progress (Minchin, 2001). It is also the case that new activism in the 1960s and 1970s served to expand inclusion of some women and people of color in some of these benefits, but even then incompletely (Kessler-Harris, 2007; Lichtenstein, 2002).

## ILE/IR: Stagnating New Deal System Collapses, Dynamic Non-Union Alternatives Rise

Recently, ILE/IR scholars have reinterpreted twentieth-century U.S. IR history, focusing on explaining why the dominant unionized/corporatist New Deal system lasting from the 1930s through the early 1970s went into an abrupt and lethal decline (Jacoby, 1997; Kaufman, 1993; Kochan et al., 1986). They attribute the decline to the vitality of employer-dominated "welfare capitalism" throughout the era of the New Deal, which escaped the attention of earlier IR scholars. The unexpected vulnerability of unionized employers to rapid economic change from the 1970s led to a new dominant IR system based on "progressive" but union-free employers.

How could a strong and durable institutional system be taken apart at all, much less so quickly? First, 1920s welfare capitalism survived (and adapted) in the 1940s–1970s period, becoming more sophisticated, and gained strength and momentum. Non-union employers also led capitalist political activism against the New Deal state and unions. For instance, the 1948 Taft-Hartley Act created vast loopholes in labor law that allowed employers to defeat new union organizing drives. In retrospect, the true apogee of union strength was really in the 1950s. From then on, dynamism in IR policy centered on the ever-expanding tool set of welfare capitalism—the latest version of the "PM tradition" now called human resource management (HRM) that contributed to the vitality of non-union companies. Even unionized companies adopted HRM practices in efforts to weaken union influence (Phillips-Fein, 2009). Besides high wages and generous benefit packages—aimed to meet the standard set by the strongest union contracts—the HRM movement sought to realize the PM vision of a humane management by surveying workers to gain a grasp of their concerns, training frontline supervisors to be more positive, and creating at least an appearance of due process through employee handbooks and "open-door" policies. As we discuss below, the velvet glove of HRM shielded an iron fist that crushed any movements toward independence through union organizing. Union busting, capital flight to non-union states or offshore locals, and "progressive management" were part of one package.

When rapid globalization met the macro crisis of 1979–1983, unionized business abandoned its cooperative relationship with unions, getting givebacks, deindustrializing much of the Midwest, and, with perhaps the singular exception of auto, shifting more aggressively to non-union operations in Southern and Great Plains rural towns or "offshore" to developing countries with low wages and labor standards. Another factor was simple contraction in the face of loss of markets to foreign competition, where companies ceded markets rather than investing in new technology and capital, instead diverting retained earnings into conglomerate purchases, as was the case in steel. Private sector union density (the unionized percentage of workers) fell by two thirds over the last three decades of the twentieth century, standing now below 8%.

## A Marxian View: Changing the Terms of Class Power, American Employer Exceptionalism

To reiterate, the central concept in a Marxian interpretation of industrial relations is relative class power. Here, we explain the crisis and implosion of the New Deal IR system as the

result of capital's regaining an upper hand from the 1970s on. The outlines of this story are well known: increasing globalization, transportation and communications technology that make it virtually costless to move production offshore, and the impetus to do so by the allure and opportunity of vast armies of cheap labor abroad. Missing from this standard story is a clear recognition that the U.S. decline in unionization and speed and extent of industrialization are unique—not found elsewhere in western and northern European nations or Japan. Our own view of American exceptionalism is that the formation and activism (agency, for short) of large industrial U.S. employers has been a pivotal component driving the United States' unique IR characteristics: the weakness of the labor left, the rapid destruction of unionization and collective bargaining in dominant industries, and the decline of U.S. labor standards and accompanying growth of inequality since the 1970s (Hillard & McIntyre, 2009a).

We begin with U.S. labor history from the 1880s to the 1920s. U.S. labor was arguably at that time as radical as European labor. But the ruthless use of force by U.S. capitalists and the weakness of the government in refereeing industrial relations (indeed, typically siding with employers by deploying troops) limited the success of the labor movement and cut off radicalism as a viable alternative to business unionism. Individual American employers had even greater relative incentive to repress labor because unionizing one company at a time put them at a competitive disadvantage; European unions had greater success in organizing whole industries (Jacoby, 1991; Wilentz, 1984).

American capitalist class exceptionalism thus traces its roots to the massive defeat of U.S. labor and popular organizations in the pre–New Deal period. Scholars comparing the labor histories of Europe and the United States conclude that U.S. employers went drastically farther and were singularly dedicated in their efforts to crush unions rather than accommodate them (Jacoby, 1991; Thelan, 2001). This exceptional commitment to crush labor was not fundamentally altered when the Great Depression and New Deal forced American capitalists, much against their will, to recognize unions' legal right to exist. As IR scholars cited above note, the New Deal period was one of vitality of non-union "welfare" employers, who sought to eliminate, not accommodate, the New Deal. Leading non-union employers, large and medium sized, led national efforts to weaken and repeal labor law and pioneered union-busting tactics (Jacoby, 1997). Modest victories turned into a collective rout when American capitalists succeeded in virtually wiping out private sector unions. The rout began in the early 1980s, when President Reagan fired 11,000 federally employed and unionized air traffic controllers on strike and permanently replaced them. As already unionized manufacturing industries contracted rapidly, depleting the numbers of existing workers with union representation, it became nearly impossible to unionize the growing service industries as employers learned, with the help of a huge industry of union-busting lawyers and consultants, that they could bend or violate labor law with impunity and prevent union campaigns from succeeding in three out of four cases, down from a more than 50% success rate in the 1940s–1960s (Freeman & Medoff, 1984; Logan, 2002). As noted below, private sector union representation in the United States has plummeted from more than 30% to single digits since 2000.

Capitalist class exceptionalism meant that free market or "neoliberal ideas" found fertile ground in the United States in the post-1970s. How exceptional is the United States? Recent work in comparative political economy places the United States in a group of "liberal market economies" that rely mostly on stock markets rather than institutional relationships in finance, give workers little in the way of employment protection, and have had high levels of inequality and relatively higher employment growth. Even within this group—all English-speaking countries—the United States stands out with much lower rates of union density, collective bargaining coverage, social spending, employment protection, family support, and poverty reduction through state redistribution, as well as much more income inequality (Pontusson, 2004). Thus, the loss of working-class economic and political strength has translated into worsened economic and social outcomes for the U.S. working class. As the Economic Policy Institute's excellent biannual publication, *The State of Working America,* has demonstrated, beginning in 1973 and accelerating in the 1980s and 1990s, median hourly wages have actually declined, low-wage jobs have proliferated, private employer–based retirement and health insurance has rapidly eroded, and annual hours worked have increased (the United States being the only advanced industrial nation that has not seen a decline of hundreds of hours annually worked), all at the same time that individual worker productivity has increased by approximately 80%. In Marxian terms, this would be an increase in exploitation sparked by the loss of working-class political and economic strength (Mishel, Bernstein, & Allegretto, 2005).

What made this possible is that the U.S. capitalist/employer class engaged in a process of "class formation" (i.e., becoming more united and stronger politically), and it built a political alliance with white working-class conservatives in rebellion against liberalism to place pro-business politicians and policies into government, symbolized by the "Reagan revolution," although it started under Democrats in the 1970s. In impressive fashion, when the opportunity for a comeback presented itself in the 1970s, U.S. capitalists built the institutions and attitudes necessary for action in their collective interest. This process of class formation included the growth of the Chamber of Commerce from 60,000 members in 1972 to more than a quarter million a year later; the movement of the National Association of Manufacturers to Washington, D.C., and the formation of the Business Roundtable, both also in 1972; and the establishment of the ultra-right Heritage

Foundation the next year, increased corporate backing for both the conservative American Enterprise Institute and the mainstream National Bureau of Economic Research, and the growing importance of right-wing foundations.

In sum, U.S. capital has maintained a long-run historical strength advantage over the U.S. working class. The New Deal era—1930s to 1970s—was a departure from this advantage because U.S. working-class strength was distinctly and unusually strong. Rapid erosion of the conditions that supported that strength (lack of international competition, a stable political coalition, etc.) and new opportunities allowed capital's ongoing efforts to defeat the New Deal IR system and dismantle it to succeed. This in turn left U.S. workers weak and their societal position ever lower, evidenced by the near destruction of private sector unionization, the consequent growth of lower waged work, and a steady weakening of the employer-based private health insurance and pension system (Klein, 2003), and a decline in U.S. labor standards (e.g., longer hours, low wages, lack of benefits).

## The Future of "Employment Relations" Study in the United States

Kaufman's influential 1993 book brought the "crisis" of the ILE/IR field into focus. It was clear that the world had changed. Specifically, the decline of unionized labor meant that the relevance of the field was called into question. Academic IR institutes were losing students and funding and were shutting down. For Kaufman, the only way out was to merge with the PM/HRM tradition, which many IR institutes did. With the decline of private sector unionization, its once influential role in making and implementing federal and state policy has severely diminished.

Despite this decline, IR scholars have continued to produce good scholarship. Emphasis on case studies, defining new issues—especially organizational/workplace redesign—and a frank recognition of previous mistakes, has produced a viable intellectual tradition. Scholarly practitioners have moved in two directions. One group has joined the broader labor studies scholarly community, which recognizes that society's progress depends on a strong labor movement. This has produced scholarship examining the use and outcome of power in union organizing. They have identified and scrutinized how employers have used legal and illegal tools to make union organizing nearly impossible, while shedding light on how clever service sector unions have overcome these barriers. Hotel workers, janitors, and low-wage health care workers have successfully organized themselves with union support through a "social movement" model. This model enlists workers' communities and community institutions in pressuring employers to recognize and bargain with workers (Bronfenbrenner, 2009; Clawson, 2003).

The other group of ILE/IR scholars has de-emphasized union strength (though quick to identify the positive role of unions in workplace productivity and implementing change) and turned to the question of workplace reform to improve the "competitiveness" of U.S. corporations. The chief recommendation here is to improve worker "voice" in management-defined "high-performance work systems" (HPWS; e.g., self-managed teams) (Applebaum, Bailey, Berg, & Kalleberg, 2000; Kochan & Osterman, 1994). In essence, these ILE/IR scholars fully joined the PM/HRM tradition in becoming management consultants, with the important caveats that the ILE scholars stressed the relevance if not superiority of implementing these reforms with the cooperation of unions and an emphasis on workers sharing in productivity gains. Regardless, this vein of work peaked in the 1990s. Continued rapid deindustrialization since 2000, widespread implementation of HPWS without gains sharing in service industries, and failure of signal examples such as Saturn Motors have sidelined the HPWS movement.

What of Marxian political economy and IR? Specifically, what are the opportunities for increased working-class political and economic strength in the twenty-first century? One component comes from a "de-centering of labor" (McIntyre & Hillard, 2007, 2009). That means recognizing that labor is performed not just in industrial and traditional service sector sites but also in the household ("domestic labor") and community. Some of this labor is paid a wage, but much is "unwaged," particularly domestic labor. Such labor has gone unrecognized by the IR field. The composition of what is considered work has also broadened; twenty-first-century labor is increasingly "immaterial" (producing services, not products) and comprises emotional, not physical, labor (caring for others; providing attention, support, reassurance). Gender is a related dimension. Domestic labor has been largely female. Women typically do waged work in emotional labor-intensive occupations. The mass entry of women into the waged workforce after 1970 has extended dramatically the problems of doing both a workplace and home shift. The "second shift" creates stress for households generally and especially for the two-shift workers who are predominantly women (Hochschild, 1989). These developments are an opportunity if, following the lead of a handful of progressive unions (e.g., the Harvard Clerical and Technical Workers), a new labor movement brings a decentered, gender-sensitive approach to union organizing, bargaining for more than the "hours, wages, and conditions" that defined the twentieth-century male "family wage." A gendered solidarity of women and men fighting for a transformation of both the household and the workplace represents the major opportunity of our time.

Finally, this model may currently exist only at the margins of our society but is not, at present, the kind of building and broad movement that labor saw a century ago when the labor question first arose. In addition, U.S. capital retains its

commitment to crush any progressive working-class movement. While the 2007–2009 financial and economic crisis, as well as Barack Obama's election, has notes of the 1934–1937 period, especially a discredited business class and free-market model, and while Obama is undoubtedly the most overtly pro-labor president in U.S. history by some measures, there is not a broad movement to carry out such an agenda. But if the crisis has taught us anything, it is that history takes surprising twists. And whatever shape it takes in the coming decades, class power will be a fundamental force in shaping that new history.

---

*Author's Note:* This chapter is in many ways a synopsis of a 20-year collaboration between the author and Richard McIntyre, Professor of Economics, University of Rhode Island. This work would also not be possible without the foundational work of Sanford Jacoby, Bruce Kaufman, and Thomas Kochan (see references below). The author thanks Professor McIntyre and Rhona Free for their helpful comments; any errors or omissions are solely the author's.

# PART II

## MICROECONOMICS

# 7

# Supply, Demand, and Equilibrium

Kevin C. Klein
*Illinois College*

The underlying foundation for much of the content for all other chapters in this reference manual is the economic concepts of supply and demand. In reading this chapter, you will begin to understand the basic concepts of supply and demand and how changes in the actions of buyers and sellers influence market prices. *Markets* are defined as any place where products or resources are exchanged. Every market has two sides: buyers and sellers. Buyers, or demanders, are those who purchase the product or resources. Sellers, or suppliers, are those who provide the products or resources for sale in the market. What motivates these market participants? Although many factors motivate buyers' and sellers' behavior, economists assume that the primary motivating factor is self-interest. Buyers are assumed to be motivated by their desire to improve overall satisfaction, or utility, in life. Sellers are assumed to be motivated by the desire to earn profits. The discussion below begins with the buyer side of the market, known as demand.

## Demand

Let us begin our discussion of demand by defining three concepts: demand ($D$), quantity demanded ($Q_d$), and the law of demand. *Demand* is defined as the amount of a product that buyers are willing and able to purchase at all prices. A consumer is said to demand a product if he or she is *both* willing and able to purchase a product. A consumer who is willing to purchase a product, but is unable to do so, is not considered to be part of the market demand because he or she will not actually purchase the product. Likewise, a consumer who is able but unwilling to buy a product is also not considered to be part of market demand. *Quantity demanded* is defined to be the amount of a product that buyers are willing and able to purchase at a *specific* price. To summarize, the difference between demand and quantity demanded for a product is that demand refers to the amount potential buyers are both willing and able to purchase at all prices, and quantity demanded refers to the amount potential buyers are willing and able to purchase at a specific price. Once these two terms are understood, it becomes possible to introduce the law of demand.

One of the most basic concepts in economics is the *law of demand.* The law of demand is simply an observation of a consumer's general response to changes in a product's price. As price decreases, consumers tend to be willing and able to purchase more of a product, and as price increases, consumers tend to be willing and able to purchase less of a product. To help visualize economic concepts, economists often try to illustrate the concepts using graphs. The law of demand is illustrated in Figure 7.1. The lines labeled $D_1$ and $D_2$ are referred to as demand curves. The lines are drawn here as linear functions to enhance the simplicity of the graph, but these lines could also be drawn as curved lines that are convex to the origin.

A *change in demand* is illustrated by a shift in the location of the entire curve. In Figure 7.1, demand is said to increase if demand changes from $D_1$ to $D_2$. An increase in demand means that consumers are willing and able to purchase more at every price. For example, the movement from point *A* to *C* represents an increase in demand because at point *A,* consumers are willing to buy $Q_1$, but $Q_2$ at point *C.* This increase in demand occurs even though the price remains unchanged at $P_1$. A decrease in demand means the consumers are willing and able to purchase less at every price and is illustrated by a shift in demand from $D_2$ to $D_1$. A *change in quantity demanded* is illustrated by

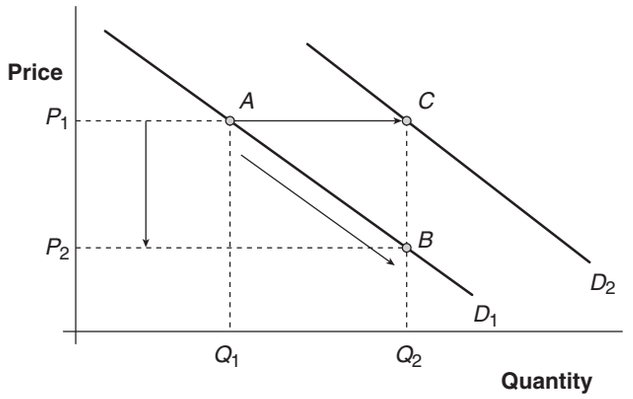

**Figure 7.1** Changes in Demand Versus Changes in Quantity Demanded

a move along the curve. In Figure 7.1, an increase in quantity demanded is illustrated by a movement from point *A* to *B*. It is important to note that the increase in consumption from $Q_1$ to $Q_2$ occurs because price has decreased from $P_1$ to $P_2$. A decrease in quantity demanded is illustrated by a movement from point *B* to *A*.

## Determinants of Demand

Many factors change a buyer's willingness or ability to purchase goods and services. These factors are known as determinants of demand. Consider the market for gasoline and what factors might influence a buyer's willingness or ability to purchase gasoline. To determine the impact of changes in each of the factors listed below, economists usually invoke the ceteris paribus assumption. *Ceteris paribus* is a Latin term usually interpreted to mean "all other factors remaining unchanged." This assumption is made to isolate the effects of a change in the factor under consideration.

### Tastes

Tastes refer to whether buyers like or dislike a product. If buyers' tastes change in favor of a product, ceteris paribus, demand increases. In the market for gasoline, when buyers' tastes change in favor of a product, the buyer is willing and able to purchase more gas at every price. Remember that this is illustrated as a movement from $D_1$ to $D_2$ in Figure 7.1. An increase in taste for gasoline would occur, for example, when consumers' tastes change toward larger vehicles such as sport utility vehicles, minivans, trucks, and high-performance sport cars. An increase in demand would also occur as consumers move to houses or apartments that are larger driving distances from their places of employment. If consumers' tastes change toward smaller, more fuel-efficient cars, or consumers prefer to live closer to work, the demand for gasoline will decrease. This is illustrated as a shift of the demand curve from $D_2$ to $D_1$.

### Income

Income refers to the amount of money consumers have available to spend on goods or services. This directly affects consumers' ability to purchase a good or service. The relationship between consumers' purchases and income can be broken into two categories.

1. *Normal goods:* Normal goods are any good or service for which consumers tend to purchase more as their income increases, ceteris paribus. Gasoline is generally considered to be a normal good. As consumers' incomes increase, they tend to purchase more gasoline for a variety of reasons. For example, some people who cannot afford a car at lower income levels may be able to purchase a car at higher income levels, and thus their demand for gasoline increases. Many other income-related reasons exist for increases in the demand for gasoline. Two other examples include more frequent and longer vacations and more cars per household as income increases. Each of these examples results in a shift from D1 to D2 in Figure 7.1.

2. *Inferior goods:* Inferior goods are any good or service for which consumers tend to purchase less as their income increases. The opposite is also true. That is, as income decreases, consumption of inferior goods tends to increase. For example, during recessions, economists expect to see consumers buying more store-brand groceries instead of name-brand products. Under this scenario, the store-brand products would be considered inferior goods. An increase in income will cause the demand for an inferior good to change from $D_2$ to $D_1$.

### Prices of Related Goods

Changes in the prices and availability of related goods will also affect the demand for a product. The relationship to related goods is broken into two categories.

1. *Substitutes:* Substitutes are items consumed in place of other goods. In the case of gasoline, several substitutes are available. If, for example, gasoline is being used to fuel a car, then consumers might purchase an electric car, thus making electricity a substitute for gasoline. Another alternative to gasoline is an ethanol blend. For example, E85 is 85% ethanol and 15% gasoline. If the price of gasoline increases, ceteris paribus, consumers will want to purchase less gasoline, and thus the demand for its substitute will increase. Yet another alternative to gasoline is diesel fuel. An increase in the price of gasoline, ceteris paribus, would cause an increase in the demand for diesel fuel as consumers switch to diesel-powered cars and trucks to avoid the rising price of gasoline.

2. *Complements:* Complements are items consumed together. In the case of gasoline, anything consumed with gasoline is its complement. For example, automobiles and trucks are complements to gasoline. Based on the law of demand, if the price of gasoline were to increase, ceteris paribus, economists would expect consumers to purchase

less gasoline. On the demand curve in Figure 7.1, this is represented as a *move along the curve* from point *B* to *A*. The decrease in purchases of gasoline would then result in fewer miles driven. Driving fewer miles results in less wear and tear on automobiles, resulting in a decrease in the demand for cars and trucks. In the market for cars and trucks, the decrease in demand resulting from an increase in the price of gasoline is represented as a movement from point *C* to *A* as the consumer moves from $D_2$ to $D_1$.

### Expectations

Consumer demand is often affected by what the consumers anticipate will happen in the future. For example, in the case of gasoline, if consumers expect the price of gasoline to continue to rise, then in the short run, consumers will quickly go out and purchase more gasoline even thought the price has not yet changed. Consequently, demand increases, shifting demand from $D_1$ to $D_2$ or a movement from point *A* to *C* in Figure 7.1. In the long run, in anticipation of long-term increases in the price of gasoline, consumers may purchase more fuel-efficient cars and trucks. These expectations result in a decrease in the demand even though the price of gas has not yet changed. Graphically, this is represented as a movement from point *C* to *A* in Figure 7.1.

### Number of Consumers

The number of people who are willing and able to purchase a product directly affects the demand for a product. In the market for gasoline, as the number of consumers increases, ceteris paribus, the demand for gasoline increases. As the number of consumers decreases, the demand for gasoline decreases.

### Government Regulations

Regulations can have a variety of effects on the demand for a product. Regulations can either increase or decrease the demand for a product depending on the nature of the regulation. For example, if the government were to increase the Corporate Average Fuel Efficiency standards for automobiles, the demand for gasoline would go down as the nation's car fleet becomes more fuel efficient. This change in standards would result in shifting the demand for gasoline from $D_2$ to $D_1$ in Figure 7.1.

It is useful to remember that any change of the determinants of demand would cause a shift of the entire demand curve, not a movement along the curve. The demand curve shifts to the right when demand increases and to the left when demand decreases.

## Supply

The other group of participants in markets is the sellers. When discussing supply, there are again three concepts to define and discuss: supply, quantity supplied, and the law of supply.

*Supply* is defined to be the amount of a product sellers are both willing and able to provide to the market at all prices. Key to this definition is that sellers have to be both willing and able to provide the product to the market. A seller who is willing to sell the product but unable to do so is not considered to be part of supply because he or she will not actually provide the product to the market. Likewise, sellers who are able but unwilling are also not considered to be part of market supply. *Quantity supplied* is defined to be the amount of a product that sellers are both willing and able to provide to the market at a specific price. The difference in these two concepts is similar to the difference between demand and quantity demanded. That is, supply refers to the entire supply relationship, while quantity supplied refers to a single price and quantity combination. Once these two concepts are understood, it becomes possible to state the *law of supply*. According to the law of supply, as price increases, sellers increase the quantity that they are willing and able to provide to the market. If price decreases, sellers decrease the quantity that they are willing and able to provide to the market. The lines labeled $S_1$ and $S_2$ in Figure 7.2 are referred to as supply curves. The lines are drawn here as linear functions to enhance the simplicity of the graph, but these lines could also be drawn as curved lines that are convex to the origin.

A *change in supply* is illustrated by a shift in the location of the entire curve. In Figure 7.2, supply is said to increase if supply changes from $S_1$ to $S_2$. An increase in supply means that sellers are willing and able to sell more at every price. For example, the movement from point *E* to *G* represents an increase in supply because at point *E,* sellers are willing to sell $Q_3$, but $Q_4$ at point *G*. This increase in willingness to sell occurs even though the price remains unchanged at $P_1$. A decrease in supply means the sellers are willing and able to sell less at every price and is illustrated by a shift in demand from $S_2$ to $S_1$. A *change in quantity supplied* is illustrated by a move along the curve. In Figure 7.2, an increase in quantity supplied is illustrated by a movement from point *F* to *G*. It is important to note that the increase in the willingness to sell from $Q_3$ to $Q_4$ occurs because price has increased from $P_2$ to $P_1$. A decrease in quantity supplied is illustrated by a movement from point *G* to *F*.

## Determinants of Supply

As we saw with demand, a number of factors influence a seller's willingness and ability to provide a good or service to the market. These factors are known as *determinants of supply*. Consider again the market for gasoline. What factors might influence a seller's willingness or ability to sell gasoline?

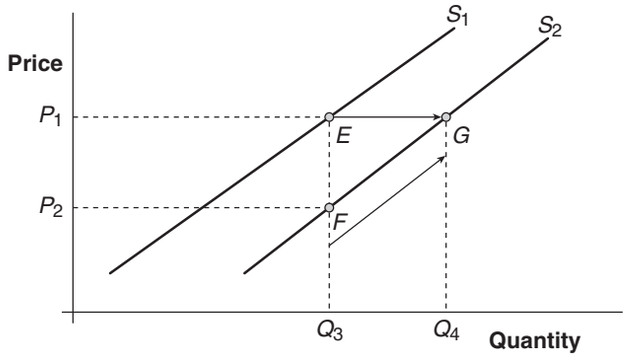

**Figure 7.2** Change in Supply Versus Change in Quantity Supplied

## Factor Costs

Factor costs refer to the amount of money paid for inputs in the production process. If factor costs increase, then supply will decrease, represented by a movement from $S_2$ to $S_1$ in Figure 7.2. For example, one of the factors of production used to produce gasoline is crude oil. If the cost of crude oil increases, this raises the cost of producing gasoline. As a result, the amount of gasoline available at every price will decrease. Consider for a moment that suppliers of gasoline are willing to sell $Q_3$ gasoline at a price of $P_2$. If the cost of producing gasoline increases, due to an increase in the cost of crude oil, then sellers would expect a higher price, perhaps $P_1$, to be willing and able to sell the same quantity. Because price must rise for suppliers to keep the quantity supplied unchanged, supply must decrease if price remains unchanged. This scenario describes a decrease in supply and is illustrated by a shift from $S_2$ to $S_1$ in Figure 7.2. If factor costs decrease, then supply will increase, represented by a movement from $S_1$ to $S_2$ in Figure 7.2.

## Technology

The quantity and quality of technology available for use in the production process affects the supply. In general, improvements in technology lower the cost of producing most goods and services. It then follows that new cost-lowering technologies result in increasing supply. This is represented by a movement from $S_1$ to $S_2$ in Figure 7.2.

## Price of Related Goods in Production

Changes in the prices and availability of related goods *in production* will affect supply. These relationships are broken into two categories.

1. *Substitutes:* Substitutes in production are items that can be produced or sold in place of other items. For example, an oil refinery can switch its production between different octane levels of gasoline depending on which octane level has a higher demand and offers higher profits. Let us say a refinery is selling 87 octane gasoline but the profits for 93 octane gasoline increase. The refiner would then want to increase its refining of 93 octane gasoline. Because the refinery has limited refining capacity, it must choose between refining more 93 octane gasoline and maintaining its current refining allocation between 87 and 93 octane gasoline. If the refinery chooses to produce more 93 octane gasoline, then the supply of 87 octane gasoline will decrease, represented by a movement from $S_2$ to $S_1$ in Figure 7.2. Note that the price of 87 octane gasoline is assumed to have remained unchanged, yet the refinery decreases its production of 87 octane gasoline. It did so because the profitability of a substitute *in production* increased.

2. *Complements:* Complements in production are products that are produced in conjunction with another product. For example, when refining crude oil for gasoline, a by-product of the refining process is liquefied petroleum gas, also known as propane. If, for example, the price of gasoline increases and the refinery wants to increase the amount of gasoline it refines, this will necessarily result in an increase in the supply of propane because gasoline and propane are complements in production. To produce more gasoline requires that more propane is also produced during the refining process. In the gasoline market described here, there has been an increase in quantity supplied, a movement from point $F$ to $G$, but in the propane market, there would be a shift in the entire supply curve from $S_1$ to $S_2$.

## Expectations

A seller's willingness and ability to provide products to the market are affected by his or her forecasts for the future. If, for example, managers of gasoline refineries expect the price of gasoline to increase, they may withhold gasoline from the market so they can sell their gasoline at higher prices. As the refineries withhold their gas from the market in anticipation of the future higher prices, the supply curve decreases, shown as a shift in supply from $S_2$ to $S_1$ or a movement from point $G$ to $E$ in Figure 7.2. In the long run, sellers of gasoline might anticipate that the population will increase and increase future sales of gasoline. In response, they may build new refineries in anticipation of the increased demand. This forecast, or expectation, of future events results in an increase in supply of gasoline, shown as a shift from $S_1$ to $S_2$ in Figure 7.2.

## Number of Sellers

The number of sellers in the market directly affects the amount of the product available for sale at every price. An increase in the number of sellers increases supply from $S_1$ to $S_2$ in Figure 7.2. A decrease in the number of sellers will decrease supply from $S_2$ to $S_1$.

### Government Regulations

Regulations can have a variety of effects on the supply of a product. Regulations can either increase or decrease the supply of a product depending on the nature of the regulation. For example, in the market for gasoline, the government could impose stricter pollution standards for oil refineries. As a result, controlling pollution from the refineries would increase and the cost of refining gasoline would also increase. As noted earlier, increases in costs result in decreasing supply. In Figure 7.2, this is represented as a movement from point $G$ to $E$ or from $S_2$ to $S_1$.

It is useful to remember that any change of the determinants of supply would cause a shift of the entire supply curve, not a movement along the curve. The supply curve shifts to the right when supply increases and to the left when supply decreases.

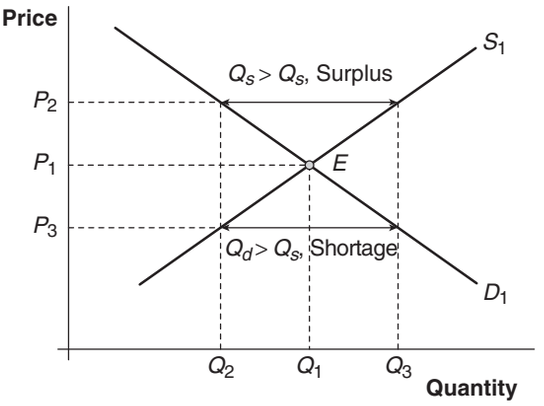

**Figure 7.3** Equilibrium

NOTES: Equilibrium occurs when $Q_s = Q_d$ at a common price. If market price is above the equilibrium price, a surplus forms. If the market price is below the equilibrium price, a shortage forms.

## Equilibrium

All markets are characterized by market participants making decisions to improve their own self-interest. As noted earlier, buyers are assumed to be motivated primarily by the desire to increase their personal satisfaction in life. Sellers are assumed to be motivated by the desire to make the largest profits possible. This interaction between buyers and sellers results in equilibrium in the market. *Equilibrium* is defined to be the point at which $Q_s = Q_d$ at a common price. If the market price is not at equilibrium, market forces drive the market toward equilibrium. If the market price is at equilibrium, there exists no market pressure to move to some other level. To better understand this concept, consider Figure 7.3.

The market represented in Figure 7.3 is in equilibrium at point $E$ because $Q_s = Q_d$ at the common price of $P_1$. To better understand the concept of equilibrium, it is useful to examine the market at other prices. First, consider a market price above the equilibrium value. At $P_2$, the quantity supplied, $Q_3$, is larger than the quantity demanded, $Q_2$. At this price, sellers are willing to provide more to the market than consumers are willing to buy. This situation is defined as a *surplus.* To combat their rising inventories, sellers begin to lower their prices, attempting to entice consumers to buy more. In addition, because of the lower price, sellers decrease the amount they offer for sale. As this process unfolds, there is an increase in $Q_d$ and a decrease in $Q_s$ as the market moves to the equilibrium at point $E$.

Now consider a market price below the equilibrium value. At the price $P_3$, the quantity demanded, $Q_3$, exceeds the quantity supplied, $Q_2$, resulting in a shortage in the market. In response to the shortage, consumers begin to bid up the price. To understand this process, consider the process of an auction. An auction usually begins with the number of willing and able buyers exceeding the amount of product available. The role of the auctioneer is to bid the price up until $Q_s = Q_d$. As the price increases, consumers begin to drop out of the bidding process. In the market represented in Figure 7.3, consumers begin bidding the price up and, as a result, some consumers begin to drop out of the market and $Q_d$ begins to fall. As the price begins to increase, sellers who are willing and able respond by increasing the amount they provide to the market, and $Q_s$ begins to increase. These changes in $Q_s$ and $Q_d$ continue until the market reaches equilibrium at a price of $P_1$ and a quantity of $Q_1$.

Ultimately, markets tend to move toward equilibrium. When market prices are too high, surpluses exist, and market forces drive the prices down to the equilibrium level. When market prices are too low, shortages exist, and market forces drive up the prices to the equilibrium price. At equilibrium, there exists no market pressure for change, and thus the price tends to stay at the equilibrium until something in the economy changes, resulting in a change in either supply or demand.

### The Algebra of Demand and Supply

The law of demand suggests that an inverse mathematical relationship exists between price and quantity demanded. The law of supply suggests that a similar but positive relationship exists between price and quantity supplied. An example of these relationships is shown in Equations 1 and 2. Assume the following hypothetical functions represent the relationship between price and quantity for gasoline:

$$\text{Demand: } P = 1{,}210 - .05Q_d. \quad (1)$$

$$\text{Supply: } P = 10 + .01Q_s. \quad (2)$$

Remember that at equilibrium, $Q_s = Q_d$ at a common price. Thus, at equilibrium, these two equations are equal.

As a result, it is possible to solve for the equilibrium price and quantity in this hypothetical model. Setting these two equations equal results in

$$1{,}210 - .05Q_d = 10 + .01Q_s. \quad (3)$$

At equilibrium, $Q_s = Q_d = Q$, and thus we can substitute $Q$ for $Q_s$ and $Q_d$. Solving for $Q$ gives us the equilibrium quantity in this market.

$$1{,}200 = .06Q, \text{ thus } Q = 20{,}000. \quad (4)$$

Substituting $Q = 20{,}000$ into either Equation 1 or 2 results in the equilibrium price.

$$P = 1{,}210 - .05Q_d = 1{,}210 - .05(20{,}000) = 210. \quad (5)$$

## Changing Equilibrium Prices and Quantity

Although markets tend to move toward equilibrium over time, should any of the determinants of supply or demand change, the result will be a tendency toward a different equilibrium.

### *The Effects of a Change in Demand*

The impact on equilibrium price and quantity of a change in demand is illustrated in Figure 7.4.

Figure 7.4 represents the market for gasoline. Assume the market is initially in equilibrium at point $E_1$. Further assume that national income statistics indicate an increase in household income, ceteris paribus. What impact would this increase in income have on the equilibrium price and quantity in the market for gasoline? At the original equilibrium price of $P_1$, consumers are now willing and able to purchase more gasoline even though the price of gasoline initially remains unchanged. In Figure 7.4, this is represented by a movement from point $E_1$ to $A$ and an increase in quantity from $Q_1$ to $Q_3$. At the initial price of $P_1$, this increase in demand causes a shortage of $(Q_3 - Q_1)$. As shown earlier, shortages result in increases in price. The increasing price causes a decrease in quantity demanded along the new demand curve, $D_2$, and an increase in quantity supplied along the supply curve. When all of these factors are combined, the market moves toward a higher equilibrium price and quantity at $P_2$ and $Q_2$.

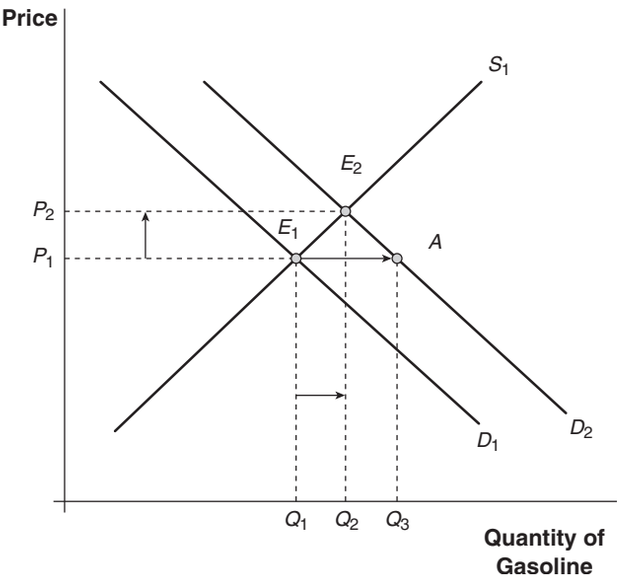

**Figure 7.4** Effects of a Change in Demand

NOTE: An increase in demand results in an increase in equilibrium price and an increase in quantity supplied from $Q_1$ to $Q_2$.

### *The Algebra of a Change in Demand*

Algebraically, a change in demand will change the demand function. For example, an increase in demand might be represented in our earlier hypothetical market for gasoline as

$$D\text{: } P = 1{,}510 - .05Q_d. \quad (6)$$

Given the original supply function of $P = 10 + .01Q_s$, solving the system of equations yields a new equilibrium price and quantity combination of $P = 260$, $Q = 25{,}000$.

This new equilibrium value verifies our graphical predictions. That is, an increase in demand should result in an increase in equilibrium price and quantity. In this case, the equilibrium price increased from 210 to 260, and the equilibrium quantity increased from 20,000 to 25,000 during the given time period.

### *The Effects of a Change in Supply*

Assume the number of sellers increases, ceteris paribus (see Figure 7.5).

The shift from $S_1$ to $S_2$ represents the increase in supply resulting from an increase in the amount of sellers who are willing and able to provide gasoline at every price. At the original equilibrium price $P_1$, this increase in supply results in a surplus equal to $(Q_3 - Q_1)$. As noted earlier, surpluses result in downward pressure on equilibrium price. As sellers reduce price and production to reduce the surplus in the market, buyers increase their quantity demanded in response to the lower price. The combination of these forces results in a decrease in equilibrium price from $P_1$ to $P_2$ and an increase in equilibrium quantity from $Q_1$ to $Q_2$.

### *The Algebra of a Change in Supply*

Algebraically, a change in supply is demonstrated by a change in the supply function. For example, an increase in supply might be represented in our earlier hypothetical market for gasoline as

$$\text{Supply: } P = 4 + .01Q_s. \quad (7)$$

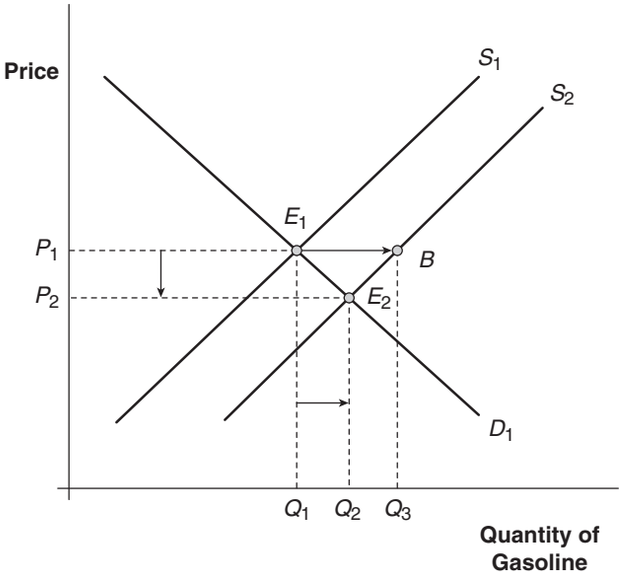

**Figure 7.5** The Effects of a Change in Supply

NOTE: An increase in supply results in a decrease in equilibrium price and an increase in quantity demanded from $Q_1$ to $Q_2$.

Given the new supply function in Equation 7 and the new demand function presented in Equation 6, solving the system of equations yields a new equilibrium price and quantity combination of $P = 255$, $Q = 25{,}100$. This change in equilibrium price and quantity verifies the graphical predictions that an increase in supply will result in a decrease in equilibrium price and an increase in equilibrium quantity. In this case, the equilibrium price has decreased from 260 to 255, and the equilibrium quantity has increased from 25,000 to 25,100.

### *The Combined Effects of Changing Supply and Demand*

If both supply and demand change simultaneously, the impacts on price and quantity may not be as certain as described in the two previous examples. Remember that an increase in supply results in a decrease in equilibrium price and an increase in equilibrium quantity. An increase in demand results in an increase in equilibrium price and an increase in equilibrium quantity. What would be the impact on equilibrium price and quantity if supply and demand both increased simultaneously? In such cases, the individual effects are combined. Because the increases in both supply and demand result in increases in the equilibrium quantities, the combined result will be an increase in equilibrium quantity. However, the result on equilibrium price is uncertain. When both supply and demand increase simultaneously, the downward pressure on price, due to increasing supply, is opposite of the upward pressure on price due to increasing demand. In such cases, it becomes impossible to predict the direction of change without additional detail about the magnitude of the changes in supply and demand. As a result, we can only conclude the direction of change is uncertain. In situations where both supply and demand change simultaneously, the direction of change in either equilibrium price or equilibrium quantity—but not both—will be uncertain unless specific information is available about the magnitude of the change. For example, when comparing Equations 1 and 2 to Equations 6 and 7, we can predict with certainty the changes in equilibrium price and quantity because the estimates of demand and supply, shown in the equations, provide the magnitude of change. If statistical data are available that allow for an accurate estimate of the supply and demand functions, the ambiguity in the direction of change is eliminated. For more information on how to develop these statistical estimates, read the econometrics chapter of this handbook, Chapter 5.

## Price Controls: Ceilings and Floors

The market process described above assumes that market participants are each making decision based on their own self-interest. Periodically, a market's equilibrium price and quantity are viewed by some market participants as undesirable. When this happens, participants on one side of the market may lobby for government intervention. If, for example, consumers believe the market equilibrium price is too high, they may lobby for governments to impose a price ceiling. A *price ceiling* is a legally established maximum price intended to lower the price below the market equilibrium price. If government agrees to establish an effective price ceiling, the ceiling will be established below the equilibrium price, as illustrated in Figure 7.6.

Recall that when market price is below the equilibrium value, the resulting shortages cause prices to increase toward the equilibrium. However, when a price ceiling is established, the ceiling price is a maximum price, and sellers cannot legally charge a higher price. As a result, the shortages created by the price ceiling are persistent and an expected long-term outcome resulting from the price ceiling. Price ceilings thus have interesting policy implications. In choosing to protect some consumers from the unwanted market price, the government is also choosing to deny other consumers access to the product as a result of the shortage. In general, economists do not recommend implementation of price ceilings because of the resulting persistent shortages. Perhaps the most famous example of price ceilings is rent controls in New York City. Although some people are able to acquire rent-controlled housing, there is a persistent shortage of housing within the city.

If producers believe the market price is too low, they may lobby for governments to impose a price floor. A *price floor,* also known as a price support, is a legally established minimum price. If the intent of establishing a price floor is to raise the price above the market equilibrium price, the floor will be established above the equilibrium price. As shown in Figure 7.6, a price floor set above the equilibrium price will result in a surplus. The price floor sends a signal to the sellers to increase their production, and for consumers, the market signal sent is to decrease their

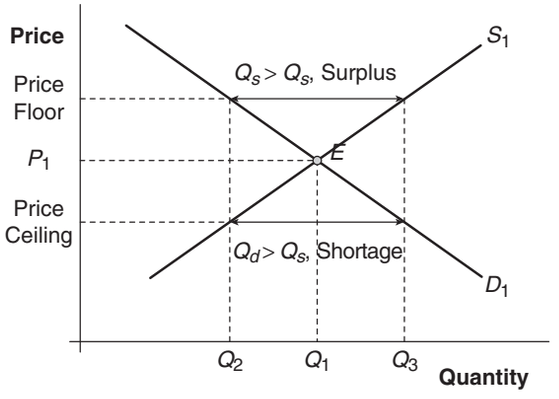

**Figure 7.6** The Effects of Price Ceilings and Floors

NOTES: Effective price ceilings result in market shortages. Effective price floors result in market surpluses.

consumption compared to the equilibrium level. The effects of a price floor are shown in Figure 7.6. The price floor encourages sellers to offer a quantity $Q_3$ for sale but also encourages consumers to buy a quantity of $Q_2$. The result is a surplus of $(Q_3 - Q_2)$. When a market price is above the equilibrium value, the resulting surpluses are normally eliminated by declining prices. However, if a price floor is established, the price floor prevents the price from falling to the equilibrium level. As a result, the surpluses created are persistent and an expected long-term outcome resulting from the price floor. Again, this result has interesting policy implications. In choosing to protect some sellers from the unwanted market price, the government is also choosing to create an unwanted surplus. For example, agricultural policies in many countries are often designed to establish price floors above the equilibrium prices. The price floors send a signal to the market participants that result in surpluses. Consequently, governments must enact other policies to deal with the problems created by the surpluses such as long-term storage and the pressures on market prices of accumulating surpluses. In general, economists do not recommend implementation of price floors. Although the price received by the producer is higher, the resulting surpluses create a new problem. To respond to the new problem, government must enact an increasing level of other policies to deal with the persistent and growing surpluses. More information on agricultural economics can be found in Chapter 58 of this handbook.

*The Algebra of Price Ceilings and Floors*

Applying algebra to the concepts of price ceilings and floors is a simple extension of the algebraic model shown earlier. Let us return to the original equations with an equilibrium price and quantity of $P = 210$ and $Q = 20{,}000$. For a price floor to accomplish its intended goal, it must be established above the equilibrium price. Assume that a price floor, $P_F$, is established at $P_F = 250$. What impact will this have on the market? With the minimum price established at $P_F = 250$, consumers are willing and able to purchase 19,200 units of gasoline based on Equation 1. At that same price, sellers are willing and able to sell 24,000 units of gasoline based on Equation 2. Thus, the price ceiling established at $P_F = 250$ results in a surplus in the market of 4,800 units.

For a price ceiling to accomplish its intended goal, it must be established below the equilibrium price. Assume that a price ceiling, $P_C$, is established at $P_C = 190$. What impact will this have on the market? With a maximum price established at $P_C = 190$, consumers are willing and able to purchase 20,400 units of gasoline, based on Equation 1, and sellers are willing and able to sell 18,000 units of gasoline, based on Equation 2, resulting in a shortage of 2,400 units of gasoline in the market.

## Case Studies

Examining a few case studies can help us better understand the dynamics of supply and demand.

### Case 1: The Market for Gasoline

The first case study is for gasoline in the Phoenix, Arizona, market in 2003. According to the Federal Trade Commission (FTC, 2005), in August 2003, the average price of gasoline in the Phoenix market rose from $1.52 per gallon during the first week of August to $2.11 by the third week of August. By the end of September, the price fell to $1.80 per gallon. What could have caused these abrupt changes in prices? Although collusion by suppliers was considered a possible cause of the price spike, the FTC concluded in its 2005 report that

> the price spike was caused by a pipeline rupture on July 30, and the failure of temporary repairs, which had reduced the volume of gasoline supplies to Phoenix by 30 percent from August 8 through August 23. Arizona has no refineries. It obtains gasoline primarily through two pipelines, one traveling from west Texas and the other from the West Coast. The rupture closed the portion of the Texas line between Tucson and Phoenix. (p. 5)

This conclusion is consistent with the equilibrium analysis shown above in Figure 7.5. The pipeline rupture resulted in a sudden decrease in the supply of gasoline to the Phoenix market. A decrease in supply results in a shortage of gasoline at the original equilibrium and a subsequent increase in price as the market moves to a new equilibrium. This can be represented as a shift from $S_2$ to $S_1$ and a movement from $E_2$ to $E_1$ in Figure 7.5. The report continues to state,

> The shortage of gasoline supplies in Phoenix caused gasoline prices to increase sharply. To obtain additional supply, Phoenix gas stations had to pay higher prices to West Coast refineries

> than West Coast gas stations were paying. West Coast refineries responded by selling more of their supplies to the Phoenix market. (FTC, 2005, p. 5)

The increase in quantity supplied by the West Coast refineries, along the new supply curve $S_1$, is consistent with the theory of supply stated above.

How did Phoenix consumers respond to the higher prices? Based on the law of demand, when prices rise, the quantity demanded should decline in response to higher prices. However, the degree to which consumers respond to higher prices depends on a number of factors, including the amount of substitutes available, the length of time involved, and the product price relative to the consumers' income or budget. The FTC (2005) commented on the consumer response by stating,

> Phoenix consumers did not respond to significantly increased gasoline prices with substantial reductions in the amount of gasoline they purchased. In theory, to prevent a gasoline price hike, Phoenix consumers could have reduced their gasoline purchases by 30 percent. Without price increases, however, consumers do not have incentives to change the amount of gasoline they buy. Moreover, even with price increases, most consumers do not respond to short-term supply disruptions such as a pipeline break by making the types of major changes—the car they drive, their driving habits, where they live, or where they work—that could substantially reduce the amount of gasoline they consume. . . . Empirical studies indicate that consumers do not easily find substitutes for gasoline, and that prices must increase significantly to cause even a relatively small decrease in the quantity of gasoline consumers want. In the short run, a gasoline price increase of 10 percent would reduce consumer demand by just 2 percent, according to these studies. This suggests that gasoline prices in Phoenix would have had to increase by a large amount to reduce the quantity of consumers' purchases by 30 percent, the amount of lost supply. (p. 5)

Readers who are interested in more information about consumer responses to price changes should read Chapter 9, Demand Elasticities, in this handbook.

## Case 2: The Market for Corn

A second interesting question to study is whether the price of corn is affected by changes in the market for biofuels. One major type of biofuel is ethanol. Ethanol is a combustible fuel that can be distilled from corn and, when mixed with gasoline, used in internal combustion engines. Rising world energy prices, combined with concerns about the potential impacts of carbon emissions on global climate change, have resulted in renewed interest in ethanol as a renewable alternative fuel for automobiles. Proponents of ethanol use claim not only that ethanol is a renewable form of energy but also that blending ethanol with gasoline will also reduce the total amount of greenhouse gas emissions. That claim is supported in an April 2009 Congressional Budget Office (CBO) report titled *The Impact of Ethanol Use on Food Prices and Greenhouse-Gas Emissions.* In this report, the CBO states that research conducted by Argonne National Laboratory suggests that, in the short run, production and consumption of ethanol will create up to 20% less greenhouse gases than will the equivalent production and consumption of gasoline (CBO, 2009, p. 10). The long-run impact of ethanol on greenhouse emission is not as clear. Regardless of the long-run impact on greenhouse emission, a series of legislative acts involving mandated use of biofuels have had a significant impact on the market for corn. Most recently, the Energy Independence and Security Act of 2007 expanded mandated use of biofuels through 2022 and will ultimately result in the production of 15 million gallons of corn-based ethanol (CBO, 2009, p. 13).

The analytical question for this case is, what impact will the use of corn for ethanol production have on the price of corn? Simple supply-and-demand analysis can be used to help determine the answer to this question. Increases in the demand for any product should, ceteris paribus, result in increases in the price. In the case of corn-based ethanol, the increased demand for corn used to make ethanol has resulted in an increase in the price of corn. The CBO (2009) report states,

> The upswing in the demand for corn to be used in producing domestic ethanol raised the commodity's price, CBO estimates, by between 50 cents and 80 cents per bushel between April 2007 and April 2008. That range is equivalent to between 28 percent and 47 percent of the increase in the price of corn, which rose from $3.39 per bushel to $5.14 per bushel during the same period. . . . As the mandated use of biofuels rises over time, increased production of ethanol and biodiesel will probably continue to push up prices for corn and soybeans. According to an estimate by the Department of Agriculture, 3.7 billion bushels of corn will be used to produce ethanol during the 2008–2009 marketing year. That estimate represents an increase of about 0.7 billion bushels over the total for the previous marketing year, which could increase the price of corn by 10 percent to 17 percent over the 2008–2009 period, all else being equal. In the long run, upward pressure on prices caused by increasing ethanol production may be alleviated by planting additional acres in corn and soybeans, increasing crop yields per acre in the United States and abroad, and improving the technologies used at refineries to allow more ethanol to be produced from each bushel of corn. (p. 18)

The CBO information can be analyzed using supply-and-demand analysis. The biofuel mandates by the Energy Independence and Security Act of 2007 will continue to increase the demand for corn. An increase in demand, ceteris paribus, will result in an increase in equilibrium price and a subsequent increase in quantity supplied, as demonstrated in Figure 7.4. For example, the CBO (2009) analysis states that in 2007, corn prices increased between 50 and 80 cents due to the increased demand for corn resulting from the production of ethanol. The biofuel mandates, which call for an increase in the use of biofuels, should thus cause a further increase in the demand for corn, ceteris paribus, and result in a continued increase in corn prices.

The long-run impact of ethanol production on corn prices is more difficult to determine because, over time, markets respond to changing prices in a variety of ways. For example, in anticipation of higher corn prices and profits, farmers are likely to plant more acreage in corn. Seed corn companies are likely to develop varieties of corn that can be planted in regions of the nation that are not traditional corn-growing regions. Growers worldwide are likely to convert acreage, including clear cutting forest areas, which have not been traditionally planted in corn. Rising corn prices will cause ethanol producers to search for alternatives to corn to make ethanol and, consequently, decreasing demand for corn. The resulting long-term change in supply and demand for corn results in an ambiguous change in the price of corn.

## Conclusion

Markets for all goods and services have two sides: buyers and sellers. The interaction of the buyers and sellers, all acting in their own self-interest, establishes an equilibrium price and quantity. While these equilibriums tend to be stable, changes in the buyers' or sellers' willingness and ability to participate in the market result in changing equilibrium prices and quantities. Sometimes, either consumers or producers are dissatisfied with the market equilibrium price. When that happens, they lobby government for price controls. This government intervention in the markets, designed to resolve a perceived problem in the market price, will create a different problem and is usually not advised by most economists.

# Consumer Behavior

Frederick G. Tiffany
*Wittenberg University*

The demand curve is one half of the familiar supply-and-demand graph that determines price and quantity exchanged in a perfectly competitive goods market. This curve shows the relationship between the price of a commodity and the quantity that buyers are willing to buy at each given price, holding all other factors constant. The shape of the curve, as well as how it shifts when various other factors do change, is explained by the theory of consumer behavior. The most important aspect of consumer theory is its conclusion that (in almost all circumstances) the demand curve for a commodity is downward sloping. This relationship is the familiar "law of demand" first articulated directly by Alfred Marshall (1842–1924) in his *Principles of Economics* (Marshall, 1930, p. 99).

Consumer theory applies equally well to tangible goods and intangible services; the words *goods* and *commodities* are often used interchangeably. The theory does not, however, apply to the demand for factors of production, such as labor, which depends on the profit-maximizing behavior of firms.

Early consumer theory grew out of the work of several economists who developed the idea that the happiness or "utility" that a consumer receives from successive increments of a commodity declines. This idea has come to be known as the principle of "diminishing marginal utility." When consumers are deciding how to allocate a fixed budget among various commodities, diminishing marginal utility guides them to spend more on a commodity if its price falls relative to the prices of all other commodities. An argument for a downward-sloping demand curve can be made based on this principle. However, without a reliable way to measure utility, the law of demand rests on a shaky foundation. Fortunately, later economists developed a theory of the consumer from which the law of demand can be derived without reference to measurable utility.

Modern consumer theory is a mathematical theory of rational choice. Individuals or households are assumed to have the ability to rank all possible combinations or "bundles" of commodities they might possibly consume. They choose the highest ranked bundle they can afford given their income and the prices of the commodities. The impact of an increase in the price of a commodity on the quantity demanded by an individual buyer depends on that buyer's reaction to two separate but related effects: the increase in the price of the good relative to the prices of all other goods (the "substitution effect") and the decrease in the purchasing power of the consumer's budget (the "income effect"). The law of demand depends on these two effects, which can be expressed without reference to measurable utility.

This chapter explains the development of consumer theory from the introduction of the idea of utility through the modern theory. The following section traces the history of the argument that diminishing marginal utility is the basis for a downward-sloping demand curve. Subsequent sections provide a description of modern consumer theory based on a rank ordering of consumption bundles. The chapter concludes with references to areas of economics to which the consumer theory model is related.

## Diminishing Marginal Utility

Consumer behavior rests on the desires that buyers have for commodities. The earliest method for representing these desires came from the idea set forth by Jeremy Bentham (1748–1832) that every human action increases or diminishes the happiness of the one taking the action (Bentham, 1907, p. 2). Eating an apple may cause a person's happiness to increase, while mopping the kitchen

floor may cause that person's happiness to decrease. The increase or decrease in happiness from each of these actions is called the "utility" from taking that action. The desire that a person has for a commodity, therefore, is related to the utility that the consumer receives from consuming it. Bentham also introduced the idea of diminishing marginal utility when he suggested that "the quantity of happiness produced by a particle of wealth (each particle being of the same magnitude) will be less at every particle: the second will produce less than the first, the third less than the second, and so on" (Bentham, 1952, p. 113). This concept has come to be known as the diminishing marginal utility of wealth (or income). The idea is that as one spends wealth, the utility received for each additional dollar is not constant but declines. Note that Bentham did not refer directly to the marginal utility of consuming a particular good or service itself.

Jules Dupuit (1804–1866) did consider the utility of consuming a particular good. In his paper "On the Measurement of Utility of Public Works" (Dupuit, 1969), he argued that the utility of water purchased from a public water system declined as successive units were consumed. At a given price, people will only buy water for which the utility they receive exceeds that price. If the price falls, buyers will purchase additional water for uses that have a utility less than the higher price but more than the lower price (pp. 258–259). Because a lower price is necessary to induce the purchase of more water, the utility of successive units must be diminishing. Following Jean Baptiste Say (1767–1832), Dupuit measured utility implicitly as the amount consumers were willing to pay to purchase a good. He was quite clear on this point: "Hence the saying which we shall often repeat because it is often forgotten: the only real utility is that which people are willing to pay for" (p. 262). Dupuit illustrated his ideas by constructing a downward-sloping "curve of consumption," with price on the horizontal axis and quantity of water on the vertical (pp. 280–281). This curve is a forerunner of the modern demand curve.

It should be noted that Dupuit's (1969) argument did not rely on the direct measurement of the amount of pleasure or pain attributable to the water consumed. He measured utility indirectly as the amount of money it would be worth to a consumer. This concept is essentially what modern economists call the consumer's "willingness to pay."

Dupuit (1969), however, focused on only a single commodity. He did not explain how a consumer would allocate a fixed budget among several commodities. Between 1854 and 1874, four different economists independently made arguments that are equivalent to the now-familiar statement that consumers will maximize utility when they choose to divide their income among commodities in such a way that the marginal value of the last dollar (or any monetary unit) spent is equal for each one. The first of these was Herman Heinrich Gossen (1810–1858), whose work was published in 1854. He stated the proposition that "man obtains the maximum of life pleasure if he allocates all his earned money between the various pleasures . . . in such a manner that the last atom of money spent for each pleasure offers the same amount [intensity] of pleasure" (Gossen, 1854/1983, pp. 108–109). This statement is equivalent to the now-familiar mathematical rule that for any set of $n$ commodities, the budget of a utility-maximizing consumer should be spent such that

$$\frac{MU_i}{P_i} = \frac{MU_2}{P_2} = \cdots = \frac{MU_n}{P_n}. \tag{1}$$

In this equation, $MU_i$ and $P_i$ denote the marginal utility of Good $i$ and the price of Good $i$, respectively, and their quotient is the marginal utility of the last dollar spent on Good $i$. Assuming diminishing marginal utility and constant prices, if for any two Goods $i$ and $j$,

$$\frac{MU_i}{P_i} > \frac{MU_j}{P_j}, \tag{2}$$

then purchasing one dollar's worth less of Good $j$ will cause a loss of utility that is less than the utility gained from spending that dollar on Good $i$ instead. Therefore, the utility from consuming these goods is not maximized. It will be maximized only if there is no opportunity to change expenditures in this way. It should be noted that with only two commodities, the expression in Equation 1 can be written as

$$\frac{MU_1}{MU_2} = \frac{P_1}{P_2}. \tag{3}$$

The ratio of the marginal utilities is equal to the ratio of the prices.

William Stanley Jevons (1835–1882), Carl Menger (1840–1921), and Leon Walras (1834–1910) each presented an argument that was equivalent to the one made by Gossen, although in different forms. Menger's (1871/1950) work in *Principles of Economics* was the least overtly mathematical, and Walras's (1977) *Elements of Pure Economics* was the most. While Gossen's work came more than 15 years prior to the others, they did not seem to have been aware of it. In the preface to the second edition of Jevons's (1871/1965) book, *The Theory of Political Economy,* he describes his surprise at discovering the existence of Gossen's work and gives Gossen credit for having "completely anticipated" his own work (p. xxxv).

Although neither Gossen nor those who followed him made it, the familiar textbook argument for a downward-sloping demand curve based on diminishing marginal utility is a direct implication of Equation 1. Suppose that the price of Good 1 falls, holding everything else in the equation constant. Then the marginal utility of the last dollar spent on Good 1 would exceed the marginal utilities of the last dollar spent on all other goods. The consumer, therefore, would increase the amount spent on Good 1 and decrease the amount spent on all other goods. If diminishing marginal utility applies to all of the goods, purchasing

more units of Good 1 would lower its marginal utility, while purchasing less of the other goods would raise their marginal utilities. This process would continue until the equation was once again satisfied. Thus, because of diminishing marginal utility, the consumer would respond to a decrease in the price of Good 1 by demanding more of it. The demand curve for Good 1 would be downward sloping. The same reasoning can be used to show that an increase in the price of Good 1 would lead the consumer to desire less of it.

Alfred Marshall's (1930) *Principles of Economics* is one of the classics of the field and was a standard textbook for many years. In his chapter on "Wants in Relation to Activities," Marshall used the idea of diminishing marginal utility as the basis for a demand curve. His argument was similar to that of Dupuit (1969). Because of diminishing marginal utility, Marshall stated,

> The larger the amount of a thing that a person has the less, other things being equal, (*i.e.* the purchasing power of money, and the amount of money at his command being equal) will be the price which he will pay for a little more of it: or in other words, his marginal demand price for it diminishes. (p. 95)

Marshall (1930, pp. 96–99) went on to derive a demand schedule and a demand curve for both the individual and the market. He also presented a version of the argument that utility is maximized when the marginal utility of the last monetary unit spent on each good is equal (p. 118).

It is important to note, however, that Marshall (1930) stated clearly that "desires cannot be measured directly, but only indirectly by the outward phenomena to which they give rise . . . in the price which a person is willing to pay" (p. 92). In a footnote, he emphasized the point, saying, "It cannot be too much insisted that to measure directly . . . either desires or the satisfaction which results from their fulfillment is impossible, if not inconceivable" (p. 92). Thus, the way was opened for a theory that does not rely on the concept of measurable utility at all.

John Hicks (1904–1989) laid the groundwork for modern consumer theory in *Value and Capital* (Hicks, 1946). He took the idea of an indifference map, developed by Vilfredo Pareto (1848–1923) in his *Manual of Political Economy* (Pareto, 1909/1971, pp. 118–122), and used it to show that a consumer can choose the optimal combination of commodities without reference to measurable utility at all. (Pareto, in turn, credited the first construction of indifference curves to F. Y. Edgeworth's [1881/1967] *Mathematical Psychics,* pp. 21–22.) For Hicks, a utility number "only tells us that the individual prefers one particular collection of goods to another particular collection; it does not tell us *by how much* the first collection is preferred to the second" (p. 17). Paul Samuelson (1915–2009), who provided the mathematical foundation for modern consumer theory, concluded that "it is only necessary that there exist an *ordinal* preference field" to derive demand curves (Samuelson, 1979, p. 93). The concept of diminishing marginal utility had run its course.

## Modern Consumer Theory

Modern consumer theory presents an argument for a downward-sloping demand curve that rests not on diminishing marginal utility but rather on what have become known as the income and substitution effects. The theory depends on a minimal number of assumptions about a consumer's ability to rank various combinations or "bundles" of commodities and some basic characteristics of all consumers' rankings. This section will set forth this argument in detail.

### Assumptions Regarding Preferences

The basic building blocks of the theory are *consumption bundles.* Suppose that there are only two goods in an economy, $x$ and $y$. A consumption bundle is an ordered pair of numbers $(x, y)$ in which each number represents an amount of the respective goods. Thus, (2, 1) represents two units of $x$ and one of $y$. A consumption bundle can include any number of goods, but using more than two introduces mathematical complications that are unnecessary for developing the basic theory. A bundle such as $(x_1, y_1)$ can be represented as a point in the commodity space defined by a set of $x$, $y$ axes. The set of all bundles in the positive quadrant defined by these axes is called a *commodity space.* It is assumed that commodities are infinitely divisible and that the space extends infinitely to the northeast.

Consumers are assumed to be able to place bundles into a rank ordering, so that for any pair of bundles $A$ and $B$, they will be able to say one of three things: They prefer $A$ to $B$, they prefer $B$ to $A$, or they are indifferent between the two. In order for these comparisons to be logically consistent, three things must be true:

1. Consumer preferences must be *complete.* Consumers must be able to state a relationship between any two bundles they are presented with. They may say that they prefer $A$ to $B$, that they prefer $B$ to $A$, or that they are indifferent between the two. They cannot say that they do not know what their preference is regarding the two. This assumption simply amounts to saying that consumers know their own preferences.
2. Consumer preferences must be *reflexive.* Consumers must be able to recognize when two bundles are identical and be indifferent between them.
3. Consumer preferences must be *transitive.* If a consumer prefers $A$ to $B$ and $B$ to $C$, then the consumer must also prefer $A$ to $C$. If the consumer is indifferent between $A$ and $B$, as well as between $B$ and $C$, then the consumer must be indifferent between $A$ and $C$. The same must be true for combinations of these relationships: For example, if the consumer prefers $A$ to $B$ and is indifferent between $B$ and $C$, then $A$ must be preferred to $C$.

Based on these three assumptions, the bundles in the commodity space can be organized into *indifference curves.* An indifference curve is a set of all bundles among which a consumer is indifferent. The set of all indifference curves for a consumer is called an *indifference map.* Each consumer has a unique indifference map that will determine the consumer's demand for each of the goods in the commodity space.

While these assumptions are all that are necessary for deriving an indifference map, two more are required to establish its familiar shape. These assumptions are not about logical consistency but about how consumers view their consumption decision. Continuing the previous numbering, they are as follows:

4. Consumers *prefer more to less.* If bundle $A$ has no less of each good than bundle $B$ and more of at least one good, then the consumer prefers $A$ to $B$. This assumption is often referred to as "monotonicity" of preferences.
5. Consumers have a *diminishing marginal rate of substitution* (MRS) between any two goods. The amount of one good ($y$) that a consumer is willing to give up to attain an additional unit of another good ($x$) gets smaller as the amount of $x$ gets larger.

## Graphical Representation of Indifference Maps

Taken together, the last two assumptions allow the drawing of an indifference map, represented in Figure 8.1a by three of the consumer's indifference curves, $I_1$, $I_2$, and $I_3$. The curves are downward sloping, with the slope becoming less steep as the amount of $x$ increases. Such curves are said to be convex to the origin. The slope along an indifference curve $\frac{\Delta y}{\Delta x}$ is the MRS because it shows the amount of $y$ that a consumer will give up ($\Delta y$) in exchange for an increase in $x$ ($\Delta x$) while staying on the same indifference curve. The indifference curves must be downward sloping because of the assumption that more is preferred to less. An upward-sloping indifference curve would violate this assumption because for every bundle $(x_1, y_1)$ on the curve, there would be another bundle $(x_2, y_2)$ in which $x_2 > x_1$ and $y_2 > y_1$. But the assumption that more is preferred to less implies that $(x_2, y_2)$ would be preferred to $(x_1, y_1)$, which violates the definition of an indifference curve.

The assumptions of transitivity and monotonicity also imply that no two indifference curves may cross one another. Suppose that two separate indifference curves $I_1$ and $I_2$ do cross. Then, because these curves are distinct, there must be at least one bundle $A$ on $I_1$ that is preferred to a

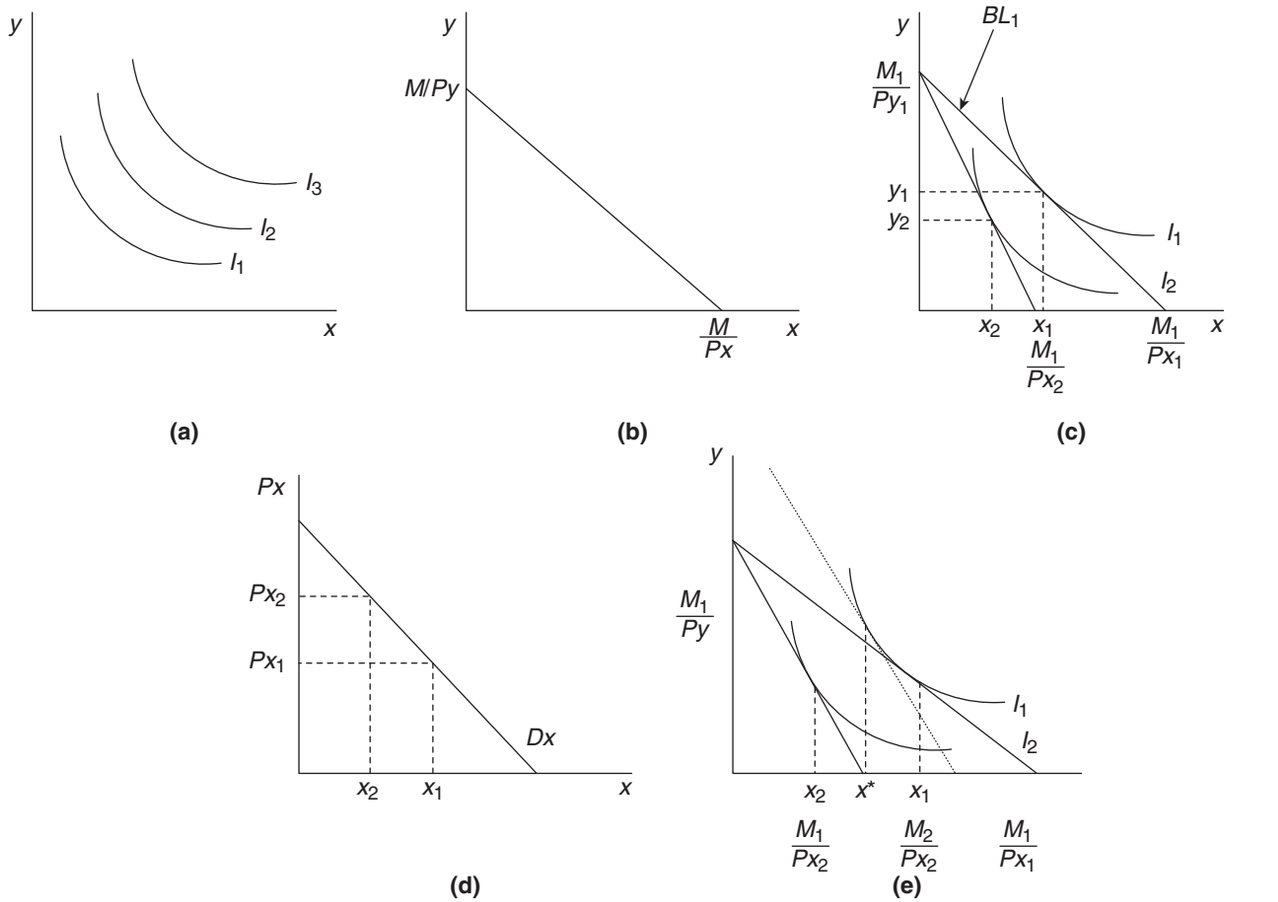

**Figure 8.1** Consumer Behavior

bundle $B$ on $I_2$. However, there must also be a bundle $C$, where the curves cross, which is on both curves. The consumer must be indifferent between $A$ and $C$ and between $B$ and $C$. However, by transitivity, if the consumer is indifferent between $A$ and $C$ and between $B$ and $C$, then the consumer must be indifferent between $A$ and $B$. But because $A$ is preferred to $B$, there is a logical contradiction because the consumer cannot prefer $A$ to $B$ and also be indifferent between these two bundles.

## Utility Functions

The concept of utility played no role in the derivation of indifference curves in the previous sections. Indifference curves depend only on consumers' ability to rank bundles consistently. However, it is convenient to give a numerical scale to the ranking of bundles. Such a scale is called a *utility function.* More precisely, a utility function assigns a number to each possible consumption bundle such that if $A$ is preferred to $B$, then $A$ is given a higher number. If the consumer is indifferent between $A$ and $B$, the utility function gives them the same number. Any function that assigns numbers in this way is acceptable. For example, suppose that bundles $A$ and $B$ are assigned utility numbers of 2 and 4, respectively. $B$ is preferred to $A$. If a constant, say 2, is added to each number, $B$ is still preferred to $A$. The same can be said for multiplying each number by a constant, taking each to a power or some combination of these "monotonic transformations." Consequently, an infinite number of utility functions can represent a given set of preferences.

A utility function can be applied to an indifference map by assigning a number to each indifference curve. Any set of numbers will do as long as curves farther from the origin receive higher numbers. The reason is as follows. Suppose that indifference curve $I_2$ is farther from the origin than $I_1$. Then, there is at least one bundle $B$ on $I_2$ that has more of both goods than some bundle $A$ on $I_1$. By monotonicity, $B$ is preferred to $A$ and receives a higher utility number. By the definition of an indifference curve, all bundles on $I_2$ have the same number as $B$, and all bundles on $I_1$ have the same (lower) number as $A$.

Once a utility function is established, it is sometimes convenient to use the idea of marginal utility within the numerical scale provided by the function. In this context, marginal utility is the change in the utility number when the amount of one of the goods is increased by a small amount, holding the amount of the other good constant (i.e., for a move horizontally or vertically from one indifference curve to another). Marginal utility can be increasing or diminishing for the same set of indifference curves depending on the particular utility function that is chosen. If a horizontal line is drawn that crosses successive indifference curves at intervals of one unit of $x$, the utility numbers where the line crosses three successive indifference curves could be 3, 5, 6 or they could be 3, 7, 12. In the first case, marginal utility would be decreasing, and in the second, it would be increasing. But the underlying preferences represented by the indifference curves would be the same. Thus, diminishing marginal utility is not an intrinsic property of preferences that meet the basic assumptions. Rank order, not the intensity of satisfaction, is all that matters.

There is, however, an important relationship between the marginal rate of substitution and the utility function that represents a particular set of preferences. Consider a movement along an indifference curve from bundle $(x_1, y_1)$ to bundle $(x_2, y_2)$. Suppose that this move takes place in two stages. First, $x$ increases by a small amount $\Delta x$, holding $y$ constant. Because more is preferred to less, the utility number for the new bundle $(x_1 + \Delta x, y_1)$ must be larger than it was for $(x_1, y_1)$. (Note that $x_2 = x_1 + \Delta x$.) The change in utility can be represented as $MUx \bullet \Delta x$, which is the marginal utility for a small change in $x$ multiplied by that change in $x$. A return to the original indifference curve requires $y$ to decrease by a small amount of $\Delta y$, holding $x$ constant at $x_2$. The change in utility from this move is $MUy \bullet \Delta y$. The sum of these two changes in utility must be zero. Thus,

$$MUx \bullet \Delta x + MUy \bullet \Delta y = 0. \tag{4}$$

This equation is algebraically equivalent to

$$\frac{\Delta y}{\Delta x} = -\frac{MU_x}{MU_y}. \tag{5}$$

The left-hand side of Equation 5 is the marginal rate of substitution along the indifference curve. Therefore, the MRS can be expressed as the ratio of the marginal utilities of $x$ and $y$. This relationship is true for any utility function that accurately represents the consumer's preferences and will be important in connecting modern consumer theory with its predecessor.

## Budget Lines

The goal of the consumer is to choose the affordable commodity bundle with the largest utility number, given the consumer's income and the prices of the goods. Therefore, it is necessary to characterize the consumer's budget constraint. The idea is simple: The sum of the amounts spent on each good must not exceed the consumer's income. The commodity bundles that satisfy this inequality are called the *budget set.* However, because consumers prefer more to less, they will never purchase a bundle that does not use up all of their income. Therefore, the only bundles that might be chosen are those on the *budget line,* which can be expressed algebraically as

$$Px \bullet x + Py \bullet y = M, \tag{6}$$

where $Px$ and $Py$ are the prices of the goods and $M$ is the consumer's income. The budget line can be graphed by solving for $y$ in terms of $x$ to get

$$y = \frac{M}{P_y} - \left(\frac{P_x}{P_y}\right) \bullet x. \tag{7}$$

The budget line can be graphed as in Figure 8.1b, with the endpoints $\frac{M}{py}$ and $\frac{M}{px}$ representing the amounts of $y$ and $x$, respectively, that could be purchased if a consumer purchased only one good. The slope of the budget line is the opportunity cost of one more unit of $x$ in terms of $y$. If, for example, $Px = 3$ and $Py = 1$, then $x$ is three times as expensive as $y$, so a consumer must sacrifice three units of $y$ to purchase one more unit of $x$.

## Choosing the Best Consumption Bundle

For a given set of prices, income, and indifference curves, a consumer will choose the bundle that is on the indifference curve farthest from the origin but still touching the budget line. Suppose that the prices of $x$ and $y$ are $Px_1$ and $Py_1$, respectively, and the consumer's income is $M_1$. Then the consumer's budget line can be represented as $BL_1$ in Figure 8.1c. Given this budget line and the consumer's indifference map, the bundle $(x_1, y_1)$ on indifference curve $I_1$ is the best the consumer can do. Note that as long as this highest indifference curve has no flat spots, no sharp corners, and does not touch the axes, it will be *tangent* to the budget line at $(x_1, y_1)$, which means that the budget line and indifference curve have the same slope. As shown above, the slope of the indifference curve can be expressed as the ratio of the marginal utilities of $x$ and $y$ (5), while the slope of the budget line is the ratio of the prices (7). Setting these equal gives

$$\frac{MU_x}{MU_y} = \frac{Px}{Py}. \tag{8}$$

As shown in Equation 3 above, this is an implication of Gossen's rule. With only two goods, it is equivalent to the consumer allocating income among goods so that the marginal utility of the last dollar spent on each good is the same, shown in Equation 1 above. Thus, modern consumer theory comes to the same conclusion that Gossen and others reached. The difference is that the utility numbers have no intrinsic meaning. They only show a rank ordering of the bundles. As shown above, if marginal utility is diminishing, a downward-sloping demand curve can be derived from these conditions. However, the same indifference curves could be ranked by a utility function that has increasing marginal utility. The next section shows how a demand curve can be derived without any reference to specific utility numbers.

## Demand Curves

A demand curve shows the quantity that a consumer will demand at each given price, with the prices of other goods, income, and preferences held constant. In Figure 8.1c, $Px_1$ and $x_1$ meet this requirement because $x_1$ is the quantity that the consumer demands at $Px_1$, given the price of the other good $Py_1$, income $M$, and the preferences captured by the indifference map. So $(Px_1, x_1)$ is a point on the demand curve for $x$, shown as $Dx$ in Figure 8.1d. To derive a complete demand curve, the price of $x$ needs to be varied, holding all other aspects of the graph constant. Suppose that the price of $x$ increases to $Px_2$. Then, as shown in Figure 8.1c, the budget line rotates inward. The vertical intercept does not change, but the horizontal intercept, the maximum amount of $x$ the consumer could buy, becomes smaller. The slope of the budget line becomes steeper because $Px$ increases relative to $Py$, which remains constant, as do income and the indifference curves. As shown in the figure, the consumer would now choose $x_2 < x_1$. $(Px_2, x_2)$ is a second point on the demand curve for $x$. The entire demand curve can be derived by simply changing $Px$, rotating the budget line, and finding the new maximizing amount of $x$ for each price.

## Engel Curves and Cross-Price Demand Curves

The basic theory of demand asserts that changes in income, preferences, or the price of other goods cause a demand curve to shift left or right. The theory of the consumer can show the effects of changes in income or the price of the other good using *Engel curves* and *cross-price demand curves.* An Engel curve shows the amount of a good that is demanded at different levels of income, holding preferences and the prices of both goods constant. It can be derived from Figure 8.1c by changing income, holding the prices of both goods constant. (This derivation is not shown in the figure.) For each different level of income, the budget line moves parallel left or right, and a new best bundle is obtained. For each budget line, the amount of $x$ demanded can then be paired with the income for that budget line and these pairs plotted with $M$ on one axis and $x$ on the other. An Engel curve for a *normal good* is upward sloping because demand increases as income increases, while for an *inferior good,* where demand decreases as income increases, the curve is downward sloping. Rice is a common example of an inferior good. If a consumer has a low income, the consumer probably eats lots of rice and little meat. If rice is viewed as "inferior" to meat, then an increase in the consumer's income, ceteris paribus, is likely to cause the consumer to demand more meat and less rice.

A cross-price demand curve shows the amount of one good demanded at various prices of the other good, holding the price of the first good and income constant. It can be derived for good $y$ from Figure 8.1c by pairing the amount of $y$ demanded from each bundle with the price of $x$, as the price of $x$ changes. Thus, the pairs $(Px_1, y_1)$ and $(Px_2, y_2)$ would be on this curve (not shown). A cross-price demand curve is upward sloping if the two goods are *substitutes* (as the price of $x$ increases, the consumer demands more $y$ to substitute for $x$) and downward sloping if they are *complements* (as the price of $x$ rises, the consumer wants less $y$ to consume with less $x$). For many people,

hamburgers and hot dogs are substitutes, while peanut butter and jelly are complements.

## Income and Substitution Effects

The downward slope of a demand curve depends on how the consumer reacts to two aspects of a change in the price of a good. The first is the change in the price of the good relative to the price of the other good. This change is represented by the change in the slope of the budget line, and the consumer's reaction to it is called the *substitution effect.* The other aspect is the change in the purchasing power of the consumer's income. This is roughly represented by the change in the size of the budget set, and the consumer's reaction to it is called the *income effect.* Showing these two effects requires a careful analysis of the consumer's move from $x_1$ to $x_2$ when the price changes.

This analysis is shown in Figure 8.1e. The best bundles at prices $Px_1$ and $Px_2$ are $(x_1, y_1)$ and $(x_2, y_2)$ as before. However, the movement between them is now broken into two parts, one due to the substitution effect and the other to the income effect. To separate these two, the following thought experiment is necessary. Suppose that in response to the increase of the price of $x$, the consumer were given just enough additional income to shift the budget line so that it would again be tangent to the original indifference curve, $I_1$. This increase from $M_1$ to $M_2$ would compensate for the loss of purchasing power caused by the increase in the price of $x$. However, the increase in the price of $x$ relative to the price of $y$ means that the slope of this augmented budget line is steeper than the slope of the original one. Consequently, the consumer would choose to consume $x^*$ rather than $x_1$ as a result of the change in relative prices. This bundle contains less $x$ and more $y$ than the original bundle. The consumer, therefore, would substitute some $y$ for $x$ simply because of the change in relative prices. This change in the amount of $x$ demanded $(x_1 - x^*)$ is called the *substitution effect.* It is always negative (i.e., the consumer always substitutes away from the good that has become relatively more expensive). But the increase in income was only a thought experiment. In fact, the consumer's real income has fallen. The effect on the amount of $x$ demanded caused only by the drop in real income is measured by finding the difference between $x^*$ and $x_2$. This difference is called the *income effect.* If the good is a normal good, then a decrease in income will cause the consumer to choose less $x$. Because both the income and substitution effects result in less $x$ being demanded, the demand curve is downward sloping.

However, the good could be an inferior good. In that case (not shown), the fall in real income, taken alone, would lead the consumer to demand more $x$. The income and substitution effects would then be working in opposite directions, and $x_2$ would be to the right of $x^*$. But as long as $x_2 < x_1$, the combined effect would still be for the quantity demanded of $x$ to fall. The demand curve would again be downward sloping but steeper than it would be for a normal good.

Finally, it is possible that the good could be so inferior that the increase from $x^*$ to $x_2$ caused by the lower real income would be greater than the decrease from $x_1$ to $x^*$ caused by the change in relative prices. In that case, the demand curve would be upward sloping, with $x_2 > x_1$ (not shown). The law of demand would not hold. A good with this property is called a Giffen good, named after Robert Giffen (1837–1910). While a Giffen good is a theoretical possibility, it is hard to imagine a real-world example. In the example above, rice would have to be so inferior that faced with the loss in purchasing power caused by an increase in the price of rice, the consumer would actually reduce meat consumption to consume more rice. Although indifference curves can be drawn to represent such preferences, they seem highly unlikely in the real world. But the important point is that demand curves are generally considered to be downward sloping precisely because such preferences are not likely.

The law of demand depends on the nature of the preferences that shape the indifference curves, not on the numbers assigned to them. The demand curve for a good is downward sloping if the good is normal or, in the case of an inferior good, if the income effect is less than the substitution effect. Diminishing marginal utility plays no part at all.

## Revealed Preference

An interesting twist to consumer theory was proposed by Paul Samuelson (Samuelson, 1938). He suggested that consumer preferences could be uncovered by observing what consumers actually choose from among bundles they can afford. Suppose that there are two consumption bundles, $A$ and $B$, on the consumer's budget line. If the consumer is observed to choose $A$, then it is "revealed" that the consumer prefers $A$ to $B$ because $A$ was chosen when both were affordable. Such a comparison can be made only between bundles that are both in the budget set. However, by changing the budget line (and set), comparisons can be made among enough different bundles that indifference curves can be sketched out. It is important to note, however, that this approach does not represent a different consumer theory. The assumptions given above are all assumed to hold. What is different is the lens through which the data of preferences are perceived.

## Intertemporal Choice

It is straightforward to apply consumer theory to consumption in different periods of time. The commodity bundles can simply be reinterpreted as including the amount of consumption of a standard good in different time periods. Thus, in Figure 8.1a, consumption in the first period (e.g., this year) would be measured along the

horizontal axis, while consumption in the second period (next year) would be measured along the vertical axis. The slope of the budget line, which represents the price of a unit of consumption this year in terms of forgone consumption next year, would be the real interest rate. By consuming a dollar's worth of the commodity now, the consumer is giving up the additional amount that could be purchased with the interest earned by saving until next year. This model can be extended mathematically to include any number of time periods.

### Choice When Future Consumption Is Uncertain

Households may need to make choices when the outcome of those choices is not certain. The most common situations involve gambles, particularly the gamble that one takes when purchasing a financial asset. Rather than being able to know for certain that an asset will allow a given amount of consumption in the future, the household may calculate the probabilistic expected value of the amount of consumption that the asset will yield. A household's attitude toward risk will determine how it views these gambles. Households may be "risk averse," meaning they would prefer a certain outcome to a gamble with the same expected value as the certain outcome. They may be "risk loving," meaning they prefer the expected value of the gamble to the certain outcome, or they may be "risk neutral," meaning they are indifferent between the two. Their attitudes toward risk will, in turn, affect the premium that must be paid to accept risk or that they are willing to pay to avoid risk. These considerations are important in Chapter 20 ("Asset Pricing Models") and Chapter 21 ("Portfolio Theory and Investment Management") in this volume.

### Welfare Economics

The effect of economic decisions on the well-being of consumers and producers is addressed in the field of economics referred to as welfare economics. Models in this field often make use of the idea of a "compensated demand curve." This curve relates price and quantity demanded when only the substitution effect is taken into account. A precise measurement of consumer's surplus, the amount by which a consumer's willingness to pay exceeds the amount the consumer pays for a unit of a good, requires using a compensated demand curve.

### Labor Markets

Even though consumer theory is concerned with commodity markets, the model presented above is applied to the supply of labor in Chapter 14, "Labor Markets" (this volume). Even though consumer theory is concerned with commodity markets, the model presented above is applied to the analysis of labor supply decisions as well. In the standard model of labor supply, households are assumed to divide their time between hours spent working for income and hours "consumed" as leisure (not earning income). The model employs indifference curves for bundles consisting of a number of hours of leisure and an amount of income earned from labor. Households choose the combination of leisure and income on the highest indifference curve touching their budget constraint. The constraint is composed of bundles of income and leisure hours that can be obtained under a given wage rate. The total number of possible hours in a day minus the hours of leisure chosen equals the hours of labor supplied.

### General Equilibrium

Models that include many markets at once are used to determine the conditions under which there exists a set of prices that will clear all of the markets simultaneously. Demand in goods markets is generally modeled using the tools of indifference curves and budget constraints described in this chapter. This volume contains a chapter on "Supply, Demand, and Equilibrium" (Chapter 7).

### Challenges to Traditional Theory

The model of consumer behavior presented in this chapter is based on strictly rational behavior. In recent decades, the new fields of behavioral economics and experimental economics have challenged traditional models by suggesting that there are bounds to the rationality that consumers can exercise. These related fields look for explanations of data that do not fit the standard theory presented in this chapter. There are separate chapters on each of them (Chapters 84 and 85) in this volume.

## Conclusion

The law of demand is fundamental to economic models of markets. The theory of consumer behavior developed in the nineteenth and early twentieth centuries derived a downward-sloping demand curve based on the concept of measurable diminishing marginal utility. Beginning with Hicks, however, modern consumer theory has shown that the law of demand can be derived based only on the consumer's ability to rank-order alternative consumption bundles and choose the most preferred bundle that falls within the set of bundles the consumer can afford given income and the prices of the goods. Thus, the demand curve familiar to all economics students has a rigorous basis in theory. The model is useful in many areas of economics, but its reliance on strictly rational behavior recently has been called into question and will likely be the subject of much future research.

# Demand Elasticities

Ann Harper Fender
*Gettysburg College*

Economic lore depicts Alfred Marshall leaping in 1881 from the low roof of the Oliva Hotel while on vacation in Palermo, Italy; Marshall, the legend continues, ran through the town's streets shouting, "Eureka, I've found it!" The legend has his excitement stemming from his discovery of a simple formalization for the concept of elasticity (Keynes, 1963).[1] Marshall was not the first to incorporate something like elasticity in his economic analysis. He was familiar with the work of mathematical economists Augustin Cournot and Johann von Thünen, both of whom developed theories of firm behavior earlier in the nineteenth century and arguably hinted at elasticity. The classical economist John Stuart Mill also discussed the impact of changes in price on quantity consumed and on the impact of tariffs on output and prices; Fleming Jenkin had alluded to the elasticity concept in 1870 (Ekelund & Hebert, 1990).

Marshall moved beyond general representations of the response of quantity demanded to a change in price. Specifically, he defined price elasticity of demand as the percentage change in quantity demanded divided by percentage change in price. It was not until 1890, when the first edition of his *Principles of Economics* appeared, that Marshall published his work on elasticity along with the many other contributions to economics that he had developed over several decades. In addition to being precise, his definition of elasticity had the benefit of being independent of the units in which price and quantity are measured, as illustrated in the next section, which also illuminates the technical rules for calculating arc and point price elasticities of demand and relates these to the geometry of demand curves. The third section explores the relationship between firm revenues and price elasticities of demand. Market power is related to price elasticity of demand, as the fourth section considers, along with the power of firms to price discriminate. The fifth section considers other demand elasticities, the factors that influence them, and their significance. Marshall extended the elasticity concept to the demand for inputs, described in the sixth section. Both classical and neoclassical economists were concerned with moral and social issues; their grappling with the concept of elasticity often resulted from concerns with how strong an effect particular public policies would have. In the seventh section, we consider how elasticity of demand matters in economic policy. Although the concept of elasticity of demand was originated over a century ago, limits on computational ability prior to the computer age made it more valuable as a theoretical than as an empirical concept. Improved data collection and the advent of high-speed computers dramatically increased the numerical estimates of elasticity, as the concluding section indicates.

## Technical Rules for the Calculation of Elasticities

Microeconomic theory develops the demand for a product or service primarily as a function of its own price, the prices of related goods and services, and income:

$$Q_d = f(p, p_r, M),$$

where $p$ is own price, $p_r$ is price of related good(s), and $M$ is income.

The definition of an elasticity is the percentage change in the dependent variable divided by the percentage change in the independent or causal variable. Thus, the price elasticity of demand is calculated as percentage change in quantity demanded divided by percentage change in price, holding all other independent variables constant:

$$\varepsilon_p^d = \{(\text{change in quantity})/(\text{base quantity})\} \bullet 100 \div \{(\text{change in price})/(\text{base price})\} \bullet 100$$

$$= \frac{\Delta Q}{Q} / \frac{\Delta P}{P}$$

$$= \frac{\Delta Q}{\Delta P} \bullet \frac{P}{Q}.$$

This also equals $\frac{d(\log Q)}{d(\log P)}$.

## Arc Elasticity

This formula for elasticity between two distinct points on the demand curve raises the question as to what is the base $Q$ and base $P$: the price/quantity combination before or after the change? To avoid ambiguity and to give the same percentage changes whether price is rising or falling, the average of the prices and the average of the two quantities are frequently used. This yields the computational formula for price elasticity of demand:

$$\varepsilon_p^d = \frac{\Delta Q}{\Delta P} \bullet \frac{\frac{P_1+P_2}{2}}{\frac{Q_1+Q_2}{2}} = \frac{\Delta Q}{\Delta P} \bullet \frac{\sum P}{\sum Q}.$$

A (relatively) simple computational formula for the price elasticity when moving from one point on the demand curve to a second point on the demand curve is then the (change in quantity divided by change in price) multiplied by the sum of prices divided by sum of quantities. This yields an arc elasticity of demand, measured for a given movement along the curve.

Consider the demand schedule in Table 9.1.

**Table 9.1** Demand Schedule

| *Price* | *Quantity* |
|---|---|
| \$9 | 0 |
| \$8 | 1 |
| \$7 | 2 |
| \$6 | 3 |
| \$5 | 4 |
| \$4 | 5 |
| \$3 | 6 |
| \$2 | 7 |
| \$1 | 8 |
| \$0 | 9 |

The arc elasticity for a change in price from \$8, with $Q = 1$, to \$7 with $Q = 2$, is

$$\varepsilon_p^d = \left\{\frac{(2-1)}{(7-8)}\right\} \bullet \left\{\frac{(7+8)}{(2+1)}\right\} = -5$$

Were price expressed in cents rather than dollars, the elasticity coefficient would be

$$\varepsilon_p^d = \left\{\frac{(2-1)}{(700-800)}\right\} \bullet \left\{\frac{(700+800)}{(2+1)}\right\} = -5.$$

Whether price is measured in dollars or cents, the percentage change in price is the same because units cancel; the elasticity coefficient is independent of the units of measurement.

Economic theory deduces that the demand curve is (usually) downward sloping; therefore, the price elasticity of demand will be negative: A fall in price will lead to a rise in quantity. Often, rather than expressing this elasticity as a negative number, its absolute value is taken and the resulting positive number is considered the value of the price elasticity. If the quantity is highly responsive to a fall in price, the percentage increase in quantity will be large relative to the percentage drop in price. The numerator of the elasticity will be larger than the denominator (in absolute value). The resulting absolute value of the price elasticity of demand will exceed 1, and the demand is elastic along that price range. If the absolute value of the elasticity coefficient is not taken, the demand curve is elastic when the coefficient is less than −1 (e.g., −5 is less than −1).

When price falls from \$5 to \$4, the elasticity coefficient is

$$\varepsilon_p^d = \frac{5-4}{4-5} \bullet \frac{5+4}{4+5} = -1.$$

The price decrease is just offset by a proportional quantity increase, resulting in an elasticity coefficient of −1, or 1 if absolute value is taken. The demand is unitary elastic for this price change.

With a price decrease from \$4 to \$3, the price elasticity of demand is

$$\varepsilon_p^d = \frac{6-5}{3-4} \bullet \frac{3+4}{6+5} = -\frac{7}{11}.$$

For this price change, the percentage or proportional change in quantity demanded is small relative to the percentage change in price (in the opposite direction). The resulting elasticity coefficient is greater than –1 or, in absolute value, less than 1; demand is inelastic for this price change. Table 9.2 summarizes these elasticities.

## Point Elasticity

A graph (see Figure 9.1) of the demand schedule in Table 9.1 illustrates the relationship between price and amount consumers are willing to buy, holding all other

**Table 9.2** Own Price Elasticities of Demand

| *State of Demand* | *Price Elasticity Coefficient:* $\varepsilon$ | *Absolute Value of Price Elasticity Coefficient:* $\lvert\varepsilon\rvert$ |
|---|---|---|
| Price elastic | $\varepsilon < -1$ | $\varepsilon > 1$ |
| Unitary price elastic | $\varepsilon = -1$ | $\varepsilon = 1$ |
| Price inelastic | $\varepsilon > -1$ | $\varepsilon < 1$ |

relevant variables constant. By convention, economists follow the Marshallian practice of plotting quantity on the horizontal axis and price per unit on the vertical axis. This graphs the inverse demand curve

$$P = f(Q).$$

Rather than considering the price elasticity of demand along an arc of the demand curve, elasticity can be calculated at a single point, for example, point *A*. A point price elasticity of demand calculates the impact on quantity when the change in price becomes very small and hence equals the derivative of quantity with respect to price times the ratio of *P* to *Q* at that point:

$$\frac{\Delta Q}{\Delta P} \bullet \frac{\sum P}{\sum Q} = \left\{ \lim_{\Delta P \to 0} \frac{\Delta Q}{\Delta P} \right\} \bullet \frac{P}{Q} = \frac{dQ}{dP} \bullet \frac{P}{Q}.$$

The slope of the demand curve is $\frac{\Delta P}{\Delta Q}$. The first term in the price elasticity of demand is the inverse of this slope. For an arc elasticity, it is the inverse of the slope for a distinct movement along the curve; for a point elasticity, it is the inverse of the slope of a straight line tangent to the demand curve at that point. The price elasticity of demand can be written as

$$\varepsilon_p^d = \left\{ \frac{1}{(\text{slope of demand curve for given price change})} \right\} \bullet \frac{P}{Q}.$$

## Elasticity and a Linear Demand Curve

The slope of a straight line demand curve is constant; the inverse of a constant slope is constant. The first term in the elasticity coefficient for a straight line demand curve is, therefore, the same for any price/quantity combination along the curve. The ratio of price to quantity varies along the curve, however. Near the vertical axis, price is high and quantity is low, and $\frac{P}{Q}$ is large. Near the horizontal axis, price is low and quantity is high, resulting in a low ratio. When $\frac{P}{Q}$ is multiplied by the absolute value of the constant inverse of the slope, the resulting elasticity varies along the demand curve. At high prices, elasticity is high, and at low prices, it is low. A linear demand curve has the algebraic form

$$P = a - b \bullet Q,$$

where *a* and *b* are constants.

The price elasticity of demand for a linear demand curve is a function of price and the vertical intercept, shown by

$$\varepsilon_p^d = \frac{1}{b} \bullet \frac{P}{Q} = -\frac{1}{b} \bullet \frac{P}{\frac{(a-P)}{b}} = (-1) \bullet \frac{P}{a-P}.$$

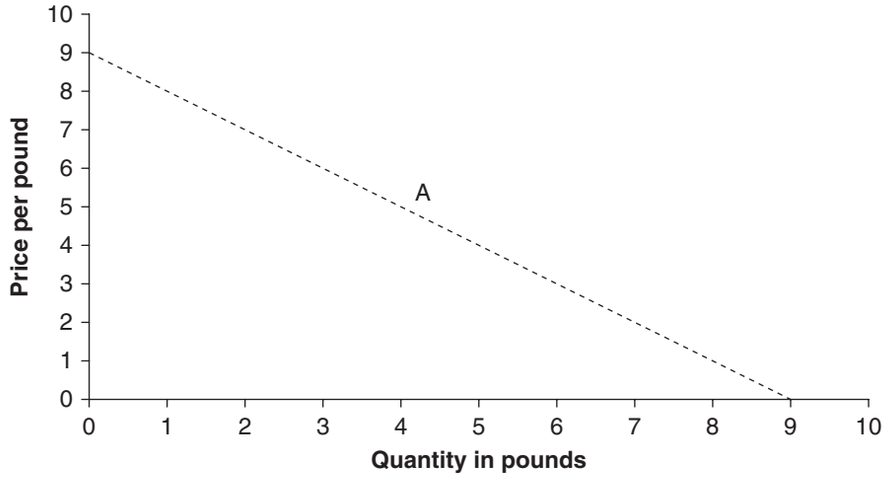

**Figure 9.1** Demand for Beef

The demand curve is unit elastic where

$$\varepsilon_p^d \quad \left\{\frac{1}{(\text{slope of demand curve for given price change})}\right\} \bullet \frac{P}{Q} \qquad 1.$$

$$\varepsilon_p^d = -\left(\frac{1}{b} \bullet \frac{P}{Q}\right) = -1.$$

Because the inverse demand is $Q = \frac{a}{b} - \frac{P}{b}$, at unit elasticity,

$$\frac{1}{b} \bullet \frac{P}{\left(\frac{a}{b}\right) - \left(\frac{P}{b}\right)} = \frac{1}{b} \bullet \frac{P}{\left(\frac{1}{b}\right) \bullet (a - P)} = 1$$

$$\frac{P}{a - P} = 1,$$

$$P = a - P,$$

$$2 \bullet P = a,$$

$$P = \frac{a}{2}.$$

Unit elasticity occurs where price is equal to half the vertical intercept on the demand curve. Because the demand curve is linear, this occurs at the midpoint of the curve (see Figure 9.2).

Flatter straight-line demand curves are described as being more elastic than steeper ones. Straight-line curves, however, have all ranges of elasticity. How can these be reconciled? If a relatively flat straight-line demand is extended until it hits both axes, it will be elastic in the upper half of its price range and inelastic in the lower half of its price range. Similarly, if a relatively steep straight-line demand curve is extended until it hits both axes, it will be elastic in the upper half of the price range and inelastic in the lower half. If a relatively steep demand curve, $D_1$, intersects a relatively flat demand curve, $D_2$, at a given point ($A$ in Figure 9.3), the curve that is steeper will have a lower elasticity at that point than the relatively flatter demand curve. Both curves have the same coordinates ($Q_A$, $P_A$), and the reciprocal of the demand curve is lower for the steeper curve than for the flatter curve. Therefore,

$$\varepsilon = \frac{dQ}{dP} \bullet \frac{P}{Q}$$

will be greater in absolute value for the flatter curve than for the steeper demand curve.

## Elasticity of Demand for Nonlinear Demand Curves

Nothing in the economic theory of demand requires that demand curves be linear; the correct form of the demand function depends on the underlying relationship between quantity and willingness to pay. The definition of elasticity can be applied to determine the elasticity coefficient for alternative specifications of the demand function. One frequently used specification of the demand function takes the following log-linear form:

$$Q = \frac{\alpha}{P^{\beta}} = \alpha \bullet P^{-\beta}.$$

where $Q$ is quantity demanded and $P$ is price; $\alpha$ and $\beta$ are parameters.

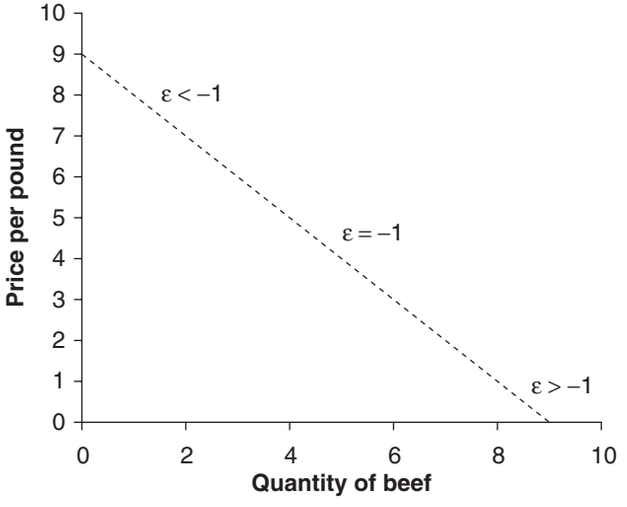

**Figure 9.2** Demand for Beef: Elasticities Along Straight-Line Demand Curve

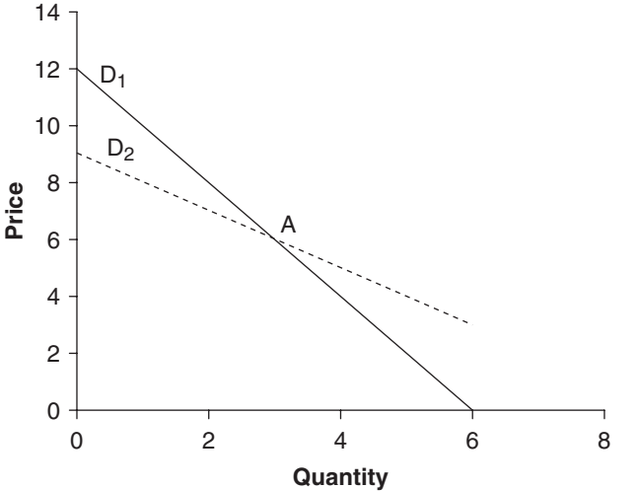

**Figure 9.3** Elasticities of Steep Versus Flat Demand Curves

The log-linear designation derives from the observation that

$$\log Q = \log \alpha + (-\beta) \bullet \log P = \log \alpha - \beta \bullet \log P.$$

Because this function is linear (in the logarithms of the variables), standard linear regression analysis permits the estimation of the parameters, $\alpha$ and $\beta$.

For this log-linear demand function, price elasticity is

$$\begin{aligned} \varepsilon &= \left(-\beta \bullet \alpha \bullet P^{-\beta-1}\right) \bullet \frac{P}{Q} \\ &= \left(-\beta \bullet \alpha \bullet p^{-\beta-1}\right) * \frac{P}{\alpha \bullet P^{-\beta}} \\ &= \frac{-\beta \bullet \alpha \bullet P^{-\beta}}{\alpha \bullet P^{-\beta}} = -\beta. \end{aligned}$$

With a log-linear demand function, the price elasticity of demand is the exponent of price in the demand function. Because the log-linear function specifies the exponent as constant, the price elasticity of demand becomes constant, unvarying as price and quantity change.

Both linear and log-linear demand specifications are relatively tractable; it is relatively easy to derive the price elasticity and relatively easy to use standard regression programs for empirical estimation. One can construct more complex demand functions, with price and quantity inversely related, and derive elasticity using that concept's definition; with greater complexity, however, come elasticities that are messier to calculate and estimate statistically.

## Price Elasticity of Demand and Revenue

Total revenue measures price times quantity for given coordinates ($Q$, $P$) on the demand curve. From the perspective of consumers, total expenditure is the equivalent of total revenue. Along the demand curve, price and quantity move in opposite direction: When $P$ falls, the quantity consumers are willing to buy increases. Change in total revenue (or total expenditures) results from price moving in one direction and quantity moving in the opposite direction and depends on the relative change in the two variables. If the rise in quantity is large relative to the decline in price, the product $P \bullet Q$ rises. Conversely, if the rise in quantity is small relative to the fall in price that induces the quantity change, total revenue (the product $P \bullet Q$) falls. The change in quantity relative to a given change in price is just the price elasticity of demand. If the percentage rise in quantity is large relative to the percentage decline in price, total revenue (expenditure) rises with a fall in price, and the elasticity coefficient is less than −1 (or greater than 1 in absolute value). If a price increase induces a large decrease in quantity demanded, the demand curve is elastic, and total revenue (expenditure on the product) falls. Thus, if demand is price elastic, price and total revenue (expenditure) move in opposite directions: A decrease in price raises total revenue, and an increase in price reduces total revenue.

If a price decrease generates a relatively small increase in quantity demanded, the percentage change in quantity divided by the percentage change in price will be greater than −1 or less than 1 in absolute value. A price decrease leads to a fall in the product $P \bullet Q$ or total revenue. Conversely, if a price increase leads to a relatively small decrease in quantity demanded, total revenue will rise with a rise in price. In this case, the price elasticity is greater than −1 or less than 1 in absolute value. If the demand curve is price inelastic, price and total revenue move in the same direction. When the demand curve has unitary elasticity, the percentage rise in quantity equals the percentage fall in price. The rise in quantity just offsets the fall in price, leaving total revenue unchanged with unitary price elasticity of demand.

Because price elasticity of demand determines the change in total revenue resulting from a price decrease/quantity increase, price elasticity also determines the marginal revenue due to a price/quantity change. Marginal revenue ($MR$) is defined as the change in total revenue resulting from a small change in quantity:

$$MR = \frac{\Delta TR}{\Delta Q}.$$

If the demand curve is elastic for a given price change, total revenue rises with a fall in price and corresponding rise in quantity. Both numerator and denominator of marginal revenue are positive, and therefore marginal revenue is greater than zero. If the demand curve is inelastic for a given price change, total revenue falls with a fall in price and corresponding rise in quantity. The change in total revenue is negative when the change in quantity is positive and the demand is inelastic. Marginal revenue with a price decrease is therefore negative. If the price elasticity of demand is unitary, total revenue is unchanged with a fall in price and corresponding rise in quantity; this results in marginal revenue of zero. Table 9.3 summarizes these relationships.

## Demand Elasticities, Market Power, and Pricing Policies

Figure 9.3 contains two demand curves, one relatively flat; the analysis explained that the flatter curve is more elastic at the intersection of the two than is the steeper curve. A single, small firm in a competitive market faces a horizontal demand curve because the firm has no power over market price; it is a price taker, accepting the market price

**Table 9.3** Price Elasticity of Demand, Total Revenue (Expenditure), and Marginal Revenue

| *Elasticity* | *Absolute Value of Elasticity* | *Condition* | *Total Revenue/ Expenditure* | *Marginal Revenue* |
|---|---|---|---|---|
| $\varepsilon < -1$, demand elastic | $\lvert\varepsilon\rvert > 1$ | Price falls, quantity rises | Rises | $> 0$ |
| $\varepsilon < -1$, demand elastic | $\lvert\varepsilon\rvert > 1$ | Price rises, quantity falls | Falls | $> 0$ (both $\Delta TR$ and $\Delta Q$ are negative, $\frac{\Delta TR}{\Delta Q} > 0$) |
| $\varepsilon = -1$, demand unitary elastic | $\lvert\varepsilon\rvert = 1$ | Price falls, quantity rises | Does not change | $= 0$ |
| $\varepsilon = -1$, demand unitary elastic | $\lvert\varepsilon\rvert = 1$ | Price rises, quantity falls | Does not change | $= 0$ |
| $\varepsilon > -1$, demand inelastic | $\lvert\varepsilon\rvert < 1$ | Price falls, quantity rises | Falls | $< 0$ ($\Delta TR$ is negative and $\Delta Q$ is positive, $\frac{\Delta TR}{\Delta Q} < 0$) |
| $\varepsilon > -1$, demand inelastic | $\lvert\varepsilon\rvert < 1$ | Price rises, quantity falls | Rises | $< 0$ ($\Delta TR$ is positive and $\Delta Q$ is negative, $\frac{\Delta TR}{\Delta Q} < 0$) |

as outside its control. It faces a horizontal demand curve. In this situation, illustrated in Figure 9.4, the price elasticity of demand for the firm is $\frac{\Delta Q}{\Delta P} \bullet \frac{P}{Q} = \frac{\Delta Q}{0} \bullet \frac{P}{Q} = \infty$, or infinitely elastic. At the other extreme is a firm facing a vertical demand curve. The elasticity of demand in this case equals $\frac{0}{\Delta P} \bullet \frac{P}{Q}$, which equals 0 or completely inelastic.

The perfectly competitive firm, which has no market power, faces an infinitely elastic demand curve. More generally, it is possible to link a firm's market power to the elasticity of demand that it faces. Abba Lerner (1934) defined a firm's market power as its ability to raise price above marginal cost, where marginal cost is the additional cost of producing one more unit of output.

$$\text{Lerner Index (of market power)} = \frac{P - MC}{P}.$$

The profit-maximizing firm will produce a quantity such that the addition to revenue equals the addition to cost—that is, marginal revenue equals marginal cost. For the profit-maximizing firm, the index becomes

$$\text{LernerIndex} = \frac{P - MR}{P}.$$

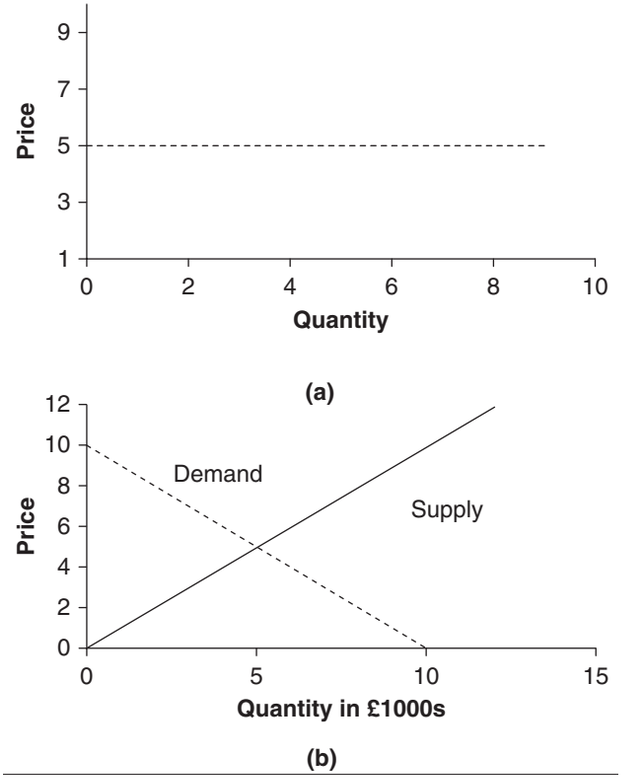

**Figure 9.4** (a) Demand Facing Competitive Firm With Industry Demand; (b) Supply and Equilibrium Price = 5

Total revenue equals price times quantity. Therefore,

$$MR = \frac{dTR}{dQ} = \frac{d(P \bullet Q)}{dQ} = P \bullet \frac{dQ}{dQ} + Q \bullet \frac{dP}{dQ}.$$

Multiplying the right-hand side of this equation by $\frac{P}{P}$ yields

$$MR \quad \frac{P}{P} \bullet \left(P + Q \bullet \frac{dP}{dQ}\right) \quad P \bullet \left(1 + \frac{Q}{P} \bullet \frac{dP}{dQ}\right) \quad P \bullet \left(1 + \frac{1}{\varepsilon}\right).$$

where the elasticity is negative. The Lerner Index of market power becomes

$$\begin{aligned} \text{Lerner Index} &= \frac{P - MR}{P} \\ &= \frac{P - P \bullet \left(1 + \frac{1}{\varepsilon}\right)}{P} \\ &= \frac{P}{P} \bullet \left(1 - 1 - \frac{1}{\varepsilon}\right) \\ &= -\frac{1}{\varepsilon} \end{aligned}$$

If the firm faces a highly elastic demand curve, $\varepsilon$ is large and $-\frac{1}{\varepsilon}$ approaches 0. Therefore, $\left(1 + \frac{1}{\varepsilon}\right)$ approaches 1, *MR* approaches *P*, and again the index approaches 0. If price elasticity of demand is low, $\frac{1}{\varepsilon}$ becomes large, and *MR* diverges from price. The Lerner Index of market power rises.

### Price Elasticity of Demand and Price Discrimination

Price discrimination occurs when different customers for whom the marginal cost of the good or service is the same are nonetheless charged different prices. An example familiar to all tuition-paying undergraduates is the service of college education. Although the list or stated price for a semester at a given school typically is the same for all registrants, financial aid programs effectively create different payments for what is essentially the same service that arguably has the same marginal cost for all consumers. For a seller to price discriminate, that seller has to have market power. Different consumers or groups of consumers must have different demands for the goods, and the seller must also be able to distinguish those willing and able to pay high prices from those willing or able to buy only at low prices. Furthermore, resale of the good or service must be costly or impossible; otherwise, low-price payers would resell to high-price buyers. Under these circumstances, the seller will find it advantageous to separate the markets, selling at a high price in the market with low price elasticity of demand and at low(er) price in the market with a high(er) price elasticity of demand. Airlines attempt to distinguish business from leisure travelers. The former, at least in boom times, are less sensitive to price of the airline ticket either because the firm is paying for it or because the financial benefits resulting from travel exceed the cost of the ticket. No business flyer has reason, however, to disclose a willingness to pay a high price. The airlines therefore set up fare structures that lead buyers to identify themselves as price insensitive or price sensitive. One such structure has lower fares for trips that include a Saturday night stay in the destination city than trips that have returns on weekdays. Presumably business travelers want to be home by the weekend, but leisure travelers are willing to "stay over" for a lower fare. Similarly, retail stores use coupons and rewards cards to distinguish those who are sensitive to price from those who are not. Carrying coupons and cards takes some time and attention, costly to those who value time and convenience more highly than they do the savings from lower price. Price discrimination can increase market efficiency in the sense of leading to higher output than would occur when a single price firm has market power. Also, charging different consumers different prices based on differing price elasticities of demand generates greater efficiency when fixed costs are high relative to variable ones—or when some costs are not easily adjusted for small changes in output. Economists interested in antitrust and regulation have become very interested in studying pricing schemes based on differences in price elasticity.

Because lower price elasticity of demand allows a firm to charge higher prices, ceteris paribus, a firm has an incentive to reduce that elasticity. One way of doing this is to generate consumer loyalty. Developing a brand name presumably does this, as does some degree of product differentiation. In these cases, if price rises, not all customers flee to alternative products. Advertising potentially increases brand loyalty and reduces price elasticity of demand.

## Other Demand Elasticities

### Income Elasticity of Demand

This chapter has focused thus far on the relationship between the price of a good or service and the quantity demanded at that price. Clearly, factors other than price of a good affect the willingness of consumers to purchase. More generally, the demand for good *x* is a function of the price of *x,* income (*M*), and price of a related good, *y.* Of

course, there may be more than one related good whose price affects the demand for *x*.

$$Q_x^d = f(P_x, M, P_y).$$

Generally, an elasticity is the percentage change in the dependent variable divided by the percentage change in the independent or causal variable, holding all other relevant variables constant. When the price of good *x* is held constant and income is allowed to vary, the resulting relationship between income and the quantity of good *x* that consumers are willing to buy is graphed as an Engel curve, as shown in Figure 9.5.

The arc income elasticity of demand along the Engel curve is

$$\varepsilon_M^d = \frac{\Delta Q}{\Delta M} \bullet \frac{\sum M}{\sum Q}.$$

The point income elasticity of demand is

$$\varepsilon_M^d = \frac{dQ}{dM} \bullet \frac{M}{Q}.$$

The first term of the elasticity is the marginal propensity to consume the good, that is, the change in the consumption of the good divided by the change in income. The second term in the point elasticity is the reciprocal of the average propensity to consume the good. Thus, the income elasticity of demand equals *MPC* ÷ *APC* for the good. At a given point, the *MPC* is the slope of the Engel curve. The *APC* is the slope of a straight line, a ray, from the origin to the given point on the Engel curve. The income elasticity of demand equals the ratio of the slope of the Engel curve at a given point to the slope of a ray from the origin to that same point. If the Engel curve is steeper than the ray from the origin, the income elasticity at that point exceeds 1. If the Engel curve is less steep than the ray from the origin at the point of interest, the income elasticity of demand at that point is less than 1.

The sign of the income elasticity provides important information. When its income elasticity of demand is positive, a good is called normal; a rise in income leads to a rise in the demand for the good, a rightward shift of the demand curve. The Engel curve is positively sloped. A good is called inferior when its income elasticity of demand is negative. When income rises, the consumption of the good falls; the demand curve for the good shifts to the left with a rise in income, and the Engel curve is negatively sloped. A good is not inherently inferior. At low levels of income, a rise in income may lead consumers to buy more low-grade hamburger. If income rises further, consumers may choose to buy less low-grade hamburger and instead buy ground sirloin.

If a good's income elasticity of demand is positive and high, greater than 1, the good is superior. In the 1950s in the United States, new housing was arguably a superior good. As incomes rose, people spent disproportionately on new housing; new housing was hard to find in city centers, and therefore the demand for suburban housing rose. Government transportation policy favored expansion of highways that connected suburban housing areas to urban and, later, suburban work centers. Urban public policy also favored separation of housing from nonhousing land use. With rising incomes, the high-income elasticity of demand for new housing combined with public policy arguably led to suburban sprawl and accelerated the decline of central cities.

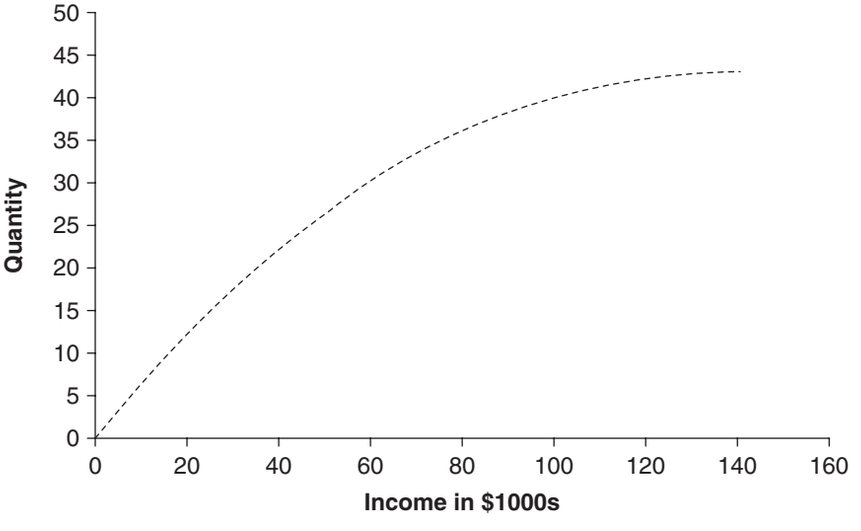

**Figure 9.5** Engel Curve

## Cross-Elasticity of Demand

The cross-elasticity of demand measures the responsiveness of demand for good *x* to the change in the price of good *y:*

$$\varepsilon_{Py}^d = \frac{\Delta Q_x}{\Delta P_y} \bullet \frac{\sum P_y}{\sum Q_x}$$

or for a point cross-elasticity of demand

$$\varepsilon_{Py}^d = \frac{dQ_x}{dP_y} \bullet \frac{P_y}{Q_x}.$$

The sign of the cross-elasticity provides useful information. If the cross-elasticity is negative, a fall in the price of good *y* causes a rise in the quantity of good *x* via a rightward shift of the demand curve for *x.* Consumers are purchasing more *x* when the price of *y* is falling. They are buying more *x* when they buy more *y*; *x* and *y* are complements. If the cross-elasticity is positive, a fall in the price of good *y* leads to a fall in the demand for *x.* The

**Table 9.4** Other Demand Elasticities

| *Type of Elasticity* | *Value of the Elasticity* | *Implications for Good x* |
|---|---|---|
| Income | $\varepsilon > 1$ | Superior |
| Income | $0 < \varepsilon \leq 1$ | Normal |
| Income | $\varepsilon < 0$ | Inferior |
| Cross | $\varepsilon > 0$ | Substitutes |
| Cross | $\varepsilon = 0$ | Unrelated |
| Cross | $\varepsilon < 0$ | Complements |

demand curve for $x$ shifts leftward with a fall in the price of $y$. Consumers substitute $y$ for $x$ when the price of $y$ falls; $x$ and $y$ are substitutes. Table 9.4 summarizes these demand elasticities.

If the demand for good $x$ is log-linear, that is,

$$Q = p_x^{\alpha} \bullet M^{\beta} \bullet P_y^{\delta},$$

the demand elasticities are the exponents of their respective variables. The "own" price elasticity of demand is $\alpha$, the income elasticity of demand is $\beta$, and the cross-elasticity of demand is $\delta$.

## Factors Influencing Price Elasticity of Demand

The modern demand curve for good $x$ is drawn assuming that income and prices of all other goods are constant; it illustrates how a change in the price of $x$ affects the quantity demanded, ceteris paribus, or "all other things constant." The calculation of price elasticity of demand for a price change is based on the same assumption. A change in the price of good $x$, with nominal income held constant, changes the real income or purchasing power of the consumer(s). Hence, along the typical demand curve, real income varies, although one can create an income-compensated demand curve, along which real income is held constant. Along an uncompensated (the more typical) demand curve, real income varies with changes in the price of $x$. If purchases of $x$ represent only a small portion of the consumer's budget, changes in the price of $x$ do not affect real income significantly. If instead purchases of $x$ represent a large portion of the consumer's income, real income effects are substantial and affect the value of the calculated price elasticity of demand, holding nominal income constant. One significant factor in determining the price elasticity of demand is the portion of the budget that is devoted to the good. The smaller the percentage of income spent on good $x$, the more inelastic the demand for the good, ceteris paribus. A doubling of the price of salt in affluent communities is unlikely to reduce consumption noticeably.

Related to this budget share effect is whether the good is normal or inferior. If the good is inferior, the real income effect of a price fall leads to a reduction in the amount of the good purchased. For most goods, this income effect is more than offset by a substitution effect, whereby the quantity of $x$ increases as it is substituted for related goods. The quantity response to a price change is lessened by the income effect, and hence price elasticity of demand is reduced as compared with normal goods.

The number of substitutes for good $x$ strongly affects the price elasticity of demand for good $x$. If $x$ has many close substitutes, consumers will shift to these substitutes when $x$'s price rises. The more narrowly a product group is defined, the higher the price elasticity. For example, the demand for fresh green peas is more elastic than the demand for fresh vegetables, which is more elastic than the demand for all vegetables (fresh, frozen, canned), which is more elastic than the demand for food. Similarly, the demand for a Toyota Prius is more elastic than demand for all Toyota automobiles; the demand for Toyotas is more sensitive to price than the demand for all motor vehicles. Even with goods for which there is no substitute (e.g., insulin for a diabetic), the real income effect of a price increase can lead to decreased consumption if prices become high enough. In lower income countries, it is not unusual for consumers to buy antibiotics one or two pills at a time because prices are high relative to money income.

A fourth factor affecting price elasticity of demand is the length of time under consideration. The longer the time period of adjustment, the more elasticity of demand is expected to be. When the price of gasoline rose in mid-2008, car owners did not immediately sell their low gasoline mileage cars for gasoline-electric hybrids or immediately sell their suburban homes to move close to public transportation. They did reduce the number of miles driven, however, but not in as great a proportion as the rise in the price of gasoline. Had prices remained high (and macroeconomic economic conditions not worsened

significantly), consumers would have adjusted over time perhaps by buying more fuel-efficient cars, considering telecommuting to work periodically, moving closer to work, or commuting with others. For these more substantial adjustments to be made, prices do have to remain high and consumers must anticipate that they will remain high. In the long run, demand is more price elastic than in the short run.

## Elasticity of Demand for an Input

Building on the work of both his classical and marginalist predecessors, Alfred Marshall (1920) considered the responsiveness of input demand to the change in the price of an input to the production process. In this he was considering joint production, where the input is one of several in the production of the output. The demand for an input is a derived demand, derived from the demand for the good that the input produces. Marshall concluded four conditions affected the elasticity of demand for the input: how essential the input was to the production of the final product, the elasticity of demand for the final product, the fraction of total cost accounted for by the input, and the elasticity of supply of cooperating inputs. The more essential the input, the lower the elasticity of demand for it. The lower the elasticity of demand for the product, the lower the price elasticity of demand for the input. The lower the fraction of total costs that the input represents, the lower the price elasticity of demand for the input. The more inelastic the supply of cooperating inputs, the lower will be the price elasticity of demand for the given input.

When contemplating an increase in the minimum wage, policy makers are concerned about the elasticity of demand for low-skill labor. If that elasticity is low, a rise in the wage will not decrease the quantity of labor demanded by much. The rising legal floor under the wage rate will not lead to a large increase in unemployment, given a relatively low elasticity of labor supply. If the demand for low-skill labor is very elastic, policy makers should be concerned about the potential impact of the rising legal wage on employment.

Labor economists are concerned about the impact on labor markets of the retirement of large numbers of baby boomers. If the demand for labor is elastic, the falling supply of labor will raise wages, but not dramatically. If the demand is wage inelastic, wages are likely to rise much more, ceteris paribus. The ease of substituting capital for labor partly determines the elasticity of demand for labor. If the supply of capital is elastic, the demand for labor will be more elastic as firms find that they can hire capital at relatively stable prices to replace the retiring boomers.

## Policy Implications

Elasticities of demand influence the quantitative impact of public policies, and hence applied and public policy microeconomists use them frequently. One important application involves the incidence of a tax. The incidence of a tax is the answer to the question, "Who pays the tax?" If the tax is levied on the seller, the equilibrium after-tax price of the product will rise and equilibrium quantity will fall. The net price to the producer must fall because the tax must be paid out of the new equilibrium price, unless price rises by the full amount of the tax. If the inverse demand for the good is $P = a - b \bullet Q$ and the inverse supply is $P = c + d \bullet Q$, the proportion of the tax paid by the consumer will equal to $b/(b + d)$. The coefficients $b$ and $d$ are the slopes of the demand and supply curves, respectively, and hence enter into the elasticities of demand and supply. Applying the definition of elasticity to these linear curves, we get the result that the proportion of the tax paid by the consumer equals $(-1) \bullet \left( \frac{1}{\varepsilon_d - \varepsilon_s} \right)$. If the demand elasticity is large, the proportion paid by the consumer is small. If the elasticity of supply is large, relative to the elasticity of demand, the consumer pays a larger proportion of the tax.

If the demand for the good is price inelastic, the effect of the tax will be higher price but not much reduction in the quantity consumed. If the purpose of the tax is to raise revenue, the tax on a good whose demand is price inelastic will be successful. Total tax collected is a function of the tax rate (either specific amount per unit of the good or ad valorem, a percentage of the good's price) times the quantity sold. If quantity does not decline much as a result of the tax, total tax collections are large. If the intent of the tax is to raise revenues, it should be levied on a good with price-inelastic demand. If demand is price elastic, equilibrium quantity will fall significantly as a result of the tax and higher price; tax revenues will be low. Policy makers seeking to discourage consumption of a particular good (e.g., cigarettes) can levy a heavy tax on the good. If demand is price inelastic, however, consumption will not fall dramatically. Some who propose hefty cigarette taxes to deter consumption argue that the real income effect of the tax increase will fall heavily upon young smokers, discouraging potential smokers before they become older income-earning addicted smokers. Older smokers, for whom the real income effect is less constraining because they have higher incomes, will continue smoking due to addiction, addiction that suggests that there are no close substitutes for cigarettes. Tax supporters argue that while the short-term effect of high cigarette taxes will be high tax revenues, in the longer run, such taxes will deter smoking.

Economists have used the elasticity concept to analyze perceived problems in many sectors of the economy,

including agriculture. They note that the demand for agricultural goods tends to be price inelastic. Large increases in agricultural productivity that increase supply lead to lower prices, and lower prices lead to lower farm revenues. The demand for agricultural goods is income inelastic in high-income countries. The demand for basic foodstuff therefore rises less than proportionately to income. As a result of both price and income inelasticity, prices of farm goods are likely to fall over time relative to the prices of nonfarm goods, ceteris paribus.

## Empirical Estimates

R. A. Lehfeldt (1914), in an early attempt to measure price elasticity of demand, examined the wheat market and found that defining the product was problematic due to the wide variation in quality. Lehfeldt impressively overcame problems of market definition and estimated the elasticity to be .6 (absolute value), but with many a caveat.

To estimate demand and demand elasticities, the empirical economist has to find relevant data. Many demand elasticity estimates focus on agricultural goods. The U.S. Department of Agriculture was established in 1862, with one of its functions being the collection and dissemination of data. There exists, therefore, a substantial data set and a policy-oriented market for studies on agricultural goods. Regulation of an industry also tends to generate publicly available data. Telecommunications and electricity were heavily regulated at national, state, and local levels from the 1930s through the 1980s and still face regulatory constraints. Both the available data and the debates over pricing schemes for regulated industries generated numerous demand and elasticity studies. For both industries, the impact of time-of-day pricing on peak load use involved elasticity considerations: If usage were highly sensitive to price, lower prices in off-peak hours could reduce peak-load capacity needs. Another public utility, water provision, is often studied for demand sensitivity to price. Government regulation generates data on liquor prices and sales, reflected in the numerous studies of elasticities of liquor demand. The same is true for cigarettes and for legal gambling. Studies of the income, price, and interest rate elasticities of demand for housing have appeared, related to the impact of this sector on the well-being of the poor, the economic condition of cities, and macroeconomic stability concerns. Mid-twentieth-century studies of transportation tended to focus on the income elasticity of demand for private versus public transportation. More recently, transportation studies have related to the need for energy conservation. The periodic "energy crises" from the 1970s to the present have stimulated price–quantity–elasticity studies of energy use, oil demand, gasoline use, and use of alternative fuels. Economists also tried to estimate price and income elasticities of demand for health insurance and health care. Many studies have sought to measure the elasticity of demand for labor, often in conjunction with predictions about the effect of a change in labor legislation. Of course, researchers have undertaken elasticity studies on many other goods and services, but availability of data and pertinence to public policy issues seem important in choice of study area.

When Marshall (1920) refined the definition of elasticity, access to computational tools limited its actual measurement. The advent and spread of high-speed computers, development of statistics software packages that eliminate tedious calculation, and the availability of electronic data sets facilitate greatly data collection and calculations. In recent years, the use of scanners by retail outlets to record price and sales has generated a potentially large data set. Although usually proprietary, such data are selectively available (e.g., in antitrust cases concerning mergers) and have been used, for example, to consider cross-elasticities of demand between alternative sources of office supplies.

As economists have noted, the concepts of price, income, and cross-elasticity are relatively simple and easy to understand. Measurement of actual elasticities quickly seems less simple. Problems occur in defining the product, in determining the appropriate time period, in determining the best functional form for the demand function, and in estimation procedures. Most daunting is that demand curves are constantly shifting, making it difficult to sort out movements along a demand curve from a shift in the demand. Nonetheless, elasticity estimates are essential to understanding economic change and to good policy making.

## Note

1. Keynes (1963) reports in a footnote that Mrs. Marshall told him that her husband had hit upon the notion of elasticity while on the roof in Palermo. His excited reaction may be pure legend.

# Costs of Production

## *Short Run and Long Run*

Laurence Miners
*Fairfield University*

When most people other than economists think of costs, they may logically think about their household budget and the cost of heating their home or the cost of sending a daughter or son to college. Economists, however, are more apt to talk about the *prices* of these items and consider how households allocate a finite income to meet family needs. When economists consider *costs,* they refer most often to the production decisions of firms—what and how much they decide to produce, how they produce it, and how much it costs. The usual free-market assumption of profit-maximizing behavior by firms is not necessary for this discussion. All firms, from small local nonprofits, such as community libraries, to large international corporations attempt to operate efficiently. That is, they strive to produce the most output at the lowest possible cost.

The purpose of this chapter is to consider the production decisions and associated costs that firms face. It should be clear at the outset that this discussion will be incomplete in that it will not consider the profitability of a firm or the particular market in which it operates. A firm may produce a safe, reliable product at minimum cost, using the best technology, but fail if there is insufficient demand for its product. Similarly, an inefficient, lumbering, pollution-generating company may make significant profits if it dominates its industry and has a loyal following of customers. This is not meant to be seen as an endorsement of any particular industry structure. Rather, it is to point out that the costs and production decisions that firms make address only part of the economic survival equation. One must also consider the demand for the firm's product and the market in which it operates. (The remaining chapters in this section, as well as many of those in Parts III and VI, address these critical issues.)

The discussion of costs in most introductory and intermediate microeconomic textbooks is theoretical in nature, and the presentation here will likewise be primarily theoretical. The first part of the chapter investigates the relationships among inputs, production, and costs of the firm. The second part of the chapter discusses the relationship between short-run and long-run costs. Following that, we consider empirical estimates of firm output and costs.

## Theory

### The Production Function

As Calvin Coolidge famously remarked, "The business of America is business." Firms come in all shapes and sizes—from small individually owned entrepreneurships to large multinational corporations. However, they all combine inputs to produce products, outputs, or goods and services. When speaking about the production process of a firm, these last expressions—products, outputs, and goods and services—can all be used interchangeably. Firms hire, rent, or purchase inputs to produce their products. Economists use production functions to investigate the way in which firms transform inputs into outputs. This relationship can be stated in general form, indicating that output is some function of inputs, or can be set up as a specific mathematical equation that can be empirically tested by collecting and analyzing data.

*Inputs*

Inputs, which are also referred to as factors of production, are broadly classified into three categories: land, labor, and capital. Land includes the property on which businesses are built, farm land, and usually the minerals and natural resources removed from the land itself. The workers employed by a firm are referred to as labor, and at least at the introductory level, these workers are assumed to be homogeneous. That is, Worker A is no different from Worker B, and workers are just as productive in their eighth hour of work as they were in their first. These simplifying assumptions allow the discussion to focus more clearly on the important relationships among inputs, outputs, and costs and do not alter the qualitative results of the model. Capital has special meaning for economists. First, capital is not money. Capital is the result of some previous production process and is typically a piece of durable equipment or machinery that a firm uses in its own production of goods and services. As examples, a shipping company may purchase trucks from a truck manufacturer; a university may purchase computers for its faculty and staff to use. It should be pointed out that the specific use of the equipment has an important bearing on how commodities are classified. If a homeowner purchases a truck to take her household refuse to the town dump, that truck is not considered capital; it is a consumer durable. Similarly, if you buy a computer so you can e-mail and send photos to your family and friends, it would not be considered a capital good. The piece of equipment must be used in the production of other goods and services, which are then sold, for it to be considered capital. The amount of money firms spend in producing or procuring capital is called investment spending or, simply, investment. People who work in financial markets often talk about their investments or the amount of capital they have invested in the (financial) market. Economists prefer to refer to these activities as *financial* investments and are consistent in their use of capital as a physical factor of production.

As another example of capital, human capital refers to the investments individuals make in themselves via education and training to become more productive workers. There is a strong analogy between physical and human capital. Both individuals and firms engage in investment spending to acquire and expand their stock of capital. Both types of capital deteriorate over time but can be renewed with additional investment expenditures. Entrepreneurial ability, a special type of human capital, is often considered a fourth factor of production. The entrepreneur assumes the risk in running a business and provides the innovation needed to effectively use the other factors of production.

Finally, firms also use a great deal of intermediate products when they produce goods and services. Intermediate products are themselves outputs of some previous production process and are then put to use in the production of some final good or service. A product is considered final when it is purchased and used by the end user or consumer. Intermediate goods get used up during the production process. For example, a construction company uses lumber when it builds a new home. The primary factors of production—land, labor, and capital—are typically not used up during the production process. To be sure, their economic lives are finite, and they deteriorate, get worn out, and depreciate, but they can be used repeatedly to produce output. Workers, machines, and the land can be used season after season, year after year, to produce products. Lumber and other intermediate products get used up during the production process. To produce additional homes, the construction company must get more lumber; it may not need to hire additional workers or purchase new capital equipment. One final word of caution is in order. Like the trucks and computers discussed previously, how the lumber is used ultimately determines how it is classified. If a homeowner purchases lumber to repair his garage, the lumber is considered a final good, not an intermediate product.

*Short- and Long-Run Output*

The production decisions that firms make can be divided into two distinct time periods: the short run and the long run. In the short run, some of the firm's inputs are fixed in quantity and cannot be changed. For most firms, labor is the factor of production that is most easily changed, and land and capital are less variable. The long run is often viewed as a planning horizon, and it is during this time that all production decisions can be modified. Firms get created and enter industries in the long run. Similarly, companies go out of business, liquidate all their assets, and exit from industries in the long run. There is no set length of time that separates the short from the long run; it depends on the nature of the firm and its production process. For a small corner convenience store, the long run may be months. For a large corporation, with many factories, it may be years. The discussion immediately below focuses on the short run; the long run will be considered subsequently.

*Marginal Analysis*

To explain the relationship between inputs and output, assume that the firm varies one input at a time and holds all its other inputs constant. All firms need to know how productive their inputs are. That is, they need to know how much an additional input will add to output (and revenue) and how much it will cost to hire (or purchase) that input. This so-called marginal analysis, or decision making at the margin, lies at the heart of all economic decisions. Firms, as well as consumers, are always dealing with finite budgets and asking themselves, "Is it worth it?" Economists use the phrase, *ceteris paribus,* or all other things unchanged, when discussing decisions made at the margin. It is convenient, therefore, to consider a short run with only one variable input.

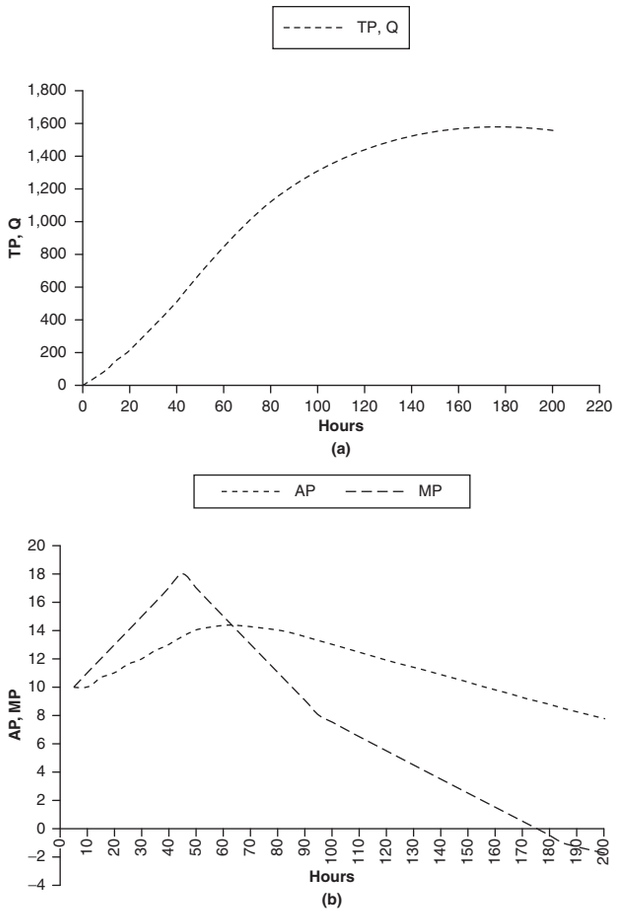

**Figure 10.1** Short-Run Output–One Variable Input: (a) Total Product; (b) Marginal and Average Product

Consider panel (a) in Figure 10.1. This diagram illustrates the firm's quantity of output ($Q$) or total product ($TP$) in the short run, with one variable input, labor. Labor is assumed to be homogeneous and is measured as the hours of labor that the firm uses with its other fixed factors of production. Note that for the most part, as the firm uses more hours of labor, output increases. At some point, however, remembering that this is the short run and other factors of production are held constant, output levels off and even decreases as the firm keeps adding more and more hours of labor. The workers simply run out of capital equipment and other factors that they can use effectively. In this diagram, this appears to happen after about 175 hours of labor.

More interesting is what happens as the firm first begins to use additional workers. Total product increases at an increasing rate. That is, the slope of the $TP$, $Q$ line gets steeper—up to a certain point. Consider a firm that removes baggage from an airplane. The firm uses some capital equipment such as the conveyor belt that is driven up to the side of the plane and the cart used to transport the luggage into the terminal. In the short run, if there is only one worker, the worker needs to get into the plane, place the luggage on the conveyor belt, and then meet it on the ground and place it on the cart. With two workers, one can stay in the plane and the other can stay on the ground. Two workers, working for 1 hour, do more than twice the work of one worker working for 2 hours alone. The marginal product, or contribution to output of the second worker, is greater than that of the first. Marginal product is measured as the change in total product divided by the change in variable input or, in this case, the change in bags removed over the change in hours of labor. Marginal product increases and the $TP$ line gets steeper, at least initially. Eventually, the marginal product has to get smaller. Remember, this is the short run, and the other factors of production are being held constant. Additions to the variable input, in this case labor, cannot keep getting more and more productive. Each additional worker has less of the fixed inputs to work with. This concept is so fundamental to the production process that economists refer to it as the law of diminishing returns or the law of diminishing marginal product. This is not a bad thing; it is both normal and natural. In panel (a) of Figure 10.1, it appears that diminishing returns set in after about 45 hours of labor. Additional hours of work still contribute positively to output. It is just that now, those marginal contributions are getting smaller, and the slope of the $TP$, $Q$ line gets flatter.

### *Marginal and Average Product*

Panel (b) in Figure 10.1 illustrates the marginal and average product curves that are associated with the total product curve in panel (a). Here, it is much easier to see where the law of diminishing returns becomes effective. Marginal product peaks at 45 hours of labor and then starts decreasing. Total product is steepest at this point and this coincides with the peak of marginal product. It is here that diminishing returns set in. As labor hours continue to increase, the marginal product of labor remains positive until about 175 hours of labor. Throughout, marginal product measures *changes* in total product as labor is increased (or decreased) by small amounts. This is precisely what the slope of the total product curve measures as well. The marginal product curve is a plot of the slopes of total product. After 175 hours of labor, total product begins to decline; the slope of the total product curve and marginal product itself become negative at that point.

Measuring average product is fairly straightforward. Like any average, it is calculated by adding up the total number of units, in this case the number of bags removed from the plane, and dividing by the number of hours (of labor). Of special interest is the relationship between average and marginal product. Note that when average product is increasing, the marginal product lies above it (although the margin itself may be decreasing). When the average is

falling, the margin lies beneath it. And when the average is flat (in the vicinity of its peak), the margin crosses the average and is equal to it.

This relationship between marginal and average is not unique to the product curves. As we will see, this relationship carries over to the cost curves and, for that matter, any other data set for which averages and marginals can be calculated. Think of the class average on an exam. If a new student takes the exam (this would be the change or marginal) and scores higher than the average, the average will be pulled up, though not all the way up to the marginal grade. Similarly, if a new student scores lower than the class average, this will bring the average down. Finally, if a new student scores exactly at the class average, the average will remain unchanged.

*Short-Run Costs*

A firm's costs are directly related to its ability to produce goods and services. Consider Figure 10.2, panel (a). In the short run, a firm's total costs are separated into fixed and variable costs. Fixed costs are associated with inputs and other items that are held constant and do not vary with output. Examples of fixed costs include the lease or rental fee a firm may pay for the use of capital equipment and the mortgage it owes on property that it owns. The key point is that these costs do not vary with the firm's level of output and must be paid even if the firm produces nothing. Hence, the total fixed cost curve is drawn as a horizontal line. Whether the firm removes 1,500 pieces of luggage from the plane or shuts down and produces nothing, these costs remain fixed—in this case, at about $1,200.

Fixed costs are an important part of determining the profitability of a firm and cannot be ignored, but they are less helpful in determining exactly how much output the firm should produce. For this, marginal cost is much more useful. Just as marginal product measures the incremental changes in output when, ceteris paribus, the utilization of a single input is changed, marginal cost calculates the additional cost associated with producing a little more (or less) output. Like marginal product, marginal cost is the same thing as the slope of its associated total and is based on the following equation: $MC = \Delta TC/\Delta Q$. Because the firm is operating in the short run, we can assume that labor is the firm's only variable input. If the wage rate ($w$) that the firm pays is fixed, or if the firm's effect on the wage rate is negligible, as would be the case if the firm were one of many firms hiring workers, the numerator of the marginal cost equation can be written as $\Delta TC = w(\Delta L)$. That is, in the short run, the firm's costs change as it uses more, or less, of the variable input, labor. Hence, the marginal cost equation can be rewritten as $MC = w\ (\Delta L)/\Delta Q$. The latter part of this equation, $\Delta L/\Delta Q$, is the inverse, or reciprocal, of marginal product. Therefore, $MC = w/MP$. Now the relationship between marginal cost and marginal product is very clear. When marginal product increases, marginal cost decreases and vice versa. It is logical that if the marginal product of an input is increasing—each additional hour of labor is adding more and more to output—the marginal cost of producing additional units of output must be falling.

Look at panel (b) in Figure 10.2. Recall that the marginal product curve looks like a hill; marginal cost looks like a "U." The two curves are mirror images of each other. Note, too, the relationship between marginal cost and both average variable and average total costs. When the margin is less than or below the average, it pulls the average down. When the averages are increasing, the margin must lie above them and pulls them up. Because fixed costs do not vary with output, the concept of a marginal or change does not apply to its shape. Like any average, average fixed cost (*AFC*) equals total fixed cost (*TFC*) divided by a number—in this case, the number of units of output. Or, $AFC = TFC/Q$. Because the numerator is a constant, as *TFC* gets divided by larger and larger units of output, average fixed costs becomes smaller and smaller.

Just as the sum of variable costs and fixed costs equals total cost, average fixed costs plus average variable costs equal average total costs. These equations are written as $TC = TVC + TFC$ and $ATC = AVC + AFC$. This last equation can be rewritten as $TC/Q = TVC/Q + TFC/Q$.

## The Shut-Down Decision

All firms, regardless of their size or the market in which they operate, need to decide how much product to produce. If the demand for a firm's output is weak, and costs exceed revenues, it may eventually decide to liquidate its assets and go out of business. This process takes time, and *exiting* from the industry occurs in the long run. Indeed, the length of time it takes a firm to act on this decision helps define just how long the long run is for firms in a particular industry. In the short run, exiting, by definition, is not an option. The firm can, however, decide to *shut down.* The firm is still very much a part of the industry. It has simply decided, for a short period of time, to produce nothing. During this period of time, the firm can send the workers home and reduce the utilization of any other variable inputs to zero. However, this firm must still pay its fixed costs—the mortgage, interest on loans, and so on. In this unpleasant situation, the firm is no longer deciding how best to maximize revenues or profits but how to minimize losses. The question the firm faces is, "Should it produce and lose money, or shut down and have to cover fixed costs completely out of pocket?" It should be clear that regardless of its decision, the firm has to pay its fixed costs. What the firm needs to determine is the following: If it produces output, will it bring in enough revenue to cover its variable costs? If it does, it can pay the workers (and any other variable inputs) and use any remaining

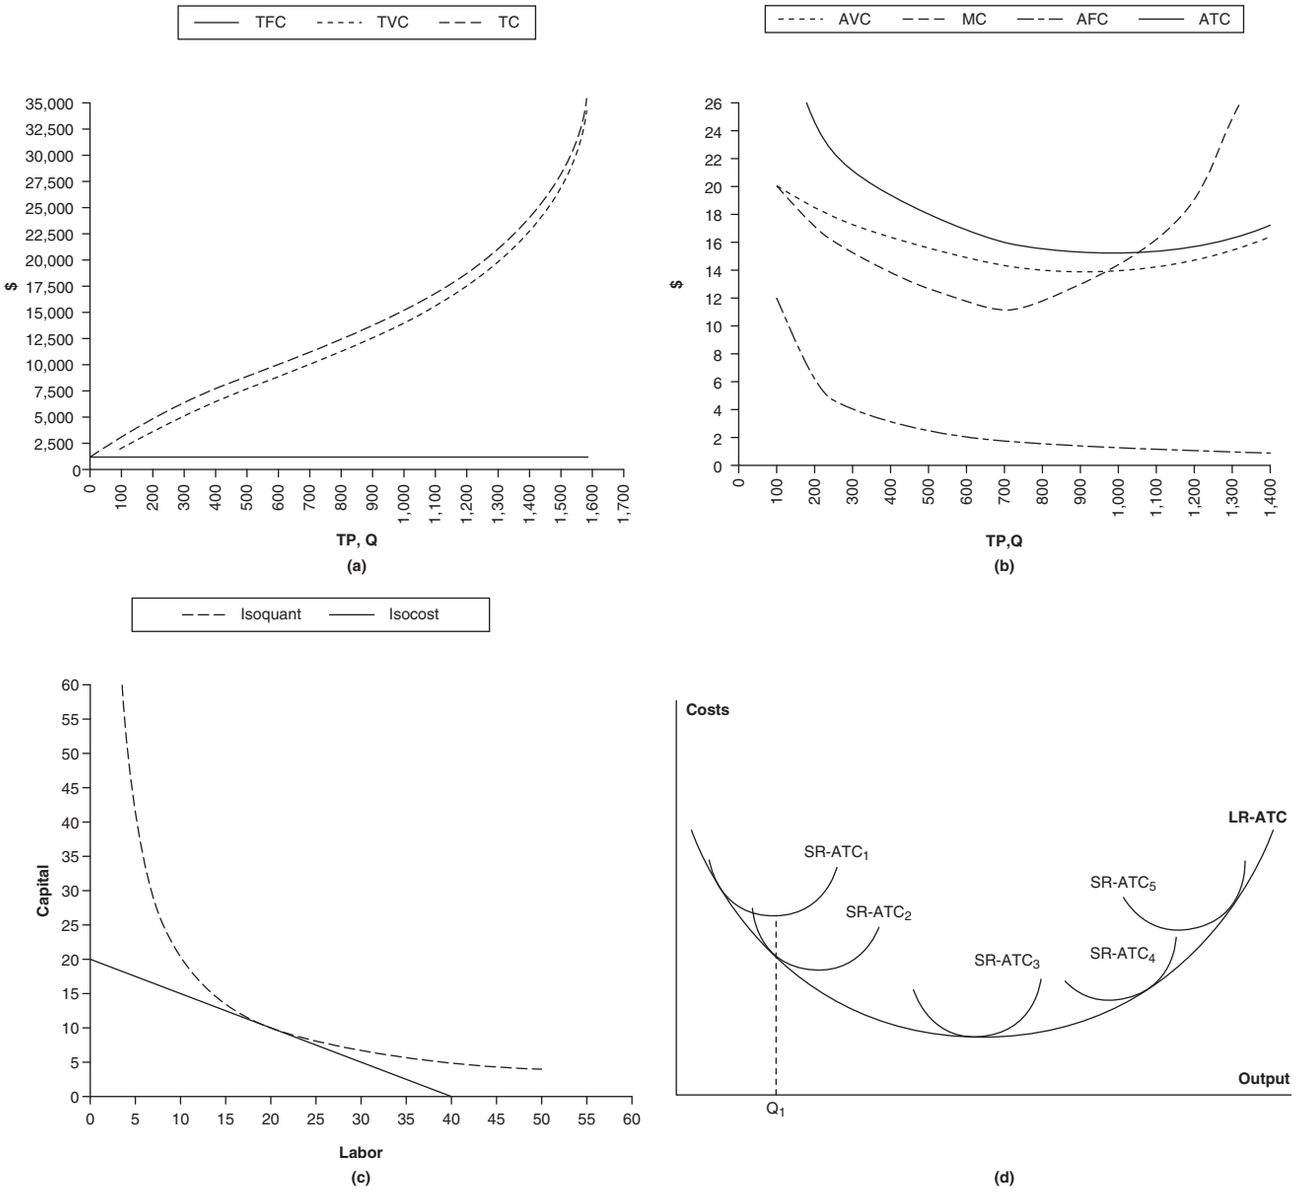

**Figure 10.2** Cost Curves: (a) Total Cost Curves; (b) Marginal and Average Costs; (c) Costs and Output With Two Variable Inputs; (d) Long-Run Average Costs

revenue to defray at least part of fixed costs. Even though the firm will be losing money, this is seen as preferable to shutting down and having to cover all of fixed costs. On the other hand, if the revenues received are not even sufficient to cover the variable costs, why incur them? Send the workers home and just worry about the fixed costs. The short-run shut down point can be seen in panel (b) of Figure 10.2. Once market price falls beneath the minimum of *ATC,* about $15.00, the firm will not bring in enough revenue to cover all of its costs. However, as long as the price remains above the minimum of average variable cost (*AVC*), about $14.00, the firm will be bringing more than enough revenue to pay all of the variable costs, so it will stay open and produce, even though it is losing money. Once the market price falls beneath the minimum of *AVC*, the firm can no longer cover its variable costs and shuts down. Based on this analysis, the short-run supply curve for firms in competitive markets is given as that portion of the marginal cost (*MC*) curve that lies above *AVC* (for a more detailed analysis of this point, see Chapter 11 [this volume]).

While the discussion up to this point has been theoretical in nature, one real-world consideration needs to be

mentioned. Firms generally are reticent to let workers go. Workers who are laid off may find work elsewhere, and when the market improves, the firm will incur the costs of searching for and training new employees. To be sure, firms do lay workers off when their market deteriorates, but the decision is never an easy one.

*Implicit and Explicit Costs*

Until this point, the discussion has focused on actual or explicit expenses that firms incur. Economists, however, are also very concerned about the less indirect or implicit costs that firms face. Implicit costs are associated with any resources that the firm owns and measure the cost of forgone opportunities when resources are used one way instead of another. Implicit costs are associated with capital equipment, retained earnings that the firm has, and the entrepreneurs' allocation of their own time. For example, if a clothing manufacturer owns sewing machines, it may need to decide if this capital equipment should be used to sew shirts or pants. If the firm chooses shirts and makes a profit doing so, it may think it is doing very well. However, the firm should also consider if it could make even *more* profit by sewing pants. *Accounting* profit considers only the difference between the revenues that a firm receives and its explicit costs. Before calculating *economic* profit, implicit or opportunity costs need to be added to the explicit costs. The implicit cost of using sewing machines to make shirts is the profit given up by not choosing the next best alternative, in this case sewing pants. These implicit or opportunity costs become important when the firm makes the "wrong" allocation (i.e., when it could have made more profit doing something else). When implicit costs are taken into consideration, accounting profits often turn into economic losses.

There are implicit costs associated with the firm's use of retained earnings or profits. It may seem logical to use funds to purchase additional capital equipment, but the firm needs to consider how else those funds could be used. Similarly, if an individual decides to use her time to start a consulting business, she may be very pleased if, at the end of a year, she has covered all her expenses and made a tidy profit. However, this individual needs to also consider what else she could have accomplished with that year of work. Perhaps she could have earned much more working for someone else. This is not to suggest that making the most money lies at the heart of all economic allocation decisions. But it certainly emphasizes that considering the alternative uses of resources and measuring the value of forgone opportunities are critical to making correct production and allocation of resources decisions.

*Social and Private Costs*

One final cost consideration that needs to be discussed before moving to the long run is the distinction between private and social costs. Social costs include the private costs that a firm incurs plus any external costs that the firm imposes on the rest of society but typically does not pay for. If a firm dumps its dirty water into a river, it may inadvertently kill some the fish. Downstream fishermen may now have to work longer and harder to catch fresh fish. Economists as well as environmentalists have long argued that firms should be accountable for all the costs associated with their production decisions. Forcing firms to take external costs into consideration increases their marginal cost. As a result, firms usually produce less and attempt to increase the price of their product. Pollution and other negative externalities have become an important area of economic analysis (refer to Chapter 22 [this volume]).

## The Long Run

In the long run, everything is variable. There are no fixed inputs, and there are no fixed costs. Decisions to enter or exit from an industry are acted on in the long run. Keep in the mind that the long run is defined as that period in which everything that the firm does can be changed. There is no specific amount of time that separates the long run from the short run; it is an industry- or even firm-specific period of time.

*Two Variable Inputs*

Conceptually, the biggest change to understand is what happens when the firm moves from one to two variable inputs. Most textbooks present the two-variable input case and then make the logical argument that proceeding to three or more variables is straightforward. The expansion of inputs to three or more is relatively easy mathematically, but output and cost diagrams become untenable when attempting to move beyond a three-dimensional diagram.

Consider the case where a firm has two variable inputs, capital and labor. Assume that the firm has determined the optimal level of output to produce, based on the demand for its product, and now needs to determine the least-cost way of producing that level of output. The input combinations and cost options that the firm faces are illustrated in Figure 10.2, panel (c). The Greek prefix *iso* means equal or same, and the isoquant curve illustrates all the combinations of capital ($K$) and labor ($L$) that produce the same quantity of output. The isocost line shows all the combinations of $K$ and $L$ that the firm could purchase or hire and spend the same amount of money.

The shape of the isoquant suggests that the firm could produce a given amount of output using a great deal of $K$ and a little $L$ or vice versa. Note that the trade-off of $K$ for $L$ is not constant, and therefore the slope of the isoquant is nonlinear. The isoquant also seems to get closer and closer to the axes but never quite touches it. Economically, this is very attractive as it suggests that the firm needs at least a small amount of each input to produce output. Machines need someone to run them, and workers require capital equipment to do work. The shape of this isoquant is based

on a famous production function called the Cobb-Douglas production function, which is discussed further in the empirical section of this chapter. In its most basic form, the Cobb-Douglas production function suggests that the output of a firm can be estimated by multiplying together the utilization of its inputs. Assume that this firm is interested in producing 200 units of output. All the *K–L* coordinates along the isoquant multiply to 200. For example, consider the following combinations of inputs: 20*K* and 10*L,* 10*K* and 20*L,* and 5*K* and 40*L.* Indeed, all the capital–labor points along this isoquant multiply to 200.

The least-cost way of producing 200 units of output will be determined by the cost of the inputs. The isocost line in the diagram illustrates all the combinations of *K* and *L* that the firm could acquire for a fixed budget, say $600. (The number 600 is chosen for illustrative purposes and yields cost-of-input prices that are intuitively appealing, but nearly any budget number could be used.) If the firm allocated all of its budget to labor, it could hire 40 labor hours or work. Hence, the hourly wage rate (*w*) is $15. Similarly, if the firm spent its entire budget on capital, it could use 20 hours of machine time. This implies that the rental rate (*r*) for capital equipment is $30 per hour. It should be noted that even if the firm owns its own capital equipment, the rental rate still applies because there is an implicit cost of using the machines for one production process as opposed to another.

This analysis assumes the firm takes the wage rate and price of capital as given and, as stated earlier, that both labor and capital are homogeneous. The slope of the isocost line is the negative of the two input price ratios, or the price of labor over the price of capital. That is, the slope equals $-w/r$, in this case −15/30, or −0.5. An understanding of the isocost line helps one understand why different firms use different combinations of inputs, even when they have the same technology and face the same production possibilities. As the wage rate falls, the isocost line becomes flatter, and the firm substitutes labor for capital. It may appear that some firms overuse labor relative to capital when in fact those firms may simply be located in areas with relatively low wage rates.

### *Economies of Scale*

Economies of scale measure how a firm's output changes when it is able to change its entire scale of operations. By definition, the discussion as well as estimates of returns to scale can take place only in the long run because the firm must be able to vary all of its inputs. There are three scale effects to consider: increasing, decreasing, and constant returns to scale.

Increasing returns to scale (RTS) means that as a firm increases the utilization of its inputs, output naturally increases but at an even faster rate. For example, if a firm doubles the utilization of its inputs, output more than doubles. Adam Smith (1776/2008) was probably the first to write about increasing RTS. In his famous example of a pin factory, Smith describes how workers specializing in the various steps of manufacturing can greatly increase the output of the firm. In addition to labor specialization, firms can also benefit by using larger, more efficient capital equipment. For many industries, this means that to produce at lower per unit cost, the scale of operation must be very large. Companies may also realize increasing RTS by receiving bulk-order discounts on the purchase of large amounts of inputs. Incorporating new technologies that become cost-effective with large-scale operations can be another source of increasing RTS. Henry Ford's development of assembly line techniques in the automobile industry dramatically lowered the per unit cost, and thereby the price, of cars.

Eventually, however, the firm may become too large to manage effectively. The scale of operations may become too complex, and communication may break down as the chain of command becomes longer and longer. Furthermore, workers may feel more and more alienated from management and the decision-making process. When this occurs, the firm experiences decreasing RTS. In this range of output, an increase in the utilization of the inputs, say by 20%, increases output, but by some smaller amount.

Constant returns to scale indicate that proportionate increases in the utilization of inputs yield a commensurate increase in the level of output. That is, changing the level of inputs, either increasing or decreasing, by 50% results in a 50% change in the level of output. Studies of returns to scale, discussed below, generally indicate that as firms grow in size, they first experience increasing RTS, then constant RTS, and finally decreasing RTS.

### *Long-Run Average Cost*

The existence of economies of scale is the primary determinant of a firm's long-run average costs. The long-run average cost curve also provides an envelope or cradle on which the firm's short-run average cost curves sit. Recall that all firms operate and produce in the short run; the long run is a planning horizon. Each of the five short-run average total curves illustrated in Figure 10.2, panel (d) represents a different-size plant or factory that a firm may decide, in the long run, to build. The inclusion of five short-run average total cost curves is for illustrative purposes. In actuality, entrepreneurs have many more long-run options to choose from.

Suppose, for example, that a firm finds itself in the short run with a demand for its product equal to output level $Q_1$. If the firm has built a factory that is too small, it may find itself on the first short-run average total cost curve ($SR - ATC_1$) and experience higher than optimal average costs. It may decide that it could appreciably lower average costs in the long run by building a larger factory and moving to $SR - ATC_2$. Building an even larger factory would lower average total costs more, but unless the firm expects a further increase in the demand for its product, it would be unwise to do so.

Notice that as the firm expands, it realizes increasing returns to scale. This is illustrated by the declining slope of

the long-run average total cost curve. Over a substantial range of output, the long-run average total cost curve is horizontal, or nearly so. This suggests that the firm's increased utilization of inputs is matched by equivalent increases in output, and therefore its (long-run) average costs are constant. This corresponds to constant returns to scale. Eventually, as the firm increases in size, it becomes too large to manage efficiently, and decreasing returns to scale or diseconomies of scale set in.

## Applications and Empirical Evidence

### Production Functions

One of the most widely tested production functions is the Cobb-Douglas (Cobb & Douglas, 1928) production function. Several factors account for Cobb-Douglas's longevity. It is relatively easy to collect the data necessary to estimate the production function. The estimation procedure itself is relatively straightforward. The economic characteristics of the production function match up reasonably well with the theoretical model of production. And perhaps most important, the empirical estimates obtained from the model have done a reasonably good job of explaining real-world production behavior.

In the two input case, the Cobb-Douglas production function can be written as $Q = A\,K^{\alpha}L^{\beta}$ where $Q$ is output, $K$ and $L$ are the capital and labor inputs, and $A$, $\alpha$, and $\beta$ are the parameters that are estimated. If there are more than two inputs, they simply get multiplied on to the equation in similar format. The summation of the estimated exponents on the inputs, in this case $\alpha + \beta$, yields an estimate of returns to scale for the industry being studied. If the sum is greater than 1, it suggests the industry is experiencing increasing returns to scale. Sums of less than 1 imply decreasing returns to scale. And if the sum of the exponents is equal to 1, the industry has constant returns scale. Furthermore, as long as each individual exponent is less than 1, the marginal product of each associated input will be declining and thereby in sync with the law of diminishing (marginal) returns.

Mansfield (1997) summarizes the Cobb-Douglas estimation results from six different studies, on 18 different industries, in five different countries. The industries studied varied widely and included examples from agriculture, manufacturing, and transportation. An examination of the estimated exponents suggests that 9 of the industries were experiencing increasing returns to scale, 6 were in the constant returns to scale range, and 3 had decreasing returns to scale. Overall, the summed exponents did not vary widely and ranged from 0.87 to 1.29. Each of the 38 estimated exponents was less than 1, supporting the law of diminishing returns. Using the estimated coefficients from the French gas industry, Mansfield was able to construct isoquants that looked very similar to those described in the theoretical model.

As appealing as these results are, the Cobb-Douglas model does have some shortcomings. Because the production function is multiplicative, it assumes that every input is used continuously. If a single input is not used, Cobb-Douglas suggests that output falls to zero. Despite the nicely shaped isoquants, the Cobb-Douglas production function does not yield the smooth bell-shaped marginal and average product curves described earlier.

These and other shortcomings have led economists to develop more realistic and hence more complicated production function specifications. One other type of production function, of which Cobb-Douglas is a special case, is the constant elasticity of substitution (CES) production function. The interested reader is referred to a classic article by Arrow, Chenery, Minhas, and Solow (1961) to study this case.

### Cost Curves

Economists have had a difficult time obtaining accurate cost data. In the first place, accounting data never include the implicit costs that are so important in economic decision making. Second, firm and industry data, when they are available, are collected on a fiscal year basis. Rarely does this coincide with either the short- or long-run time periods of economic analysis. Third, inputs are often used in different ways to produce different products. This makes it difficult to assign costs specifically to the production of any one good or service.

Nevertheless, costs, like production functions, have been studied widely. The results (Mansfield, 1997), while even more widely dispersed than production function estimates, are very interesting. Studies of long-run average cost, across a wide range of industries, over a long period of time, show little evidence of decreasing returns to scale. Rather than suggesting that decreasing returns rarely occur, it is more likely that when they become evident, entrepreneurs act quickly to eliminate them by reducing the scale of operations and perhaps creating separate companies.

Several studies, across a wide range of industries, indicate that long-run average costs may be "L"-shaped but with the horizontal portion of the L extended out to the right. That is, the industry first experiences increasing returns to scale, and then as it grows enjoys constant long-run average costs (and constant returns to scale) over a wide range of output.

A fewer number of studies suggest that increasing returns to scale are evident. This implies that the long-run average cost curve is negatively sloped. If an industry is experiencing increasing returns to scale, there is a strong incentive (as long as there is sufficient demand for the product) to increase the scale of operations because revenues are increasing and average costs are falling. Assuming demand is strong, economic theory suggests that industries will expand through the range of output in which they experience increasing returns. This is not because this is an undesirable position to be in. It is exactly the opposite: If there are increasing returns to scale, there is an incentive to grow bigger and benefit from even more increasing returns.

Clearly, the area of cost estimation is one where more careful work by economists is needed. Replicating studies with new sources of data can be a way to lend greater support (or doubt) to earlier work. The development of new economic software models and estimation procedures will help in this analysis.

## Conclusion

Whether a firm is in business to make profits or promote the common good, the importance of carefully analyzing cost and production decisions cannot be overstated. Without a firm handle on the way inputs can be combined to produce products and the cost of acquiring those inputs, a firm will surely fail.

It is hoped that this discussion, while being primarily theoretical, helps clarify some very real-world concerns. For example, the conceptual distinction between the short and long run helps to clarify the difference between shutting down a firm and exiting from the industry. Holding some inputs constant may not seem entirely logical but drives home the importance of determining just how productive individual inputs are.

Economic models are often evaluated on two fronts—how well they explain concepts and how well they predict. This analysis has focused primarily on explaining how firms make decisions. While more work needs to be done on acquiring reliable data, the correlation between theoretical explanation and reality seems strong.

# Profit Maximization

Michael E. Bradley
*University of Maryland, Baltimore County*

Mainstream microeconomics generally assumes that firms seek to maximize economic profit, the difference between total revenue and total economic costs. This, like many others in economics, is an unrealistically simple picture of the way that firms actually make decisions. Economists make many such unrealistic assumptions that abstract from and simplify the "real world" to explain economic phenomena and generate empirically testable predictions.

Assuming that firms act rationally to maximize profit is critical for analyzing and explaining the firm's choices of outputs of goods and factor inputs. The theory of production and cost collapses without assuming profit maximization or some other maximizing assumption. For example, a production function determines a single output from each bundle of factor inputs, but technology and resource quality define only the maximum output that can be produced with a given bundle of inputs, and there is nothing to prevent firms from producing less than the maximum output. If we assume that the firm seeks to maximize profit, it follows that it will produce only the maximum output from any given bundle of inputs or that it will use the combination of inputs that produces a given output at the lowest cost.

## Profit Maximization: The General Case

### Assumptions

Because profit is the difference between the revenue and cost generated by factor inputs and outputs, the profit-maximizing model assumes given production, revenue, and cost functions. These, in turn, are defined only for given resource quality, technology, product prices, and factor prices.

In addition to the assumptions that define production and cost functions, the simple profit-maximizing model assumes that individual firms have no effect on price (perfect competition), that there is a predictable relationship between output and price (monopoly), or that the rival firms in imperfectly competitive markets react predictably to each other's actions in the market. It also generally ignores or assumes away risk and uncertainty, or at least that the firm's economic expectations are unchanged.

### Revenue, Cost, and Profit

In its simplest form, the problem for the firm is to maximize profit ($\pi$), which is the difference between total revenue ($TR$) and total economic or opportunity cost ($TC$)—that is, to maximize

$$\pi = TR - TC. \tag{1}$$

The mathematical conditions for maximum profit apply to all profit-maximizing firms' choices in product and factor markets.

### Profit and Output

The profit-maximizing firm will choose the output ($q$) that maximizes

$$\pi(q) = TR(q) - TC(q), \tag{2}$$

where $\pi(q)$, $TR(q)$, and $TC(q)$ are profit, revenue, and cost functions, respectively. Total revenue is simply the price of the product ($P$) multiplied by output ($q$), or

$$TR(q) = Pq. \tag{3}$$

Output decisions are made in the short run, in which at least one of its factor inputs is fixed and does not vary with

output. The firm's short-run total cost is the sum of its fixed and variable cost, or

$$TC(q) = FC + VC\,(q) \tag{4}$$

where $TC(q)$ is the short-run total cost function, $VC(q)$ is the variable cost function, and $FC$ is fixed cost that does not vary with output. Substituting (4) and (3) into (2), the profit function becomes

$$\pi\,(q) = TR(q) - TC(q) = Pq - [FC + VC\,(q)]. \tag{5}$$

## Marginal Profit

Solving (5) for the output that maximizes profit is straightforward, *if* the firm has complete information—the price at which it can sell its output, its production function, and factor prices. However, firms seldom if ever have all of the information to find their profit-maximizing outputs by solving a profit equation. Economists in the "Austrian" tradition do not view profit maximization as solving an equation based on known information, but entrepreneurial "groping," or looking for ways to increase profit in a world of incomplete and diffused information.

Firms arrive at their maximum profit by trial and error, making small changes in output (and price if they can affect the price at which they sell) as long as these changes cause profits to rise. In economic terms, they will maximize profit at the margin where the last change in output causes no change in profit. If the firm changes its output by some small $\Delta q$, profit will change by

$$\Delta\pi(q) = \Delta TR(q) - \Delta TC(q). \tag{6}$$

If $\Delta TR(q) > \Delta TC(q)$, $\Delta\pi(q) > 0$, the firm will increase profit by increasing output. If $\Delta TR(q) < \Delta TC(q)$, $\Delta\pi(q) < 0$, the firm will increase profit by reducing output. If $\Delta TR(q) = \Delta TC(q)$ and $\Delta\pi(q) = 0$, profit is stationary—either a maximum or minimum value.

The firm's marginal profit is the rate at which profit changes with output, or the change in profit per unit of change in output. Dividing (6) through by $\Delta q$, marginal profit is

$$\frac{\Delta\pi(q)}{\Delta q} = \frac{\Delta TR(q)}{\Delta q} - \frac{\Delta TC(q)}{\Delta q} = MR(q) - MC(q), \tag{7}$$

where $MR(q)$ is the marginal revenue and $MC(q)$ is the marginal cost of the last change in output.

## Choice of Output

Although the firm does not have all of the information assumed in the production, cost, and profit functions, it will continue to make trial-and-error adjustments of output until profit stops rising at a stationary value with

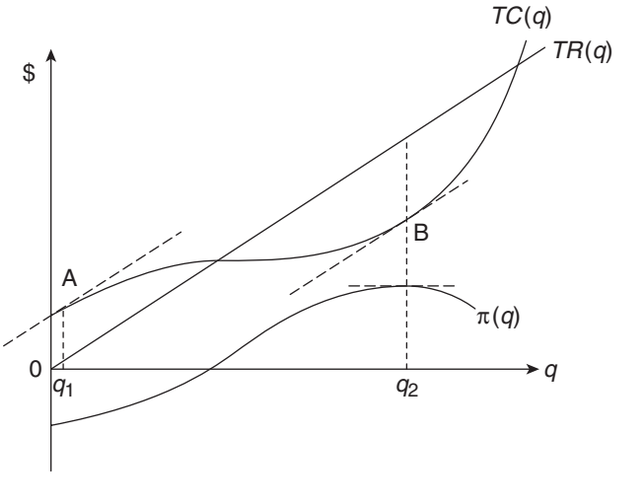

**Figure 11.1** Minimum and Maximum Profit

$$\frac{\Delta\pi(q)}{\Delta q} = MR(q) - MC(q) = 0, \text{ or} \tag{8a}$$

$$MR(q) = MC(q). \tag{8b}$$

This is the necessary condition for maximizing profit. However, it is also the necessary condition for minimizing profit.

For example, in Figure 11.1, $MR(q) = MC(q)$, and marginal profit is zero at $q_1$ and $q_2$. At $q < q_1$, $\Delta\pi(q)/\Delta q < 0$, and at $q > q_1$, $\Delta\pi(q)/\Delta q > 0$, which means that moving away from $q_1$ increases profit, and profit is at a local minimum. The opposite is true at $q_2$. At $q < q_2$, $\Delta\pi(q)/\Delta q > 0$, and at $q > q_2$, $\Delta\pi(q)/\Delta q < 0$, which means that moving away from $q_2$ will cause profit to fall, and profit is at a local maximum.

A firm is maximizing profit if it satisfies the necessary condition,

$$\frac{\Delta\pi(q)}{\Delta q} = 0, \text{ or } MR(q) = MC(q), \tag{9}$$

and the sufficient condition,

$$MR(q) > MC(q) \text{ and } \frac{\Delta\pi(q)}{\Delta q} > 0 \tag{10a}$$

for smaller outputs, and

$$MR(q) < MC(q) \text{ and } \frac{\Delta\pi(q)}{\Delta q} < 0 \tag{10b}$$

for larger outputs.

The sufficient condition for maximum profit is satisfied if the slope of $MR(q)$ is less than the slope of $MC(q)$—that is, if

$$\frac{\Delta MR(q)}{\Delta q} < \frac{\Delta MC(q)}{\Delta q}, \tag{11}$$

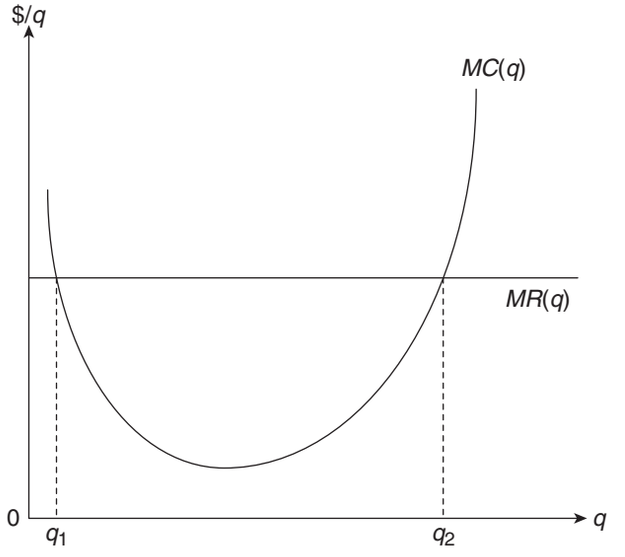

**Figure 11.2** Marginal Cost, Marginal Revenue, and Minimum and Maximum Profit

and $MC(q)$ cuts $MR(q)$ "from below."

In Figure 11.2, for example, $MR(q)$ is constant, and $MR(q) = MC(q)$ at $q_1$ and $q_2$. At $q_1$, $\Delta MR(q)/\Delta q = 0 > \Delta MC(q)/\Delta q < 0$, and profit is at a local minimum. At $q_2$, $\Delta MR(q)/\Delta q = 0 < \Delta MC(q)/\Delta q > 0$, which satisfies the sufficient condition for maximum profit.

## Shutting Down

The firm's profit-maximizing (or loss-minimizing) choice may be to "shut down" and produce zero output. A profit-maximizing firm will produce its profit-maximizing output $\overline{q} > 0$ only if

$$\pi(\overline{q}) \geq \pi(0). \tag{12}$$

If $\pi(\overline{q}) = \pi(0)$, the firm would do no better by producing than shutting down, and it would be at its shutdown point. If $\pi(\overline{q}) < \pi(0)$, the firm would do better by shutting down and producing $q = 0$. This would be the case if the firm's total revenue from producing, $TR(\overline{q})$, is less than the *variable cost* of producing $\overline{q}$. In the long run, with all factor inputs variable, all long-run cost, $LRTC(q)$, is variable, $\pi(0) = 0$, and the firm will shut down in the long run if $TR(\overline{q}) < LRTC(\overline{q})$ and $\pi(\overline{q}) < 0$.

In the short run, the firm incurs the costs of its fixed factor inputs ($FC$), even if the firm does not produce, so short-run profit at zero output is

$$\begin{aligned} \pi(0) &= TR(0) - TC(0) = \\ TR(0) &- VC(0) - FC = -FC \end{aligned} \tag{13}$$

because $TR(0) = VC(0) = 0$. The firm will produce its profit-maximizing output $\overline{q} > 0$ in the short run if $\pi(\overline{q}) \geq \pi(0) = -FC$.

The firm is at its short-run shutdown point if $\pi(\overline{q}) = \pi(0) = -FC$. At this point,

$$\pi(\overline{q}) = TR(\overline{q}) - [FC + VC(\overline{q})] = -FC \tag{14a}$$

$$\pi(\overline{q}) = TR(\overline{q}) - VC(\overline{q}) = 0 \tag{14b}$$

$$TR(\overline{q}) = VC(\overline{q}). \tag{14c}$$

Dividing (10a) through by $\overline{q}$, the firm is at its short-run shutdown point if

$$\frac{P\overline{q}}{\overline{q}} = \frac{VC(\overline{q})}{\overline{q}} \tag{14d}$$

$$P = AVC(\overline{q}). \tag{14e}$$

If the firm is exactly at the shutdown point, we do not know whether it would produce or shut down because there is no net benefit from producing. If $P > AVC(\overline{q})$ and $TR(\overline{q}) > VC(\overline{q})$, it will produce in the short run, even if its revenue does not cover all of its costs. If $P < AVC(\overline{q})$ and $TR(\overline{q}) < VC(\overline{q})$, the firm does better by shutting down and producing no output.

The only difference between the short-run and long-run shutdown points is the absence of fixed costs in the long run because all of the firm's inputs and costs are variable. In the long run, then, the firm is at the shutdown point if

$$\pi(\overline{q}) = TR(\overline{q}) - LRTC(\overline{q}) = 0 \tag{15a}$$

$$TR(\overline{q}) = LRTC(\overline{q}). \tag{15b}$$

Dividing (15a) through by $\overline{q}$, the firm is at its long-run shutdown point if

$$P = LRAC(\overline{q}). \tag{15c}$$

In short, to produce its profit-maximizing output in the long run, the firm's revenue must at least cover its long-run total costs, all of which are variable, or the price of its output must at least cover its long-run average cost. Again, the firm realizes no net benefit from producing at the shutdown point.

## Producer Surplus: Net Benefit From Producing

If a firm can realize more profit or incur a smaller loss by producing than by shutting and producing zero output, it will realize a net benefit from producing, or producer surplus. Because the firm would realize no net benefit from producing if $TR(q) = VC(q)$, we can define producer surplus as

$$PS(q) = TR(q) - VC(q) \tag{16a}$$

in the short run, and

$$PS(q) = TR(q) - LRTC(q) \tag{16b}$$

in the long run with all costs variable.

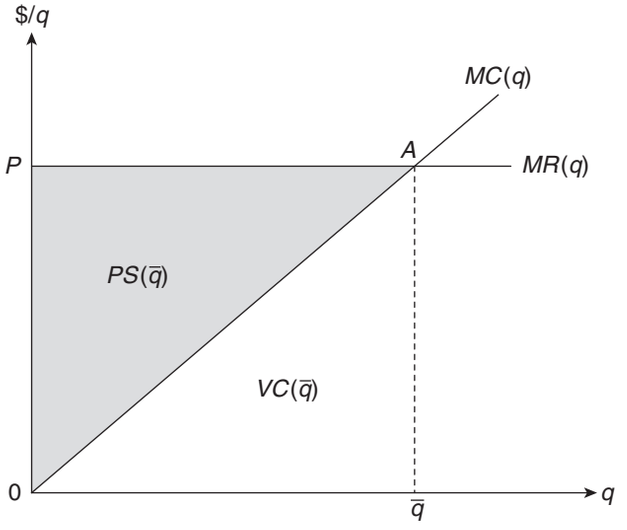

**Figure 11.3** Maximum Profit and Producer Surplus

Producer surplus is illustrated graphically in Figure 11.3. For simplicity, assume a linear marginal cost function, $MC(q)$. If the firm is a price taker and faces a constant price for its output, then price and marginal revenue are identical, $P \equiv MR(q)$ The firm maximizes profit at $\overline{q}$, where $P \equiv MR(\overline{q}) = MC(\overline{q})$ The firm's total revenue is $TR(\overline{q}) = P\overline{q} = AREA\ OPA\overline{q}$. Variable cost is the sum of the marginal cost of outputs between 0 and $\overline{q}$,

$$VC(q) = \sum_{q\ 0}^{\overline{q}} MC(q), \tag{17}$$

or the area under the marginal cost curve $0A\ \overline{q}$. Producer surplus is

$$\begin{gathered} PS(\overline{q}) = TR(\overline{q}) - VC(\overline{q}) = \\ AREA\ OPA\overline{q} - AREA\ OA\overline{q} = \\ AREA\ OPA. \end{gathered} \tag{18}$$

In the short run, the firm may realize producer surplus, even if it incurs an economic loss, as long as it covers its variable costs. However, in the long run, there is no distinction between producer surplus and profit because long-run costs are all variable—that is, in the long run,

$$PS(q) \equiv \pi(q) = TR(q) - LRTC(q). \tag{19}$$

A firm realizes a rent if it is more than compensated for producing rather than not producing. The firm in Figure 11.3, for example, earns no rent on the last, or marginal, unit produced. However, it does realize an intramarginal rent on the units up to the marginal unit because it receives a price and marginal revenue above the marginal cost of these units, and $TR(\overline{q}) > VC(\overline{q})$. Because variable cost just compensates the firm for producing rather than not producing, producer surplus is a form of intramarginal rent.

## Choice of Factor Inputs

If the firm produces its profit-maximizing output, obviously it must employ its profit-maximizing factor inputs. We can simplify our analysis by assuming that there are only two factors of production, labor ($n$) and capital ($k$). Combinations of factors will generate profit of

$$\pi(n,k) = TR(n,k) - TC(n,k), \tag{20}$$

assuming a production function $q = q(n,k)$ and a profit function of

$$\pi(n,k) = Pq(n,k) - TC(n,k). \tag{21}$$

With a variable labor input and fixed capital input in the short run,

$$\begin{gathered} \pi(n,k) = Pq(n,\hat{k}) - TC(n,\hat{k}) = \\ Pq(n,\hat{k}) - wn(q) - P_k\hat{k}, \end{gathered} \tag{22}$$

where $w$ is the wage per unit of labor and $P_k\hat{k}$ is the cost of the fixed input, or $FC$.

With capital fixed, we can express output as a function of the variable labor input alone because $\hat{k}$ is a parameter. This gives us the short-run profit function

$$\begin{gathered} \pi(n,k) = Pq(n) - wn(q) - P_k\hat{k} = \\ TR(n) - VC(n) - FC. \end{gathered} \tag{23}$$

The firm reaches its profit-maximizing input of labor by making trial-and-error adjustments as long as they cause profit to rise. Changing the variable input, $n$ in this case, affects profit by changing output and revenue and by changing cost. From (23), changing $n$ by some small $\Delta n$ changes profit by

$$\Delta\pi(n) = \Delta TR(n) - \Delta TC(n). \tag{24}$$

The marginal profit is the rate at which $\pi(n)$ changes with $n$, or the change in profit per unit of change in labor,

$$\begin{gathered} \frac{\Delta\pi(n)}{\Delta n} = \frac{\Delta TR(n)}{\Delta n} - \frac{\Delta TC(n)}{\Delta n} = \\ MRP(n) - MFC(n), \end{gathered} \tag{25a}$$

where

$$MRP(n) = \Delta TR(n)/\Delta n \tag{25b}$$

is the marginal revenue product of the variable factor input ($n$), and

$$MFC(n) = \Delta TC(n)/\Delta n \equiv \Delta VC(n)/\Delta n \tag{25c}$$

is the marginal factor cost of the variable input ($n$).

If $MRP(n) > MFC(n)$, profit varies directly with the labor input, and the firm would increase its profit by increasing its labor input. Conversely, if $MRP(n) < MFC(n)$, profit varies inversely with the labor input, and the firm would reduce its labor input to increase profit. The firm will stop changing inputs when profit stops rising. This occurs where the marginal profit from the last change is

$$\frac{\Delta\pi(n)}{\Delta n} = MRP(\overline{n}) - MFC(\overline{n}) = 0 \tag{26a}$$

$$MRP(\overline{n}) = MFC(\overline{n}), \tag{26b}$$

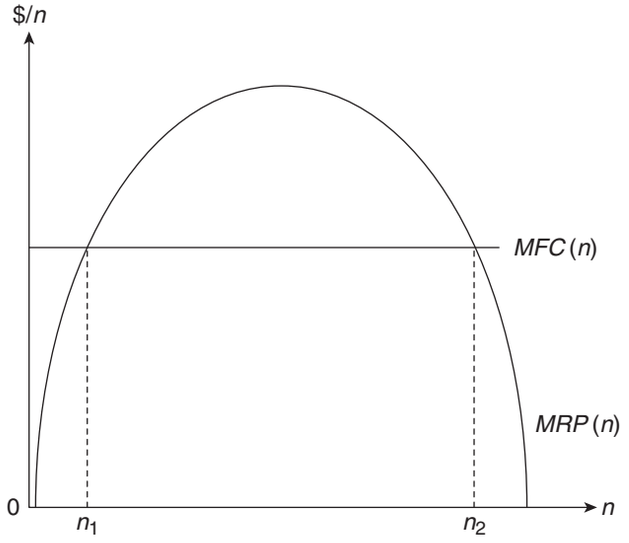

**Figure 11.4** Profit-Maximizing Labor Input

which is the necessary condition for a profit-maximizing labor input ($\bar{n}$). This is true at the minimum profit as well as the maximum, so we have to specify that $\pi(n)$ is at its maximum if $MRP(\bar{n}) = MFC(\bar{n})$, and $MRP(\bar{n}) > MFC(\bar{n})$ for smaller inputs and $MRP(\bar{n}) < MFC(\bar{n})$ for larger inputs.

In Figure 11.4, for example, $MFC(q)$ is constant, and $MRP(n) = MFC(n)$ at $n_1$ and $n_2$. Both of these inputs satisfy the necessary condition for a maximum (26a & b). However, the sufficient condition is satisfied only at $n_2$, which is the firm's profit-maximizing labor input. Profit is at its minimum value at $n_1$. Graphically, the necessary and sufficient conditions for maximum $\pi(n)$ are satisfied where $MRP(n) = MFC(n)$, and $MFC(n)$ "cuts $MRP(n)$ from below." At $n_1$, $MRP(n) = MFC(n)$, $MFC(n)$ "cuts $MRP(n)$ from above," and $\pi(n)$ is at a minimum.

## Profit-Maximizing Factor Inputs and Output

We can verify easily that if the firm is producing its profit-maximizing output where $MR(\bar{q}) = MC(\bar{q})$, it must employ its profit-maximizing factor inputs where $MFC(\bar{n}) = MRP(\bar{n})$. First rewrite the equations for $MRP(n)$ and $MC(q)$.

$$MRP(n) = \frac{\Delta TR(n)}{\Delta n} = \frac{\Delta q}{\Delta n}\frac{\Delta TR}{\Delta q} = MP(n)MR(q) \quad (27a)$$

$$MC(q) = \frac{\Delta TC(q)}{\Delta q} = \frac{\frac{\Delta TC}{\Delta n}}{\frac{\Delta q}{\Delta n}} = \frac{MFC(n)}{MP(n)}. \quad (27b)$$

If the firm employs its profit-maximizing labor input, it will produce its profit-maximizing output because

$$MFC(\bar{n}) = MP(\bar{n})MR(\bar{q}) \quad (28a)$$

$$\frac{MFC(\bar{n})}{MP(\bar{n})} = MR(\bar{q}) \quad (28b)$$

$$MC(\bar{q}) = MR(\bar{q}). \quad (28c)$$

Similarly, if the firm is producing its profit-maximizing output, it must employ the profit-maximizing factor input, because from (27b),

$$MC(\bar{q}) \equiv \frac{\Delta TC}{\Delta q} = \frac{\frac{\Delta TC}{\Delta n}}{\frac{\Delta q}{\Delta n}} = \frac{MFC(\bar{n})}{MP(\bar{n})} = MR(\bar{q}) \quad (29a)$$

$$MFC(\bar{n}) = MR(\bar{q})MP(\bar{n}) = MRP(\bar{n}). \quad (29b)$$

Thus, profit maximization is not a single choice but a choice of the profit-maximizing output and the profit-maximizing factor inputs.

## Average Revenue Product and the Shutdown Point

The firm's average revenue per unit of a variable input (labor, in the above analysis) is the average revenue product,

$$ARP(n) = \frac{TR(n)}{n}, \quad (30a)$$

where $n$ is the labor input and $TR(n)$ is the total revenue generated by labor. The revenue per unit of labor depends on the output per unit of labor, or average product,

$$AP(n) = \frac{q(n)}{n}, \quad (30b)$$

and the average revenue per unit of output,

$$AR(q) = \frac{TR(q)}{q}. \quad (30c)$$

Combining (30a), (30b), and (30c), average revenue product is

$$ARP(n) = \frac{TR(n)}{n} = \frac{TR(q)}{q}\frac{q}{n} = AR(q)AP(n). \quad (30d)$$

If the firm sells all units of its output at the same price ($P$), then $AR(q) \equiv P$, and average revenue product is

$$ARP(n) = P \bullet AP(n). \quad (30e)$$

We know that the firm will shut down and produce $q = 0$ if its maximum profit from producing, $\pi(q)$, is less than the profit from not producing at all, $\pi(0)$. This means that the firm will hire its profit-maximizing labor input, $\bar{n} > 0$, only if its profit is no lower than if it shut down and hired no labor input—that is, it will produce its profit-maximizing output and hire its profit-maximizing labor input, $\bar{n} = n(\bar{q})$, only if $\pi(\bar{q}) \geq \pi(0)$ and employ its profit-maximizing labor input only if $\pi[n(\bar{q})] = \pi(\bar{n}) \geq \pi(0)$.

At the shutdown point, $\pi(\bar{n}) = \pi(0)$. In the short run,

$$\begin{aligned} \pi(0) &= TR(0) - TC(0) \\ &= TR(0) - VC(0) - FC = -FC, \end{aligned} \quad (31)$$

so the firm is at its shutdown point in the labor market if

$$\pi(\bar{n}) = TR(\bar{n}) - VC(\bar{n}) - FC = -FC \tag{32a}$$

$$TR(\bar{n}) = VC(\bar{n}) = w\bar{n} \tag{32b}$$

$$\frac{TR(\bar{n})}{\bar{n}} = \frac{w\bar{n}}{\bar{n}} \tag{32c}$$

$$ARP(\bar{n}) = w. \tag{32d}$$

If the firm has to pay a wage above $ARP(\bar{n})$, it will shut down because its revenue will be insufficient to cover its variable costs.

## Choosing the Profit-Maximizing Capital Input

Usually, the analysis of short-run profit maximization assumes a fixed capital input and variable input, but this does not have to be the case. We could also assume a fixed labor input and variable capital input, in which case the conditions for choosing the profit-maximizing capital input would be the same as for the profit-maximizing labor input—namely,

$$\frac{\Delta\pi(\bar{k})}{\Delta k} = MRP(\bar{k}) - MFC(\bar{k}) = 0 \tag{33a}$$

$$MRP(\bar{k}) = MFC(\bar{k}). \tag{33b}$$

However, capital is a much broader and more complex class of inputs than labor. It is easy to imagine a unit of labor as a worker-hour, worker-day, and so on. It is not so easy to imagine a unit of capital because capital includes financial capital (loanable funds), human capital, machinery and other producer durables, and structures. Moreover, current outlays on capital generate revenue and profit (if any) in the future, and the future is uncertain. This means that we have to introduce some special features of capital that affect both its *MRP* and its price and *MFC*.

First, there is the issue of time, which Alfred Marshall (1961) termed "the source of many of the greatest difficulties in economics" (p. 109). Because we do not know the future exactly, the revenue from capital is an expected value—that is,

$$TR(k) = expected\ TR(k) \tag{34a}$$

$$MRP(k) = \frac{expected\ \Delta TR(k)}{\Delta k}. \tag{34b}$$

Time also complicates things because, even with no uncertainty, risk, or inflation, \$1 today is worth more than \$1 tomorrow, next year, or 10 years from now. The present value of \$1 in the future is \$1 discounted by a pure real interest rate ($r$) after $t$ periods in the future is

$$PV(1) = \frac{1}{(1+r)^t}. \tag{35}$$

This means that $MRP(k)$ is the present value of the expected future revenue, or

$$MRP(k) = \frac{expected\ \Delta TR(k)}{\Delta k}\left(\frac{1}{(1+r)^t}\right). \tag{36}$$

It also means that $MRP(k)$ can change if economic expectations and/or the time preference for income now over income in the future change.

Uncertainty and risk also affect the price or user cost of capital, $P_k$. If firms finance their capital outlays by borrowing, they have to pay interest to lenders. If they self-finance their capital outlays, they forgo the interest they could have earned on the funds. Risk and uncertainty are real costs of employing capital, which means that the cost of capital includes a risk premium, $R$. The risk premium is zero for completely safe capital projects and varies directly with the riskiness of projects. Specifically, $R$ is a function of the probability of the success from the project ($p$) and the variance of returns—algebraically, $R_i = R_i(p, \sigma)$, where $p$ is the probability of success and $\sigma$ is the variance. The degree of risk and $R_i$ vary inversely with $p$ and directly with $\sigma$.

Finally, we have to consider that capital depreciates with use and that the depreciation rate, $d$, is another element of the cost or price of using capital. If we put all of the elements together, the price of a \$1 capital outlay becomes

$$P_k = 1 + r + R(p, \sigma) + d. \tag{37}$$

We can apply the necessary and sufficient conditions and notations for choosing the profit-maximizing input of variable labor to choosing the profit-maximizing variable capital input. However, we have to consider the greater complexity of the capital decisions by the firm.

## Profit Maximization in the Long Run

The analysis of profit maximization in the long run is quite straightforward—in some respects, a simpler problem than short-run profit maximization.

With labor and capital both variable in the long run, the firm will minimize the cost of any output where the additional output per dollar spent is equal for the last units of labor ($n$) and capital ($k$) employed, or where

$$\frac{MP(n)}{w} = \frac{MP(k)}{P_k}, \tag{38a}$$

from which it is obvious that

$$\frac{w}{MP(n)} = \frac{P_k}{MP(k)} = MC(q) = LRMC(q). \tag{38b}$$

Since $LRTC(q)$ is the minimum cost of producing any output, (38a) is true at all points on the $LRTC(q)$ curve, and (38b) is true at all points on the $LRMC(q)$ curve.

The firm maximizes profit in the long run at outputs and factor inputs of $\bar{q}$, $\bar{n}$, and $\bar{k}$, where

$$\frac{P_k}{MP(\bar{k})} = \frac{w}{MP(\bar{n})} = MC(\bar{q}) = LRMC(\bar{q}) = MR(\bar{q}) \tag{39a}$$

$$\frac{w}{MP(\bar{n})} = MR(\bar{q}) \tag{39b}$$

$$w = MR(\overline{q})MP(\overline{n}) = MRP(\overline{n}) \tag{39c}$$

$$\frac{P_k}{MP(\overline{k})} = MR(\overline{q}) \tag{39d}$$

$$P_k = MR(\overline{q})MP(\overline{k}) = MRP(\overline{k}). \tag{39e}$$

This satisfies the necessary conditions for profit-maximizing output and factor inputs. As in the short run, if the firm is producing its profit-maximizing output, it must be employing the profit-maximizing inputs of labor and capital.

As in the short run, the shutdown point in the long run is reached if the total revenue from the firm's profit-maximizing output just equals variable cost. However, with all inputs variable, all long-run costs are variable. Thus, the firm reaches its shutdown point if, at its profit-maximizing output, $\overline{q}$,

$$TR(\overline{q}) = LRTC(\overline{q}) \tag{40a}$$

$$P = LRAC(\overline{q}). \tag{40b}$$

With no fixed cost, there is no distinction in the long run between profit and producer surplus because long-run $\pi(0) = 0$, and producer surplus at any $q > 0$ is $PS(q) = TR(q) - LRTC(q) \equiv \pi(q)$.

The general conditions for profit maximizing apply to all profit-maximizing firms. Now, we can apply this analysis to profit-maximizing choices and their implications for economic efficiency in different type of markets.

## Profit Maximizing in the Perfectly Competitive Economy

Perfect competition is the "zero-friction" case in economics. In terms of profit-maximizing choices, the essential assumed property of perfect competition is that all individual firms are price takers in product and factor markets. The individual firm is too small relative to the market to affect the prices at which it sells its output or purchases the use of factors of production. For the perfectly competitive firm, product and factor prices are constants that do not vary with the firm's output or employment of factor inputs.

### Choice of Output

Like any profit maximizer, the perfectly competitive firm maximizes profit at the output $(\overline{q})$, where $MR(\overline{q}) = MC(\overline{q})$ and $\Delta MR(q)/\Delta q < \Delta MC(q)/\Delta q$. The firm's marginal revenue function is

$$MR(q) = P + \frac{\Delta P}{\Delta q}. \tag{41a}$$

If the firm can sell any output it could produce at a constant $P$, then $\Delta P/\Delta q \equiv 0$, and marginal revenue is identical with price because

$$MR(q) = P + \frac{\Delta P}{\Delta q} = P + 0 \equiv P. \qquad MR(q) \equiv P. \tag{41b}$$

It follows that, for a price-taking firm,

$$\frac{\Delta MR}{\Delta q} \equiv 0. \tag{41c}$$

Graphically, if $P$ is constant, $\Delta TR(q)/\Delta q = MR(q) \equiv P$, and $MR(q) \equiv P$ is simply a horizontal line at $P$, as in Figure 11.2.

The necessary condition for maximizing profit for a price-taking firm is where

$$MC(\overline{q}) = MR(\overline{q}) = P. \tag{42}$$

In Figure 11.2, $MC(q) = MR(q) \equiv P$ and $\Delta\pi(q)/\Delta q = 0$ at $q_1$ and $q_2$. Profit is at a minimum at $q_1$ because $\Delta MC(q)/\Delta q < 0 < \Delta MR/\Delta q = 0$. At $q_2$, $\Delta MC(q)/\Delta q > 0 > \Delta MR/\Delta q = 0$ , which is necessary and sufficient for maximum profit. Because the price taker's $MR$ is constant, it will maximize profit where $P$ = rising $MC(q)$, as at $q_2$ in Figure 11.2. This is not necessarily true if the firm is not a price taker.

### The Firm's Shutdown Point and Supply Curve

Supply curves or supply functions exist only in perfectly competitive markets in which the firms are price takers. Plug in a price, and the firms supply their profit-maximizing output, where $MC(q) = P$, which means that only price-taking firms have supply curves, and market or industry supply curves only exist in markets in which the firms are price takers. If a firm is large enough relative to the market that its output decisions affect the price, there is no price for the firm to "take," and consequently there is no supply curve.

Of course, if the price is below the firm's shutdown price and its profit-maximizing output cannot cover variable cost, it will not produce or supply any input.

Remember that at the shutdown point, $TR(\overline{q}) = VC(\overline{q})$, $P = AVC(\overline{q})$, and $\pi(\overline{q}) = \pi(0) = -FC$. For a price taker, $P \equiv MR(\overline{q})$, and it is at its shutdown point where

$$P \equiv MR(\overline{q}) = MC(\overline{q}) = AVC(\overline{q}) \tag{43}$$

which occurs at the minimum point on the $AVC(q)$ curve where $MC(q) = \min AVC(q)$. The price-taking firm will shut down and produce $q = 0$ if $P < \min AVC(q)$. For any $P > \min AVC(q)$, the firm will produce and supply the quantity $(q_s)$, where $P = MC(q_s) \geq AVC(q)$. This generates the firm's supply curve $q_s(P)$ in Figure 11.5.

In Figure 11.6, the perfectly competitive firm's $q_s(P)$ is the portion of $MC(q)$ above the minimum point on $AVC(q)$, where $MC(q) = \min AVC(q)$. If $MC(q)$ and $AVC(q)$ are

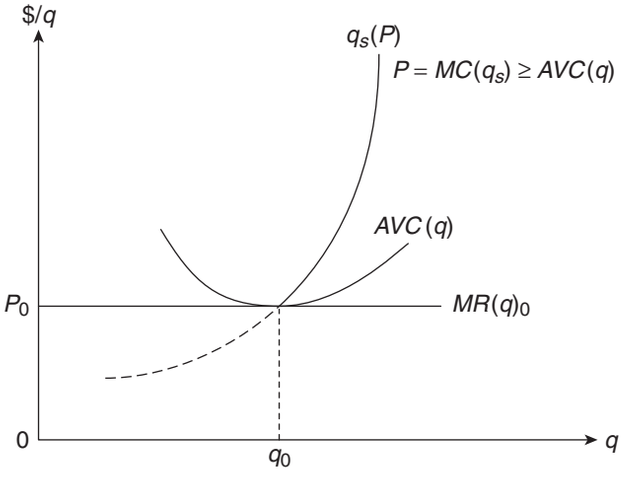

**Figure 11.5** Shutdown Point and the Competitive Firm's Supply Curve

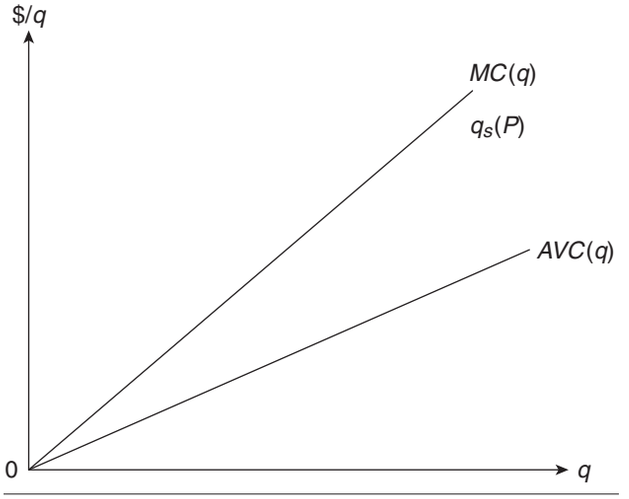

**Figure 11.6** Marginal Cost, Average Variable Cost, and Competitive Firm's Supply Curve

linear, as in Figure 11.6, $MC(q) > AVC(q)$ for all $q > 0$, and the entire $MC(q)$ curve is the firm's short-run supply curve.

## Choice of Inputs by the Perfectly Competitive Firm

In an economy in which all markets are perfectly competitive, the individual firms are price takers in product and factor markets—that is, the prices of the firm's output and of the factor inputs are constants. If labor is a variable factor input, the firm maximizes profit, $\pi(n)$, where $MFC(\overline{n}) = MRP(\overline{n})$ and $\Delta MFC(n)/\Delta n > \Delta MRP(n)/\Delta n$, which satisfies the necessary and sufficient conditions for maximum $\pi(n)$.

As a price taker in the labor market facing a constant wage ($w$), the marginal factor cost of labor is simply the wage. If $w$ is constant, then $\Delta w/\Delta n \equiv 0$ and

$$MFC(n) = w + n\frac{\Delta w}{\Delta n} \equiv w. \tag{44}$$

The firm in a perfectly competitive labor market then will maximize profit by employing labor where

$$MFC(\overline{n}) \equiv w = MRP(\overline{n}) \tag{45a}$$

and

$$\Delta MFC(n)/\Delta n \equiv \Delta w(n)/\Delta n \equiv 0 > \Delta MRP(n)/\Delta n. \tag{45b}$$

These are the necessary and sufficient conditions for the profit-maximizing labor input, $\pi(n)$. Because the firm in a competitive factor market is a price taker, this means that the firm will maximize $\pi(n)$ where $w = MRP(\overline{n})$ on the downward sloping segment of $MRP(n)$, as in Figure 11.4.

### *Marginal Revenue Product (MRP) and Value of the Marginal Product (VMP)*

The marginal revenue product of an input—labor ($n$), for example—is the value of the last unit employed to the profit-maximizing firms that employ labor. We have already shown that $MRP(n) = MP(n)MR(q)$. The value, or marginal benefit, of the last unit of labor employed to the consumers of the output it produces is the value of the marginal product of labor,

$$VMP(n) = MP(n)P, \tag{46a}$$

because the price of the output $P$ is the marginal benefit that consumers derive from it.

If the firm is a price taker in the sale of its output,

$$\Delta P/\Delta q \equiv 0, \text{ and } MR(q) = P + (\Delta P/\Delta q)q \equiv P. \tag{46b}$$

This means that for a price taker in the product market,

$$MP(n)MR(q) \equiv MP(n)P \tag{47a}$$

$$MRP(n) \equiv VMP(n). \tag{47b}$$

The value of the last unit of labor hired to the profit-maximizing firm is the same as its value to the consumers of the goods it produces.

If we combine these results, when the perfectly competitive firm employs its profit-maximizing input of labor ($n$) or any other variable factor input,

$$w = MRP(\overline{n}) = VMP(\overline{n}). \tag{48}$$

This maximizes the net benefits to the firm and the consumers of their output. *This is true only if the firm is a price taker in the product market.*

### The Shutdown Point and the Firm's Factor Demand

Demand functions, or demand curves, generate a single quantity demanded at a given price and exist only if individual buyers are price takers who cannot affect the market-determined price. In the factor market, this means that the firms will have demand curves for variable factors of production, such as labor, only if they are price takers in the factor market.

Thus, the quantity of labor demanded $(n_d)$ by a firm in a competitive labor market will be where

$$w = MRP(n_d). \tag{49}$$

If the firm is also a price taker in the product market,

$$w = MRP(n_d) = VMP(n_d). \tag{50}$$

A firm will shut down and hire $n = 0$ if it cannot cover the variable cost of the output it produces. If the firm is a price taker in the labor market, it is at its shutdown point if $w = MRP(\overline{n}) = ARP(\overline{n})$. Because $MRP(n) = ARP(n)$ only at the maximum $ARP(n)$, the firm's shutdown point is where

$$w* = MRP(n) = \max ARP(n), \tag{51}$$

where $w*$ is the "shutdown" wage.

Obviously, a profit-maximizing firm would never hire a quantity of labor or any variable input if its $MRP(n) < 0$ because it is technologically inefficient. Even if labor were free ($w = 0$), hiring labor beyond the point where $MP(n) = MRP(n) = 0$ (and $q(n)$ is at its maximum) would reduce profit.

Putting all of this together, in a competitive factor market in which the firms are price takers, the profit-maximizing choices of the firm generate its factor demand curve, which is the segment of its $MRP(n)$ between the shutdown wage and $MRP(n) = 0$.

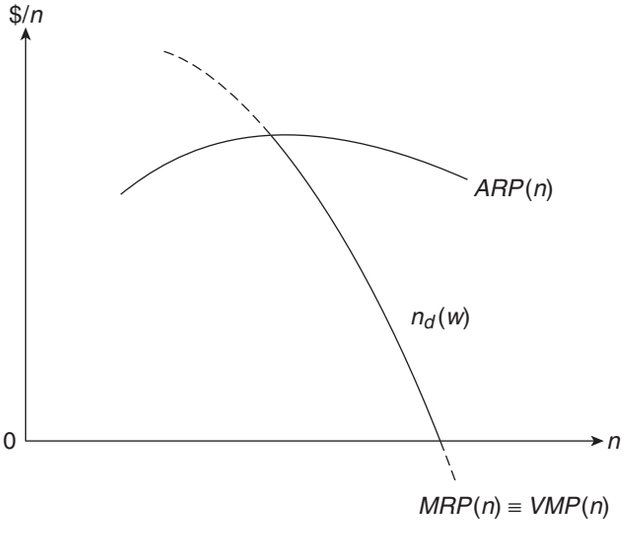

**Figure 11.7** Shutdown Point and Competitive Firm's Demand for Labor

Thus, in Figure 11.7, the firm's demand for labor is $n_d(w)$, on which $0 \leq w = MRP(n) \equiv VMP \leq \max ARP(n)$. If the firm is not a price taker in the labor market—a monopsonist, for example—it has no demand for labor because its choice of labor input determines the wage, and there is no constant wage that the firm must "take."

## Market Power and Profit Maximization

Firms with market power are not price takers. If a firm's output is large relative to the market or if it can differentiate its product from that of other firms, then its output will affect the price at which it sells. Unlike the price taker in perfect competition, a firm with market power can raise its price without losing all of its customers and reducing the quantity of its output demanded to zero, and it sell more of its output by lowering its price.

If the firm is a large user of a factor of production relative to the factor market, its input decisions affect the price of the input. The conditions for profit maximization are the same whether firms have market power or not, but the existence of market power produces some important differences from the "zero-friction" perfectly competitive case.

### Monopoly in the Product Market

The simplest case in which an individual firm has market power in the sale of its output is a monopoly, which is the only firm in the market. The monopoly model can be extended to markets that are not strictly monopolies, if the individual firm is large relative to the market and does not consider the actions of other firms.

#### *Monopoly Profit-Maximizing Output*

The necessary and sufficient conditions for maximizing profit by a monopolist are familiar: $MR(\overline{Q}) = MC(\overline{Q})$ (necessary) and $\Delta MC(Q)/\Delta Q > \Delta MR/\Delta Q$ (sufficient), where $Q$ is the quantity produced for the entire market. However, because the monopolist is not a price taker, some differences from the competitive case have important implications for the relationship between the interest of the firm in maximizing its profit and society's interest in efficiency and welfare.

#### *Price and Marginal Revenue*

A monopolist faces a negatively sloped market demand curve, so price is not constant for all outputs. It is more convenient if we think of the monopolist facing the inverse market demand curve, which expresses price as a function of quantity demanded. With a negatively sloped market demand curve, $\Delta Q_D/\Delta P < 0$ and $\Delta P/\Delta Q_D < 0$, so the price at which the monopolist sells its output is a function of output, $P(Q)$, and price varies inversely with output.

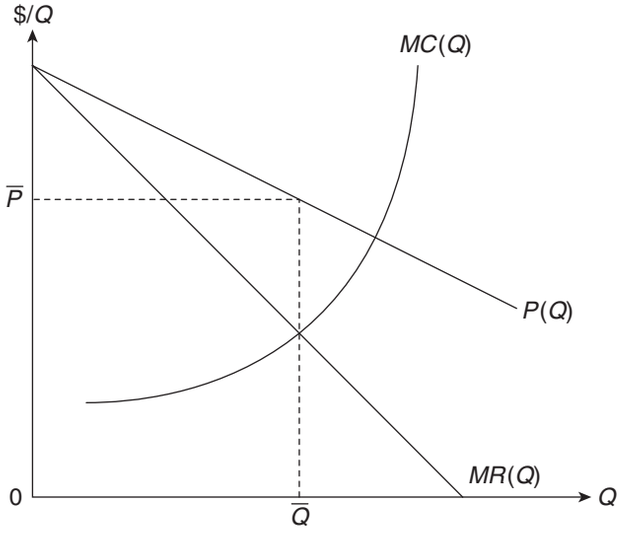

**Figure 11.8** Monopoly Profit-Maximizing Output and Price

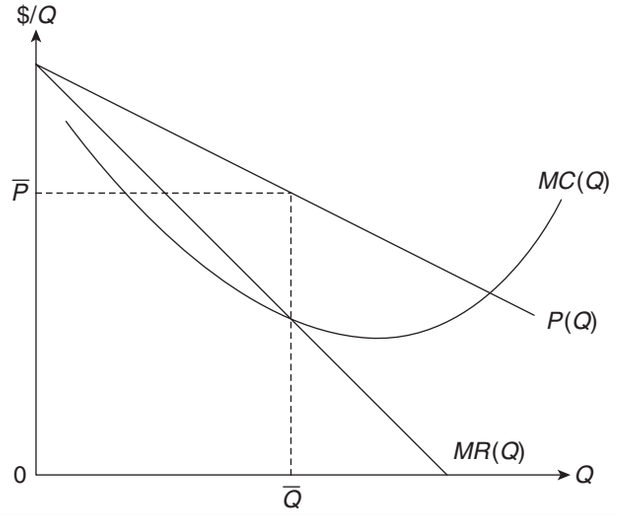

**Figure 11.9** Monopoly Profit Maximization With Falling Marginal Cost

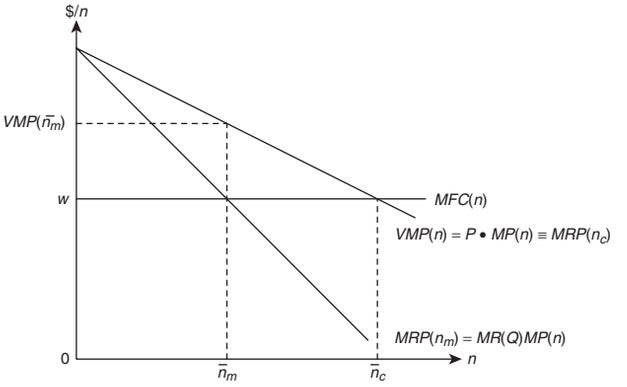

**Figure 11.10** Competitive Firm and Monopoly Profit-Maximizing Labor Input

The monopolist's marginal revenue is less than price. If the monopolist increases output, for example, this will lower the price. The change in revenue is the sum of the additional revenue from the additional output at the lower price and the lost revenue on the original output that it sold at the higher price. The monopolist's marginal revenue is

$$MR(Q) = \frac{\Delta TR(Q)}{\Delta Q} = P(Q) + \frac{\Delta P(Q)}{\Delta Q}Q < P(Q), \qquad (52)$$

because $\Delta P/\Delta Q < 0$. For example, with a linear inverse demand curve $P(Q)$ in Figure 11.8, $MR(Q)$ falls faster than $P(Q)$ as $Q$ increases and $P(Q) > MR(Q)$.

Unlike the price taker, a monopoly may maximize profit with $MC(q)$ falling. For example, in Figure 11.9, the firm's profit-maximizing output is $\overline{Q}$, where $MR(\overline{Q}) = MC(\overline{Q})$, $\Delta MC(Q)/\Delta Q > \Delta MR(Q)/\Delta Q$ (both slopes are negative), and $MC(q)$ cuts $MR(q)$ "from below."

## Monopoly Profit Maximization in the Labor Market

Monopoly in the product market affects the labor market as well as the product market. A monopolist in the product market need not have market power in the labor market. For example, the only barbershop in a small town has no effect on the market wage for barbers. For simplicity, we will assume a monopoly in the sale of its output that is a price taker in the labor market.

### *Marginal Revenue Product and Value of the Marginal Product*

We saw above that for a price taker in the product market, $P \equiv MR(q)$, and $MRP(n) \equiv VMP(n)$ in the labor market. The price-taking firm thus maximizes its profit by hiring labor to the point where $w = MRP(\overline{n}) = VMP(\overline{n})$.

For the monopoly, however, $MR(Q) < P(Q)$, which means that the monopolist's *MRP* is less than *VMP:*

$$MRP(n_m) = MR(Q)MP(n_m) < P(Q)MP(n_m) = VMP(n_m). \qquad (53)$$

In Figure 11.10, for example, note that the monopoly's $MRP(n_m)$ falls faster than $VMP(n_m)$ as it employs more labor.

### *Choice of Labor Input*

If the monopoly in the product market is a price taker in the labor market—that is, $MFC(n) \equiv w$—then $MRP(n) \equiv w$ and $VMP(n)$ are both linear and are both less than $ARP(n)$. If this were a perfectly competitive firm in the product market, it would hire $\overline{n}_c$, where $w = MRP(\overline{n}_c) \equiv VMP(\overline{n}_c)$. However, with monopoly in the product market, it will hire only $\overline{n}_m$,

where $w = MRP(\overline{n}_m) < VMP(\overline{n}_m)$. In other words, other things equal, a profit-maximizing monopoly will hire less labor to maximize profit than will a price taker in the product market.

## Monopoly Profit-Maximizing and Deadweight Loss

*Deadweight Loss in the Product Market*

The price-taking firm in a perfectly competitive product market maximizes profit by producing where the marginal benefit of the last unit of output to consumers just equals the marginal cost of producing it, as well as by employing labor where the value of the marginal unit of labor to the firm and to the consumers of the additional output is equal.

However, when the monopolist maximizes profit,

$$P(\overline{Q}) > MR(\overline{Q}) = MC(\overline{Q}), \tag{54}$$

which generates a deadweight efficiency loss from underproduction because

$$P(\overline{Q}) = MB(\overline{Q}) > MR(\overline{Q}) = MC(\overline{Q}). \tag{55}$$

In Figure 11.11, the efficient output and price are $\hat{Q}$ and $P(\hat{Q}) = MB(\hat{Q}) = MC(\hat{Q})$. This maximizes the combined net benefits to producers and consumers, or the sum of producer surplus and consumer surplus.

However, the monopoly maximizes profit by producing $\overline{Q}$ where $MR(\overline{Q}) = MC(\overline{Q})$ and charging a price of $\overline{P} = P(\overline{Q}) > MC(\overline{Q})$. At this price and output, $MB(\overline{Q}) > MC(\overline{Q})$ and there is a deadweight efficiency loss from underproduction equal to the shaded area in Figure 11.11. Unlike the price taker who must produce where $P = MC(\overline{q})$, a monopolist cannot maximize profit and produce the output that maximizes net benefits to producers and consumers,

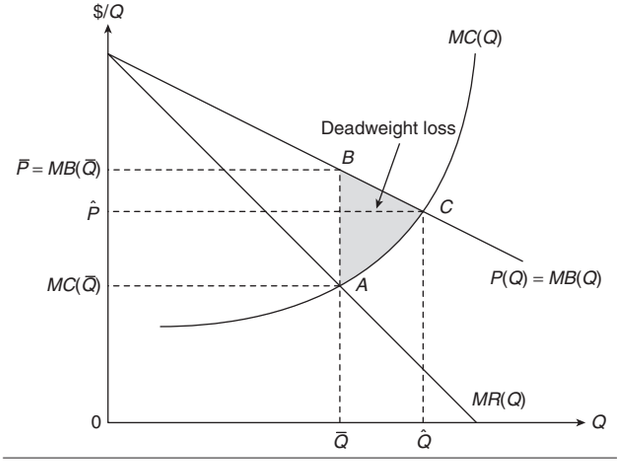

**Figure 11.11** Monopoly Equilibrium and Deadweight Loss

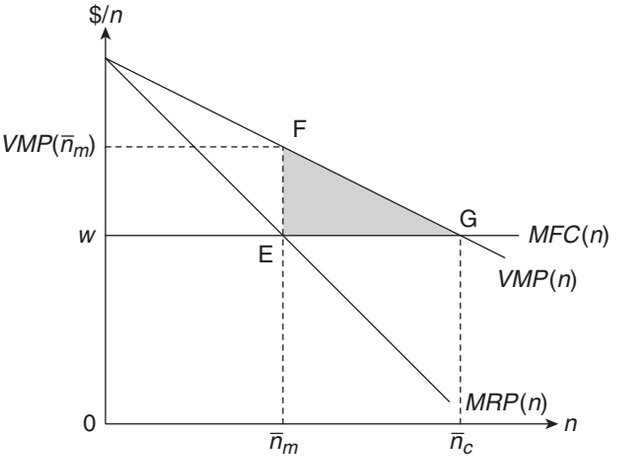

**Figure 11.12** Monopoly Labor Input and Deadweight Loss

and there is a conflict between the monopoly's interest in maximizing profit and society's interest in efficiency.

*Deadweight Loss in the Labor Market*

We know that price takers in the product and labor markets will maximize profit by employing labor where $w = MRP(\overline{n}_c) = VMP(\overline{n}_c)$ in Figure 11.12. This is efficient because the value of the last unit of labor hired by the firm equals the marginal benefit to consumers of the additional output produced by the marginal unit of labor.

However, a monopolist in the product who is a price taker in the labor market maximizes profit by employing labor to the point where

$$w = MRP(\overline{n}_m) < VMP(\overline{n}_m), \tag{56}$$

as shown in Figure 11.12. Because $VMP(\overline{n}_m) > MFC(\overline{n}_m)$, the additional benefits to consumers exceed the additional costs of employing more labor, and there is a deadweight loss of net benefits from underemployment at the monopoly's profit-maximizing employment of labor, equal to the shaded area *EFG* in Figure 11.12.

## Market Power and Profit Maximizing: Labor Market Monopsony

In labor markets in which an individual firm employs a sufficiently large share of the total employment that its employment choices affect the wage, the individual firm is not a price taker in the labor market. The simplest such case to analyze is a monopsony, in which there is only one firm in the labor market. The classic historical examples were the infamous "company towns" in isolated mining and lumber areas, in which a single firm employed all of the labor in the local labor market. Most of the "company

towns" are gone now, but there are still some markets in which individual firms or cartels of firms have considerable power over the wage that they pay—for example, professional sports teams and leagues, the NCAA in scholarship collegiate sports, universities in the hiring of college faculty, and "contractors" of undocumented alien workers.

*Wage and Marginal Factor Cost*

Like the price taker in the labor market, the necessary condition for maximizing profit by a monopsony firm in the labor market is $MFC(\overline{N}) = MRP(\overline{N})$, where $N$ is the total labor employed by the monopsony, the only employer in the labor market. However, the monopsony faces the market supply of labor and does not "take" a constant wage.

As in the monopoly model, it is easier if we consider the labor supply curve as $w(N_s)$ instead of $N_s(w)$. Assuming a positively sloped labor supply curve, by far the most plausible case, $\Delta w(N_s)/\Delta N > 0$. This means that the monopsony's $MFC(N)$ is

$$MFC(N) = w + \frac{\Delta w}{\Delta N} N > w(N), \tag{57}$$

which is shown graphically in Figure 11.13.

*Profit-Maximizing Input*

As a profit maximizer, the monopsonist will employ $\overline{N}_M$, where $MFC(\overline{N}_M) = MRP(\overline{N}_M)$. However, it will pay the supply price of this labor input, $w(\overline{N}_M)$—that is,

$$w(\overline{N}_M) < MFC(\overline{N}_M) = MRP(\overline{N}_M). \tag{58}$$

This result is shown graphically in Figure 11.13.

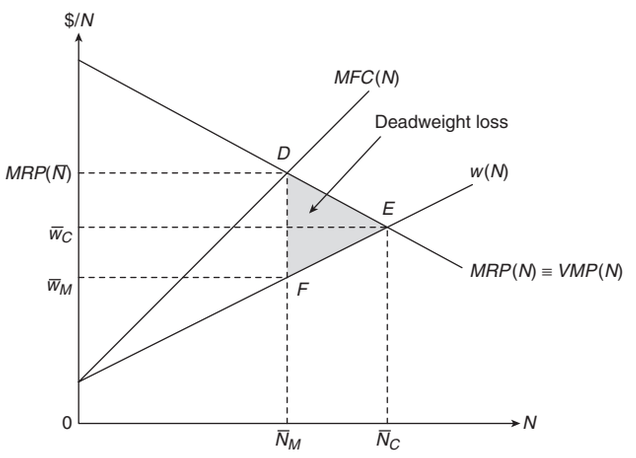

**Figure 11.13** Monopsony Profit-Maximizing Labor Input, Wage, and Deadweight Loss

If this were a competitive labor market, individual firms would maximize profit by hiring where $w \equiv MFC(n_c) = MRP(\overline{n}_c)$ on their demand curves for labor, and aggregate employment would be $\overline{N}_c$ at the competitive wage $w_c = MRP(\overline{N}_c)$. Thus, we would predict that a monopsony firm will hire less labor and pay a lower wage than the competitive equilibrium employment and wage.

*Monopsony and Deadweight Loss*

Labor in a monopsony market is paid a wage below its marginal revenue product, or the firm pays a wage less than the contribution of the marginal unit of labor to the firm's revenue. The difference between *MRP* and the wage is sometimes called monopsonistic "exploitation," which has strong normative implications of economic justice, but there are important efficiency implications as well.

If we assume for now that the monopsonist in the labor market is a price taker in the product market, then $MRP(N) \equiv VMP(N)$. The competitive employment and wage are efficient because the values of the marginal unit of labor to firms and consumers of output are equal. However, the monopsonist pays $w(\overline{N}_M) < MRP(\overline{N}_M)$, and there is a deadweight efficiency loss of area *DEF* in Figure 11.13.

*Bilateral Monopoly Profit Maximization*

A firm may have market power in product and factor markets. The simplest case is a monopoly in the product market that is also a monopsony in the factor market, or a bilateral monopoly. Like other profit-maximizing firms, the firm will produce where $MR(\overline{Q}) = MC(\overline{Q})$ and employ labor where $MRP(\overline{N}) = MFC(\overline{N})$.

However, because it is a monopolist in the product market, $MR(Q) < P(Q)$, therefore $MRP(N) < VMP(N)$ for a bilateral monopoly. As a monopsonist in the factor (labor) market, its $w(N) < MFC(N)$. The bilateral monopolist maximizes profit, then, by employing labor and paying a wage at which

$$w(\overline{N}) < MFC(\overline{N}) = MRP(\overline{N}) < VMP(\overline{N}). \tag{59}$$

This pushes the profit-maximizing employment and wage even lower than with monopoly or monopsony alone, widens the gap between $VMP(\overline{N})$ and $w(\overline{N})$, and increases the deadweight efficiency loss.

Figure 11.14 compares the results of profit maximization in the labor market in a competitive economy, monopsony in the factor market, and bilateral monopoly with monopsony in the factor market and monopoly in the product market. In the bilateral monopoly, the firm maximizes its profit by employing $\overline{N}_M'$ units of labor and paying a

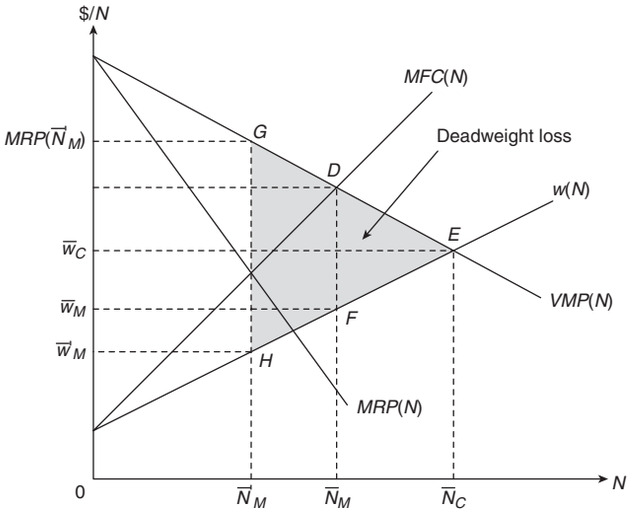

**Figure 11.14** Bilateral Monopoly, Labor Input, Wage, and Deadweight Loss

wage of $w\left(\overline{N}_M'\right)$. This is a lower wage and level of employment than the competitive case where $\overline{N}_c$ units of labor are employed at a wage of $w_c$. Employment and the wage are also lower in the bilateral monopoly than in the monopsony market, in which $\overline{N}_M$ units of labor are employed at a wage of $w(\overline{N}_M)$.

The deadweight efficiency loss in a bilateral monopoly combines the deadweight loss from monopoly in the product and from monopsony in the labor market. In Figure 11.14, for example, the bilateral monopoly deadweight loss is the area *GHE*. With monopsony alone, the deadweight loss is the area *DEF* from Figure 11.14.

## Why Profit Maximization?

Profit maximization is a plausible assumption to make about the motives of the decision makers who make the firm's choices. It is reasonable to assume that private firms are interested in their profits and that higher profits are better than lower profits. However, there is a longstanding controversy and large economic literature criticizing the profit-maximizing assumption as a highly unrealistic and simplistic picture of the operation and objectives of firms in modern industrial and commercial economies.

The people who make decisions in firms generally have multiple objectives in addition to profit. Proprietors of small businesses are motivated by their utility, which includes profit but also includes consuming leisure. The stockholders who own corporations are interested in the growth of the firm, the firm's share of its market, and the value of their shares in addition to the firm's profit.

Although the holders of voting stock own corporations, corporations are controlled by boards of directors and professional managers. Corporate managers may be more interested in maximizing their own utility, subject to the interests of the stockholders. If the performance of a corporation is unsatisfactory to stockholders, the stockholders may sell their shares, and depressed share prices will make it difficult for the firm to secure the necessary credit to conduct business.

Management in large corporations is conducted through a complex managerial bureaucracy in which lower level managers are generally more interested in satisfying their superiors and ultimately the stockholders than the corporation's profit. Simple profit maximization does not capture the complexity of decision making in large corporations.

Even among economists who accept the broad assumption that firms are maximizers, there are a number of alternatives to the assumption that they seek only to maximize profit. For example, Professor William Baumol (1967) constructed an analytical model in which the firm seeks to maximize its sales revenue, subject to a minimum profit constraint.

Some economists question whether firms, particularly corporations, actually *maximize* anything. Behavioral theories of the firm generally assume that managers are not maximizers but *satisficers.*

Modern economists in the "Austrian" tradition generally argue that while firms may seek maximum profit, they seldom if ever reach the goal because incomplete and diffused information would be required for maximizing profit. Rather, they argue that entrepreneurs are constantly "groping" for unexploited profit opportunities. They also argue that the simple assumption of profit maximization, particularly in perfectly competitive markets, understates or eliminates the active role of entrepreneurship in the choices that firms make.

Why, then, does mainstream microeconomics stick with the profit maximization assumption at all? The main reason is that most of the alternative models of the firm based on more extensive and realistic assumptions about the firm are much more complex than the profit-maximizing model, and most do not generate simple empirically testable explanations and predictions. Milton Friedman (1953) argued convincingly that as long as the firms behave "as though" they are profit maximizers, the profit-maximizing assumption is useful, even though it tells us little about the actual processes by which an actual firm makes its decisions.

Also, some of the "other" variables that motivate the firm's choices are directly related to profit. Share prices and the value of the firm tend to vary directly with profit. When firms fail to make stock analysts' predicted profit, or when the firms themselves project lower earnings and profits, this tends to depress share prices. Similarly, high earnings and profits tend to raise share prices and the value of the firm. Managers who are interested in protecting high salaries and generous perquisites are more likely to achieve higher utility

in a profitable firm than in one that is failing or facing the prospects of failure or a buyout by another firm. If proprietors seek to maximize their utility subject to income, and their firms' profits are the proprietors' incomes, it follows that profit has a positive utility to the proprietors.

Profit maximization remains a key assumption in the economics of the firm, even with its unrealistic and simplified picture of decision making by those who control firms because of its simplicity and the fact that the general explanations and predictions hold up well empirically. However, it is not a complete or very realistic picture of how those who control the firm make choices in product and factor markets.

# Imperfectly Competitive Product Markets

Elizabeth J. Jensen
*Hamilton College*

Any introductory course in microeconomics spends a considerable amount of time examining perfectly competitive markets. It is important to understand this model; it serves as a benchmark for examining other industry structures and the welfare consequences of moving away from perfect competition. However, it is also important to look at imperfectly competitive output markets—markets in which products are not perfectly homogeneous or in which there are only a few sellers. While the perfectly competitive model assumes a large number of buyers and sellers, each of which is a price taker, the monopoly model assumes the opposite: one seller with complete control over price. Structurally, most markets are neither perfectly competitive nor monopolistic; they fall somewhere in between these two extremes of the competitive spectrum. The "in-between" markets are classified as either monopolistic competition or oligopolies depending on the number of firms in the market and the height of barriers to entry and exit. We turn first to monopoly.

## Monopoly

A monopoly is the only producer of a good for which there are no close substitutes. This puts the monopolist in a unique position: It can raise its price without losing consumers to competitors charging a lower price. Thus, the monopolist *is* the industry and faces the downward-sloping market demand curve for its product. The monopolist can choose any point along that demand curve; it can set a high price and sell a relatively small quantity of output, or it can lower price and sell more output.

Very few—if any—industries in the real world are pure monopolies. Examples of industries that come close include public utilities such as the local distributor of electricity or natural gas, the cable company in most communities, and, in a small isolated town, the local grocery store or gas station. Nonetheless, this model highlights how a firm with market power chooses its output level and price and helps us understand the welfare consequences of this choice.

### Marginal Revenue

All firms, ranging from perfectly competitive firms to monopolies, maximize profits by producing the quantity of output for which marginal revenue equals marginal cost. Recall the definition of marginal revenue: the additional revenue a firm receives from selling one additional unit of output. Because a monopoly faces the market demand curve, the only way it can sell an additional unit of output is by lowering the price it charges on *all* units. Consequently, marginal revenue for a monopoly has two components: an output effect and a price effect. The monopoly gains revenue from the additional unit of output sold but loses revenue on all of the units previously sold at a higher price. Marginal revenue incorporates both the gain and the loss; Figure 12.1 shows this trade-off.

At price $P_1$, the monopoly sells $Q_1$ units of output, and total revenue is the area of the rectangle $OP_1AQ_1$. To sell an additional unit of output, the monopoly has to reduce price to $P_2$, leading to total revenue of $OP_2B(Q_1 + 1)$. The monopoly gains rectangle $Q_1CB(Q_1 + 1)$ in total revenue; this area is equal to $P_2$. However, because of the lower price, the monopoly loses area $P_1AC\,P_2$, which is the initial quantity

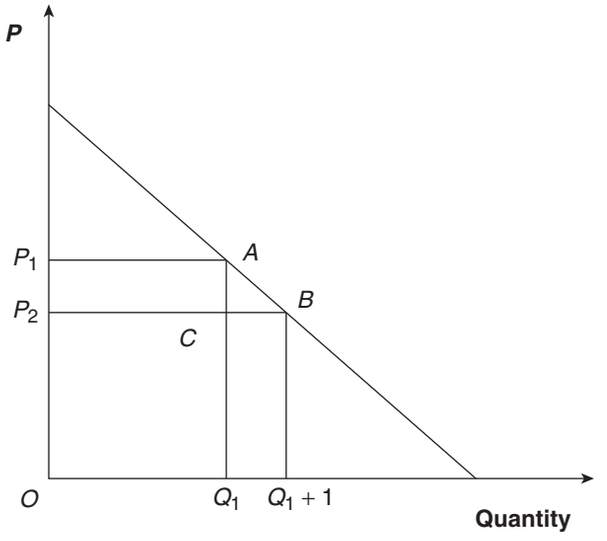

**Figure 12.1** Changes in a Monopolist's Total Revenue Resulting From a Price Cut

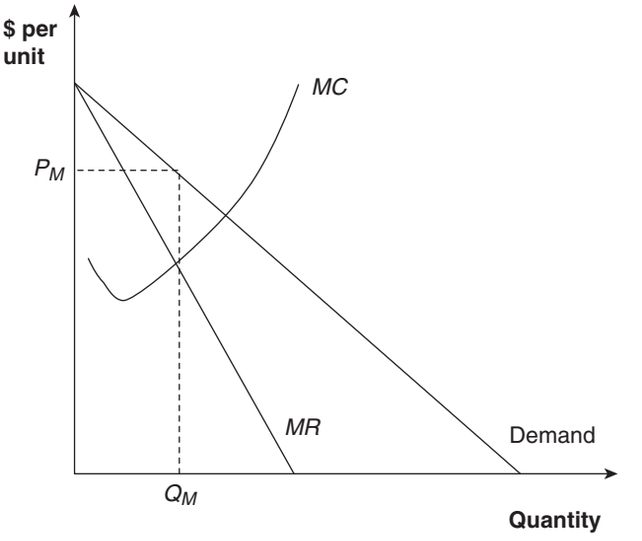

**Figure 12.2** Profit-Maximizing Quantity and Price for a Monopolist

sold times the change in price. Marginal revenue, the sum of the two, is thus always less than price for a monopoly. The precise relationship between marginal revenue and price is given by

$$MR = P + Q\frac{\Delta P}{\Delta Q}.$$

This can also be written as

$$MR = P\left(1 - \frac{1}{|\varepsilon|}\right),$$

where ε is the price elasticity of demand. Rewriting the relationship in terms of the elasticity of demand highlights the fact that even a monopolist must consider consumers' ability and willingness to change quantity in response to a change in price.

Graphically, the marginal revenue curve lies below the market demand curve at each level of output. While the exact relationship between marginal revenue and demand depends on the shape of the demand curve, there is a useful relationship between any linear demand curve and its marginal revenue curve. Specifically, the marginal revenue curve will also be linear, with the same vertical intercept as the demand curve but twice the slope. Consequently, the horizontal intercept of the marginal revenue curve is half the horizontal intercept of the demand curve. For example, if the market demand curve is given by $P = 160 - Q$, then the corresponding marginal revenue curve is given by $MR = 160 - 2Q$. This mathematical relationship, sometimes called the twice-as-steep rule, can be helpful in graphing demand and marginal revenue and in doing algebraic problems.

## Profit Maximization

Figure 12.2 shows that $Q_M$, where marginal revenue equals marginal cost, is the profit-maximizing quantity of output for the monopolist.

At any output level below $Q_M$, marginal revenue is greater than marginal cost, so producing an additional unit of output will increase profits; at any output level greater than $Q_M$, marginal cost is greater than marginal revenue, so the monopoly can increase profits by cutting back on quantity. Once the firm has chosen $Q_M$, it uses the market demand curve to determine the profit-maximizing price, $P_M$. Setting this price will enable the monopoly to sell its desired quantity of output. As the figure shows, price is greater than marginal cost for the profit-maximizing monopolist.

Continuing with the algebraic example, suppose the monopolist faces constant marginal and average costs of \$10. Setting marginal revenue, $160 - 2Q$, equal to marginal cost, we find that a profit-maximizing monopolist wants to sell 75 units of output. Substituting $Q = 75$ into the market demand curve, $P = 160 - Q$, shows that the monopolist will set price equal to \$85, considerably above the marginal cost of \$10.

## The Welfare Effects of Monopolization

Because the monopolist *could* have chosen to produce the perfectly competitive output level but did not, we would expect that monopolization of an industry makes the firm better off. However, because prices are higher and output is lower under monopoly than under perfect competition, we would also expect that consumers are worse off under monopoly. To see these effects and to look at total welfare, economists use consumer and producer surplus.

Figure 12.3 compares a market under perfect competition and under monopoly, assuming that costs are the same under both industry structures.

The perfectly competitive output is $Q_{PC}$; the perfectly competitive price is $P_{PC}$. Consequently, consumer surplus under perfect competition is area *ABC*, and producer surplus is area *CBD*. If the industry is monopolized, price

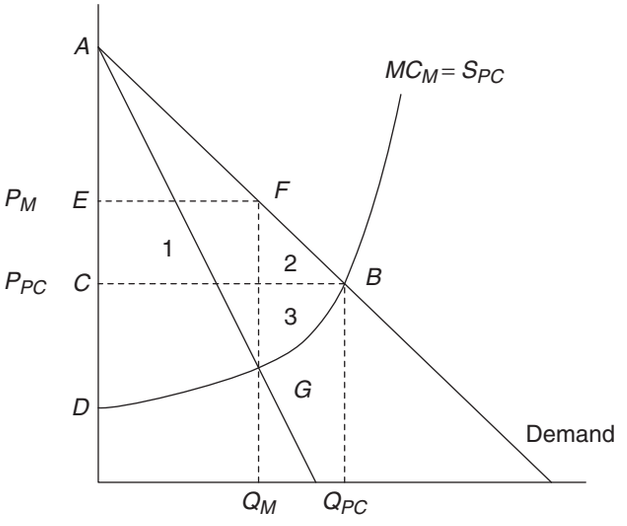

**Figure 12.3** Welfare Loss Due to a Monopoly

increases to $P_M$ and quantity decreases to $Q_M$. Consumer surplus is now area *AEF*, so consumers lose Areas 1 and 2. Producer surplus under monopoly is area *EFGD*, so producers gain Area 1 and lose Area 3. Because Area 1 is transferred from consumers of the good to the owner(s) of the monopoly, it is *not* a loss of welfare from society's point of view. However, Areas 2 and 3 are clearly losses to society, reflecting surpluses that would have gone to some group under perfect competition. This loss, called, the deadweight loss, measures the misallocation of resources due to monopoly.

The deadweight loss arises because the monopoly price is greater than the marginal cost of the good. Even though some consumer is willing to pay more for an additional unit of the good than it would cost to produce that unit, the monopolist does not produce it. This is the fundamental problem associated with monopoly power; understanding this helps us understand concern about any firm with market power and public policy toward such firms.

## Monopolistic Competition

In many industries, consumers do not view products of different firms as perfectly homogeneous—that is, products are differentiated. Sellers differentiate their products in many ways, including physical characteristics, location of stores, service, and warranties. Sellers also try to create subjective image differences, persuading consumers that their brand of shampoo, toothpaste, or laundry detergent is different from (and better than) other brands. A consumer chooses Herbal Essences shampoo instead of Dove or Pantene partly based on color, scent, packaging, and image (correct or incorrect) about how the shampoo will work. Because of product differentiation, some consumers will pay more for Herbal Essences shampoo.

Procter & Gamble, through its Clairol division, is the sole producer of Herbal Essences, giving it some monopoly power. This implies that the demand curve for Herbal Essences is downward sloping, in contrast to the perfectly horizontal demand curve faced by a seller in a perfectly competitive market. But the market power of a monopolistically competitive firm is limited because there are many producers of similar products. While a consumer might pay $0.50 or $1.00 more for a bottle of Herbal Essences, she is unlikely to pay $5.00 more. Thus, the downward-sloping demand curve for Herbal Essences is relatively elastic.

The second important characteristic of a monopolistically competitive market is easy entry and exit. If firms are making positive economic profits, new firms will develop their own brands and enter the market. Similarly, existing firms will leave the market if their products are unprofitable. Consequently, economic profits must equal zero when a monopolistically competitive industry is in long-run equilibrium.

### Equilibrium in the Short Run and in the Long Run

Figure 12.4(a) shows short-run equilibrium for a monopolistically competitive firm.

The profit-maximizing firm will produce $q_{SR}$, where marginal revenue equals marginal cost. In this case, the corresponding price, $P_{SR}$, is above average cost so the firm earns a positive economic profit in the short run.

As in perfect competition, positive economic profits cannot persist in the long run. The profits will encourage other firms to spend the funds necessary to develop, produce, and advertise new products. Over time, this entry will shift each existing firm's demand curve to the left until economic profits reach zero. Figure 12.4(b) shows the long-run equilibrium: The firm produces $q_{LR}$, where marginal revenue equals marginal cost and where price equals average cost. Because entry and exit are easy, no firm can make economic profits in the long run even though each firm has some market power.

### Welfare Effects of Monopolistic Competition

Economists have identified two sources of inefficiency in a monopolistically competitive market. First, note from Figure 12.4(b) that the firm produces a smaller output level than that which minimizes long-run average cost. This excess capacity indicates that if there were fewer firms in the industry, each could operate at a larger scale and a lower average cost. The second source of inefficiency results from the fact that in both the short run and the long run, price is greater than marginal cost. Consequently, as in monopoly, there is a deadweight loss in a monopolistically competitive market; each firm chooses to produce at an inefficiently small output level considering consumers' preferences.

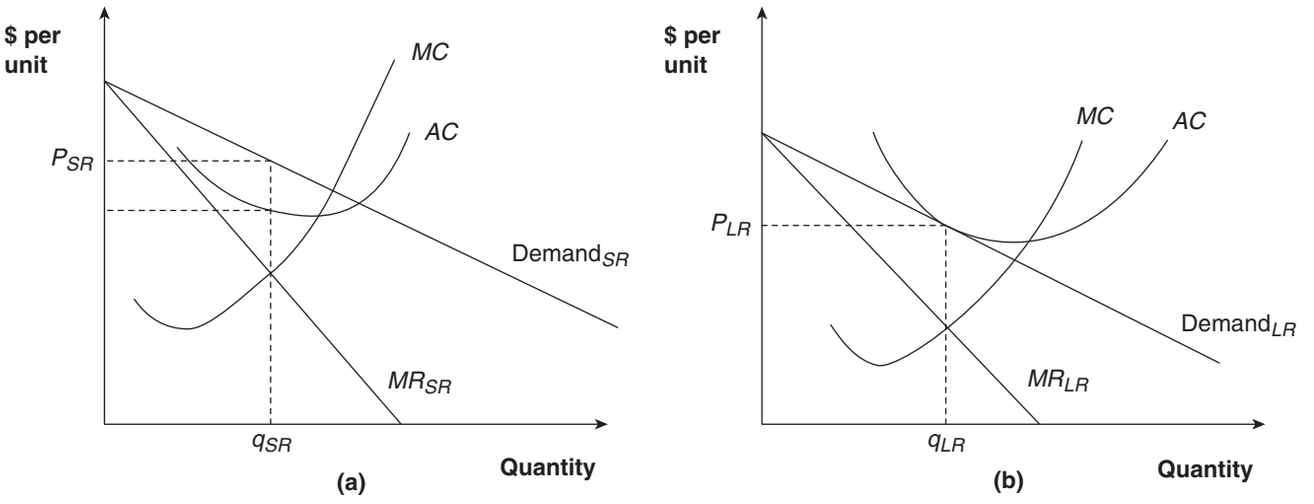

**Figure 12.4** (a) Short-Run and (b) Long-Run Equilibrium Under Monopolistic Competition

While these inefficiencies are costs to society, consumers undoubtedly value the opportunity to choose among a variety of products with different characteristics. Although it is hard to quantify the gains from product diversity, it is possible that they outweigh the welfare costs. This is especially likely when brands are reasonably substitutable; if no firm has much monopoly power, deadweight loss is small, and the firm is operating close to the minimum average cost.

## Oligopoly

An oligopolistic market consists of only a few producers. Furthermore, entry by new firms into the market is impeded; consequently, firms in an oligopolistic industry can earn substantial economic profits over the long run. Products produced by oligopolies can be relatively homogeneous, like steel, or differentiated, like automobiles. Many industries are oligopolistic, including aluminum, cigarettes, breakfast cereals, petrochemicals, computers, and tennis balls.

Predicting oligopolistic price and output or decisions about nonprice strategies such as advertising or investment decisions is complicated. Because of the small number of firms in the industry, oligopolists recognize their interdependence. Kellogg's understands that its actions affect General Mills and other manufacturers of breakfast cereals. Similarly, General Mills knows that what it decides matters for Kellogg's. Each firm realizes that any significant move on its part, such as a decision to cut price by 10% or to run a new advertising campaign, is likely to result in countering moves by its competitors. Firms therefore have to try to determine their competitors' probable responses as they make their decisions. Not surprisingly, these strategic considerations can be complex, suggesting that there is not just one model of equilibrium in an oligopoly, as there is in perfect competition, monopoly, or monopolistic competition. Factors such as whether firms are competing in prices or in quantities, the extent of information they have about their rivals, and how often they compete with each other matter in modeling choices in an oligopoly. Consequently, when examining the competitiveness of real-world oligopoly markets, it is important to combine theory with empirical evidence, remembering that "one size does not fit all." Before turning to specific models, we consider some of the important factors to think about.

### Competing in Quantities or Competing in Prices?

In some industries, it makes sense to think of firms choosing the price of their output and then selling as much as they can at that price. If they can easily produce an additional unit of output, firms will compete with each other based on price. Examples include the computer software, video games, and insurance industries. However, in other industries, firms have to choose their production capacity in advance, and quantity cannot be changed quickly or easily. Firms in these industries choose quantity with price adjusting to clear the market. Such industries include steel, automobiles, and passenger aircraft. As we will see, choosing prices instead of choosing quantities leads to a different oligopoly equilibrium.

### Collusion or Competition?

Another consideration is how oligopolists interact in their attempts to maximize profits. Perhaps they collude with each other, working to maximize joint profits and dividing up the market. If firms can see the "big picture," they will realize that collusion is more profitable in the long run than competing with and undercutting each other. However, any collusive agreement faces two types of problems. First, each individual firm is tempted to cheat on the

agreement to increase its short-run profits. And second, firms have to pay attention to the relevant law. In the United States, it is illegal to write a contract to keep prices high. Consequently, collusive, joint-profit-maximizing agreements are more stable in some industries than in others, depending on how easy it is to reach an agreement without overt collusion and how quickly a firm can increase output if it tries to take sales from a rival.

## Simultaneous or Sequential Decision?

Sometimes oligopoly firms must choose their strategies simultaneously or at least close enough together in time that they are deciding without knowing their competitors' decisions. For example, Sears and Best Buy choose prices for flat-screen TVs without knowing what price the other store has chosen that day. Coca-Cola and Pepsi decide on new advertising campaigns without seeing each other's plans. However, in some situations, one firm acts first, and then other firms decide how to respond. Sequential business decisions include entry decisions in which potential competitors must decide whether to enter a particular market and bargaining decisions such as those in which a firm negotiates with its suppliers over prices. In modeling oligopoly behavior, it is important to think about whether the particular interaction is better thought of as simultaneous or sequential.

## Equilibrium in an Oligopolistic Market

To think about market price and output in an oligopoly, we must first consider what an equilibrium would look like when firms are explicitly taking each other's behavior into consideration. The principle used in many models of oligopoly behavior is the Nash equilibrium, named in honor of the mathematician John Nash who developed it. When an industry has reached a Nash equilibrium, each firm is doing the best that it can given the choices made by its competitors. In this equilibrium, no firm has an incentive to change its strategic choices unilaterally. This concept is a powerful one; with it in hand, we can turn to some common models of oligopoly. To keep things simple, we will focus on duopoly markets, those in which two firms are competing with each other; these results do generalize to markets with more than two firms, although the math becomes more complicated.

## Models of Oligopoly

### *The Cournot Model*

First introduced by the French economist Augustin Cournot in 1838, the Cournot model has turned out to be a powerful model, applicable in many situations. In its simplest form, it depicts a duopoly; the firms produce a homogeneous product, have the same marginal costs, and know the market demand curve. Firms in this model are choosing quantity and are choosing simultaneously and independently.

To be concrete, let us use the market demand from the discussion of monopoly, $P = 160 - Q$; assume that each duopolist operates with constant marginal and average cost of 10, as the monopolist did. Each firm maximizes profits, taking into account the amount of output it expects its rival to produce. Thus, Firm 1 sees its demand curve, called the residual demand curve, as $P = 160 - q_2 - q_1$. Because Firm 1 thinks of the quantity produced by Firm 2 as constant, its marginal revenue curve is given by $MR_1 = 160 - q_2 - 2q_1$, derived using the twice-as-steep rule from monopoly. As always, profit maximization requires setting marginal revenue equal to marginal cost. Doing this and solving for $q_1$ gives us

$$q_1 = \frac{(150 - q_2)}{2}.$$

This relationship, called the reaction function, shows the profit-maximizing output level for Firm 1 given any output level chosen by Firm 2. So, for example, if Firm 1 sees that Firm 2 is producing 10 units of output, it would choose to produce 70 units of output.

Similar reasoning leads to the reaction function for Firm 2, given by

$$q_2 = \frac{(150 - q_1)}{2}.$$

Because each firm chooses its output level according to its reaction function, the Cournot equilibrium is found at the intersection of the two. Solving the two equations together for the example gives equilibrium quantities of 50 units of output for each firm. Note that this equilibrium is a Nash equilibrium: Each firm is maximizing its profits given the level of output produced by its competitor, so neither firm wants to change its output level. With total output of 100 units, the market price in equilibrium is \$60. Profits, calculated using the formula $(P - AC) \times q$, are thus \$2,500 for each firm, so total industry profits are \$5,000.

To get some perspective on this equilibrium, it is useful to compare it to both perfect competition and monopoly. Under perfect competition, price would equal marginal cost, \$10; total output would be 150; and no firm would make economic profits. As we saw earlier, the monopoly output is 75 and the market price is \$85; monopoly profits are (\$85 − \$10) × 75, or \$5,625. Thus, we see that the Cournot duopolists produce less output and make considerably more profits than competitive firms; we also see that they do not do as well as colluding firms working together to produce the monopoly outcome.

### *The Stackelberg Model*

Suppose now that one of the duopolists can choose its output level first; its competitor then observes this output level and reacts to it. While the Cournot model makes sense for an industry composed of basically similar firms, the Stackelberg model might be more appropriate for an industry in which one firm typically is the leader in introducing new products or determining output levels. For

example, IBM has been the leader in the mainframe computer market for many years.

Let us continue the example, assuming that Firm 1 is the leader and Firm 2 is the follower in the industry. Because Firm 2 chooses after Firm 1, it treats Firm 1's output as given and will use the Cournot reaction function,

$$q_2 = \frac{(150 - q_1)}{2},$$

to select its output level. The leader, however, can take advantage of its leadership position to do better than it would do under Cournot. The leader uses its knowledge of the follower's reaction function in making its own decision:

$$P = 160 - q_2 - q_1 = 160 - \left(\frac{150 - q_1}{2}\right) - q_1$$
$$= 160 - 75 + \frac{q_1}{2} - q_1 = 85 - \frac{q_1}{2}.$$

Using the twice-as-steep rule, the corresponding marginal revenue for Firm 1 is given by MR = 85 – $q_1$; setting this equal to marginal cost of $10 tells us that the profit-maximizing quantity for the Stackelberg leader is 75. The follower will then produce 37.5 units of output for a total industry quantity of 112.5; the market price will be $47.5. As expected, Firm 1's profits, $2,812.50, are better than under the Cournot model. However, Firm 2's profits under Stackelberg fall to $1,406.25; indeed, the follower does only half as well as the leader in this model.

The result that the leader does considerably better than the follower is an important feature of the Stackelberg model. Remember that the two firms produce identical products and face the same, constant marginal cost, so the advantage for the leader is not a result of product differentiation or better technology. In addition, Firm 2 does worse in Stackelberg despite the fact that it has concrete information about Firm1's choice—information it does not have in the Cournot model. The key difference between the two models is that Firm1's Stackelberg choice to produce a large quantity of output (75 units in the example) is irreversible. To maximize profit, the follower has no choice other than to take this large output level as given and produce a smaller quantity of output itself. Stackelberg's modification to Cournot's initial model is important, showing us that moving first clearly has advantages.

*The Bertrand Model*

A different modification of Cournot's model, developed by another French economist, Joseph Bertrand, in 1883, looks at the equilibrium that results if oligopoly firms choose price rather than quantity. As in Cournot's model, firms produce a homogeneous product and make their decisions simultaneously. It turns out that choosing price instead of quantity has a dramatic effect on the outcome.

In our example, each firm has a constant marginal cost of $10; market demand is $P = 160 - Q$. Because products are identical, the firms realize that if their prices differ, consumers will buy from whichever firm has the lower price. If they charge the same price, consumers will be indifferent between the two, so the firms will split the market.

Imagine that you are deciding on price for one of the two firms. If you expect your competitor to set price anywhere above marginal cost, you have an incentive to set price just below the competitor's price and take the entire market. But of course, your competitor reasons similarly, hoping to undercut your price. Consequently, the only Nash equilibrium for the simple Bertrand model is the competitive equilibrium. Each firm will set price at marginal cost, $10, producing 75 units and making zero economic profit. At this point, neither firm wants to change its price: Raising price would lead to losing all sales to the rival, and lowering price below $10 would result in losses on every unit of output.

Economists have shown that introducing product differentiation, cost differences across firms, or capacity constraints to the Bertrand model results in an equilibrium price above marginal cost. Still, the Bertrand model shows the importance of the choice of the strategic variable. Choosing price instead of quantity leads to a strikingly different equilibrium, illustrating again the importance of looking carefully at the way any real-world oligopolistic industry works when thinking about its competitiveness.

## Game Theory

As we have seen, analyzing oligopoly behavior is complicated because of the strategic interactions among the firms. Economists have adopted tools in game theory, developed initially as ways to think about military strategy during World War II, to analyze these interactions. Indeed, although the models we have already considered were developed before the pioneering work in game theory, economists have shown that they fit within this theoretical framework.

Game theory has two branches. Cooperative game theory assumes that firms work together to maximize joint profits, dividing up the market among them. In noncooperative game theory, firms act independently, attempting to maximize individual profits while taking their rivals into account. We turn first to this type of game, looking at a classic game theory example that illustrates the problem faced by oligopolists.

*Simultaneous Games: The Prisoner's Dilemma*

Suppose that BASF and Merck are the only producers of vitamin C and that they are choosing quantity in a simultaneous game. Also, to keep things simple, assume that each firm can pick only one of two alternative quantities: 20 million tons or 30 million tons. Given these simplifying assumptions, the outcomes of combinations of choices can be represented in a payoff matrix containing four cells, shown as Figure 12.5.

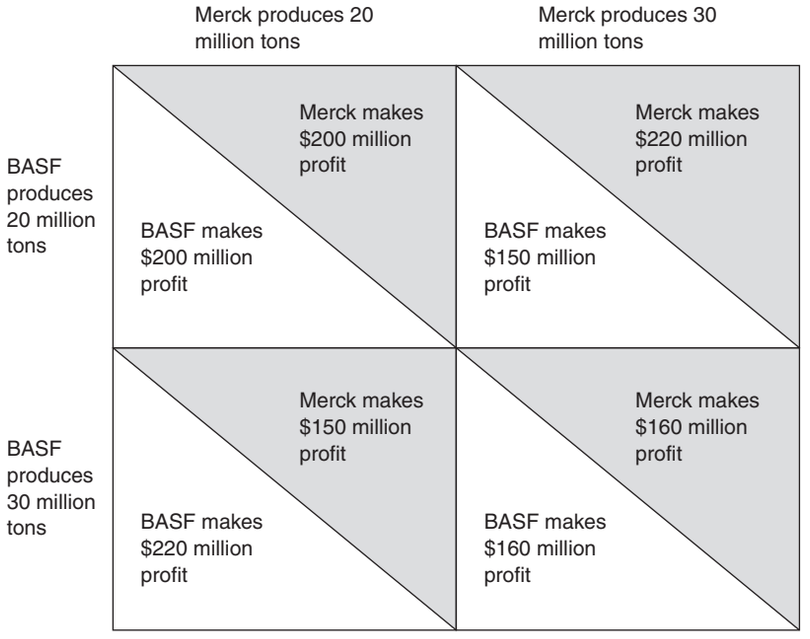

**Figure 12.5** Payoff Matrix for Firms Choosing Quantity of Output

The payoff matrix shows that joint profits of the two firms are maximized if each produces 20 million tons of vitamin C; this would be the cooperative outcome. However, imagine that you are deciding on production for BASF. If you expect Merck to produce 20 million tons, you can earn higher profits by cheating on the collusive agreement and increasing your output to 30 million tons ($220 million in profits is better than $200 million in profits). On the other hand, if you expect Merck to increase its output to 30 million tons, then you also want to produce the larger output level ($160 million in profits is better than $150 million). Of course, decision makers at Merck reason the same way; producing 30 million tons is called a dominant strategy because it is the best choice regardless of the other firm's actions. Thus, the Nash equilibrium is for both firms to produce 30 million tons of vitamin C even though each ends up with lower profits than at the cooperative outcome. This example helps us understand why it is often difficult for oligopolists to maintain an agreement about quantity, price, or other strategic variables.

This outcome is frustrating for the two firms. If they had some way of enforcing cooperative behavior, such as signing an unbreakable contract, they could avoid the prisoner's dilemma equilibrium. However, even if the firms could figure out how to write an enforceable agreement, they would be subject to antitrust law, which holds such agreements illegal. Thus, it seems as if the undesirable noncooperative equilibrium, with both firms producing 30 million tons of vitamin C, is the inevitable outcome. Might anything change this?

### *Overcoming the Prisoner's Dilemma?*

If firms are playing a prisoner's dilemma game only once, they will arrive at the noncooperative Nash equilibrium. But most oligopolists interact with each other repeatedly. Using our simple example, BASF and Merck regularly have to decide how much vitamin C to produce. Consequently, in addition to thinking about short-run profits, managers are likely to consider the long-run implications of a decision to "cheat" on their reputation and on other firms' reactions. Each firm may reason that production decisions in the current period are a signal about intentions in future periods, understanding that it is actually in its own long-run best interest to help the other by restricting output. This resolution of the prisoner's dilemma can thus occur even without explicit collusion or an enforceable agreement about strategy; economists call such behavior tacit collusion.

Tacit collusion is successful in some oligopolistic industries but not in others. Looking at real-world oligopolies, we can identify several key factors that complicate life for oligopolists, making it more difficult to collude tacitly or undermining the stability of any arrangements:

- *Large number of firms.* Suppose that the China Pharmaceutical Group joins BASF and Merck in the vitamin C industry. With three firms in the industry instead of two, the reward to any firm for cheating—the gain in short-run profits—increases compared to the gain with only two firms. Also, with more firms, it becomes harder to monitor rivals' actions. As the number of firms in an industry increases, tacit collusion is less likely to be successful.
- *Low industry concentration.* Consider two industries, each with 10 firms; in Industry 1, the two largest firms control 80% of the market, while the combined market share of the two largest in Industry 2 is 20%. In Industry 1, the two largest firms can behave as price leaders with the smaller firms following, making coordination easier.

On the other hand, it is more difficult to know who will lead on price changes, advertising campaigns, or other strategic decisions in Industry 2, where market share is more evenly divided.

- *Cost asymmetries.* If firms have different costs, it is difficult to agree on output and price. High-cost firms would prefer a higher price and lower combined output; low-cost firms would prefer greater industry output and a lower price. Also, differences in costs across firms affect firms' incentives to cheat on any agreement: Low-cost firms have more incentive to cheat than high-cost firms because they will gain more in profits by expanding output.
- *Product differentiation.* Vitamin C is a fairly homogeneous product, so producers would need to coordinate only on a single price or level of output. On the other hand, consider an industry such as the beer industry; coordination in this industry would require a schedule of prices for products ranging from India pale ale to stout to pumpkin ale. The more differentiated products are, the more possibilities there are for disagreement and difficulty in recognizing whether rivals are cheating on an agreement.
- *Rapid rate of innovation.* Not surprisingly, tacit collusion is more difficult in industries experiencing a high rate of technological change than in industries in which product characteristics are stable. Consider, for example, the cell phone industry and the rapid evolution of products within this industry. The frequent changes in product characteristics, production costs, and demand complicate life for oligopolists.

### *Sequential Games*

In sequential games, players move in turns. The Stackelberg model, in which one firm sets output before the other, is an example of a simple sequential game. Other examples include capacity investment by an incumbent firm and a potential competitor's decision about whether to enter a market or a new advertising campaign by one oligopolist and its rivals' responses. Firms may also make decisions about adopting new technology sequentially. As we saw in the Stackelberg model, changing the setup of a strategic game from simultaneous to sequential affects the outcome. Here we examine a simple entry-deterring game to illustrate solution concepts for sequential games.

Suppose that a small town in New Mexico currently has no drugstore. Executives at CVS have decided to enter this market and must decide what size store to build. They know that the opportunity cost of the funds necessary to build the store is 12%—that is, the store must earn a rate of return of at least 12% to be a worthwhile investment. If CVS builds a small store in the town, it will earn economic profits with a rate of return of 25%. Because of higher costs, the rate of return for a larger store will be only 18%.

Based on this information, it seems obvious that CVS should build the smaller store. However, the executives at CVS know that Kinney Drugs is also considering entering this market. If CVS builds a small store and Kinney enters, each will earn a 15% rate of return. If CVS builds a large store and Kinney enters, both will have to cut prices; each firm will earn only 10%, thereby incurring economic losses.

Sequential games are analyzed using a decision tree, such as that shown in Figure 12.6.

Each box or decision node represents a point where one of the firms must make the decision shown in the box. CVS makes the initial decision about size of store, and then Kinney responds by deciding whether to enter the

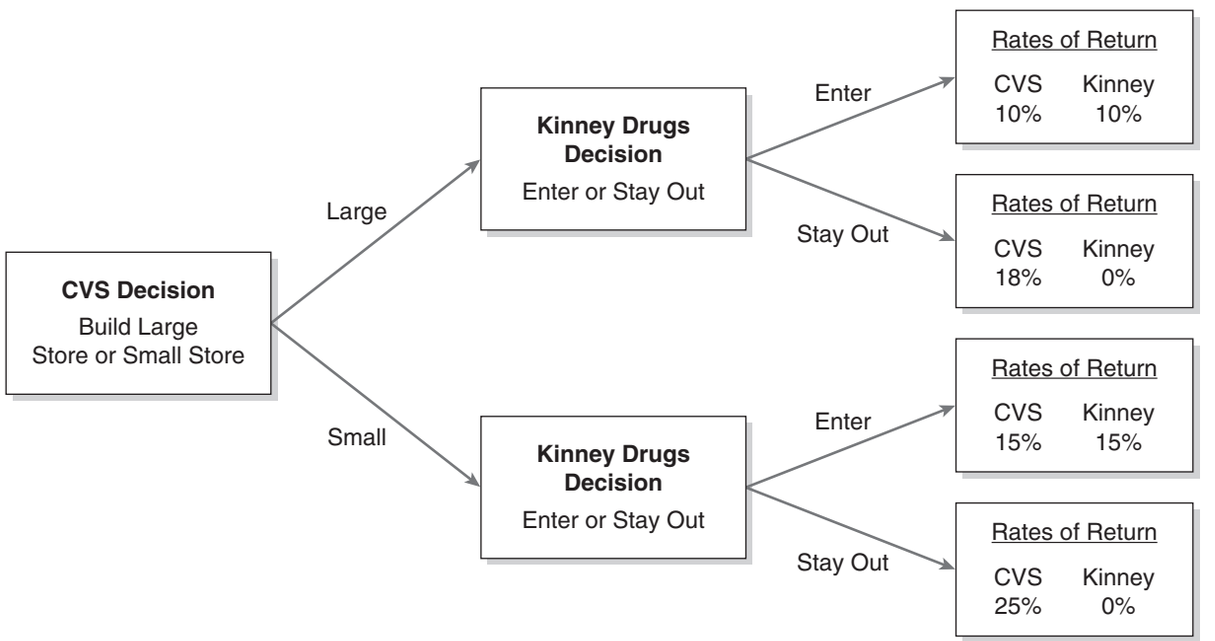

**Figure 12.6** Deterring Entry by Capacity Decision

market. The boxes on the right-hand side show the rates of return resulting from each combination of choices.

To solve a sequential game, firms should look ahead and then reason back. From the rates of return, CVS can reason that if it builds a small store, Kinney will enter, lured by the prospect of a 15% rate of return. On the other hand, if it builds a large store, Kinney will not enter the market: A 10% rate of return is below the opportunity cost of the funds. Thus, CVS understands that its two possible outcomes are rates of return of 18% or 15%; the profit-maximizing choice is to build the large store, deter entry, and earn 18%. Even though CVS would like to earn 25%, this outcome is not attainable as long as Kinney is behaving rationally.

Executives at CVS might well be frustrated by this and wonder if a *threat* to expand its store in the event of entry by Kinney Drugs would be enough to deter entry. Figure 12.7 shows the game tree for this scenario.

In this situation, CVS builds a small store but announces that it will expand its store if Kinney enters the market. Using the solution technique of looking ahead and reasoning back, we see that CVS's threat is not credible. Once Kinney Drugs has entered the market, CVS would be shooting itself in the foot by expanding, earning a rate of return of 10%—below the opportunity cost of its funds—instead of making positive economic profits at a 15% rate of return. The only equilibrium for this scenario is for Kinney to enter the market and for CVS to accommodate the entry by staying small.

This simple example illustrates the use of decision trees to help firms predict the actions of rivals and think through the implications of strategies. It also highlights the importance of *credibility*. An incumbent firm playing a sequential game must often make a *commitment*—to additional capacity, to a particular advertising strategy, to a new product—to change a strategic choice by potential or actual rivals. Economists have extended the analysis of sequential games to situations in which games are repeated, information is uncertain, and incumbents can be weak or strong, but the basic solution principle of looking ahead and reasoning back still applies. Decision trees are widely used in business planning.

## Limiting Market Power: The Antitrust Laws

Market power on the part of firms reduces consumer surplus and creates deadweight loss. Because of concerns about these adverse effects, governments in most countries have enacted policies related to market structure and behavior of firms. In the United States, Congress passed the first federal antitrust law, the Sherman Antitrust Act, in 1890. This act resulted from political pressures associated with the changing organization of American industry. Before the Civil War, high transportation costs kept the geographic size of most markets relatively small. After the Civil War, several factors led to the growth of national industrial markets: mass production techniques, a national railroad system, the development of modern capital markets, and the liberalization of the laws of incorporation in several states. As national markets arose, many small regional manufacturers faced increasing competition; farmers also were unhappy about what they saw as the abuses of firms with market power. Both the Democrats and the Republicans included planks in their party platforms opposing the trusts during the 1888 election, and Senator John Sherman introduced the first antitrust bill in the Senate shortly before the election. The bill was signed into law on July 2, 1890.

The Sherman Act has two substantive sections. Section 1 states in part, "Every contract, combination in the form of a trust or otherwise, or conspiracy, in restraint of trade of commerce among the several states, or with foreign

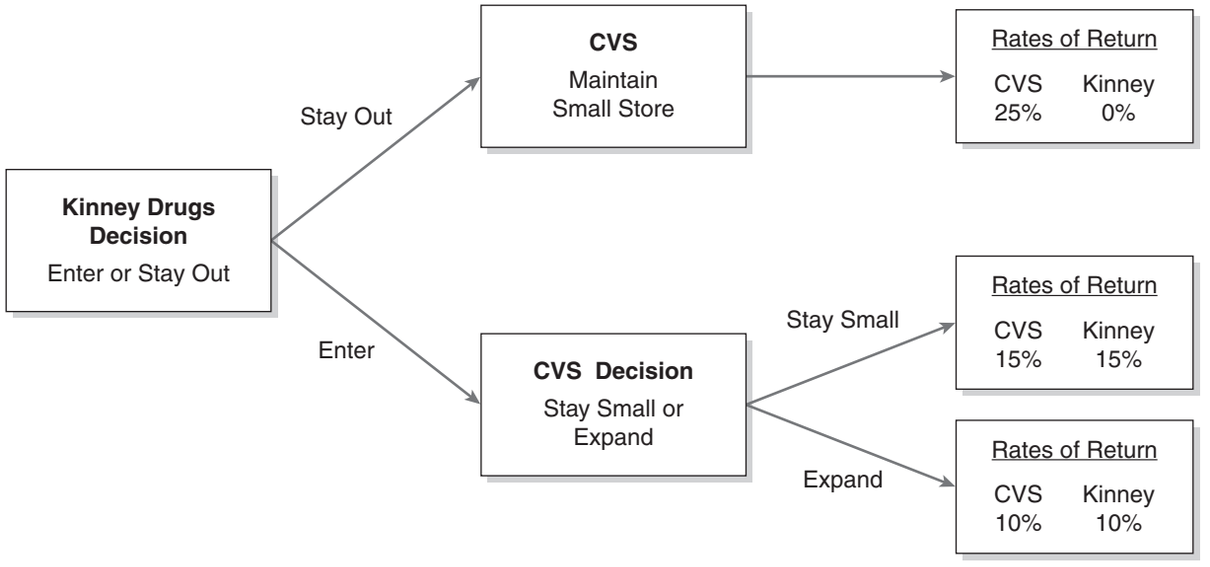

**Figure 12.7** Examination of Credibility of a Threat

nations, is hereby declared to be illegal." Section 2 includes language that "every person who shall monopolize, or attempt to monopolize, or combine or conspire with any other person or persons to monopolize any part of the trade or commerce among the several States, or with foreign nations, shall be deemed guilty of a misdemeanor."

Although this language sounds quite strong, the legal interpretation and implications led to problems soon after the law was passed. By making it illegal for rival firms to collude with each to fix prices, Section 1 paradoxically strengthened the incentive of competitors to merge. In part, this act led to the first major merger wave in the United States at the turn of the century. The wording of Section 2 of the Sherman Act led to some confusion about what, in fact, constituted a violation. In a famous ruling in 1911 (the *Standard Oil* decision), the Supreme Court annunciated a precedent that has come to be known as the Rule of Reason. According to this interpretation, only *unreasonable* attempts to monopolize are illegal; the mere possession of market power is legal as long as it is not a result of aggressive business tactics aimed at obtaining a monopoly.

In 1914, Congress responded to concerns about the Rule of Reason and about some specific business practices by passing two additional major pieces of antitrust legislation, the Clayton Act and the Federal Trade Commission Act. The four substantive sections of the Clayton Act targeted certain specific types of business conduct. Specifically, Section 2 forbade price discrimination, although it provided for three defenses that have turned out to be fairly large loopholes. Section 3 forbade *tying contracts,* which force a buyer to purchase one good in order to buy another good, and *exclusive dealing arrangements,* which require a buyer to purchase its entire supply of some good from one seller. Section 7 targeted the horizontal mergers that took place after the passage of the Sherman Act, making it illegal for a company to acquire the stock of another corporation if the acquisition would "restrain commerce in any section or community or tend to create a monopoly of any line of commerce." Finally, Section 8 prohibited interlocking directorates between any two competitors, making it illegal for the same person to serve on the board of directors of rival companies.

The Federal Trade Commission (FTC) Act established the Federal Trade Commission, an independent antitrust agency empowered to enforce the Clayton Act. In addition, Section 5 of the FTC Act directs the commission to "prevent persons, partnerships, or corporations, except banks, and common carriers subject to the acts to regulate commerce, from using unfair methods of competition in commerce." Although this seems like a broad mandate, in fact, the FTC had little power in its early days, with its only remedy being the power to issue cease-and-desist orders. Also, economists have pointed out that what some firm regards as an "unfair" method of competition may increase overall competition and benefit consumers.

The next major piece of antitrust legislation in the United States, a product of the Great Depression when countless numbers of businesses failed, is the most controversial. The Robinson-Patman Act concerns price discrimination, amending part of the Clayton Act and adding provisions declaring specific types of price discrimination illegal regardless of the reason underlying their use. In practice, the Robinson-Patman Act often has been used to protect individual firms rather than competition.

In 1950, Congress passed the final major amendment to the Clayton Act. The Celler-Kefauver Act closed a loophole in the original act. Firms had discovered that, as written, the act forbade corporations from merging by buying the stock of their competitors but *not* by directly acquiring rivals' assets. The 1950 amendment put some teeth into the restrictions against anticompetitive mergers.

More than a century of experience with antitrust law has shown the importance of interpretation by the courts. During the past 40 years, antitrust policy itself has undergone a considerable transformation as industrial organization economics has come to play an increasingly important role. This process continues with the outcome unclear. However, it is exciting to know that economic analysis is now central to enforcement policy in the Justice Department and the Federal Trade Commission and to decisions made in courts. The interaction between advances in economic theory and implementation and interpretation of antitrust policy is rewarding for economists and policy makers alike.

# Predatory Pricing and Strategic Entry Barriers

Bradley P. Kamp
*University of South Florida*

The classic definition of predatory pricing is pricing below cost with the intention of running a competitor out of business. In more general terms, predatory pricing is a price reduction that is only profitable because of added market power the predator gains from eliminating, disciplining, or otherwise inhibiting the competitive conduct of a rival or potential rival (Bolton, Brodley, & Riordan, 2000). Claims of large companies preying on their smaller competitors are commonplace, starting during the formation of trusts during the late nineteenth century up through charges against Wal-Mart today. Yet in the two most recent, precedent-setting predatory pricing cases, the Supreme Court observed that "there is a consensus among commentators that predatory pricing schemes are rarely tried, and even more rarely successful" (*Matsushita Electric Industrial Co. v. Zenith Radio Corp.,* 1986), and "predatory pricing schemes are implausible . . . and even more implausible when they require coordinated effort among several firms" (*Brooke Group Ltd. v. Brown and Williamson Tobacco Corp.,* 1993). The goal of this chapter is to present a brief history of predatory pricing, beginning with the era of trusts. The debate as to the rationality of predatory pricing will be examined, followed by a discussion of what is currently recognized by the courts as an act of predation. A look at research since *Brooke Group* ensues. As the recoupment of lost profits during the period of predation is now a necessary condition to be guilty of predatory pricing, strategic entry barriers will be examined. Possible explanations of the prevalence of predatory pricing cases are offered, with a discussion of claims against Wal-Mart to follow. Some short remarks conclude.

## Predation and Trusts

During the era of trust building, predatory pricing was believed to be a commonly employed business practice. This was predation of the price discrimination variety—firms would cut prices in some markets to influence rivals while leaving prices higher in other markets. Many cases have been examined by antitrust scholars, including trusts in gunpowder (Elzinga, 1970), sugar (Zerbe, 1969), cornstarch/syrup (*United States v. Corn Products Refining Co.,* 1916), tobacco (Burns, 1986), and matches in Canada and the British "fighting ships" (Yamey, 1972). Perhaps the best-known accusation was put forth by Ida Tarbell in her 1904 book *The History of Standard Oil Company.* Coupled with testimony during the antitrust case against Standard (*Standard Oil Co. of New Jersey v. United States,* 1911), it was widely believed that Standard did employ predatory pricing along with other anticompetitive practices. Even today, the Standard Oil case is often the first antitrust case presented in introductory economics texts.

Standard was accused of using its monopoly power to price discriminate, undercutting rivals in some locations, while subsidizing losses with profits from other locations. Similarly, it maintained its monopoly position by selectively cutting prices in markets where competitors dared to

enter. It was widely agreed that predatory pricing played an important role in Standard's monopolization of oil refining. So concerned were regulators about the effectiveness of predatory pricing in securing monopoly power that predatory pricing was included in the list of business practices specifically outlawed by the Clayton Act of 1914 and again in the Robinson-Patman Act of 1936.

The Standard Oil case also led to the first major questioning of predatory pricing as a viable business practice. In his groundbreaking paper, John McGee (1958) scoured the court records, closely examining each of Standard's 123 known refinery purchases. He found numerous contradictions to what would be considered classic predation. First, predatory pricing assumes that a large firm locally cuts prices while subsidizing the losses from profits elsewhere (i.e., the deep-pockets argument), yet Standard had less than 10% of the refining market as late as 1870. Predatory pricing strategies cannot explain how Standard obtained the necessary monopoly power to prey. McGee was the first to point out that when engaged in a price war, the larger supplier suffers the larger loss. In many regions, Standard had 75% or more of the local market, meaning that in a below-cost price war, Standard's losses would be at least three times those of the other competitors combined. In addition, a refinery does not just disappear when production stops. There is no reason why a competitor cannot shut down during the price war, then commence production once Standard raises price to recover the losses. McGee posited that obtaining competitors through mergers would be less costly, because the combined firm could earn monopoly profits right away, rather than suffer losses during a price war of unknown length. In addition, there should be some agreeable price, between the rents earned in a competitive market and those earned in a monopoly. McGee found that Standard obtained its monopoly through mergers rather than predation. Most of these mergers were of the friendly type, where owners and managers of the purchased refineries kept their positions. In other cases, owners who had sold to Standard opened new refineries in markets where Standard had a presence. Neither of these should occur if Standard used predation, because such an adversarial relationship would not lead to a cordial working agreement. McGee also refuted the argument that Standard used predation to lower the purchase price. To quote McGee: "I can not find a single instance in which Standard used predatory price cutting to force a rival refiner to sell out, to reduce asset values for purchase, or to drive a competitor out of business" (p. 157).

## Chicago and Post-Chicago Schools

Located at the University of Chicago during his Standard Oil study, McGee is a leading member of the Chicago school of antitrust scholars. The terms *Chicago* and *post-Chicago* arise frequently in the antitrust literature. Most Chicago scholars have some relation to the University of Chicago, but scholars who are skeptical about predatory pricing, regardless of affiliation, are classified as "Chicago school." *Post-Chicago* refers to scholars active primarily in theoretical industrial organization who examine the possibility of predation as an equilibrium strategy. There is no general consensus among post-Chicago scholars as to the viability and frequency of predatory pricing.

The general view of predation held by the Chicago school is that it is not a rational, long-run profit-maximizing strategy. The costs of predation must be offset by future monopoly profits, which are highly uncertain. Without postpredation barriers to entry, the monopoly price cannot be sustained, and no harm comes to consumers. Under this scenario, no action should be taken against aggressive pricing campaigns, even if competitors are injured. The benefits to consumers of vigorous price competition dominate any costs to the firms. Other classic presentations of the Chicago perspective on predatory pricing include Robert H. Bork (1978), Frank H. Easterbrook (1981), and John Lott, Jr. (1999). The current requirement of recoupment crystallized in *Brooke Group* (to be discussed in detail below) was first explicitly defined in a lower court case heard by Easterbrook (*A. A. Poultry Farms, Inc. v. Rose Acre Farms, Inc.,* 1989).

One perceived weakness of McGee's (1958) argument was its somewhat static approach. The effect of predation in one market on rivals or potential rivals in other future markets was never explicitly examined. Game theory allowed economists to explicitly model such strategic behavior. The seminal paper in this area, Selten's (1978) chain store paradox, showed that preying could not be an equilibrium strategy, even when considering its effect on future rivals. A series of papers followed, each relaxing one or more of Selten's assumptions. The authors working in this area form the "post-Chicago school."

The post-Chicago school examines the possibility of successful predation in a formal, equilibrium setting. These game-theoretic models include predation as a possible strategy and find that under certain assumptions, predatory pricing can be a rational, equilibrium strategy. These models expand the finite, full-information models of McGee and Selten into a more complex, dynamic world of imperfect and asymmetric information. The post-Chicago literature analyzes two major sets of models: those based on asymmetric financial constraints and those based on signaling. Ordover and Saloner (1989) present a thorough discussion of the post-Chicago literature.

Models involving asymmetric financial constraints trace their origin to Telser's (1966) "deep-pockets" argument. The predator has greater resources and can outlast the prey during a below-cost price war. In Telser's model, predatory pricing was not part of an equilibrium because under common knowledge, the potential prey would leave at the first opportunity rather than fight a price war it knew it was destined to lose. Predatory pricing does arise as an equilibrium strategy in works by Fudenberg and Tirole (1985, 1986). In these models, there is an information asymmetry in the credit

market. By preying in one period, the predator can lower the expected value of the prey's assets, leaving the prey unable to obtain financing in future periods.

Predatory pricing can be used as a signal to influence expectations of future profitability held by rivals, potential entrants, or even the creditors of the prey. Early papers by Milgrom and Roberts (1982) and Kreps and Wilson (1982) added an information asymmetry to the chain store model. Both showed that if the predator knew more than the potential entrants, predation could be an equilibrium strategy, although not necessarily the only equilibrium. A predatory price might be used to signal low costs (Milgrom & Roberts, 1982) or that the predator is aggressive and prefers preying to accommodating (Kreps & Wilson, 1982). A predatory price might be part of an equilibrium where the exit of a rival does not occur. Predation is used to change the prey's behavior, possibly to obtain better merger terms (Saloner, 1987). Critical to all of the post-Chicago school models is the assumption of an information asymmetry. Predation is successful only when the predator knows something that the prey or financial market does not and can use pricing strategies to influence beliefs about the unknown. When the uncertainty is in both directions (i.e., when the predator does not know everything about the prey as well), the likelihood of successful predation drops.

## What Constitutes Predation

Under the Sherman and Clayton Acts, a firm could be found guilty of predatory pricing if it priced sufficiently lower in markets where it faced competition than in markets where it did not. Predatory pricing cases were infrequent until passage of the Robinson-Patman Act in 1936. Undercutting the price of a local firm by a large, multimarket firm was prima facie outlawed. In the 1940s, the Federal Trade Commission (FTC) stepped up its enforcement of the Robinson-Patman Act, with plaintiffs winning most litigated cases, including at least some cases where there was not clear predation (Koller, 1971). Antitrust scholars refer to this as the "populist era" of predatory pricing enforcement (Bolton et al., 2000).

The Robinson-Patman Act protected businesses from larger rivals. However, little notice was given to the benefits to consumers arising from lower prices and more vigorous competition. A large firm might undercut a local firm's price not because it is a predator but perhaps to capture some of the local firm's rents. The way that predatory pricing was viewed under Robinson-Patman varied considerably. In the precedent-setting 1967 *Utah Pie* ruling, evidence of predatory intent and an unreasonably low price were sufficient for a verdict of predation. However, the *Utah Pie* ruling neglected to specifically define what was meant by an "unreasonable" price. In their 1975 paper, Areeda and Turner tied the definition of a predatory price directly to the costs of the predator. A price was found to be predatory if it was below the predator's average variable cost (used as a proxy for marginal cost). The "Areeda-Turner rule," or some slight variation, was quickly and widely adopted by the courts. Predation suddenly became more difficult to prove: In the 7 years following the article's publication, plaintiffs' success rate dropped to only 8%, as compared to 77% during the populist era (Bolton et al., 2000). To date, the Areeda-Turner rule remains an important factor in determining predatory pricing violations. However, pricing below average variable cost is no longer sufficient to be guilty of predatory pricing.

In the *Matsushita* case, the Supreme Court, for the first time, looked beyond short-run losses and weighed the possibility of recoupment in its decision. The Court held, "The success of any predatory scheme depends upon maintaining monopoly power for long enough to both recoup the predator's losses and to harvest some additional gain" (*Matsushita Electric Industrial Co. v. Zenith Radio Corp.,* 1986). As the plaintiffs failed to offer convincing evidence of possible recoupment, the Court found it unnecessary to conduct a detailed inquiry into whether the defendant's prices were below costs. In the most important precedent-setting case of late, *Brooke Group Ltd. v. Brown and Williamson Tobacco Corp.* (1993), the prospect of recoupment was the primary determinant of whether damage to competition had occurred. At the appellate level, the Fourth Circuit Court of Appeals acknowledged that prices below some measure of costs are necessary to prove predation. However, the court ruled that predation also required "the rational expectation of later realizing monopoly profits. The failure to show this additional aspect is fatal" (*Liggett Group, Inc. v. Brown and Williamson Tobacco Corp.,* 1992). The Supreme Court declined to enter the conflict over measures of costs but concentrated instead on the plausibility of recoupment. The Court ruled that when assessing the plausibility of recoupment, the analysis must first "demonstrate that there is a likelihood that the predatory scheme alleged would cause a rise in prices above the competitive level" and these prices during the recoupment stage must "be sufficient to compensate for the amounts expended on the predation, including the time value of the money invested in it" (*Brooke Group Ltd. v. Brown and Williamson Tobacco Corp.,* 1993, p. 2589). The Court offered examples of where predation would be unlikely to lead to recoupment: where barriers to entry are low or where the market structure is diffuse and competitive. In the final ruling on *Brooke Group,* the Court found that recoupment, and therefore predatory pricing, was implausible given the oligopolistic nature of the market. For a thorough examination of recoupment standard put forth in *Brooke Group,* see Elzinga and Mills (1994).

To be found guilty of predatory pricing today, evidence must be presented that the defendant priced below some measure of cost *and* that recoupment of losses suffered during the period of predation (recoupment of losses is the subject, not pricing below cost and recoupment) is probable. The recoupment standard is critical and difficult for the plaintiff to prove. Zerbe and Mumford (1996) provide a

detailed examination of the first 14 post–*Brooke Group* cases. In fact, since *Brooke Group,* the FTC has not successfully prosecuted a single firm.

## Current Research in Predatory Pricing and Strategic Entry Barriers

While the courts of late remain skeptical about the prevalence of and damages caused by predatory pricing, it continues to be an area of active research. The requirement that price lies below some measure of cost raises some concerns. Edlin (2002) examines the possibility of predation when prices stay above costs. In addition, cost-based rules would miss an important method of predation—the raising of competitor's costs. Granitz and Klein (1996) applied econometric techniques not available to McGee and presented evidence that Standard Oil did in fact use this method of predation.

Theorists working in the field of predatory pricing express concern that the courts have rarely cited the strategic (i.e., post-Chicago) literature, even though this literature offers an array of models where predation is a rational, profit-maximizing strategy. It is important to note that in every strategic model, predation occurs in equilibrium only if recoupment is possible. Of course, recoupment is only possible if there is some barrier to entry, so this line of research could be thought of as the study of strategic entry barriers. The arguments put forth in the strategic entry barrier literature are not in conflict with the crux of the *Brooke Group* ruling. Rather, some economists worry that the courts are inadequately assessing the probability of recoupment. Courts that fail to recognize market imperfections might miss possible ways these imperfections can be exploited to keep rivals out.

Critical in McGee's (1958) critique of the Standard Oil case was the assumption that costs were similar across firms. When markets work well and technology is easily transferable, such as in oil refining, this assumption is reasonable. But some markets fail to meet these conditions. One example is when production exhibits a learning curve, where costs fall as a producer obtains more experience in production. Cabral and Riordan (1994, 1997) show that a learning curve can be manipulated to create a barrier to entry. In such models, a firm preys early to increase output, thereby moving farther down the learning curve and eventually gaining an entry-deterring cost advantage. This behavior clearly meets the predatory pricing standards put forth in *Brooke Group.* However, the welfare effects of such predation are indeterminate. As stated in the conclusion of the 1997 paper, "The information requirements of fashioning an effective legal rule against harmful predation are formidable" (p. 168). A similar stance was taken by Chiaravutthi (2007), who studied the possibility of successful predation in a market with network externalities. A network externality occurs when the benefit of joining a network increases with the number of members. Chiaravutthi found that in a laboratory setting, predatory pricing is often a successful strategy. Predation increases membership early, raising the value to potential members above that of other networks and creating an entry barrier. The welfare effects of successful predation were again ambiguous, and the author concluded that "all in all, it seems extremely difficult to frame a legal rule that would make the correct diagnosis in all cases" (p. 169). Note that it was the market failure, not the laboratory setting, that resulted in successful equilibrium predation in Chiaravutthi's model. Earlier lab testing of predatory pricing in well-behaved markets was not quite as successful (see Gomez, Goeree, & Holt, 1999, for a survey of laboratory-based predatory pricing research).

Since Chamberlain (1933), it has been widely accepted in the industrial organization literature that product differentiation is a potential source of market failure. Schmalensee (1978) showed that product differentiation can be an effective barrier to entry. Lindsey and West (2003) examined the effects of predatory pricing in a market with differentiated products. They found (via simulation) that with product differentiation, predatory pricing is a possible equilibrium strategy. However, the authors did not explicitly address recoupment or welfare effects.

During the 1980s, much research was undertaken in finance on the imperfections inherent is capital markets. Bolton and Scharfstein (1990) showed that these imperfections can lead to an entry barrier necessary for successful predation. Entrants into an industry typically have implicit agreements with their backers for additional postentry financing. This financing is often conditional on early post-entry performance. By preying, an incumbent firm can reduce the entrant's profits, increasing the chance that additional funding will be denied. Additional work in the field of financial market predation includes Bulow and Rogoff (1989) and Diamond (1989). All of the authors stress the relevance of their models in rapidly evolving industries where firms rely heavily on venture capital for financing.

The discussion on recoupment standards continues. Iacobucci (2006) examines Canada's wavering on recoupment post *Brooke Group.* He presents a strong argument that recoupment tests reduce the chance of improperly characterizing lawful price reductions as predatory. A debate between some of the brightest scholars working in the field was published in the *Georgetown Law Journal* in 2001 (Bolton, Brodley, & Riordan, 2000, 2001; Elzinga & Mills, 2001). Bolton et al. (2000, 2001) take the view that the courts need to pay more heed to strategic models. They present a series of tests that would better enable the courts to discover possible strategic entry barriers that currently go unnoticed. Elzinga and Mills (2001) point out the strong assumptions in the strategic models and worry that applying theoretical models to actual firm behavior would be extremely difficult. Perhaps their position is put forth best in the following quote: "If you are hunting for a predator and mistakenly shoot a competitor, you injure consumers" (p. 3).

## The Prevalence of Predatory Pricing Cases

If predatory pricing is not a viable business practice, why do we still see lawsuits claiming predation? The first reason was discussed above: Strategic predatory pricing is taking place, but the courts are not sophisticated enough to recognize it. Perhaps a plaintiff knows competition has been harmed by predation and that recoupment will be possible. Given that antitrust awards are automatically trebled, it is worth taking the chance to conceivably become the new precedent-setting case.

Baumol and Ordover (1985) provide another explanation of predatory pricing cases: use of the antitrust laws to facilitate tacit collusion. Collusion between competitors to restrict output (i.e., raise price) is against U.S. law. However, it is widely held that there is extensive tacit or informal collusion throughout the economy. Baumol and Ordover present a scenario where industry rivals threaten predatory pricing suits against competitors that make a competitive price cut. Given the expense of fighting a predatory pricing lawsuit (e.g., American Airlines spent $20–$30 million to fight the suit brought by Continental; Clouatre, 1995), such threats can be effective deterrents to competition. Harrington (2004) formally examined the effects of antitrust laws on the stability of cartels. He found that it is possible that such laws, which were enacted to fight cartels, might actually increase the viability of a cartel.

A simpler, nonstrategic explanation is that the plaintiff does not know its rival's costs. What seems to be a predatory price (i.e., a price significantly below the plaintiff's costs) might not actually be below the defendant's costs. Kamp and Thomas (1997) modeled such a situation, where a rival firm's quality (and therefore costs) was uncertain. Due to a secret quality cut, what appeared to be a predatory, below-cost price was actually a price that was still above cost. The necessary condition of a below-cost price is not met, and the courts would find in favor of the defendant. A final possibility is that a below-cost price is set to capture a larger market share, without regard to possible recoupment. Thomas and Kamp (2006) present several plausible reasons why at least some managers, and perhaps even many managers, sometimes choose to pursue higher market share by cutting prices, even when the price cuts and higher market share reduce profitability. Under either of these types of predation, current predatory pricing policy yields desirable antitrust enforcement outcomes.

## Wal-Mart

Since 1990, no firm in the United States has generated more claims of predatory pricing than Wal-Mart. The Bentonville, Arkansas–based retailer obtained its position as the largest retailer in the United States primarily by offering "everyday low prices." Sometimes its competitors believe that these low prices are too low, even below costs. Perhaps the most important predatory pricing suit against Wal-Mart was filed in the Faulkner (Arkansas) County Chancery Court by three local pharmacies in 1991 (*American Drugs, Inc. v. Wal-Mart Stores, Inc.,* 1993). The plaintiffs claimed that Wal-Mart violated the 1937 Arkansas Unfair Trade Practices Act by routinely selling pharmaceutical products below cost. Strong evidence was provided that Wal-Mart priced certain items below its wholesale cost. One of the plaintiffs testified that he stocked his own store from Wal-Mart, as the retail price was below the lowest wholesale price he could find (Kurtz, Keller, Landry, & Lynch, 1995). This strategy is not unique to the Wal-Mart case: During an early twentieth-century attempt at predatory pricing, Dow purchased bromine offered on the U.S. market at below costs by its German competitor and resold it for a profit in Europe (Levenstein, 1997). In 1993, the Faulkner Court found Wal-Mart guilty of predatory pricing. Wal-Mart was ordered to stop charging below-invoice prices for its pharmaceuticals and to pay the three plaintiffs $289,407 (Boudreaux, 1996). Wal-Mart appealed to the Arkansas Supreme Court (*Wal-Mart Stores, Inc. v. American Drugs, Inc.,* 1995), and in January 1995, the Court ruled by a 4–3 decision to overturn the lower court verdict and dismiss the case.

More recently, in 2001, Wal-Mart and the Wisconsin Department of Agriculture reached a settlement over claims that Wal-Mart sold butter, milk, laundry detergent, and other staples below costs in five Wisconsin cities. In the settlement, Wal-Mart admitted no wrongdoing and was not required to pay a fine. However, it agreed to pay double or triple fines for any future violations. In 2007, Wal-Mart was forced to eliminate its low-priced generic prescription plan for certain drugs in nine states, as their price was below their true costs. While questions remain as to whether Wal-Mart's aggressive pricing harms competition, there is no debate as to the benefits of low prices to its customers.

## Conclusion

The debate about the existence and feasibility of predatory pricing shows no sign of stopping. Currently, the courts take a somewhat skeptical view of the viability of predatory pricing. Showing that price was below cost is not enough: It is now the plaintiff's responsibility to show that the predator will be able to recover its losses suffered while preying. Much to the chagrin of theorists working in industrial organization, the courts of late have been unwilling to refer to the strategic literature when ruling. The makeup of courts changes, however, and there is no guarantee that we have reached a steady state regarding predatory pricing.

As long as rival firms engage in intense price competition, there will continue to be claims of predation. And as long as firms price below costs, economists will attempt to model predatory pricing as an equilibrium, profit-maximizing strategy.

# Labor Markets

Kathryn Nantz
*Fairfield University*

Work is a part of life for almost all people around the world. Though the types of work people do and the conditions under which that work is done vary endlessly, people get up each morning and choose to use their human capital in ways that generate some sort of productive good or service or that help prepare them to be productive economic citizens in the future. Some of this work is done in the privacy of the home, where beds are made, children are raised, and lawns are mowed. While this unpaid productive activity is essential to a well-functioning economy, this chapter addresses work time and skills that are sold in markets in exchange for wages and other compensation.

The purpose of this chapter is to explore the unique nature of labor markets and to consider how these markets will evolve in response to changes in the nature of the work people do over time. Use of labor, like any economic resource, has to be considered carefully in light of productivity and opportunity costs. Though many factors affect this decision-making process, in most cases labor is allocated by market forces that determine wages and employment.

That said, several characteristics of labor as a resource create complexities. First, the demand for any type of labor services is derived from, or dependent on, the demand for the final product that it is used to produce. This means that highly trained and productive workers are only as important in production in an economy as there is demand for the product they produce. Second, because labor cannot be separated from the particular persons who deliver the resource, the scope of responses to labor market decisions is broad and affects outcomes in significant ways. The sale of labor services generates the majority of household income around the world—income that is used to sustain workers and their families. This means that labor markets determine, to a large extent, what resources a household has available and thus the quality of life for the members of the household. Decisions become very complex when workers and their families begin considering not only job market choices but also premarket education and training that might be required to prepare individuals for particular occupations.

## Theory of Labor Market Allocation

As with all markets, buyers (employers or contractors) and sellers (employees) communicate their needs and offers with one another and exchange labor services for wages and other compensation. Some important assumptions underlie this model. First, assume that the wage and other monetary compensation is the most important determinant of behavior. This allows the construction of a model that has wages on the $y$-axis and quantity exchanged on the $x$-axis. Everything else held fixed, buyers and sellers will respond most directly to price signals exchanged between the two groups. Second, assume that workers are somewhat homogeneous—that is, that workers can be easily substituted for one another in any particular market. (Differences across workers will be explored later in this chapter.) Third, assume that workers are mobile and can move to places where there is excess demand for labor with their particular skills and away from places where there is excess supply of labor with their particular skills. Finally, assume that wages are flexible; they can move up or down in response to market signals.

Given these assumptions, the next step is to consider the behavior of buyers and sellers in what can be referred to as perfectly competitive markets for labor. In such markets, many relatively small employers hire relatively small amounts of labor; neither employers nor employees acting alone are a significantly large enough share of the market to be able to affect market wages. An example of this might be a college in New York City that hires administrative assistants. There are many such assistants in the market looking for jobs and many alternative employers, so both buyers and sellers have to accept the going wage for such work.

## Labor Demand

Employers seek workers based on workplace needs and based on the demand for the good or service being produced. In addition to the market wage, employers consider the productivity of labor, the ability to substitute across other inputs in the production process, and the prices of other inputs when making hiring decisions.

Labor productivity is determined by a variety of factors, including human capital investments made by the worker himself or herself or the employer, skills and talents, and the quantity of capital and technology that the worker has at his or her disposal. As might be assumed, the greater the investment made in an individual worker, the greater his or her productivity. Like with any other investment opportunity, the investor spends money now (e.g., gets a master's degree in social work or an MBA), hoping to eventually reap the benefits, in terms of greater income earning potential, in the future.

Substitution of inputs can be easy or difficult, depending on the production process being considered. For example, in an accounting firm, junior and senior partners might be equally productive (though not, perhaps, in the minds of important clients). Junior and senior partners can be relatively easily substituted for one another as tax forms are prepared. However, in a telemarketing firm, each caller needs to have his or her own phone. If an employer hires more callers but buys no more phones, no additional calls will be made. It might be easy to substitute junior for senior account managers, but it is impossible to substitute callers for telephones.

Understanding these sorts of trade-offs is very important for a firm; as the prices of inputs (junior and senior account managers or callers and phones) change, the employer will want to shift the input mix so that output is produced as efficiently and cheaply as possible. However, depending on the degree of substitutability, the changing input prices will create incentives to use more of the input that is becoming relatively cheaper and less of the input that is becoming relatively more expensive.

In spite of these other factors and their importance, firms tend to hire a greater number of hours or workers in the market, and more firms become buyers in a given market, as wages and compensation fall—everything else held constant. This empirically based conclusion is consistent with the law of demand. There is an inverse relationship between the quantity of labor demanded in a market and the price of labor in that market.

## Labor Supply

Workers seek jobs based on their own skills and talents and based on the variety of factors that help to determine their income needs. Preferences over alternative jobs are important—some workers seek jobs that provide them with a sense of pride, accomplishment, and satisfaction. In other cases, workers have a preference for maximizing their own personal income, and so they search for jobs that are high paying, regardless of their other characteristics. Happily, the diversity of jobs combined with the heterogeneity of workers and their preferences generates labor markets that provide incentives for employers and for workers. Jobs that are distasteful to many workers for one reason or another (washing windows on skyscrapers or cleaning out pig sties) attract workers who are less averse to the negative aspects (heights or smells), and/or the work commands wage premiums that accrue from smaller pools of available workers. Thus, workers sort toward jobs that best meet their particular preferences and monetary needs.

Most often, workers consider the expected wage to be a key factor, if not the key factor, in determining what jobs to seek and accept. For some jobs where compensation is based on productivity (sales commissions, as an example, for real estate agents), there can be significant wage uncertainty. This uncertainty means that a job with a high wage might not be as appealing as a job with a lower wage that offers more security. For example, a worker might put her desire to be a professional tennis player aside in favor of the more stable employment position of a bookkeeper if she has elderly parents who need her care. High wages alone are not enough to attract workers to jobs; it is the entire employment package, and the level of employment and compensation risk, that must be considered when choosing a labor market to enter.

Given these other factors and their importance, workers tend to offer more hours in the market, and more workers enter a given market, as wages and compensation rise—everything else held constant. This empirically based conclusion is consistent with the law of supply that governs most market settings. There is a direct relationship between the quantity of labor supplied to a market and the price of labor in that market.

## Market Equilibrium

When economists speak of equilibrium, they are using the term as any other scientist would—as a state of the world that, once reached, will not change unless a significant force acts upon it. Equilibrium price and quantity in a

labor market is reached when there is no further tendency for wages or quantity of labor bought and sold to change, unless there is a change in the market that affects the demand curve or the supply curve.

Consider Figure 14.1. At W2, Q3 workers are demanded, and Q3 workers are supplied. Note that if the wage is W1, the quantity of workers demanded is greater than the quantity of workers supplied. There is a shortage of labor; the quantity of labor employers are willing and able to hire is greater than the quantity of labor people are offering for sale. Wages will rise as firms outbid one another to attract the workers they need. On the other hand, at W3, the quantity of workers demanded is less than the quantity of workers supplied. There is a surplus of labor; the quantity of labor employers are willing and able to hire is less than the quantity of labor people are offering for sale. Wages will fall as workers have to accept lower wages if they hope to gain employment. Thus, the only point at which wages and employment will not be under pressure to rise or fall is at W2, and it is defined as the current equilibrium in this market.

Note several things about this equilibrium price and quantity. First, economists often refer to this point as *market clearing;* this means that everyone who wants to buy labor at this wage rate can and everyone who wants to sell labor at this wage rate can. There is no excess supply or excess demand at the equilibrium wage. Second, although the market clears at this point, it is not necessarily a "good" wage and quantity combination. There are people in the market who would like to purchase labor at wages below W2 who cannot do so (Q3–Q6), and there are people in the market who would like to supply labor at wages above W2 who cannot find jobs (Q3 and above). They are left out of the market under these supply and demand conditions, and that might not be good for the workers or their families if they are unemployed or for the firms if they need workers to produce output to sell in the marketplace. Finally, note that some markets are very volatile, and so even though there are equilibrium wages and quantities exchanged, supply and/or demand are shifting significantly and often. For example, consider dockworkers. When a ship arrives at a port, the workload is heavy and demand for workers is high. However, when there are no ships in port, either because demand for the goods coming in has fallen or because supply has been affected by weather or other factors, demand for workers is low or nonexistent. These sorts of big swings in demand for workers can lead to significant wage volatility. It will become clear that unique sorts of contractual arrangements will be required to be sure that workers will be available for these types of tasks.

## Imperfect Competition

The perfectly competitive market model applies when there are many, many workers in a market that also supports many, many employers. However, what if this is not the case? What if there is a single large employer that dominates the market for a particular type of labor? For example, major league baseball employs almost all of the professional baseball players in the United States. How does this situation impact the distribution of resources in a labor market? How will the equilibrium wage and quantity of labor exchanged be different under these circumstances?

*Monopsony power* refers to the ability of a single employer to control the terms of employment for all of, or a portion of, its workforce. The first significant examples of monopsonies emerged during the industrial revolution when factories (coal mines, steel mills, etc.) opened in small towns; the mine or the factory became the most significant employer in the town or local area, and workers

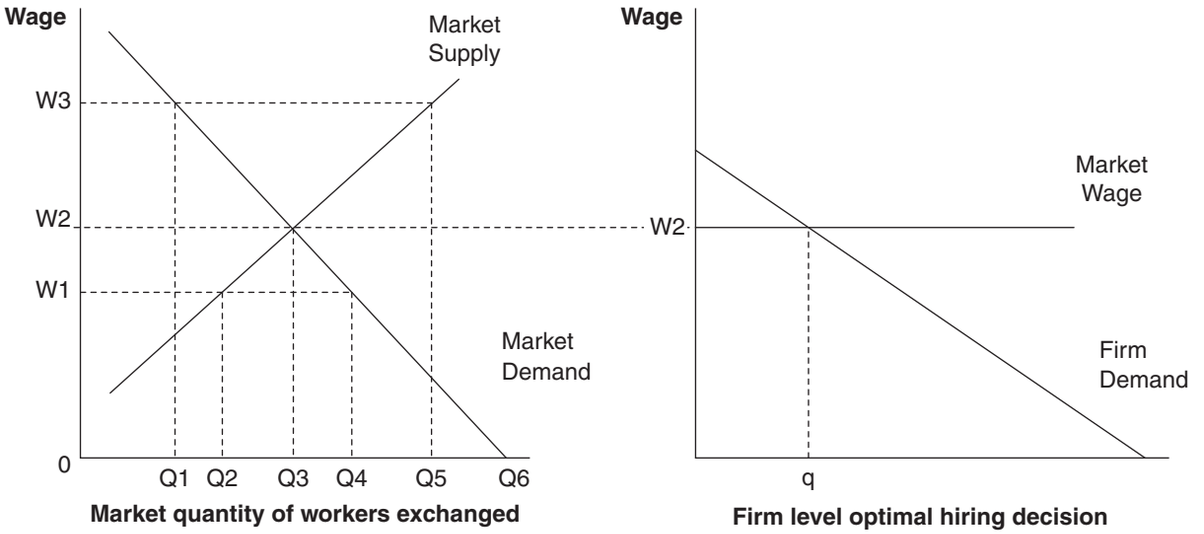

**Figure 14.1** Perfectly Competitive Market for Labor and Firm Level Employment

had few other job opportunities. Because workers had limited alternative employment options, the firms were able to pay lower wages and exploit the workforce in a variety of other ways. In some cases, firms also established company stores that became monopolies in the provision of goods and services. Thus, the workers were subject to monopsony power in the terms of their employment and monopoly power in the markets in which they spent their income.

In response to this exploitation of workers by monopsonistic employers, workers formed unions—collective organizations of sellers that formed to gain some bargaining power in negotiations with their employers over the terms of their contracts. These unions gained legal status in most countries around the world in the late nineteenth and early twentieth centuries. However, in some countries that are at the earlier stages of industrialization, unionization and other types of worker movements may still be illegal or nonexistent. Union history and activity is addressed in a separate chapter in this collection.

Consider the model in Figure 14.2. The labor demand curve, described as for the perfectly competitive market in Figure 14.1, depends on the output market in which the firm sells its final product and the productivity of its workers. However, now rather than paying a wage imposed by the free marketplace, firms have the ability to set wages at the lowest level possible. Firms are not assumed to be wage discriminators; all workers are paid the same amount per quantity supplied. (Wage discrimination is possible but is not considered here.) The key is that firms pay the lowest price they possibly can, given by the market supply curve at the optimal level of employment, and then increase the wage for all by the smallest amount possible, moving up the supply curve, when employment is increased by a small amount.

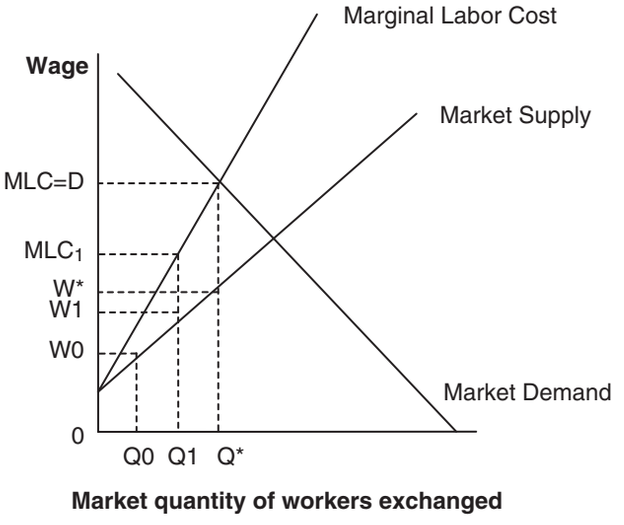

**Figure 14.2** Monopsony Labor Market

Using Figure 14.2, suppose the current level of employment is Q0 and the wage is W0. If the labor monopsonist chooses to increase employment by one worker, labor costs increase by the amount of the wage payment to the new worker but also by the increased wage that has to be paid to all of the existing workers. Firms cannot discriminate and so must pay the same higher wage to all workers of the same type if a marginal worker is to be hired. Thus, the increase in the costs of employment to the firm in this market when a marginal worker is hired is greater than just the wage paid to the new worker; the marginal labor cost (MLC) of hiring one additional unit of labor is *greater than* the wage paid to that one marginal unit. The MLC curve lies everywhere above the supply curve because at any quantity of labor, MLC is greater than the wage.

In these imperfectly competitive markets, firms choose to hire where MLC intersects the demand curve, at MLC = D and Q*. This means the amount of money that comes into the firm when a marginal unit of labor is hired is just equal to the amount of money that goes out when the marginal unit of labor is hired. However, firms are able to pay a wage that is lower than the value of the marginal worker to the firm (W*). This wedge between the value of the worker to the firm and the wage paid has ignited anger among philosophers and workers around the world for hundreds of years. They read Karl Marx's *Communist Manifesto* and believe in the labor theory of value, that the entire value of a final good or service should accrue to the labor inputs that were used to produce it. This alternative to a market model of wage determination had tremendous impacts on economies around the world during the twentieth century and will continue to affect decisions regarding trade-offs between the efficiency and equity of economic outcomes for years to come.

## Applications and Empirical Evidence

There are endless applications of labor market theory to be found in economies around the world. Three of the most significant will be considered here, but the ideas presented can be adapted to fit a variety of other circumstances.

### Economics of the Household or the New Home Economics

Increased labor force participation rates for women around the world, particularly in industrialized countries, were a major feature of the twentieth century. In addition to changing the landscape of labor markets, this phenomenon has had tremendous impacts on households, on families, and on the ways that cultures proscribe the management of unpaid work within the household. According to the U.S. Census Bureau, in 1900, 20% of women in the United States participated in the labor force (U.S. Department of Commerce, 1975). By 2000, that

percentage had increased to 59.9% (International Labour Office [ILO], 2003). By contrast, in 2000 the female labor force participation rate was only 16.3% in Pakistan, 39.6% in Mexico, and 49.2% in Japan. These differences are significant and reflect alternative cultural norms and government support for medical care, child care, and other such programs that make it easier for women to enter the workforce.

In the United States, women began entering the labor market in significantly greater numbers during World War II to replace male employees who were fighting overseas. However, at the end of the war, women were forced out of employment in many cases by men, who were assumed to be heads of households, returning from active duty. It was not until the 1960s that women began to make their way back to work. Many factors can account for this, including the development of safe and reliable birth control, increased access to college and university education for women, declines in birthrates, and increases in divorce rates.

Economists like Gary Becker and Jacob Mincer, who first began investigating family decision making in the early 1960s, used models of international trade to explain how the law of comparative advantage applied equally well to household specialization and trade and to international specialization and trade. These models showed that, when the opportunity costs differed for family members producing the same goods, household production would be more efficient if each member produced those goods and services that they produced with lowest opportunity costs. Trade within the household ensured that each member would be able to consume a mix of goods and services.

This model helped provide some insights into the nature of household production, but it immediately led to alternative explanations and theories. Economists like Barbara Bergman and Julie Nelson have cited alternative explanations for the household structure that we most commonly see around the world—the male head of householder working in the labor market and supporting the efforts of other family members who are engaged in production within the household or human capital formation. One explanation might be found in bargaining models, which describe women and children who are less powerful in the household due to the absence of monetary income or having to depend on an altruistic head of household for economic resources. This means that the typical household structure is the result of differences in access to resources and bargaining power rather than any sort of efficiency in allocation processes or gains from trade explanation. In other cases, the household resource distribution system could be modeled as a Marxist process of exploitation; the "haves" (aka workers in the labor market) exploit the "have nots" (aka nonmarket workers in the household) to pursue their own self-interest and personal resource accumulation. These alternative models of resource allocation within the household have become increasingly important as economists have tried to better understand the nature of social problems like discrimination and domestic abuse.

## Differences in Wages Across Occupations

In most economies, on average, doctors make more money than nurses, highway construction workers make more money than assembly line workers, plumbers make more money than administrative assistants, and stockbrokers make more money than teachers. Why is there so much wage dispersion in labor markets? What causes wages to vary so significantly across different types of workers and occupations?

There are a variety of answers to this question, but the key is that wages are often used to compensate for other aspects of a job that make it more or less attractive. For example, consider two jobs that are very similar in many ways: doctor and nurse. They both work in the same offices or hospitals, they both care for patients who have some form of health issue, and they both report to the same board of trustees or corporate owners of a health care facility. Because of these similarities, one might make an argument that the pay for these two occupations should be equal—what accounts for the differential in wages?

The key here lies in the significant difference in education and training required by doctors compared to nurses, in most cases. According to the Bureau of Labor Statistics, it takes 11 years of higher education, on average, to become a doctor, while the average registered nurse has a 4-year bachelor's degree (U.S. Department of Labor, 2008–2009a, 2008–2009b). If people are to find the additional time spent in education and training, not to mention the added responsibility of being a doctor rather than a nurse, worthwhile, there must be some hope of a future payoff. It is true that many doctors find great satisfaction in helping patients, but additional pay into the future must be expected in order to repay student loans and to cover the opportunity cost of lost wages during long years in school. This sort of return to education and training compensates for an aspect of becoming a doctor that is negative and that would discourage entrants from pursuing the occupation.

In another example, highway construction workers versus assembly line workers, compensation is provided for risk of injury on the job. Though both these occupations typically require dexterity, strength, and concentration, the highway construction worker faces a much greater risk of injury while at work than does the assembly line worker. According to a brief prepared by Timothy Webster (1999) for the Bureau of Labor Statistics, the number of injuries on the job for workers in construction and manufacturing jobs were almost equal; however, construction workers were almost four times as likely to die on the job than manufacturing workers. In this case, the higher wages paid to construction workers, who have similar levels of education and training as manufacturing workers, compensates for the much higher risk of death while on the job.

In other cases, higher wages compensate for unpleasantness on the job. Some of the most unpleasant working conditions can be found in meatpacking plants or in other food processing plants. Steel mills are notoriously hot and loud. Offshore oil drilling requires long periods away from home. Work in chemical plants may increase the risk of illness or cancer. All of these negative aspects of jobs lead to lower supplies of labor at any wage rate and hence higher wages.

One last aspect of an occupation to be considered is wage risk. Though two jobs, stockbroker and college professor, might have the same *expected* wage, the level of risk and uncertainty can be very different. For example, according to the 2005–2006 annual survey by the American Association of University Professors (2006), the average salary for a full professor was $94,738; typically a full professor has job and income security guaranteed by tenure but little hope of additional compensation. The Bureau of Labor Statistics cites the average salary for financial services sales agents in 2006 to be $111, 338; the bonuses and extra compensation available to such workers runs into the millions of dollars in some cases, but as we saw during 2008, job security in such positions is nonexistent when financial services industries feel the sting of recession (U.S. Department of Labor, 2007). Wage and employment risk must be compensated for by the prospect of big wins and large bonus plans.

Given the model of labor markets presented earlier, it is clear that interaction between the demand for labor and the supply of labor determines the equilibrium wage to be paid to workers. The sorts of job characteristics described above all affect the size of the applicant pool available to take on certain types of jobs and hence the position of the labor supply curve.

## Unemployment

Though labor markets clear when quantity demanded is equal to quantity supplied, as described above, there are workers who are still seeking to work once the market clears, just at wages that are above market equilibrium. When people are actively seeking work but cannot find it, they are officially counted among the unemployed. Though in most all markets for goods and services that achieve equilibrium there are buyers and sellers who cannot participate because prices are too high or too low, when this happens in labor markets, households are left without income and other compensation, like health insurance and retirement plans. Hence, unemployment of labor resources has direct and immediate impacts on the lives of everyone who depends on the productivity of the unemployed worker.

To be unemployed according to the measures used in most industrialized countries, a worker has to be actively seeking work. The unemployment rate measures the percentage of the labor force, which includes those employed plus the unemployed who are actively seeking work but cannot find it. Sometimes the labor force participation rate is a better measure of how intensively productive resources are used in an economy; this measures the percentage of a total population (civilians, noninstitutionalized, over the age of 16) that is either employed or unemployed but actively seeking work. These measures can be applied to subpopulations so that economists can also track unemployment and labor force participation rates by gender, location, racial and ethnic origin, age cohort, and so forth. Given the significance of employment to both individual workers and to national productivity, it is important to watch for trends and understand patterns that might be occurring and their impacts on public policy.

Note that not every member of a population is included in the labor force, and not every person who is pursuing productive activities in an economy is included in the labor force. For example, discouraged workers, defined as people who are not working and have stopped seeking work, are not part of the labor force. People who volunteer in a variety of unpaid capacities, who are working in unpaid internships, or who are engaged in unpaid household or family production, are not included as part of the labor force. Employment data provide a proxy for the extent to which an economy is using its labor resources but come nowhere near truly measuring the output of labor resources in an economy over time.

Unemployment takes a variety of forms and can be considered more or less significant depending on its type. Frictional unemployment tends to be short in duration. When workers lose jobs, it naturally takes some time and effort to seek out and select new job opportunities. Contrast this with structural unemployment, which tends to be long term and occurs because a worker's skills no longer fit the mix of jobs available in the economy in which he or she lives or because a worker lacks the skills needed to find a job that can use them. Seasonal unemployment occurs when the demand for workers of a particular type just does not exist at particular times of the year (there are no blueberries to pick in Maine in January), while cyclical unemployment occurs because demand for labor of many types decreases when the level of economic activity declines (fewer boat salespersons are needed during a recession.)

Figure 14.3 describes the path of unemployment in the United States for the 1999 to 2009 period. It is clear that recessionary pressures in late 2007 and 2008 had a tremendous impact on labor markets and on the number of jobs available to job seekers. Unemployment is referred to as a *lagging indicator* of the level of economic activity, which in this case means that recessionary pressures on other aspects of the economy, like demand for final goods and services or prices of other significant inputs like oil, were impacted months before firms began to lay off workers or decrease hiring. Toward the end of the recession, although other aspects of an economy might be showing marked signs of improvement, the unemployment rates might still be rising. Thus, it is very important that economists and policy makers use movements in unemployment rates with

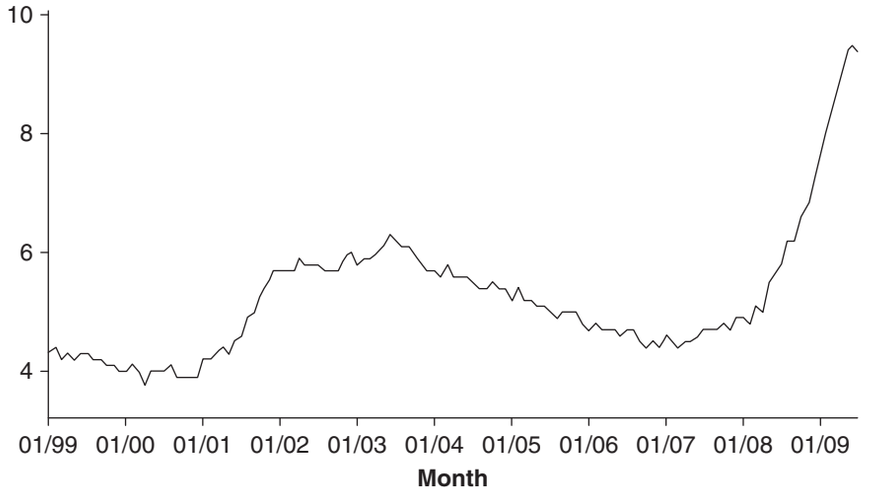

**Figure 14.3** U.S. Unemployment Rate (Seasonalized) 16 Years and Over

SOURCE: U.S. Department of Labor, Bureau of Labor Statistics (n.d.).

extreme care when making predictions about the health of the overall economy.

Table 14.1 describes unemployment rates for a variety of Organisation for Economic Co-operation and Development (OECD) countries. It is clear that industrialized countries have different experiences in their own labor markets. This is caused by a variety of factors, some political and cultural in nature and others having to do with the product mix that the country produces or with historical factors that influence production and consumption. For example, Germany's relatively higher unemployment rates may be due to its recent incorporation of East Germany as part of its economic base or to its generous social safety net that allows the unemployed to receive a greater package of benefits. It could be due to the changes in migration regulations and expectations that have come along with expanding membership in the European Union. It could also be due to the strong manufacturing tradition in Germany that may be increasingly moving to lower-wage countries. All of these sorts of factors must be weighed when comparing unemployment rates across time and across economies.

Though unemployment is always painful for the individual experiencing it, structural unemployment is the type that causes most distress for economists. It leads to an extended lack of income for individuals and their families and can lead to serious psychological problems, including depression, that can lead to other social ills, including domestic violence and substance abuse. The severity of these problems often depends on the social safety provided by the government for the unemployed, which differs widely across countries around the world. Though most industrialized countries have some level of support for unemployed workers, the level of support, the nature of the support (pure monetary support vs. access to job training and/or education), as well as the stigma attached to accessing this support, affect the willingness and ability of workers to remain unemployed.

## Policy Implications

There are many, many public policy implications of labor market decisions and outcomes, some affecting the demand side of the marketplace and some affecting the supply side. Labor markets play fundamental roles in an economy, providing inputs for production, giving people a sense of purpose and well-being, and providing income and economic resources for household consumption. Unemployed workers tend to be angry voters, so most governments around the world embrace full employment, variously defined, as an important component of political and economic stability.

### Employment Policy

Should the goal of an economy be to eliminate all unemployment? Should governments and policy makers establish programs that lead to an unemployment rate equal to zero? Two questions arise here: (1) Is it possible to have no unemployment, and (2) is it desirable to have no unemployment?

**Table 14.1** Comparative Rates of Unemployment Across Industrialized Countries

| | *US* | *Canada* | *Australia* | *Japan* | *France* | *Germany* | *Italy* | *Sweden* | *UK* |
|---|---|---|---|---|---|---|---|---|---|
| 2005 | 5.1 | 6.0 | 5.1 | 4.5 | 9.6 | 11.2 | 7.8 | 7.7 | 4.9 |
| 2006 | 4.6 | 5.5 | 4.8 | 4.2 | 9.5 | 10.4 | 6.9 | 7.0 | 5.5 |
| 2007 | 4.6 | 5.3 | 4.4 | 3.9 | 8.6 | 8.7 | 6.2 | 6.1 | 5.4 |

SOURCE: U.S. Department of Labor, Bureau of Labor Statistics (2009).

Economists sometimes use the term *natural rate of unemployment,* defined as the level of unemployment that will exist in an economy at full employment. This seeming oxymoron is actually a way of describing an economy that has reached a rate of productivity that can be maintained without placing inflationary pressure on resource prices or undue stress on productive resources of all sorts. The natural rate of unemployment in the U.S. economy seemed to be around 5% through the 1990s, but then as the combination of low interest rates and war in Iraq stimulated production, it seemed as though the natural rate fell to around 4.5%. In the United States, because government policy makers and the Federal Reserve Board can both impact the level of overall economic activity, the goal is to achieve a stable level of output and employment in the long run that guides decision making and policy action.

To steer the economy toward full employment, the government can use fiscal policies that affect aggregate demand. In some cases, this means changing the level of spending on some combination of entitlement programs and discretionary spending projects. For example, in 2008, when the U.S. economy seemed headed for a deep recession, the government increased the duration of unemployment benefits, shifted resources into "shovel ready" spending projects like roads and bridges, and promoted the Cash for Clunkers program to increase household spending on new automobiles.

Other government policies directly subsidize job training for workers whose skills do not match current job offerings. This might involve grants to subsidize college students (Pell grants, for example) or more targeted initiatives designed to train workers for occupations that are expected to expand in the near future. For example, the Employment and Training Administration (ETA) administers federal government job training and worker dislocation programs, federal grants to states for public employment service programs, and unemployment insurance benefits. These services are primarily provided through state and local workforce development systems.

In response to the significant challenges presented to American workers by the recession, the American Recovery and Reinvestment Act of 2009 (Recovery Act) was signed into law by President Obama on February 17, 2009. As part of this plan, the ETA will be a key resource for the administration's "Green Jobs" initiative. As described on the ETA Web site (www. doleta.gov),

> The Green Jobs Act would support on-the-ground apprenticeship and job training programs to meet growing demand for green construction professionals skilled in energy efficiency and renewable energy installations. The Act envisions sound and practical energy investments for 3 million new jobs by helping companies retool and retrain workers to produce clean energy and energy efficient components or end products that will result in residential and commercial energy savings, industry revenue, and new green jobs throughout the country.

This type of public policy, directed at workforce development and training, is designed to move workers into productive sectors of the American economy, making important human capital investments that lead to viable employment as well as to a more stable economy.

## Employment Taxes

Income and other employment taxes play an important role in providing incentives for workers to participate in labor markets. One of the primary methods of taxation used by governments at many levels is to directly tax income. Typically, a percentage of each dollar earned is paid as tax, and in many cases the percentage increases as total income increases, making income taxes progressive in structure. This means that workers pay increasing percentages of marginal income as tax as income increases.

Income taxes serve a variety of purposes. First, they provide money to finance government expenditures. Local, state, and federal levels of government all need revenues in order to provide services; income taxes provide that revenue in many cases. Second, income taxes can affect the behavior of workers. If income taxes are increased, workers might increase their participation in labor markets in order to make up for household income lost to tax payments. However, workers might decrease their participation in labor markets in order to take advantage of the now lower opportunity costs of spending time out of the labor markets. That is, because effective wage rates fall as income tax percentages increase, it is less expensive to spend time out of the labor market.

If income taxes are decreased, workers might increase their participation in labor markets because the opportunity cost of spending time out of the labor market has increased. Higher effective wage rates mean that it is more expensive to spend time out of the labor market. However, workers might decrease their participation in labor markets because they can earn the same level of income now with less time spent on the job.

These opposing responses to changes in income tax rates make it very difficult to determine the right mix of policy to achieve government objectives. If the goal is to encourage workers to provide more work hours, should taxes be increased or decreased? If the goal is to encourage workers to provide fewer work hours, should taxes be increased or decreased? Policy has to be very carefully determined, based on the average levels of income earned in a particular market or the historical response of workers to tax changes in the past. For example, typically low-wage workers respond to increases in tax rates by working more hours. If the goal of policy is to encourage workers with jobs to provide a greater number of hours, it is smart to increase income tax rates. On the other hand, if the goal is to encourage labor force participation among discouraged workers, the appropriate policy is to increase the effective wage by lowering tax rates. This means that the opportunity

costs of remaining unemployed have increased and it is now more expensive to stay out of the labor force.

### Minimum Wages

In some instances, government policy makers intervene in markets for a variety of goods and services by setting legal minimum prices. These price floors, set to protect sellers of a good or service, provide sellers with higher levels of income than they would receive if the market equilibrium were allowed to allocate resources. Price floors are used in a variety of markets for goods and services in the United States, particularly in markets for agricultural products like cheese, milk, and sugar.

Minimum wages are used in labor markets for the same reasons. Legal minimum wages provide low-wage workers with protection from wages that may be low because of large supplies of workers who enter these markets. Particularly in urban areas or areas near borders, where large numbers of immigrant workers tend to settle, minimum wages help to alleviate poverty among the nation's most vulnerable populations.

In the United States, the federal government established mandatory minimum wages through the Fair Labor Standards Act in 1938. In the midst of the Great Depression, this policy was designed to provide minimal levels of income for workers who were trying to make their way back into labor markets after extended spells of unemployment. In 2009, the federal minimum wage was increased from $6.55 per hour to $7.25 per hour. Some states, particularly those with very high costs of living, like Connecticut, set their minimum wages higher than what is federally required. Though federal lawmakers have increased the wage several times in recent years, the federal minimum is not indexed to inflation or to increases in labor productivity, and so workers have no guarantee that they will maintain purchasing power over time or that their compensation will rise as their own productivity increases.

Increases in the minimum wage have become quite controversial in most of the countries or markets in which they are imposed. Some argue that establishing wage floors causes higher levels of unemployment in affected markets. For example, some people argue that in the market for people who wash dishes in New York City, if firms are required to pay higher wages, they will move up their demand curves and hire fewer worker hours. Others argue that though this might be true, the demand for dishwashers in New York City is highly inelastic; this means that when wages rise, quantity demanded falls, but by a relatively small amount. So the question becomes an empirical one: When wages rise in low-wage labor markets, how significant is the decrease in quantity of labor demanded? If this decrease is small, then the income gains to workers who remain employed create greater benefits, even though some workers are forced out of the labor market. Many studies have been conducted to measure this impact, particularly on teenage workers, who are the most common recipients of the minimum wage. Though results are mixed, most conclude that the negative impact of increases in the minimum wage on employment in affected markets is small or nonexistent.

A more extreme form of the minimum wage that is gaining momentum is the *living wage.* This is defined as a minimum amount of money required by a worker to maintain his or her own living within a particular market. The Universal Living Wage Campaign is based on the premise that anyone working 40 hours per week should be able to afford basic housing in the market in which that labor is exchanged; this obviously requires higher hourly wage rates far in excess of the federal minimum wage. For example, the living wage in 2002 was $10.86 in New Haven, Connecticut, and $10.25 in Boston, Massachusetts. Even at these higher levels, the price elasticity of demand for labor in low-wage markets is quite inelastic, indicating that increasing wages to even this level will not result in significant increases in unemployment.

## Future Directions

Labor markets are complex and dynamic, and so the possibilities for future directions are endless. The Bureau of Labor Statistics projects significant changes in the labor force in the coming years, as follows. Fewer younger workers will be available to enter the labor force, and most of the growth in the supply of labor will come from new immigrants to the American economy. On the demand side, manufacturing jobs will continue to move overseas, while job growth in the green economy and service sector will continue to increase (Toossi, 2007). Combined with these demographic and sector shifts, several other factors will help to determine the nature of labor markets in the coming decade.

### Technology

As technology provides greater opportunities to enhance worker productivity, it also provides applications that replace worker effort with machines, computers, and robots. This tension between labor and capital as substitutes in production (capital equipment and technology replacing humans in production processes) and as complements in production (capital equipment and technology increasing the productivity of humans in production processes) will not be resolved easily and will need to be considered on a case by case basis across the economy as new technology changes the nature of the work that people do.

### Immigration Policy

As noted above, immigrants are almost certain to account for a significant portion of the growth in the labor force in the next decade. Immigrants enter the United States seeking higher income and living standards than they have experienced in their home countries. Given the

inequality in the distribution of income and wealth around the globe, as long as immigrants can gain access to the American marketplace, the investment in migration is more than worth the costs in terms of personal and family dislocation and downward job mobility.

The key to predicting the impact of this immigration is the degree to which U.S. citizens are able to provide welcoming communities for workers from other countries. Though a variety of laws and regulations limit the ability of firms and communities to discriminate against workers they do not want to accept, equal treatment and opportunity is not the norm in many regions of the country. This means that social networks among immigrant populations become more and more important, and the ability of immigrants to gain access to skills, attitudes, and workplace norms will be crucial if labor productivity is to continue growing as new migrants are absorbed into American life.

The burden of accommodating large immigrant populations can be quite overwhelming to a community. Particularly if border communities like Miami, Los Angeles, and Houston are considered, increases in immigration (both legal and illegal) strain public services like hospitals and schools. Even when people in a community want to welcome productive workers into their midst, they may find it difficult to provide for them in ways that are equitable.

### Labor Unions

The union movement in the United States has declined steadily during the past five decades, with membership down to around 12% of the labor force from around 30% in the late 1950s. There are many reasons for this decline, some economic and some political. The primary sectors of the economy that led the union movement have declined in importance in recent years, led by autoworkers, mine workers, and garment workers. All of these industries have seen increasing competition from international producers and have subsequently been unable to compete with firms in the global economy that have gained a variety of efficiencies in production and employment.

Further, changes in the political climate have made it increasingly more difficult for unions to organize workers. On August 3, 1981, more than 12,000 members of the Professional Air Traffic Controllers Organization (PATCO) went on strike and were subsequently fired by President Ronald Reagan, who determined that the strike was illegal. This decision, in one instant, shifted the balance of power between firms and unions significantly in the direction of employers. From that time, policy and decisions by the National Labor Relations Board (NLRB) began to work in favor of the employer and more often against the ability of workers to form collective bargaining arrangements with their employers. Note that the labor movement in other countries, particularly in Europe, remains strong, with around half of all workers unionized in Great Britain, Germany, Austria, and Italy.

Finally, as the manufacturing sector of the economy has shrunk, the service sector has grown tremendously, representing nearly 80% of business activity in the United States today. Service employees have historically been difficult to organize because they are often female dominated (women are more difficult to organize) and often dispersed across a wide variety of work settings (small offices, working from remote locations, etc.). Unless employees in service industries find ways to unionize more effectively, the union movement will continue to lose relevance in the American economy.

## Conclusion

In a perfect world, labor markets allocate human effort in production toward its most productive use. This chapter has endeavored to explain that allocation process by exploring the behavior of buyers and sellers in markets for human resources and then introduced the role of government policy makers in altering these market-determined outcomes.

The key to understanding the nuances of labor market behavior is in remembering that work is a fundamental source of human dignity. Though economists often focus on labor as a productive resource, which it of course is, there are aspects of the relationship between employer and employee that are clearly emotional, value laden, and culturally determined. This leads to a level of complexity in resource allocation that we do not see with other productive inputs like computers, robotics, or acres of land. However, it is this complexity that provides us as economists with rich avenues for intellectual investigation and policy analysis.

# Wage Determination

Kenneth A. Couch
*University of Connecticut*

Nicholas A. Jolly
*Central Michigan University*

Wage determination refers to the market process that establishes the amount a firm pays a worker for a unit of time. A market exists when there is demand for and supply of a product. In the case of the labor market, firms demand individuals' time as an input for production, and workers supply it. The nature of the labor market, including the number of firms and special qualities of workers, influences the wage determination process. Other social institutions such as the government and interactions between individuals, including those characterized by racism and sexism, also influence payments made to workers. This chapter discusses the basic process of wage determination along with the influences of market structure, government regulation, and other social interactions on it.

One reason wage determination receives broad attention among economists is that payments to labor constitute roughly 70% of the gross domestic product of every industrialized country. Most societies would like to put government policies in place to positively influence wage growth because, in aggregate, what people can earn relates directly to the material well-being of a country; however, this requires an understanding of what factors influence the level and growth of wages over time. Perhaps the most important determinant of wage rates is the level of education a person receives; however, theory indicates that general education will have a different impact on labor markets than specific training related to one industry or occupation. Governments attempt to directly affect the mix of general and specific skills among members of the labor force. Thus, studies of wage determination relate directly to choices of broad social policies aimed at influencing individual and social welfare.

Another reason this topic receives substantial attention is that many societies have concluded that payments in the labor market should be determined by individual productivity and not by such factors as gender or race. Laws prohibiting these discriminatory practices reflect this social judgment. Studies of differences in wage rates for people who have the same qualifications but are not of the same gender or race seek to gauge the extent of discrimination in the labor market.

In discussing wage determination, it is important to understand what the term *wage* means. A wage rate is a payment from a firm to a worker for an increment of time. Most commonly, a wage rate is a payment for an hour of effort. However, the term, at times, can capture weekly, monthly, or annual pay. Restricting wages to reflect money paid to a worker for a defined period of effort isolates the payment from its interaction with hours of work in determining earnings, which is a separate concept. Examining the simultaneous determination of the hours individuals choose to work given the wage rate they receive is a standard topic within labor economics; however, it is beyond the purposes of this chapter.

This chapter first discusses how the structure of the labor market determines wages. This section emphasizes that the number of firms demanding labor significantly alters the wages workers receive in the market. It also discusses the role of labor unions relative to large employers.

The chapter then proceeds to discuss how investments in human capital in the form of general education and on-the-job training alter the wage a worker receives. The discussion then moves on to consider different theories of how wages change over the typical person's lifetime. The next major topic is discrimination's affect on wage determination. Finally, the chapter discusses the role of government in setting boundaries on market outcomes, followed by a brief discussion of policy implications and directions for future research.

## Market Structure

This section provides an explanation of how the structure of the labor market affects wages. The discussion begins with a review of how wages are set in a perfectly competitive labor market. One of the most important characteristics of competitive markets is that there are many firms competing for workers' services. When this condition is not present, employers do not face competition for employees and have more freedom to set wages. At the extreme, there is only one firm seeking to hire workers. Economists refer to this type of market as *monopsonistic.* To emphasize the importance of market structure, this section explores the differences between monopsony and competitive markets. The section concludes by discussing how labor unions can counteract the market impacts of large employers as well as other effects attributed to them.

### Perfect Competition

Supply and demand characterize every economic market. Market supply is a summary of the total quantity of a good available at different prices. Market demand is a summary of the willingness to purchase at different prices.

In the case of the labor market, individuals supply, and firms demand, time. Individuals expect payment for their time, and they must decide, given their tastes and other sources of income available to them, how many hours they would be willing to provide at different wage rates. Summed across all workers, this linkage between the differential willingness of workers to provide time to the market as wage rates vary determines aggregate supply in the labor market, the total amount of labor available at different wages. Generally, workers are willing to provide more hours of their time to employers when wage rates are higher. Therefore, aggregate supply increases with the wage rate.

Demand for labor arises from the usefulness of workers to individual firms. Firms require labor to produce goods, and the dollar amount of total production associated with each additional worker is his or her value to the firm. Firms pay for additional labor as long as the dollar value of the additional productivity of another worker exceeds the wage paid for that person's time. As long as the dollar value of the productivity of more labor exceeds the required payment, the firm's profits expand, thus giving it an incentive to hire more. For a given type of labor, summing the demand across firms determines at different wage rates how much labor is used in total. If the wage rate is high, firms hire fewer workers and if low, they use more labor. Therefore, the demand for labor expands as wage rates fall.

Equilibrium in a perfectly competitive market occurs when the quantities of aggregate labor supply and demand are equal. Because the wage rate determines the quantity of labor supplied and demanded, the wage that prevails in a competitive market is such that the number of individuals willing to work equals the number of workers firms wish to hire. Thus, the interactions of aggregate demand and supply determine the market wage rate. This implies that firms pay the same wage rate to all workers. When economists speak of wage determination, at the most basic level, this is the rate of pay for a unit of labor determined by the interaction of market demand and supply.

For this theory to be operational, many assumptions must hold. First, the basic theory applies to one uniform type (homogenous) of labor. The theoretical model also assumes that there are many workers. Therefore, firms can hire as much labor as they would like at the prevailing wage. Theory also assumes that there are many employers competing for the time of the workers and that each firm is small relative to the market. These assumptions imply that neither a single worker nor a single firm has influence to negotiate for higher or lower wages. This is important because it means that if one employer tries to underpay workers relative to the going wage rate, workers can turn to other firms for employment. Free mobility of workers across many employers helps maintain the wage rate in the perfectly competitive model. The equilibrium wage in a perfectly competitive market is known as the *competitive wage rate.*

When any one of these assumptions fails, alternative market structures arise. Because the assumption that fails is associated with a competitive market, it is a case of *market failure* because it represents a departure from perfect competition. To illustrate this point, the next section considers the case of a market with one employer, monopsony.

### Monopsony Markets

The difference between a monopsonistic labor market and a perfectly competitive one is that under monopsony there is only one firm, the monopsonist. One assumption of a competitive market is that all firms are relatively small so that no single employer has influence over the competitive wage. However, if there is only one employer, then hiring decisions of the firm determine the wage paid to workers.

In this market, one firm determines the amount of labor used. As the firm expands its use of labor, it will have to

pay a higher wage rate in order to make more workers willing to supply their time. Assuming the firm pays all equivalent workers the same pay, when it hires one new person, it must raise the pay rate of all current employees by an amount equal to the difference between the wage they were formerly paid and the new, higher one. Correspondingly, the firm views the additional cost of each individual worker hired as being far higher than what it might expect to pay one more person. This consideration leads the firm to hire fewer workers than would be employed in a competitive market. Because the firm uses less labor than would be employed in a competitive market and it can attract smaller amounts of labor at a lower wage rate, workers receive less pay than they would if many employers were active in the market. The result of having one firm hire all workers is lower pay and less employment than would be observed in a competitive labor market.

### Labor Unions

Economists initially developed the monopsony model to explain one-company towns that characterized industries like mining (Pencavel, 1991). A company might locate an iron ore deposit and purchase the rights to it, and as it organized the extraction process, it would be the only firm to hire miners at that location. Individuals viewed these firms as paying workers too little and working them too hard, which is consistent with the general outcomes of the theoretical model. In contemporary markets, economists use monopsony to describe hiring for hospitals in towns where there are no competitors, as well as professional sports where a single league employs all players.

Labor unions have always formed to enable workers to bargain more effectively with very large employers. Unions such as the United Mine Workers and the National Football League Players Association formed to raise more effectively worker concerns with employers than a single individual could. To be most effective, unions must organize the relevant pool of labor for an employer so that they can credibly threaten to disrupt business if the employer does not address workers' concerns.

By organizing workers for an industry, unions have the ability to determine the amount of labor supplied to a firm at a given wage rate. In the monopsony model, a firm employs fewer workers because the cost of hiring an additional worker is larger than in a competitive market. Unions have the ability to set a uniform wage rate equal to what it would be in a competitive market through bargaining, and this can potentially raise both wage rates and employment back to the competitive level.

These positive views of unions are tempered by the observation that as workers vote on contracts, older workers are protected under union rules by seniority from being fired and are thus more likely to support demands and vote for pay packages that set wages above the level that might exist in a competitive market. To the extent that this is true, because the demand for labor declines as wages rise, this will reduce employment to below the level expected in a competitive market.

Unions receive a great deal of scrutiny for their impact on reducing the competitiveness of firms. If unions raise wages above levels observed in nonunion enterprises, then they arguably place the firm at a price disadvantage unless the higher cost is justified by increased productivity. Only 15% of all full-time workers over the age of 25 belonged to a union in 2000. By 2007, this percentage declined to 13.3% among all workers and was less than 10% among private sector employees. Because of this limited coverage, unions have less of a role in wage determination in contemporary labor markets than in times past. See William Dickens and Jonathan Leonard (1985) for an analysis of the determinants of the decline in union membership.

## Human Capital Acquisition

The previous section emphasized how market structure and worker responses to it affect wage determination. Rather than acting collectively, workers may make individual efforts to raise their rate of pay by investing in themselves to increase their productivity. Early work by Gary Becker (1962) and Jacob Mincer (1974) first conceptualized the idea that individuals may invest in themselves, hoping to recoup that expense through increases in their rate of pay. Thus, individuals may choose to invest in their human capital much as firms do for physical machinery.

Although most people think of investments in human capital as originating from the individual, firms have an incentive to invest in workers when this helps tie workers to them. Thus, the basic theory distinguishes between general skills that are transferable across firms and specific skills that raise productivity only for a specific employer. When skills are transferable to other firms, employers will not finance their acquisition. If skills are specific to a single employer, then firms should finance their acquisition.

The discussion here proceeds assuming that formal education leads to the formation of general skills that are transportable across employers. The reader should bear in mind that firms do have an incentive in some circumstances to invest in formal education.

### Formal Education

Education increases worker productivity. Because increased productivity brings value to the firm, education should increase the pay an individual receives. In deciding whether to pursue a course of education, such as a bachelor's degree, an individual must examine not only the short-term earnings impact, but also the long-term effect of education on earnings. If the person is going to pursue a degree at a university, then most of the costs will occur

in the early years and increased earnings will come later. So the individual should consider what the total stream of earnings from the additional education would be over his or her lifetime in current dollars. The individual must also consider what earnings would be in current dollars over a lifetime without the investment. By making a direct comparison of the earnings paths with and without the additional investment in terms of current dollars, individuals can calculate the rate of return that would occur if they spend money on raising their education level. Because individuals can invest their money elsewhere, a rational person should compare the rate of return from pursuing education to possible returns from alternative investments. Individuals will pursue education as long as the rate of return on that investment is at least as large as from other opportunities.

Becker (1962) also outlined two major factors thought to impact individual investments in education. The first is ability. If people differ in their ability to process information, then when exposed to the same material, they will carry away different levels of comprehension and effectiveness in transforming the information into productive workplace skills. Individuals should consider their ability levels as they make decisions about how much education to pursue. Students receive a considerable amount of information on their academic ability. Grades and standardized tests are routine. Theory suggests that students who have received feedback that their academic ability is relatively low would invest less in education because it would not raise earnings as much as for those with greater ability.

The other major factor that influences the amount of education pursued is the availability of financing. Many students take loans to pursue further years of education, while others receive grants, scholarships, or financial assistance from their family. If a person receives money to help pay for education through scholarships, grants, and no/low-interest loans, then the cost of education decreases and the rate of return increases. Reducing the cost of education in this manner encourages higher amounts of educational investments.

Social observers are concerned that these two factors are positively correlated. Students who have stronger backgrounds and higher ability may also be more likely to come from families with more resources. Weaker students may come from families that have fewer resources. Because stronger students would pursue more education in the absence of free financing and weaker students less, a positive correlation of ability and financing reinforces those patterns.

In terms of influencing wage determination, those with more formal education generally receive higher wages because they possess more skills. Employers look at courses of education as one factor that determines whether a worker carries useful skills. Because workers who are more skilled receive higher pay, many countries emphasize improvements in their national education systems as a method of raising average rates of pay and material well-being.

## On-the-Job Training

In some cases, firms may have an incentive to invest in general skills of workers through on-the-job training. However, most employers use this method to teach skills that are useful only in their own firm. If firms did invest in general education for workers, the employees would receive a wage rate low enough to pay fully for the training. Here, the discussion focuses on training in specific skills. The seminal work of Becker (1962) and Mincer (1974) also explains the role of on-the-job training.

Specific training increases workers' productivity with their current employer after it is completed. From the perspective of the firm, if the worker quits after receiving training, then the firm absorbs the lost cost of instruction. From the employees' perspective, if they take reduced pay during the training period, and the firm fires them, then the workers have made a human capital investment that is worthless to other potential employers. Because both parties have something to lose, they need a positive incentive to participate in on-the-job training.

The firm and the worker share the risks of on-the-job training by splitting the costs and the benefits from it. With specific training, workers earn lower wages than they might receive elsewhere during the training period. However, as long as the wages are reduced by a fraction of the training costs, the worker shares only part of the cost of investment. So the firm and worker bear part of the cost. After training is completed, workers' pay remains below the actual value of the increased output associated with their new skills, but they will receive a wage that is larger than what they would earn at a different employer both at that moment and over their career. Thus, both the worker and firm have a positive incentive to participate in specific training.

## General and Specific Training and Displaced Workers

To examine empirically how general and specific human capital affects wage determination, economists examine the experiences of displaced workers. Job displacement refers to the loss of employment due to plant closure or large-scale layoff. While it is possible that employers use layoffs to purge problematic workers from a firm, when layoffs are of a massive scale or when an entire firm closes, economists view this type of event as beyond the control of the worker. Because of this, researchers treat events like plant closure as naturally occurring social experiments. The workers who lose jobs change firms. Thus, the component of wages related to specific firms is lost. By comparing displaced workers' wages to those of individuals who remain continuously

employed, researchers can get an idea of the proportion of wages related to specific ties to individual firms.

Empirically, when workers experience job displacement, earnings drop significantly. In summaries of the literature, Lori Kletzer (1998) and Bruce Fallick (1996) report that earnings are below where they would be if displacement had not occurred for several years afterward; however, earnings usually recover to within 10% to 15% of their prior level in a 5-year period. The magnitude of displaced workers' long-term earnings losses provides an estimate of the proportion of wages related to firm-specific factors.

Because the U.S. education system emphasizes the acquisition of general skills, one might be interested in knowing whether this small proportion of skills arising from attachment to specific employers is unique to the United States or if other countries exhibit this pattern. There is reasonable evidence from France (Abowd, Kramarz, & Margolis, 1999) and Germany (Couch, 2001) that the proportion of pay attributable to specific employers is in the range of 10% to 20% as is the case for the United States (Couch & Placzek, in press).

## Why Are Age-Earnings Profiles Positively Sloped?

The method of discovery in any science, including economics, involves formulating theories meant to be useful in explaining empirical observations. Researchers gauge the validity of competing theories by examining whether they are consistent with empirical reality.

Human capital theory (Becker, 1962; Mincer, 1974) originally sought to explain why wages grow at younger ages, peak at midlife, and decline afterward. The extension of human capital theory to life cycle considerations by Yoram Ben-Porath (1967) predicts that early in life people should specialize in acquiring general skills because forgone earnings are smaller costs of acquiring education at younger ages. As individuals enter the labor market and obtain general skills from work and specific skills from employers, wages will grow over time. Eventually, as workers' energy declines and reinvestments in skills taper off, wages fall. Finally, the worker exits the labor market.

The previous section described the proportionate contribution of general and specific skills to wage growth. However, economists debate about how strong the linkage is between wage growth and worker productivity at any given point in time. There are two major alternative theories of why wages grow over time: efficiency wages and job matching. Efforts to test the theories simultaneously in order to determine which effect is dominant are ongoing in the profession.

### *Efficiency Wages*

In many workplaces, employers face difficulty in knowing whether their employees are putting forth the appropriate level of effort. When employees use paid time for nonwork activities, they are shirking their responsibilities. One way employers respond to this behavior is by using wages to encourage greater effort, or efficiency, from workers (Krueger & Summers, 1988).

Early in an individual's career, a firm might choose to pay wages that are smaller than the actual value of the person's product. This can be an effective device for learning which employees are most committed to the firm. However, if workers do not expect full payment for their efforts, they will move to a higher-paying employer because the total stream of compensation would be larger. To offset this concern, the firm must overpay the workers later in their career. Additionally, these theories require the firm to have the ability either to terminate older workers so that total compensation over their lives does not exceed the value of their output, or to use other mechanisms such as the structure of pension payments to induce retirement of workers at a desired point. The essential distinction between this and human capital theories is that over the majority of the individual's life cycle, wage rates are not tied to the dollar value of worker productivity at a point in time.

One common example of a labor market with efficiency wages is academics. Younger faculty are often more productive than their older counterparts. Whether a new faculty member will receive tenure (a guarantee of employment) is normally determined 6 years after beginning employment. A university may be concerned that once a professor receives tenure that person will reduce his or her level of productivity. For the first 6 years, the university underpays and overworks junior faculty. The university heavily scrutinizes their productivity records. This screening is arguably sufficient to assure that the person being evaluated is devoted enough to research and teaching that he or she will remain productive after receiving tenure. Often, when a professor receives tenure, pay increases. When older professors are not as active in producing research, they receive wages that are large relative to their productivity.

The above example describes how efficiency wages work to increase productivity over time. Firms also use efficiency wages in a static context to increase worker productivity. In that case, efficiency wages are payments by firms structured to provide incentives to workers to be more productive or efficient in their efforts. Examples of efficiency wages include payments aimed at maintaining a healthy workforce, attracting more productive workers, and keeping employees from shirking their responsibilities.

### *Job Matching*

Job matching theory provides an alternative view of wage growth. According to this theory, workers seeking employment receive job offers. As workers and firms

match, they both need to discover whether the match is good. This discovery process takes time. During this process, workers are willing to accept lower wages in the hopes that the match is good. If firms and workers decide that the match is good, then wages increase and the pay is higher because the firm finds that the worker is valuable. Because the worker is happy there, the employment relationship is more durable. Thus, this theory predicts that wages grow over time primarily because of a good initial match with a firm. Empirical evidence from Robert Topel (1991) supports this theory because it finds that neither the length of time a person has spent in the labor market nor the length of time a person has worked for a particular employer is systematically reflected in wages.

## Discrimination

Generally, there are three actors in the market: workers, firms, and customers. Becker (1971) explained how in a complete economy discriminatory behavior by any one of these actors affects wages. He defined discrimination as what occurs when someone in a market is willing to pay a price for prejudice against a person or group. Prejudice in a labor market entails treating someone differently because of nonmarket factors unrelated to productivity, such as gender or race.

If employers discriminate against a group, then they will act as if the wage they must pay for a worker has an extra price embedded in it. This means that if a firm hires someone it dislikes, then that worker must accept lower pay.

Similarly, if customers are prejudiced, then they will pay a higher price for a product rather than do business with someone they dislike. Some businesses counter customer prejudice by hiring minorities for jobs that are not visible to the public. For minority-owned firms to gain business of prejudiced customers, they must accept reduced payment for their services.

Workers themselves can also be prejudiced. There are jobs that some think of as appropriate only for a certain type of worker. For example, many think of caregiving jobs as being most appropriate for women. Social pressure exists for women to accept caregiving roles not only in life but also in their choice of work (Friedan & Quindlan, 1964). When this type of pattern arises, workers can be crowded into specific occupations. This oversupply of labor depresses wages in those markets.

### Measuring Discrimination

Ronald Oaxaca (1973) developed a method to measure the impact of discrimination in labor markets. This method estimates how much of a pay gap between minority workers and a comparison group (usually prime-aged white males) arises because of observed factors. After accounting for observed differences in productivity, the remainder, or residual, is interpreted to be an upper bound on discrimination's effect on wages.

Beginning in the 1970s, wage inequality increased in the United States for all groups of workers. According to research by Gottschalk and Moffitt (1994), approximately half of the increase in inequality is unexplained. Using Oaxaca's method, this increasing inequality would be included in the residual or unexplained category. To correct this, Chinhui Juhn, Kevin Murphy, and Brooks Pierce (1993) extended Oaxaca's method so that general increases in wage inequality common to all workers would not be attributed to discrimination.

### The Black-White Pay Gap

Kenneth Couch and Mary Daly (2004) show that for both recent entrants to the labor market and prime-aged workers, the overall black-white pay gap in the United States has declined to historic lows. For prime-aged workers, the overall pay gap remains at about 25%, with about half of it unexplained. This unexplained component provides an upper bound on discrimination's impact on pay. For those with less than 10 years of experience, the pay gap is around 15%, with about 80% of the gap unexplained. For both prime-aged and younger male workers, discrimination appears to reduce wage rates of blacks by approximately 12 percentage points.

### The Male-Female Pay Gap

In recent estimates of gender discrimination's impact on wages, Louis Christofides, Qi Li, Zhenjuan Liu, and Insik Min (2003) report that among participants in the labor market, women's pay remains at about a 26% deficit relative to men. Nine percentage points of that gap are explained by observable differences between women and men.

## Policy Implications

The government takes two broad philosophical approaches to intervening in markets. The first approach entails identifying a market failure and trying to correct it through regulation or taxation. The second approach arises when there is no specific market failure but the competitive outcome is socially unacceptable and needs alteration even if there are costs, in terms of economic efficiency, of doing so.

It is not always easy to determine which perspective is behind government action because most intervention in economic affairs requires agreement of many people holding different views. Nonetheless, it is clear that the government is active in managing rates of pay, market structures, educational attainment, and discrimination in the labor market.

## Rates of Pay

Since the passage of the Fair Labor Standards Act in 1938, the U.S. Congress has set minimum rates of pay for workers in specific industries and occupations. Proponents of minimum wage statutes argue that some jobs are beneath the dignity of American workers (see the discussion in Burkhauser, Couch, & Glenn, 1996). According to this view, even if raising wages reduces demand for workers and unemployment rises, losing those jobs is appropriate because Americans should not work for such low pay. Others (Card & Krueger, 1997) have argued that imposing minimum wage standards is inconsequential because this legislation has no adverse affects on employment. However, this is a point of contention in the profession (Burkhauser, Couch, & Wittenberg, 2000).

Some argue that there are more effective ways than legislating minimum wages to get money into the hands of the working poor. This is because many who work for the minimum wage are teenagers or secondary earners in the household. For example, for every dollar of cost, direct tax rebates put approximately $0.85 into the hands of a low-income household versus $0.15 out of every dollar of a minimum wage increase (Burkhauser, Couch, & Glenn, 1996). Regardless of whether one agrees that minimum wages reduce employment or truly assist the working poor, it is undeniable that federal and state governments intervene directly in the labor market.

## Market Structure

The primary motivation for regulating industrial structure is to prevent the deleterious effects that arise from having too few firms in a market. The U.S. government assesses whether mergers of large corporations would create an anticompetitive environment within an industry. The authority to assess the appropriateness of firm mergers is established through statutes, including the Sherman Antitrust Act, the Clayton Act, and the Federal Trade Commission Act.

Most researchers who study the impacts of antitrust regulation focus on the impacts on consumer prices or the negative effects for U.S. firms in international markets if the firms' sizes are insufficient to compete effectively. As discussed previously, another positive impact of retaining a large number of smaller firms in an industry is a more competitive market for workers. Economic theory suggests markets with more firms will tend to pay higher wages.

## Educational Policy

Because of its role in developing worker skills, the formal educational system in every country is linked to the labor market. At the secondary level, some courses impart general skills useful to anyone as they move toward becoming a functioning adult in society. Other courses impart general skills while tracking students into college. Students who are not interested in postsecondary education and have specific job interests receive training through vocational courses designed for specific occupations (automotive technician, electrician) while still in high school.

Across countries, the amount of emphasis placed on each of these components varies. Each country makes decisions regarding the educational system's structure, intending to promote wage growth. For example, in the United States, roughly twice as many students as in Germany attend postsecondary education. Few students at the secondary level in the United States participate in education aimed at a specific occupation, while formal occupational apprenticeships are normal in Germany among high school students not tracked toward college (Couch, 1994). The advantage the United States hopes to gain by having more workers trained with higher levels of general skills is greater worker flexibility. Germany hopes to have workers who are more productive because they are more specifically trained for their occupation. Germany hopes that the higher productivity arising from more skills that are specific will justify higher wages and result in more vital, competitive firms. A consensus has not evolved as to which system is better.

Countries also vary in their approaches to reducing the influence of family wealth on educational attainment. One's birth family is a matter of luck, and denying an able student access to education because of lack of financing is economically inefficient because a valuable resource is underused. Most would say that to limit a person's outcomes based on his or her birth family is also unfair. In the United States, the system of universities consists of both private and public institutions, most of which charge tuition. To increase access, government loans and grants are available to students, and the terms and amount of financing are related to family background. In many other countries, the university system is public. Once a student graduates from high school and qualifies for admission to a university, the government pays tuition and other expenses. Whether the education system is public or private, the availability of courses and the extent of public subsidy reflect considerations of economic efficiency, fairness, and long-term economic welfare.

## Discrimination

When someone is treated differently because of color or gender rather than productivity, it is understandable that inefficiency results. If the most able person to complete a job is from a minority group and prejudice relegates that person to some other occupation, then a loss of productivity results. Moreover, differential treatment based on race or gender is patently unjust.

For reasons of justice as well as economic efficiency, the government plays an active role in ensuring that persons

of equal capability receive equal treatment. In the United States, most of the laws that prevent discrimination arose in the 1960s. The Equal Pay Act of 1963 established that men and women working in jobs that require "equal skill, effort, and responsibility" receive equal pay. The Civil Rights Act of 1964 made it illegal to discriminate in employment practices based on "race, color, religion, sex or national origin." Executive Order 11246, signed by President Lyndon Johnson in 1965, prohibited employment discrimination by contractors performing work for the federal government. It also resulted in the establishment of the Office of Federal Contract Compliance, which oversees the affirmative action plans of employers doing business with the federal government.

After these measures were enacted, racial pay inequality declined rapidly in the United States (Couch & Daly, 2004); however, concurrently, racial differences in employment widened (Fairlie & Sundstrom, 1999). It is hard to understand why the proportion of minorities employed would fall and proportion of minorities unemployed would rise in a period when relative pay rose. Recently, this same pattern has arisen again. Racial pay inequality declined in the 1990s, yet observable factors cannot explain the racial difference in unemployment (Couch & Daly, 2004; Couch & Fairlie, 2008). Two principal explanations have emerged for this phenomenon. Some think that discrimination that used to be operational in steering minorities to lower-paid occupations in a firm and denying promotional advances may have moved into the hiring decision (Couch & Fairlie, 2010). Others argue that expansion of government assistance programs has raised unemployment among less-skilled workers (Murray, 1986).

Gender pay differences have been more static over time. Some think that this is due to the passage of laws aimed at reducing racial discrimination at the time when women from the baby boom generation were entering the labor force. There is some evidence that to meet hiring goals for minorities, employers substituted African Americans for women. Additionally, even though average family sizes have declined, women are more likely to have interruptions in their labor market experiences relative to men, and this would reduce their value to employers. These factors help explain, in part, why the observed male-female pay gap for people with comparable education and experience remains persistent.

## Future Directions

While research has lead economists to understand a great deal about the processes by which wage rates are set and the broad set of influences on wage rates, much remains to be learned. For example, economists have yet to determine which theory of wage growth best describes the operation of the labor market. The reason that understanding this is important is that if much of wage growth is determined by being matched into a good job rather than from investing in the expensive process of skill formation, then from a policy perspective, greater effort should be devoted to getting workers into the right firm.

Similarly, while a great deal has been learned about the role of prejudice in the labor market, a clear explanation has not emerged as to why relative pay rates of minorities and whites have converged but rates of unemployment have diverged. Some research points to factors that are likely to be part of the explanation, but no convincing, comprehensive explanation has emerged.

## Conclusion

The rate of pay for workers is one of the basic determinants of individual well-being. The combination of wages and hours worked ultimately determines workers' earnings. Admittedly, most individuals do live in a familial context that also affects their economic circumstances. Nonetheless, the wage rate individuals can earn, along with the time they have available for work, places a fundamental constraint on their consumption possibilities.

Average wages place a similar constraint on societal well-being. Government action can influence many of the factors that affect wage rates. The government has determined that some wage rates are too low to be socially acceptable and has set limits. Similarly, an industry with too few firms deviates in important ways from a competitive market structure, and the government reviews corporate mergers likely to affect adversely the relevant industry. The skills that individuals would like to develop to raise their own productivity are seen as vital to economic progress, and every country manipulates its educational policy to try to assist skill development among its citizens. Having all citizens participate in the economy on an equal basis also promotes economic efficiency, and governments routinely take measures to make opportunities uniform for all citizens.

# Role of Labor Unions in Labor Markets

Paul F. Clark and Julie Sadler
*Pennsylvania State University*

Labor unions are organizations formed by employees for the purpose of using their collective strength to improve compensation, benefits, and working conditions through bargaining; to bring fairness to the workplace through the provision of due process mechanisms; and to represent the interests of workers in the political process. Economists have traditionally viewed unions as functioning as labor market monopolies. Because they raise wages above the competitive levels set by the market, economists argue that labor unions create inefficiencies resulting in the loss of jobs and in greater income inequality in the workforce. For this reason, economists view unions as an undesirable interference in the operation of the market (Booth, 1995; Friedman & Friedman, 1980; Simons, 1948). However, some economists argue that in addition to their negative monopoly face, unions have a second, positive collective voice face. They further argue that, on balance, the positive impact of unions outweighs the negative (Bok & Dunlop, 1970; Freeman & Medoff, 1984; Reynolds & Taft, 1956).

This discussion focuses on the role unions play—and the impact they have—in contemporary society and in the labor market. The chapter first examines the historical development of American unions. Next, it discusses the structure and government of modern unions and membership trends. The industrial relations process through which unions advocate for their members is outlined. Finally, the chapter examines the impact of unions and evaluates the two faces of unionism.

## Why Do Unions Exist?

Unions are formed by employees who desire to improve their compensation, benefits, and working conditions and to bring greater fairness and due process to their workplace. Employees recognize that unless they have unusual or unique skills or talents, individuals have very little influence with their employers and very little power to improve the conditions under which they work. However, by banding together, workers are able to exert collective pressure that is more likely to force an employer to make specific improvements in the workplace. This collective power can also be used to obtain improvements through the political and legislative processes.

## What Do Unions Do?

Economists generally assert that when employees are dissatisfied with their jobs, the only rational option available to them is to exit or quit their job and reenter the labor market to seek a better situation. However, some economists recognize that employees have a second alternative. Rather than exit their workplace, they can engage in *voice.* Engaging in voice involves trying to convince an employer to make changes in the workplace that will address employee dissatisfaction.

Employees readily understand that if they engage in voice behavior as individuals, they will probably have little success in convincing their employers to make significant

changes. Even if an employee threatens to quit, an employer can, in most cases, easily replace one worker. Employees also recognize that if they combine their individual voices with those of the other employees in their workplace, they will be significantly more likely to persuade an employer to make changes. Unions are the mechanisms employees form in order to use their collective power.

Over time, employees have come to use the collective power of unions in three different ways. First, they engage in collective bargaining with employers in an effort to establish a legally binding contract that details the compensation, benefits, and working conditions in their workplaces. The goal of such a process is to negotiate terms that are better than those set by the labor market. Unions use the threat of a strike (a work stoppage that puts economic pressure on an employer by halting the production of a product or the provision of a service) to push employers to make improvements in these areas.

Second, unions establish processes and mechanisms through which employees can have a greater say in decisions that affect them. These processes can take many forms, including the establishment of grievance procedures that give employees due process when disciplined and employee involvement programs, such as labor–management committees and quality-improvement plans. All of these processes are established through negotiations between the employer and the union and ultimately give employees an opportunity to voice concerns and participate in decisions about how work will be organized.

Third, the collective power of unions can be used to shape the legal and political environment in which they operate. Unions have long understood that forces beyond the employer and union relationship affect the union's ability to represent its members' interests. To varying degrees, unions have actively worked within the legal and political realms to mold this environment, as well as to obtain workplace improvements through the political and legislative processes. The local, statewide, and national membership of a union represents a significant voting bloc. Unions are able to provide campaign support for local, state, and federal politicians. In addition, unions help register people to vote, provide information to members and the public regarding politicians' stance and record on employment-related issues, raise funds for candidates, and engage in get-out-the-vote initiatives. Using these financial and organizational resources, unions work "to reward labor's [political] friends, and punish its [political] enemies" (Gould, 2004, p. 2). They also actively lobby for legislation that will benefit their members and against legislation they believe will be detrimental to their interests.

## Historical Development of Unions

Most labor historians generally agree that the first real union in the United States was formed by shoemakers (then called *cordwainers*) in Philadelphia in 1792. By 1806, the courts banned the cordwainers, and all other unions, as conspiracies in restraint of trade. When this decision was overturned in 1842, the government found other ways to discourage the formation of unions, including issuing injunctions and the use of police and militia to put down strikes, demonstrations, and other forms of collective action. Meanwhile, most employers used a variety of strategies to fight the unionization of their workforce, including firing union activists and blacklisting them so they could not find other employment, evicting pro-union employees and their families from company-owned housing, and engaging in violence against workers who tried to organize.

These efforts on the part of employers did not entirely prevent workers from forming local, and even national, unions, but they did succeed in keeping unions relatively weak and on the defensive. However, legislation passed in the midst of the Great Depression as part of the New Deal changed the legal status of unions and ensured their existence as a central part of the U.S. economy. The National Labor Relations Act (NLRA), passed in 1935 as part of President Franklin Roosevelt's New Deal, changed public policy toward unions in a dramatic, even radical, way. After more than a century in which government often assisted employers in the suppression of unions, the NLRA now granted most American workers in the private sector a legal right to organize, bargain collectively, and engage in strikes, if they choose to do so. Employers vehemently opposed the legislation, but it was declared constitutional by a 5–4 vote of the Supreme Court. The passage, and confirmation of the constitutionality of the NLRA by the Supreme Court in 1937, meant that the federal government would no longer side with employers against unions; rather, it would actively protect workers' rights to organize, bargain, and strike. The NLRA included a set of rules that would dictate how employers and unions would deal with one another in the future. The violence and chaos that characterized union–employer relations for more than a century was replaced by a systematic process of industrial relations that is still in use today. And while the relationship between unions and management is still adversarial, the inherent conflict between the two parties is worked out under the rule of law, with strikes by unions and lockouts by employers used minimally and as a last resort.

One other major historical development that played a significant role in the formation of the contemporary American labor movement was the rise of public sector unions in the 1960s and 1970s. While the NLRA granted the right to organize, bargain, and strike to millions of American workers, it did not extend those rights to employees working for federal, state, or local government. These public employees did not begin to gain such rights until more than 25 years after the act's passage.

Federal workers were the first government employees to gain the right to organize and bargain collectively. However, the bargaining rights extended to them under Executive Order 10988 in 1962 were (and are) limited. For

example, federal employees were not granted the legal right to strike.

The rights of state and local government employees to form unions and bargain are granted on a state-by-state basis. A majority of states grant public employees the right to organize a union. Most also extend some rights to bargain collectively to those who organize a union (although some states, mostly in the South, do not). But only 11 states allow even some of their state and local government employees the right to strike. And while many states grant public safety employees (i.e., police, firefighters, and prison guards) some bargaining rights, none grant these workers the right to strike.

## Contemporary American Unions

Unions are part of the economic framework of most developed, and many developing, nations. This is particularly the case in Western industrialized countries. However, the unions that have developed and operate in the United States over the last two centuries are somewhat unique compared to their counterparts in other nations. One of the most significant ways that U.S. unions have differed historically from unions in other countries is their acceptance of capitalism and rejection of socialism. Socialism has long been an integral part of the labor movements that developed in the United Kingdom and Ireland, western Europe, and Australia and New Zealand over the past 200 years. Even Canadian unions have had a tradition of supporting socialist principles. This uniqueness is sometimes referred to by historians as *American exceptionalism* and is a function of the American labor movement's acceptance of capitalism (Lipset, 1997).

At various points in America's history, there have been labor organizations that have promoted a socialist ideology. In the late 1800s, the leaders of the Knights of Labor led a quasi-socialist movement that attempted to organize workers on a massive scale. Initially, American workers flocked to the organization, and by 1886, the Knights had grown to 700,000 members. However, the membership quickly became disillusioned by the organization's lack of tangible gains, and by the late 1890s, the Knights of Labor had largely disappeared.

In the early 1900s, another socialist union, the Industrial Workers of the World (IWW, also known as the *Wobblies*) was founded. The Wobblies were even more committed to socialism than the Knights of Labor and much more militant. Their union was based on the principle that "the working class and the employing class have nothing in common" and their stated goals were the "overthrow of capitalism" and the "seizure of the means of production" (Dubofsky, 2000).

While the IWW did attract over 100,000 members by 1917, American workers were fundamentally uncomfortable with their brand of revolutionary, socialist unionism. This, combined with heavy-handed attacks on the organization from federal, state, and local governments, led to the demise of the Wobblies as a labor union of significance (Dubofsky, 2000).

Historians suggest that the collectivism promoted by these two particular groups did not win the hearts and minds of the vast majority of American workers because of the uniquely American culture and worldview that were emerging in the late 1800s and the early 1900s. This culture emphasized individualism, egalitarianism, and a general suspicion of government, all of which were consistent with capitalism and at odds with socialism. If American workers had not embraced these capitalistic principles, the American labor movement could have taken a very different shape (Lipset, 1997).

### Union Membership and Density

As U.S. unions developed during the twentieth century, both the number of union members and union density (the percentage of the labor force that belongs to a union) in the United States fluctuated over time. Figure 16.1 depicts the changes in union density.

From a high of 35.5% in 1945, union density fell over the next six decades to a low of 12.1% in 2007. Among the factors cited for this decline are structural changes in the economy (particularly the shift from an industrial-based to a service-based economy that occurred in the last 20 years), increasingly aggressive efforts by employers to fight unionization, weakening labor laws, and changes in the public's attitudes toward unions. The overall union density rate includes employees in both the private and the public or government sectors. However, the trends in these two sectors have been very different over the last 40 years. Although private and public sector union density rates were both around 25% of the labor force in the mid-1970s, in the decades that followed, public sector union density rose to nearly 40%, while private sector union density rates fell below 10% (see Figure 16.2). The higher union density rate in the government sector is partly explained by differences in labor law that make it easier for public sector employees to organize unions. A second commonly cited reason for the difference is the relative mobility of jobs in the private sector versus the immobility of public or government jobs (i.e., private sector jobs are far more likely to move within the United States or overseas to avoid unionization than are public sector jobs).

In addition to varying over time and across the public and private sectors, union density rates also vary geographically and by industry. States with relatively high union density are located in the Northeast, the Midwest, and the West Coast. In 2008, New York had the highest union density of any state at 24.9%, followed by Hawaii (24.3%) and Alaska (23.5%). Low rates are the norm across the South and in the southwestern states. North Carolina (3.5%), South Carolina (3.7%), and Georgia (3.9%) had the lowest rate of union density in 2008 (Bureau of National Affairs [BNA], 2009). Among industries with high rates of union density in 2008

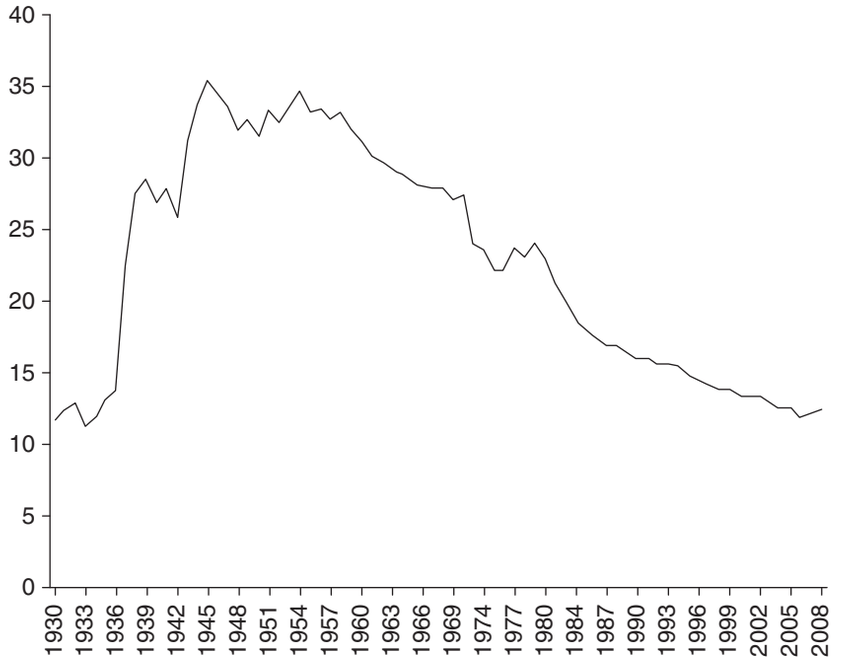

**Figure 16.1** Percentage of Employees That Are Members of a Labor Union in the United States From 1930 to 2008

SOURCES: Data from 1930 to1970 are from Census Bureau Report (2001). Data from 1973 to 1981 are based on results by Hirsch and Macpherson (2009), which uses information from a May CPS data report. Data from 1983 to 2008 were provided directly to the authors from the Bureau of Labor Statistics (BLS, 2009a, 2009b) with the following explanations: (a) Beginning in 2000, data refer to private sector wage and salary workers; data for earlier years refer to private nonagricultural wage and salary workers, (b) Data for 1990 to 1993 have been revised to reflect population controls from the 1990 census, and (c) Beginning in 2000, data reflect population controls from census 2000 and new industry and occupational classification systems. BLS has an online source for the CPS 2000 to 2008 data at http://www.bls.gov/cps/cpslutabs.htm. *Employees* refers to those who receive a wage or salary working in nonagricultural industries in the private and public sectors. No data were available from 1971 to 1972 or for 1982.

were utilities (electric power, natural gas, water supply, etc.) at 26.9%, transportation and warehousing (transportation of passengers and cargo, warehousing and storage of goods, etc.) at 21.3%, and telecommunications (telephone service, cable and satellite television, Internet access, etc.) at 19.3%. Industries with low union density included insurance at 1.0%, finance (banks, savings and loans, brokerages, etc.) at 1.3%, agriculture at 2.8%, food service (restaurants, fast food, caterers, etc.) at 3.1%, and retail trade (stores, catalog sales, etc.) at 5.2% (BNA, 2009a).

While union membership has historically been drawn from the ranks of blue-collar workers in the manufacturing, coal, utilities, transportation, and construction industries, the proportion of the contemporary labor movement's membership made up of white-collar and professional employees has been increasing (although union density for these workers still remains relatively low). Actors, writers, athletes, nurses, teachers, sales representatives, school principals, musicians, and software engineers have joined unions in greater and greater numbers in recent years. The potential for growth in this area presents a great opportunity for American unions. The degree to which they can take advantage of this opportunity may determine how relevant the American labor movement will be in the years ahead.

Labor unions are not by any means solely an American phenomenon. In fact, unions are a significantly more important part of the economies of most industrialized nations than in the United States. In 2006, the United States ranked 22nd of 24 nations, with only France (8.3%) and the Republic of Korea (11.2%) having labor movements that represented a lower percentage of the labor force. Countries with the highest union density rates were Sweden (78%), Finland (74%), and Denmark (70%). It is important to note that union density rates have been declining in most developed countries, although the decline appears to be slower for most other nations than for the United States (Chang & Sorrentino, 1991; Visser, 2006).

## Union Structure and Government

To understand how unions function as organizations, it is necessary to understand how they are structured and governed. The structure and government of most unions is similar to the structure of American government in that it has three levels—local, state or regional, and national.

The basic structural unit of a labor organization is the local union (in some unions the local might be referred to as a lodge or a branch). A local union often consists of the employees in a single workplace (a factory, an office, a warehouse, etc.), although sometimes a local can represent more than one workplace, and in very large workplaces, there can be more than one local union (e.g., one local might represent production and maintenance employees, while a second local represents the office workers). One of the most significant things about a local union is that it is the main point at which members interact with, or experience, the union. The local union is governed based on a local constitution or bylaws that establish how the local will operate. Typically, the local union constitution outlines how officers are elected, what their terms of office will be, what their duties are, as well as how decisions regarding the administration of the local, the bargaining of contracts, and the calling of strikes will be made. The exact structure of a local union will depend in part on its size and on the industry within which it operates. Because most local unions are affiliated with a

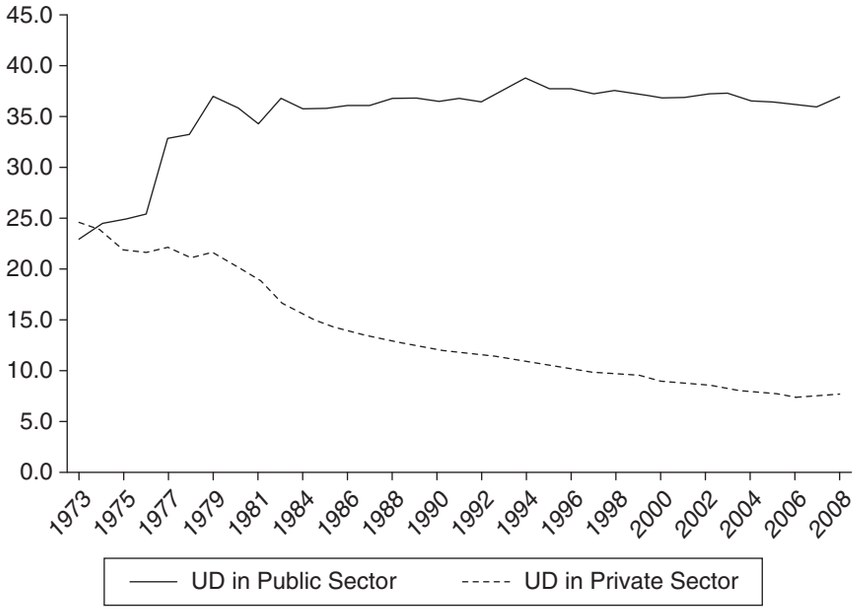

**Figure 16.2** Union Density in the Public and Private Sectors

SOURCES: Data for 1973 to 1981 are from Hirsch and Macpherson (2009). No actual data exist for 1982. Data from 1983 to 2008 were provided directly to the authors by the BLS (2009a, 2009b) with the following explanations: (a) Beginning in 2000, data refer to private sector wage and salary workers; data for earlier years refer to private nonagricultural wage and salary workers, (b) Data for 1990 to 1993 have been revised to reflect population controls from the 1990 Census, and (c) Beginning in 2000, data reflect population controls from Census 2000 and new industry and occupational classification systems.

national or an international union, the local union structure will also be influenced by the practices of the parent organization.

The second level of union structure is the regional or state level. This is an intermediate level of the union that serves as a link between the national and local levels. The regional or state level brings locals belonging to the same national or international union in a given geographic region together for their mutual benefit. This level also often provides professional union representatives to assist the local unions. These individuals usually have significant experience and expertise in organizing, contract negotiations, and grievance handling/arbitration and provide advice and assistance to the local unions.

The national or international union represents the third level of union structure. A national union brings together its local unions within the United States. An international union is similar to a national union except that it has local unions and members in Canada (and sometimes in U.S. territories such as Puerto Rico and Guam). National and international unions perform numerous functions. They bring locals together to use their collective power in negotiations with larger national and multinational employers. National and international unions also provide the formal structure and mechanisms for their members' interests to be voiced and heard in national politics and in addressing other important issues. Additionally, national and international unions support regional/state and local union initiatives and needs by providing services (e.g., legal, research, education) to these levels of the union.

It is important to note that unions—at the local, regional or state, and national/international levels—are mandated by federal law to operate democratically. The Taft-Hartley Act of 1947 (a series of amendments to the NLRA) and the Labor-Management Reporting and Disclosure Act (LMRDA) of 1959, also known as the Landrum-Griffin Act, established basic or minimum requirements for how elections are to be held, who can hold an elected position, and what the terms of office will be. These laws also mandate that all levels of all unions must file detailed reports accounting for every cent that is collected and spent and listing the salaries and expenses of all employees.

There is a fourth level of union structure and government called the *federation.* Unlike the other three levels discussed previously, a labor federation is not a union, nor is it a part of a union. It is a body that brings together many different unions into a loose alliance. This alliance helps the individual unions pursue their common interests by sharing information and bringing the collective authority and resources of the individual unions together. In some ways, a labor federation is analogous to the U.S. Chamber of Commerce in the business community. In the same way that a labor federation is not a union, the Chamber is not a business. Rather, it is a federation of businesses.

There are currently two labor federations in the United States. The first, the American Federation of Labor and Congress of Industrial Organizations (AFL–CIO), was founded in 1955. The second, Change to Win (CTW), was formed in 2005 by unions that disaffiliated from the AFL–CIO. The CTW unions split with the AFL–CIO over a number of policy differences, including CTW's perception that the AFL–CIO was not placing sufficient emphasis on organizing new union members.

In 2009, the AFL–CIO consisted of 56 national and international unions with a total membership of 11 million, while CTW had 7 affiliates totaling 6 million members. While most U.S.-based national and international unions belong to one of these two federations, not all national or international unions are affiliated with a labor federation. In fact, the largest American union, the National Education Association (NEA), does not belong

to either the AFL–CIO or CTW. However, other than the NEA, the unions that not affiliated have relatively small memberships and little influence nationally (Sloane & Whitney, 2010).

## The Industrial Relations Process

### The Three Steps

To understand the role that unions play in labor markets, it is helpful to understand the process by which employees form unions and, once formed, how unions negotiate contracts and resolve day-to-day differences with employers.

The industrial relations, or union–management relations, process consists of three steps. For most private sector workers, these steps are spelled out in the NLRA. For railroad and airline workers, they are spelled out in the Railway Labor Act. For public sector employees who have been granted the rights to organize and bargain and in a few cases to strike, these steps are addressed in various federal and state laws. The processes differ from law to law but generally have much in common.

The first step in the process involves the organization of a union. Under the NLRA, this occurs in one of two ways. If a majority of employees in a workplace sign representation cards, the employees can request that their employer voluntarily recognize the union. If the employer refuses, the employees can then present these cards to the National Labor Relations Board (NLRB) and ask for a certification election (note, while it is necessary to have a majority of employees sign cards to ask for voluntary recognition, only 30% are required to request an election). Once the cards are verified, the NLRB will order that an election be held within 45 to 60 days.

In the time between the filing of cards and the election, the union and the employer will both conduct campaigns to convince the employees to vote for or against unionization. At the end of the campaign, a secret ballot election is typically held. Most employers do not opt to voluntarily recognize a labor union, despite having evidence from a third party that a majority of those workers want to form a union. For the union to be certified, a majority of employees voting in the election must vote for the union. Once a union is certified or voted in, the employer is obliged to engage in bargaining with that union.

The second step in the industrial relations process is collective bargaining. Collective bargaining involves the employer and representatives of the union meeting to negotiate over compensation, benefits, hours, and working conditions for unionized employees. In the bargaining process, the union usually presents proposals for improved wages and benefits, and the employer responds with counterproposals for less generous improvements (or during downturns, reductions in compensation and benefits).

In the small percentage of cases where the parties cannot reach an agreement on the terms of the new collective bargaining contract, one side or the other might engage in strategies to force the other side to change its position. For unions, this would normally take the form of a strike, a tactic in which the union's members refuse to work in an effort to put economic pressure on the employer by disrupting its ability to operate. As a counterbalance to a strike, private sector employers, under certain conditions, can lockout, or voluntarily close, their businesses in an effort to deprive employees of their income.

It is important to note that a very, very small proportion of negotiations involve either a strike or a lockout. The vast majority of collective bargaining negotiations conclude with the two sides agreeing to a contract without any disruption of work. The end result of collective bargaining is a contract (also known as a labor agreement). Contracts are for fixed periods of time, normally 3 to 4 years, although they can be of shorter or longer duration.

Once the parties agree to a contract of a fixed duration, they enter the third step of the industrial relations process. This step is sometimes called the contract administration step. It involves the implementation of a mechanism called a grievance procedure for systematically resolving disputes that arise during the term of the contract. While both parties to the contract may intend to abide by the agreement, there may be incidences when the employer or the union may misinterpret or misunderstand the intent of a specific section in the contract. Disputes might also arise over union concerns that the employer is not following the contract (e.g., an employer does not follow the provisions relating to promotion in choosing a person for a vacated position).

Prior to the passage of the NLRA, unions would sometimes strike over such issues, but today they are settled peacefully through the grievance procedure. This is a quasi-judicial process in which disputes are worked out during a series of meetings involving employer and union representatives. If the issue is not resolved at the first-step meeting, the union can appeal to a second and third step. Each meeting involves different union and management representatives with increasing authority and expertise in addressing the dispute resolution. Most disputes are successfully resolved within the first three steps of the grievance process. However, if no resolution is reached between the parties, the case goes to arbitration, a quasi-judicial process that involves a hearing before an arbitrator (a sort of judge). The arbitrator is usually empowered by both parties to issue a final and binding decision.

A relatively high percentage of cases taken to arbitration involve disciplinary charges against employees (demotions, discharges, etc.). The grievance procedure provides disciplined workers with due process, including an opportunity to present their sides of the story and have their day in court. From the union members' point of view, this is one of the most important benefits a union provides its members—a voice in resolving disputes between an employee and a manager.

### Distinctive Features of the U.S. Industrial Relations System

Just as American unions are somewhat different from their counterparts in other parts of the world, so is the system of industrial relations in the United States. The system is distinctive in four major ways.

#### *Decentralization*

The focal point for collective bargaining in the United States is the individual workplace or bargaining unit (a factory, an office, etc.). This is the unit in which employees organize to form a union. While these bargaining units can be combined into multi-unit structures for the purpose of negotiating a uniform contract across multiple workplaces operated by one employer (as in large corporations like General Motors, U.S. Steel, etc.), the vast majority of collective bargaining in the United States involves a single local union and a single employer negotiating a labor agreement for a single workplace.

While industry-wide collective bargaining is rare in the United States, national labor agreements covering entire industries are much more common in the United Kingdom, western Europe, and Australia. In some U.S. industries, large employers do negotiate company-wide contracts that can cover hundreds of workplaces (this is the case in the auto industry and its three majors employers, General Motors, Ford, and Chrysler), but again, this is the exception and not the rule.

#### *Exclusive Representation*

A second practice that differentiates the U.S. collective bargaining system from others in the world is exclusive representation. The NLRA provides that only one union can represent the employees in a bargaining unit. If workers in a unit decide to organize and are successful in convincing a majority of those employees who vote in the election to support the union, that union becomes the exclusive representative for those employees. No other union can represent any of the workers in that unit. In addition, the union that wins the election acquires the responsibility to represent all employees in that unit, not just the employees who voted for the union.

In many other countries, unions represent only that part of a bargaining unit that chooses to be represented by a particular union. This proportional representation can result in multiple unions representing different percentages of the employees in a given unit (i.e., Union A might represent 40% of the unit; Union B, 30%; Union C, 20%; etc.). Employers are forced to deal simultaneously with multiple unions in that unit, a situation that can be chaotic, confusing, and disruptive.

#### *The Role of Labor Contracts*

In the U.S. system, the heart of any union–management relationship is the contract. These contracts are the end product of bargaining and spell out, with precise language and great detail, what the compensation, benefits, hours, working conditions, local practices, disciplinary processes, and grievance procedures will be. These contracts are often long and complex (the General Motors–United Auto Workers' contract is an almost 1-inch-thick booklet of very small print). This contrasts with the United Kingdom's and western Europe's approach in which negotiations focus on only a handful of issues (wages, some benefits, etc.). The resulting contract is much more limited in scope. Issues not addressed are resolved as they arise, in a more informal process by the parties.

#### *The Role of Government*

A fourth difference between the U.S. system of collective bargaining and the system in most countries is the larger role that the U.S. government plays in determining, regulating, and enforcing the bargaining process. Legislation like the NLRA, the Railway Labor Act, and federal and state public sector labor laws detail how a union is formed, who can be included in that union, the obligations the parties have to bargain with each other, when bargaining occurs, and more.

U.S. labor laws also specify in great detail what the parties must bargain over (mandatory issues); what they cannot bargain over (prohibited issues); and what they may, but are not required to, bargain over (voluntary issues). Again, in the United Kingdom and western Europe, the government does not get involved to as great a degree in either the process or the substance of negotiations. These issues are largely left to the parties.

## The Impact of Unions on Labor Markets

As suggested earlier, economists have traditionally viewed unions as monopolies that interfere with the efficient operation of labor markets. They do so in three main ways.

First, unions raise wages above the competitive levels set by the market. In doing so, they cause employers to hire fewer workers than they would otherwise. The evidence does, in fact, indicate that unions increase wages. In 2008, the BLS (2009c) reported that the median weekly earnings of union members employed full time was $886, while full-time nonunion workers earned $691, a difference of 28% (see Figure 16.3).

A comparison of earnings by occupation indicates that this earnings premium is present in most occupations (see Table 16.1).

The impact of unions on wages is even greater than indicated by the union–nonunion wage differential. This is because nonunion employers often raise the wages of their employees above what they would otherwise pay to reduce the likelihood that their employees will organize a union. The phenomenon of unions indirectly causing an increase

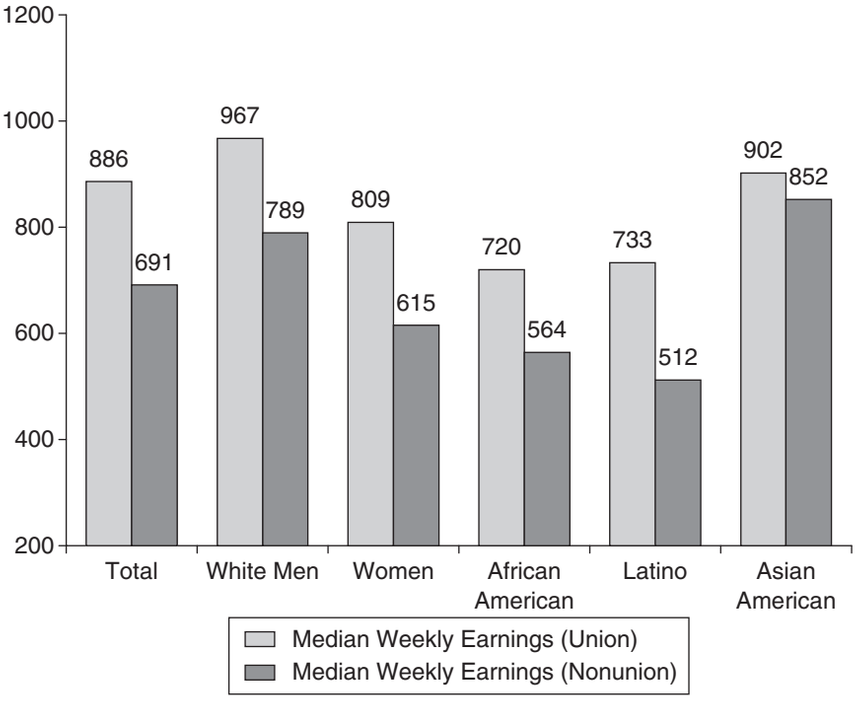

**Figure 16.3** Comparison of Union and Nonunion Median Weekly Earnings 2008
SOURCE: BLS (2009c).

in the wages of nonunion employees is called the *union threat effect* (Filer, Hamermesh, & Rees, 1996).

Economic theory suggests that artificially raising wages results in a reduction in the number of jobs because employers buy less labor as the price increases. And as those employees who have lost their jobs search for work in the nonunion sector, they bid down wages there. In essence then, some of the wage increases won by unions come at the expense of lower-paid or unemployed workers. For this reason, many economists argue that the interference of unions in the operation of the market causes inefficiencies. This leads to the conclusion that, on balance, unions play a harmful role in the market.

Many economists believe that unions contribute to inefficiency in a second way by engaging in strikes. When unions call strikes in an effort to increase their bargaining power, productivity falls. At the firm level, this ultimately lowers profitability; at the national level, it reduces gross national product (GNP) (Freeman & Medoff, 1984).

Third, economists believe that unions reduce efficiency through the imposition of work rules and work restrictions with which nonunion employers are not saddled. One often-cited example is work jurisdiction rules in which employees have strictly observed job descriptions that prevent them from doing even the simplest of tasks that are not a part of their jobs. Where work jurisdiction rules exist, some economists argue that these provisions have a negative impact on individual and firm-level productivity (Filer et al., 1996).

However, other economists question this view of unions. They believe that "markets are competitive enough to give unions little or no power to extract monopoly wages" (Freeman & Medoff, 1984, p. 7). They reason that unions really acquire monopoly power only when they organize an entire market or are present in a noncompetitive market (Filer et al., 1996). They also point out that strikes involving 1,000 workers or more have fallen steadily in this country from a modern high of 470 in 1952 to 44 in 1990 to 15 in 2008 and that the percentage of estimated working time lost for those same years fell from 0.14 to 0.02 to 0.01 (BNA, 2009). They also note that strikes occur in other industrialized countries and usually at higher rates that more than offset the cost of strikes in the United States. Last, they argue that restrictive work rules may have been a problem in the past but that many unions have worked closely with employers to eliminate these practices and to find ways to more efficiently produce goods or provide services.

Over the last 25 years, another perspective on unions, based on the writings of Hirschman (2007), but most effectively articulated by Freeman and Medoff (1984), has gotten significant attention and has influenced economists' views of unions in important ways. This collective voice/institutional response perspective suggests an alternative to the classic market mechanism of exit and entry. Economic theory posits that exit occurs in a perfectly competitive market in which "no individual can be made better off without making someone worse off " (Freeman & Medoff, p. 8). The freedom that dissatisfied employees have to leave bad employers and go to work for good ones contributes to the efficiency of the market. If this system works as assumed, unions can interfere only with the free operation of the market and create inefficiencies (Bennett & Kaufman, 2007).

Freeman and Medoff (1984) contend that employees can deal with workplace problems in two ways. They can exit (quit—the only option available to workers according to classical economic theory) or they can engage in voice by speaking up and trying to change the conditions with which they are dissatisfied. Regarding the exit option for dissatisfied workers, Freeman and Medoff argue that these self-regulating mechanisms of markets are not perfect because actors do not have complete information and there are significant mobility costs for employees who choose to exit. And should employees consistently exit the firm when dissatisfied, the

**Table 16.1** Earnings by Occupation, 2008 Full-Time Wage and Salary Workers' Median Weekly Earnings in Dollars

| | *Union* | *Nonunion* | *Percentage of Union Advantage* |
|---|---|---|---|
| Community and social services occupations | 983 | 743 | 32.3 |
| Education, training, and library occupations | 974 | 765 | 27.3 |
| Arts, design, entertainment, sports, and media occupations | 1,110 | 858 | 29.4 |
| Health care practitioner and technical occupations | 1,070 | 943 | 13.5 |
| Health care support occupations | 526 | 457 | 15.1 |
| Food preparation and serving-related occupations | 502 | 398 | 26.1 |
| Building and grounds cleaning and maintenance occupations | 596 | 412 | 44.7 |
| Construction and extraction occupations | 992 | 621 | 53.0 |
| Installation, maintenance, and repair occupations | 1,002 | 729 | 37.4 |
| Production occupations | 765 | 567 | 34.9 |
| Transportation and material moving occupations | 789 | 550 | 43.5 |

SOURCE: BLS (2009c).

result is high turnover in the workforce, which is costly to employers. Voice can, in fact, reduce costs to both employers and employees by drawing attention to bad employment practices and resolving them. Freeman and Medoff point out that voice expressed by an individual is much less likely to be effective in resolving problems, particularly in a large workforce, than is voice expressed by a group. And because the most effective way to express collective voice is through a union, they conclude that unions can have a positive impact on efficiency in a workplace.

The view that unions interfere with the efficient operation of the market continues to be the prevailing opinion in the field of economics. But the case made by Freeman and Medoff (1984) that, in addition to their negative monopoly face, unions also have a positive voice face has forced the economics profession to reconsider the conventional wisdom about unions.

## Conclusion

By any account, labor unions have played a significant role in American society for most of the nation's history. And while their influence has declined over the last 25 years, the modern American labor movement represents millions of employees in thousands of large and small workplaces across the country.

Most economists have viewed unions through the lens of neoclassical economic theory, concluding that they act as monopolies that create inefficiencies in the labor market, resulting in the loss of jobs and greater income inequality in the workforce. In their view, unions have also had a negative impact on efficiency through the conduct of strikes and by the institution of cumbersome work rules and work restrictions.

This assessment of unions has been challenged in recent years by a minority of economists who downplay the monopoly face of unions. These scholars argue that strikes no longer cause significant disruption to the economy and that unions have greatly loosened restrictions on work rules. And they argue that unions have a second voice face that plays a positive role in the workplace by allowing employees to address problems that would otherwise cause them to exit or quit. This side of unions benefits both employees and employers by reducing turnover, improving productivity, and bringing fair treatment and due process, two of the core values of American democracy, to the workplace.

It remains to be seen whether this minority view of unions can make inroads into the traditional view that has prevailed in the field of economics for a very long time.

# Game Theory

Indrajit Ray
*University of Birmingham*

Game theory, within the discipline of economics, has perhaps been the most discussed field in the past half century—it has revolutionized the study of economics, inspired hit films, and crept into the popular awareness. The success story of game theory as a research area can easily be found in the advancement of field-specific journals and the many Nobel Prizes awarded to game theorists within the past two decades.

As it offers powerful tools for understanding strategic interactions, game theory is being increasingly applied not just within economics (such as industrial organization, political economy, international trade, environmental economics) but also in other subject areas, such as politics, sociology, law, biology, and computer science. It is not surprising that game theory has gained enormous popularity and importance as a teaching module within any (undergraduate or graduate) program in economics and other related subject areas.

So what exactly is game theory? What is a game for that matter; what makes a game, a game that's being theorized here? The answer is simple: Game theory is nothing but an interactive decision theory involving more than one individual (decision maker). Game theory offers mathematical models to study conflict and cooperation between intelligent and rational decision makers. The decision makers here are called the players. These players are assumed to be intelligent and rational in the sense that they can identify their own objectives and can choose the best among a set of alternatives by comparing outcomes and performing necessary calculations.

There are many real-life examples of games—board games such as chess and checkers are games that are theorized. However, many televised "game" shows are not games as they do not involve interactive decision making. Indeed, many real-life situations can be modeled and analyzed using game theory. Common examples include auctions of goods ranging from artwork to 3G mobile network license, wage bargaining by any union, voting in committees, and so on.

Game theory, as a subject and a field of research, has evolved over the decades in the past century. In the early years, game theory clearly was identified as an applied topic in mathematics (game theorists then were applied mathematicians, unlike present-age game theorists who are pure economic theorists). The subject perhaps got its independent status in the 1940s with the publication of Von Neumann and Morgenstern's (1944) book and the doctoral thesis of John Nash, later published as papers (Nash, 1950a, 1950b).

Broadly speaking, the theory can be classified under two areas: noncooperative game theory and cooperative game theory. The models and solutions used to analyze conflict (and possible cooperation) among interactive individuals (decision makers) constitute noncooperative theory. On the other hand, models of cooperative game theory assume all possible coalitions may form and thus take coalitions (and not individuals) as the building blocks of the theory. The solutions of the cooperative theory analyze possible ways of sharing the benefits achieved by cooperation in a coalition among individuals.

Research in game theory in the past 60 years or so has made sharp turns in terms of its focus. In its early years (in the early twentieth century) as a topic in applied mathematics, a specific form of a two-person noncooperative game, called the "zero-sum game" (in which one player wins what the other player loses), was the center of attention. Then, in the 1950s and the 1960s, the study of cooperative games was in fashion while from the 1970s onwards, noncooperative theory stole the focus. Perhaps it is an irony that John Nash, who essentially initiated the

modern theory of noncooperative games with the concept of the Nash equilibrium (Nash, 1950b), was also the author of a path-breaking work in cooperative theory known as the Nash bargaining solution (Nash, 1950a).

Following the latest trend in the subject of game theory, we mainly deal with the modern notions of noncooperative game theory (with almost no mention of the early research on zero-sum games) in this chapter. Only the last section of this chapter is devoted to the field of cooperative game theory. We believe this treatment is justifiable in a reference collection for twenty-first-century economics!

## Models

Models of noncooperative games are nothing but tools to turn any appropriate real situation into a "game." The modeler, before analyzing the game, must translate any situation into the language of the theory. The model describes a well-defined problem or a situation as a game. It is important to note that the model, once well formulated, stands independent of the analysis and the proposed "solutions" of the corresponding game. The theorists and the practitioners may differ in their analysis of the game; however, the model should be objectively presented. In this section, we will present different models of noncooperative game theory that are suited to describe different situations as games. No analysis or solution of the games will be presented in this section; the following section is devoted to such analyses.

A noncooperative game is used to describe any strategic interaction among agents and is characterized by who the "players" are, what the possible alternative "actions" or "strategies" available to each player are, and what the "payoffs" to each player are when different strategy combinations are chosen. The key ingredient of a game is the fact that the payoff to a player depends on not just his or her own choice of strategy or action but on other players' strategies as well and that every player is fully aware of this interdependence.

Noncooperative games can be broadly classified into two groups depending on how they are played. Some games are played simultaneously; that is, in these games, the players choose their strategies simultaneously, not observing (any part of) each others' choices. Note that the phrase "simultaneously played" is not used literally; it need not imply that the choices are made at the same time, as long as the players do not observe others' strategies. For example, voting can be viewed as a simultaneously played game, played by the voters who can very well cast their votes at different times.

In contrast with simultaneously played games, some games are played sequentially over time and thus are called sequentially played games. The players in these games choose their actions in a particular sequence according to the rules of the game.

Simultaneously played games are often called normal-form or strategic-form games. The ingredients of any simultaneously played game are the players, their possible actions, and the outcomes depending on the chosen actions.

We focus on "finite" games where the set of players denoted by $N = \{1, \ldots, n\}$ of the game is a finite set and the sets of actions (often called the "pure strategies") available to each player, denoted respectively by $S_1, \ldots, S_n$, are all finite. $s_i \in S_i$ denotes a typical action or a pure strategy for any player *i.* The outcomes of the game depend on the choices made by all the players. An outcome can thus be associated with an $n$-vector of actions (pure strategies) denoted by $s = (s_1, \ldots, s_n) \in S = \prod_i S_i$ (the product set). Such a vector $s \in S$ is known as a strategy profile indicating a chosen strategy by each of the players. We use $s_{-i}$ to denote the choices made by all but player *i.*

Each player has a preference ordering over these outcomes. The preferences can be represented by utility functions denoted respectively by $U_1, \ldots, U_n$. These provide payoff numbers to the players for each outcome of the game. Such a game, $G = < N, S_1, \ldots, S_n, U_1, \ldots, U_n >$ provides a complete description of the situation and the rules of the game.

It is important to highlight here that we assume that the rules of the game and the situation described in the model are known to the players. Moreover, the players know that the other players know and that the other players know that they know and so on. In other words, we assume that the game is "common knowledge" among all players. It is indeed important to maintain this assumption in all the models we discuss here as we need our players to realize that they all play the same game.

A two-person strategic-form game can easily be described in a table, often called the normal-form table. It is a convention to represent the rows of the table as the pure strategies of Player 1 (thus called the row player) and the columns as those of Player 2 (thus called the column player). Each cell of the table is thus a strategy combination of the game and therefore represents an outcome that is associated with two payoff numbers. The first number in each cell is Player 1's payoff while the second is for Player 2.

We now consider some examples of simultaneously played games in which there are only two players, each with two strategies. All these games thus can be represented by a $2 \times 2$ normal-form table.

Our first $2 \times 2$ noncooperative game has the feature that in each of its outcomes, a player wins the amount that the other loses. Such two-person noncooperative win-lose games are known as zero-sum games as the sum of the payoffs in each cell is zero. The game can be associated with a situation of "matching pennies" where both players put a penny on the table with head (*H*) or tail (*T*) up. Player 1 wins (Player 2 loses) when both pennies have the same side (*HH* or *TT*) while Player 2 wins (Player 1 loses) otherwise. The table in Figure 17.1 describes the game.

The second game is perhaps the most talked about game in economics. The story behind the game involves two convicts who may or may not admit their guilt individually; the game, however, applies to many social situations in general. The two choices available to the players are to cooperate or not to cooperate (defect) with the fellow player. As the table in Figure 17.2 describes, the outcome in which both players choose to cooperate is socially optimal, in the sense that it maximizes the sum of the payoffs achieved from different outcomes; however, as we will find out later, this outcome may not be achievable when the players play this game just once (repeating the same game will lead to the cooperative outcome).

The following two games describe situations involving desirable coordination between two players. The first situation (as in Figure 17.3) is that of pure coordination between two choices *A* and *B*, where the outcomes are ranked in the same order by both players. Both players will get positive payoffs if they coordinate to play the same strategy and get nothing if they do not; moreover, playing *A* leads to a better outcome to both than that from playing *B*.

The second situation (as in Figure 17.4) is often called the battle of the sexes, where the two players, the husband and the wife, choose to go to either a football match (*F*) or a concert (*C*). This game also has the coordination feature that the players will get positive payoffs if they play the same strategy and get nothing if they do not. However, the two coordinated outcomes are ranked differently by the players; the husband prefers the outcome (*F*, *F*) while the wife prefers (*C*, *C*).

The final example in this series, called "chicken," describes a situation where each of the two players can be aggressive (*A*) or passive (*P*), resulting in the outcomes depicted in Figure 17.5.

Tables are useful to describe games of two players only. Clearly, normal-form games may involve more than two players. Tables may still be used to describe three-person games, in a manner suggested below; however, for games with more than three players, one cannot use the tabular representation.

Consider a three-person game in which each player chooses either *S* or *N*, as described in Figure 17.6. The strategies of Player 1 (the row player) are the two rows, those of Player 2 (the column player) are the two columns, and those of Player 3 are the two matrices. There are eight possible outcomes corresponding to the eight ($2 \times 2 \times 2 = 8$; each of three players has two strategies) strategy profiles. These are the eight cells in the two tables.

The payoffs from the outcomes are given in the respective cells with the three numbers, respectively, to Players 1, 2, and 3. For example, when Player 1 plays *S*, Player 2 plays *N*, and Player 3 plays *S*, they get payoffs of −1, −2, and −1, respectively.

**Figure 17.6** A Three-Person Game

The second class of models in noncooperative theory is known as sequentially played games. As the name suggests, these games are used to describe situations in which players take decisions in a specified sequence as in board games. These games are also known as extensive-form games and are described by a structure called a game tree.

As in normal-form games, the (main) ingredients of an extensive-form game are players, their choices, the outcomes (depending on the choices made), and the payoffs to the players from each outcome. All these are described in a game tree with nodes and branches.

An extensive-form game can be identified as a rooted tree with a set of nodes, one of which is a distinct initial node. All the nodes other than the initial one are connected by a precedence function; that is, for any node, there is an immediate predecessor of that node. The terminal nodes are those for which there exists no successor.

A path is a finite sequence of nodes from the initial to a terminal node. Note that in these games trees, any path, starting from the initial node and ending at a terminal node, can be recognized by the particular terminal node at which it ends. In the next section, we will see that this important feature helps us to solve such games easily.

Formally, the set of players is $N = \{1, 2, \ldots, n\}$. All nonterminal nodes are partitioned into $n$ subsets, $X_1, \ldots, X_n$, where $X_i$ is the set of nodes at which player $i$ moves. At any $x \in X_i$, player $i$ has to choose an action that is identified by an immediate successor node in the tree. For game trees that are finite (i.e., the game ends after finitely many moves), we can observe, at the completion of the game, a path leading to a terminal node. Each terminal node therefore can be associated with an outcome of the game and will be assigned with payoff numbers for each player.

Consider, for example, the following version of an "ultimatum game" of splitting \$10 in which Player 1 moves first and has three choices of keeping ($K$) the sum to himself or herself, sharing ($S$) it equally with the other player, or giving ($G$) the amount to the other player. Player 2 then moves, after observing Player 1's choice, and has two choices of accepting ($A$) or rejecting ($R$) Player 1's call. If Player 2 accepts the proposal, he or she gets the corresponding outcomes; otherwise, he or she gets nothing. The tree in Figure 17.7 describes the game in extensive form. The payoffs are at the end of each outcome (terminal node) with the first number to Player 1 and second to Player 2.

Extensive-form games differ from normal-form games not just in structure but also rather crucially in the issue of what information is available to (some of) the players as the game progresses. The information structure becomes a component of the model and is described suitably in the tree.

Some players may receive information during the game as a part of the underlying situation. Information given to the players may differ depending on the situation. The different information may come to some of the players from "nature" (natural course), denoted by Player 0 in the game, or from actions chosen by other players.

Such informational uncertainties during the game are denoted by information sets. An information set is a set of nodes in which a player who is making a choice has no information to distinguish the nodes in that set while other players may be able to do so.

Consider, for example, a card game in which Player 1 first picks a card from a deck and sees its color (that Player 2 cannot). The color of the card, which may be black ($B$) or red ($R$) with equal chances, is thus the information given to Player 1. After seeing the color, Player 1 can "raise" ($r$) the stake or "fold" ($f$). Player 1 wins if the color of the card, when revealed, is red. If Player 1 raises, Player 2, who does not know the color, can then "meet" ($m$) or "pass" ($p$).

The tree in Figure 17.8 describes the situation in which first nature (also called "Player 0") chooses the color of the card (black or red with probability ½ each) that Player 1 observes before making a choice. The two nodes where Player 2 has to move are put under one set. These two nodes are not distinguishable from the viewpoint of Player 2, who in both cases has only observed that Player 1 has raised (chosen $r$); however, Player 2 does not have the information regarding the color of the card (whether it is $B$ or $R$) and therefore cannot distinguish between the nodes. (The tree here is used simply to describe the structure, and the payoffs at the end are omitted as the stakes in the card game can be anything.)

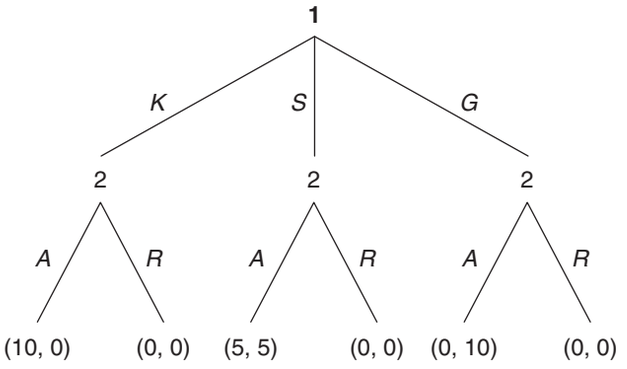

**Figure 17.7** An Ultimatum Game

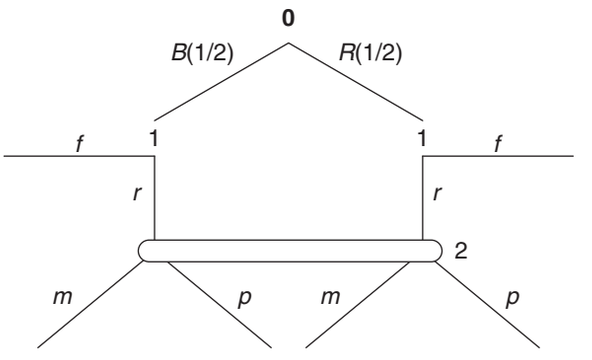

**Figure 17.8** A Card Game

Consider also a situation in which Players 1 and 2 must decide whether to carry an umbrella when leaving home. They know that there is a 50–50 chance of rain. Each player's payoff is −5 whether he or she does not carry an umbrella and it rains, −2 if he or she carries an umbrella and it rains, −1 if he or she carries an umbrella and it is sunny, and 1 if he or she does not carry an umbrella and it is sunny. Player 1 learns the weather before leaving home; Player 2 does not, but he or she can observe Player 1's action before choosing his or her own.

The above situation can be described by the tree in Figure 17.9 where nature (Player 0) first chooses the weather condition—rain (*R*) or sun (*S*)—with equal chances (probability 1/2). Player 1 learns the condition, and in each of the two cases (nodes), he or she has two choices: either to carry an umbrella (*U*) or not to carry (*N*). Player 2 then observes Player 1's choice (but still does not know the precise weather condition) and then must choose either to carry an umbrella (*U*) or not to carry (*N*).

The tree in Figure 17.9 has four nodes in which Player 2 makes a choice. These four nodes are put into two different information sets for Player 2, who does not know the weather condition but can observe Player 1's move. Player 2 observes Player 1 carrying an umbrella in the two nodes in the left information set in the tree; however, he or she cannot distinguish these nodes as he or she does not learn the weather condition. Similarly, in the right information set, he or she sees Player 1 without an umbrella and knows nothing about the weather. As earlier, the payoffs are given at each of the terminal nodes.

Both the examples above describe situations in which (some of the) players get some information (such as the color of the card in the card game) during the game. Thus, when the game is played, players will have different information that is indicated by players' information sets. These games are called games with imperfect information.

We should make a comment here that games with imperfect information are modeled distinctly from situations (games) where players may have different information that is relevant to the game, before the game starts. This sort of prior (to the game) and private (to individual players) information is modeled as games with incomplete information and will be discussed later in this section.

Games that have no informational asymmetry among the players at any stage (prior to or during the game) are known as games with complete and perfect information (such as board games like chess).

Before discussing games with imperfect information further, we should spell out an important assumption behind these models. We assume that the players remember all the past moves and the information provided to them in any stage of the game. Hence, these (extensive-form) games are called games with "perfect recall."

Extensive-form games with imperfect information distinguish players' (pure) strategies from their chosen actions. Actions are players' moves or choices that they decide upon whenever they have to during the game. Strategies, on the other hand, are plans for the whole game. In an extensive-form game, players may move in different time periods, in different stages (nodes) in the game within different information sets. The strategies therefore should be "complete" plans, in the sense of being exhaustive over time stages and being contingent upon the information sets; that is, a strategy for a player must describe what the player does whenever he or she has to move (at every stage and at each of his or her information sets in the game).

For example, in the above card game, Player 1 has to move in two information sets, each being a singleton (with only one node). In the first node (singleton information set), Player 1 knows that the color of the card is black, while in the second node (singleton information set), the color is red. The action to be chosen in each node is either *r* or *f*. A strategy for Player 1 must completely specify what he or she does when the color is black and what he or she does when the color is red. *rf* denotes such a strategy, which implies that Player 1 chooses *r* (raises) when the color is black and chooses *f* (folds) when the color is red. There are thus four such possible strategies—namely, *rr*, *rf*, *fr*, and *ff*—that describe completely what Player 1 does contingent on the information on the color of the card.

Similarly, in the umbrella game, the strategies of Players 1 and 2 should completely specify what they do in the different information sets in which they have to choose an action. In this game, Player 1 has two information sets,

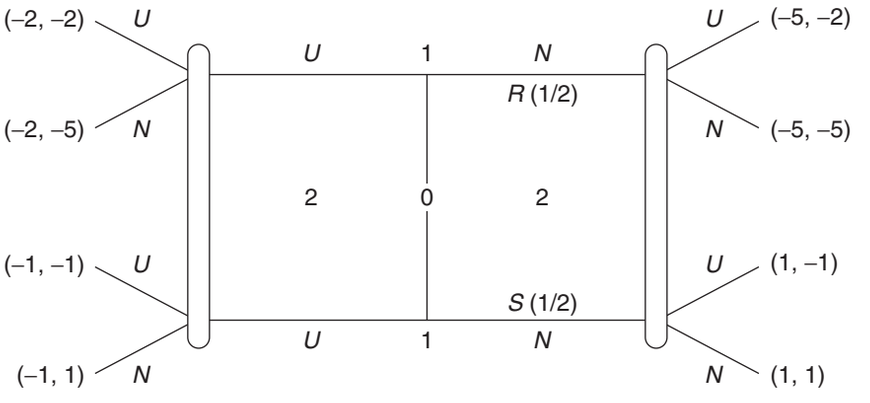

**Figure 17.9** The Umbrella Game

and both are singletons (consisting of only one node), as he or she knows the weather condition. Player 2 also has two information sets, as explained earlier, each with two nondistinguishable nodes, as he or she observes Player 1's choice but does not know the weather condition.

Player 1's (pure) strategy should specify what he or she plans to do when it rains and what he or she does when it is sunny. For example, the plan *UN* denotes that Player 1 chooses to carry an umbrella (*U*) when it rains and chooses not to carry (*N*) when it is sunny. The four possible pure strategies for Player 1 thus are *UU*, *UN*, *NU*, and *NN* denoting what he or she does when it rains and when it does not.

Similarly, the strategies of Player 2 specify what actions he or she chooses in two different information sets he or she has to act on. A complete plan for Player 2 thus also has two components; however, it is contingent on his or her information only, that is, his or her observation of Player 1's move (and not the weather condition). For example, the plan for Player 2, denoted by *UN*, suggests that Player 2 chooses to carry an umbrella (*U*) in his or her left information set when Player 1 carries an umbrella and chooses not to carry (*N*) in his or her right information set when Player 1 does not carry. Thus, the four possible pure strategies for Player 2 also are *UU*, *UN*, *NU*, and *NN;* however, these denote what Player 2 does when Player 1 carries an umbrella and when Player 1 does not.

It is sometimes easier to analyze normal-form games. Given the strategies or complete plan of actions, one can now transform an extensive-form game into a normal-form game. Such normal-form representations include the players and their complete plans as strategies.

For example, the normal form corresponding to the umbrella game has four (pure) strategies for each player. It can be described by a table as shown in Figure 17.10. Each cell in the table denotes an outcome corresponding to the profile of plans chosen by the players with payoffs being the expected payoffs from following those plans.

To understand the (expected) payoffs illustrated in each cell, take, for example, the case where the players follow the plans *UN* and *UN*, respectively. Under these plans, if it rains, Player 1 will carry the umbrella (as he or she knows that it will rain) and Player 2 will also carry (as he or she sees Player 1 carrying), while if it is sunny, Player 1 will not carry the umbrella (as he or she knows the weather) and Player 2 will also not carry (as he or she sees Player 1 not carrying). The game thus ends up in either of the two terminal nodes where the payoffs are (–2, –2) and (1, 1). With a 50–50 chance of rain, the expected payoffs thus will be (–0.5, –0.5).

As mentioned earlier, players may have private information before they start playing the game, which is not in the description of the game. This sort of prior and private information can be modeled as types of players. These games are known as games with incomplete information or Bayesian games.

| | *UU* | *UN* | *NU* | *NN* |
|---|---|---|---|---|
| *UU* | –1.5, –1.5 | –1.5, –1.5 | –1.5, –2 | –1.5, –2 |
| *UN* | –0.5, –1.5 | –0.5, –0.5 | –0.5, –3 | –0.5, –2 |
| *UN* | –3, –1.5 | –3, –3 | –3, –0.5 | –3, –2 |
| *NN* | –2, –1.5 | –2, –2 | –2, –1.5 | –2, –2 |

**Figure 17.10** Normal-Form Table for the Umbrella Game

A Bayesian game is described by the set of players, the strategies of players, the different types of the players, prior beliefs held by the players over others' types, utility functions depending on the type, and strategy profiles.

For example, in the Bayesian game described by the tables in Figure 17.11, each player has two strategies, and Player 2 has two types. The prior beliefs held by Player 1 about Player 2's types ($t_2$ = 1 or 2) are given by the probabilities 0.6 and 0.4, respectively.

All the above models simply describe different situations as games. We have not made any attempt to analyze the games to find what rational players should or would do while playing these games. The next section is devoted to such analyses.

## Solutions

We are now ready to analyze our games. We look for a "solution" (a specific outcome) of a game. It may not be a prescription in the sense that the solution does not really tell us how to play a given game. We, the theorists, are rather trying to understand how (rational and intelligent) players think and play games.

The strategy profile associated with the solution-outcome of a game presents an "equilibrium" behavior. The advancement of game theory is indeed demonstrated in the power of theoretical solutions to explain observed behavior and in many laboratory-based experiments where players follow equilibrium behavior. The critics, however, often claim that theoretical solutions fail to offer any prediction in some experiments and thereby question these equilibrium concepts. For a balanced and advanced discussion, see Camerer (2003). For an alternative approach to justify theoretical notions, one may consider "revealed preference in games" (Ray & Zhou, 2001).

To find an acceptable solution, we must first consider the concept of dominance. A strategy is dominated if it generates lower payoffs than some other, dominating strategy of that player, whatever the opponents' strategies. For example, in the $2 \times 2$ game in Figure 17.12 (only Player 1's payoffs are shown), the strategy *B* for Player 1 is (strictly) dominated by the dominant strategy *T* as *T* generates (strictly) higher payoffs.

A dominant strategy equilibrium is a strategy profile where each player is playing a dominant strategy. For example, in the prisoner's dilemma game discussed earlier (in Figure 17.2), (Defect, Defect) is the dominant strategy equilibrium as Defect is the dominant strategy for both players.

Unlike the prisoner's dilemma, most games do not possess any dominant strategy equilibrium. Some games, however, can be solved by a process of "iterative elimination of dominated strategies." As the players do (should) not play dominated strategies, we eliminate them from the game one by one and thus reach a solution or an equilibrium of the game.

For example, in the two-person game in Figure 17.13, the strategy $R$ for Player 2 is dominated by the strategy $M$ and thus can be deleted from the game. Once $R$ is deleted, in the rest of the game, the strategy $T$ for Player 1 is dominated by the strategy $B$ and hence should be deleted. In the rest of the game, clearly, the strategy $M$ is dominated for Player 2 and hence can be deleted. Thus, the outcome $(B, L)$ turns out to be the solution of this game based on the process of iterative elimination of dominated strategies.

It should be pointed out here that the order of elimination may matter and may produce different solutions for different orders used, if the process involves weak dominance (where the payoffs in the dominated strategies are weakly worse).

One may also consider domination by a randomized strategy. For example, in the game in Figure 17.14 (only Player 1's payoffs are shown), the strategy $M$ for Player 1 can be dominated if Player 1 is allowed to choose the strategies $T$ and $B$ with equal probabilities. In this game, this random choice of Player 1 will generate an expected payoff of 0.5, which is higher than that from the strategy $M$ for him or her. Thus, $M$ is dominated by the strategy $(½T, ½B)$.

Strategies such as $(½T, ½B)$ are called "mixed" strategies. Mixed strategies are probability distributions over the pure strategies. These are randomly chosen by a player according to the probability distribution. They can be also interpreted as beliefs held by a player over the other player's strategies.

Allowing for mixed strategies, a (normal-form) game $G = < N, S_1, \ldots, S_n, U_1, \ldots U_n >$ can now be extended to $< N, \Sigma_1, \ldots, \Sigma_n, u_1, \ldots, u_n >$ in which $\Sigma_i$ denotes the set of all mixed strategies of player $i$, where $\sigma_i \in \Sigma_i$ is a typical mixed strategy and $u_i$ is the expected utility of player $i$. To find the expected payoff from a profile of mixed strategies, note that the mixed strategies are chosen "independently," and hence the joint probability of a particular pure profile $s = (s_1, \ldots, s_n) \in S$ is simply the product of the probabilities $\sigma_i(s_i)$. Hence, $u_i(\sigma_1, \ldots, \sigma_n) = \Sigma_{s \in S} [\prod_i \sigma_i(s_i)] U_i(s)$.

For extensive-form games, randomization can be viewed in two ways. In such games, as mentioned earlier, a strategy is a complete plan of actions indicating what a player does in each of his or her information sets. A mixed strategy thus is a distribution over these complete plans. For example, in the umbrella game, a mixed strategy for Player 1 is a probability distribution (say, ¼ each) over the four pure strategies *UU*, *UN*, *NU*, and *NN*. Clearly, mixed strategies defined this way are difficult to understand and

(a)

| | *L* | *R* |
|---|---|---|
| *T* | 1, 2 | 0, 1 |
| *B* | 0, 4 | 1, 3 |

| *M* | 0, ... | 0, ... |
| *B* | –1, ... | 2, ... |

**Figure 17.14** A Game Where a Randomized Strategy of Player 1 Is Dominant

interpret. Instead, one may work with another way of randomizing called behavioral strategies, which allow mixing over actions within each of the information sets for each player. For example, in the umbrella game, Player 1 may play a behavioral strategy that randomizes (say, ½–½) over the actions *U* and *N* when it rains and randomizes (say, ¼–¾) when it is sunny. Behavioral strategies clearly are easy to interpret and handle. Moreover, it can be technically proved that mixed and behavioral strategies are mathematically "equivalent."

Not many games can be solved by eliminating dominated strategies. Hence, we need other concepts to find an acceptable solution. The most popular equilibrium solution concept in game theory is the Nash equilibrium, named after John Nash, who introduced this notion (Nash, 1950b). Before we define this equilibrium notion for a (normal-form) game, we first focus on the concept of "best response" of any player against his or her opponents' strategies.

For example, in the game of chicken (as in Figure 17.5), the best response for a player can be easily demonstrated. The best response for a player in this game is the strategy *P* if the opponent plays the strategy *A* and vice versa.

In a Nash equilibrium strategy profile, every player plays the best response against the other players' strategies specified in the profile. The interpretation is that in equilibrium, everybody is playing the best possible strategy, given that the others are also playing their best strategies. Assuming everyone else's strategy, no player can be (strictly) better off by deviating unilaterally. Clearly, a solution achieved through the elimination of dominated strategies is also a Nash equilibrium.

Formally, $s^*$ (a strategy profile) is a Nash equilibrium if for all $i$, $u_i(s^*) \geq u_i(s_i, s^*_{-i})$, for all other $s_i$. For example, in chicken, $(A, P)$ is a Nash equilibrium.

For extensive-form games, where players move sequentially, one may use Nash's notion of equilibrium by treating players' strategies as complete plans of actions before play begins. Also, one can find the Nash equilibrium in behavioral strategies for extensive-form games by checking the equilibrium condition for each player.

For Bayesian games, a Bayesian Nash equilibrium is a strategy profile (one strategy for each type of each player) such that each type is maximizing (expected) payoff given others' strategies. For example, in the game in Figure 17.11, the profile $[(T; (L, R)]$ is a Bayesian Nash equilibrium. Indeed, in this game, the strategies *L* and *R*, respectively, are dominant for the two types of Player 2.

Unfortunately, there may be games for which there are no Nash equilibria in pure strategies. For example, in the matching pennies game (as in Figure 17.1), none of the four outcomes is a pure Nash equilibrium.

One may define, similarly, Nash equilibrium in mixed strategies. $\sigma^*$ is a Nash equilibrium if, for all $i$, $\sigma^*_i$ is the best response against $\sigma^*_{-i}$. John Nash has proved the theorem that a Nash equilibrium in mixed strategies always exists. Nash equilibrium in pure strategies exists under some conditions (the proof of these theorems uses a mathematical "fixed-point theorem").

It can be mathematically proved that for any mixed strategy $\sigma_i$ to be the best response for any player $i$, it must be the case that all the pure strategies in its support (on which player $i$ is mixing) are best responses as well. Thus, the player has to be indifferent in equilibrium (otherwise he or she would not mix). Using this technical result, in a $2 \times 2$ game, we can get two indifference equations, solving which we can find the Nash equilibrium in mixed strategies.

For games with a continuum of strategies, one can find the best response of a player using the first-order conditions. The Cournot (Nash) equilibrium for an oligopoly market is an example of this.

## Refinements

The Nash logic ignores the sequential and the informational structure in extensive-form games and, therefore, sometimes may not be justifiable. Consider the entry deterrence game as in Figure 17.15, in which there are two firms (players); one is a possible entrant (Player 1) to an industry in which there is an incumbent (Player 2). The potential entrant moves first and has two choices, to enter (*E*) and to stay out (*O*). If it does not enter, the game ends, while if it enters, the incumbent then has two options: to accommodate (*A*) and to fight (*F*).

The game can be analyzed in its normal form as described by the table in Figure 17.16.

The above game has two pure Nash equilibria, $(O, F)$ and $(E, A)$. Indeed, in the equilibrium profile $(O, F)$, the

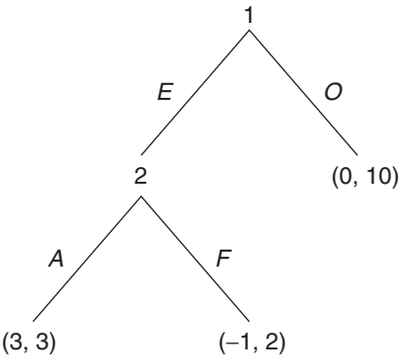

**Figure 17.15** An Entry Game

| | *A* | *F* |
|---|---|---|
| *E* | 3, 3 | –1, 2 |
| *O* | 0, 10 | 0, 10 |

**Figure 17.16** Normal Form of the Entry Game

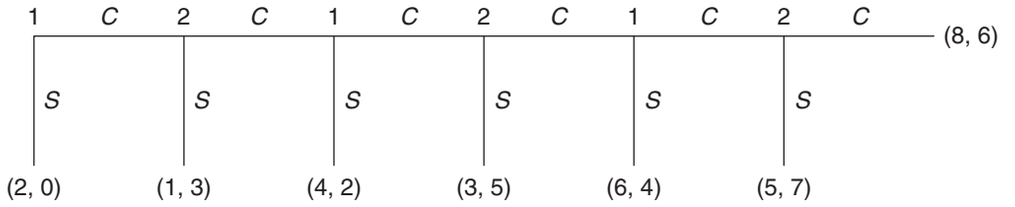

**Figure 17.17** A Centipede Game

entrant is playing the best response *O*, as it believes that the incumbent will choose *F*. However, this belief is based on an "incredible threat." *F* is not optimal in the unreached "subgame" (intuitively, the "game" below a nonterminal node) in which the incumbent has to make a choice (the incumbent did not make any choice here as the game ended when the entrant chose *O*).

A subgame perfect equilibrium, as defined by Selten (1965), is a strategy profile that induces a Nash equilibrium in every "subgame" of the original game, even if it is off the equilibrium path. Clearly, subgame perfect equilibrium refines the set of Nash equilibria. In the above example, (*E*, *A*) is a subgame perfect equilibrium, while (*O*, *F*) is not.

Any finite extensive-form game with perfect information (no information set in the tree) can be solved using "backward induction." This induction process finds the optimal actions of the players in the "last" subgame first and then, given these actions, works backwards to the beginning to find the subgame perfect equilibrium of the game.

Consider the two-player "centipede" game as in Figure 17.17, in which each player sequentially chooses either to continue (*C*) or to stop (*S*). Backward induction implies that the unique subgame perfect equilibrium is to play *S* for both players in every stage. Thus, the game should be stopped in the very first stage. This outcome has been the center of attention of a long debate (for a recent update on this, see Palacios-Huerta & Volij, 2009).

For games with imperfect information, just the notion of subgame perfection may not be enough to justify a solution. The concepts of perfect Bayesian equilibrium and sequential equilibrium were introduced to incorporate a set of beliefs over all information sets. These solutions consist of strategy profiles and beliefs such that each player is playing the best strategy given the beliefs (sequential rationality), and the beliefs are consistent, both on and off the equilibrium path (Kreps & Wilson, 1982).

## Correlation

In noncooperative games, how one can generate strictly higher (expected) payoffs than the Nash equilibrium payoffs is an important and interesting question. One answer lies in *correlation* among players.

The concept of correlation in games can best be associated with the notion of *mediation*, as often seen in many real-life political scenarios, where decision makers go to an independent and nonstrategic mediator and choose their actions based on the suggestions of the mediator. A (direct) correlation device can be identified as a mediator who can help the players to play a given game. The mediator (correlation device) randomly picks an outcome (a strategy profile) of the game, according to a probability distribution, and privately recommends to the players to play the respective part of the outcome.

A (direct) *correlated equilibrium* (Aumann, 1974, 1987) is a mediator whose recommendations the players find optimal to follow obediently—that is, following the mediator's recommendations constitutes a Nash equilibrium of the extended game. Correlation typically improves upon Nash equilibria of the original game; notable exceptions are zero-sum games and a class called "strategically zero-sum" games identified by Moulin and Vial (1978). The notion of correlation can be suitably extended to finite games with incomplete information (Forges, 1993, 2006).

For example, consider the game of chicken as in Figure 17.5 and the correlation device as in Figure 17.18.

The correlation device is nothing but a probability distribution, *P*, over the four pure outcomes of the game. The device first selects a "cell" and sends private messages, and the players play the game. In the extended game, each player has four strategies out of which "follow obediently" is a strategy. The device is called a correlated equilibrium if the obedient strategy is a Nash equilibrium in the extended game.

Formally, a device *P* is called a correlated equilibrium if, for all $i$, for all $s_i \in S_i$, $\Sigma_{s-i} P(s_{-i}, s_i)\, u_i(s_i, s_{-i}) \geq \Sigma_{s-i} P(s_{-i}, s_i)\, u_i(t_i, s_{-i})$, for all other $t_i \in S_i$ (that is, $s_i$ is the best response for player $i$ against the opponents' strategies of following their recommendations).

| | *A* | *P* |
|---|---|---|
| *A* | 0 | 1/3 |
| *P* | 1/3 | 1/3 |

**Figure 17.18** A Correlation Device for Chicken in Figure 17.5

Note that there may be multiplicity of equilibria; that is, obedience is just one Nash equilibrium, but other equilibria may exist.

One may also extend mediation to Bayesian games that are described by players, types, and strategy sets. A mediated mechanism, denoted by $\mu$, is simply a map from $T = \prod_i T_i$ where $T_1, \ldots, T_n$ are respectively the set of types for each player to the probability distributions over $S$, denoted by $\Delta(S)$. In this extended game, the players report types (or messages) to the mechanism, get recommendations (or messages) from the mechanism, and then play the original game.

A strategy of a player in the extended game, extended by the mechanism, is to report a type and then play a strategy in the game. A mechanism $\mu$ is called a "communication equilibrium" if honesty and obedience is a Nash equilibrium in the extended game.

Policy making can be associated with designing a mechanism that is incentive compatible (to satisfy the equilibrium condition above) and individually rational (implying that the payoffs from the mechanism are no worse than the outside option, normalized to zero, that is, $u_i(\mu \mid t_i) > 0$, for all $i$, for all $t_i \in T_i$).

## Repetition

The motivation for studying repeated games comes from the prisoner's dilemma game as discussed earlier (Figure 17.2).

The question is how to achieve the socially optimal outcome (Cooperate, Cooperate) as an equilibrium outcome. The answer lies in repetition of the same game again and again. If we interact repeatedly, we may introduce a social norm that incorporates nice behavior and punishment.

The research in repeated games has indeed achieved the desirable outcome as an equilibrium and found the structure of the strategies (behavior) to support this. Also, the different forms of behavior can be analyzed as finite machines (automata).

Let $G = < N, S_1, \ldots, S_n, U_1, \ldots, U_n >$ be a basic normal-form game that can be repeated, possibly, infinitely many times. This is unlike the bargaining game discussed earlier where the game may potentially go on for infinitely many periods. If $G$ has a unique Nash equilibrium, then the subgame perfect equilibrium of the finitely repeated version of this game is the Nash equilibrium of $G$. For example, for a finitely repeated prisoner's dilemma, the only equilibrium is (Defect, Defect) in every period.

In an infinitely repeated game, a strategy of player $i$ is a function that assigns a strategy in $S_i$ to every sequence of outcomes (history), and the preferences are defined over (infinite) sequences of outcomes (numbers).

The result (folk theorem) suggests that every feasible individually rational payoff can be supported as a Nash equilibrium outcome. The proof of the theorem uses the notion of a "trigger" strategy that cooperates until the opponent defects and then punishes forever.

One may analyze strategies for any infinitely repeated game using finite machines or automata (Rubinstein, 1986). The interpretation is that a player implements a strategy using a machine. For example, the trigger (also called the "grim") strategy can be described as a machine that has two states. In the first state of the machine, the player cooperates. The machine moves to the second "absorbing" state only when the opponent defects and defects forever.

## Cooperation

Cooperative game theory studies coalitions (groups) and how they share the benefits, assuming that the worth of a coalition can be shared among the members and that the utility is "transferable."

These models are known as games in coalitional form. The literature does not ask how the coalitions form or which coalition is more likely to form. We assume all possible coalitions are available. The ingredients of this model are coalitions and their values.

Let $N$ be the set of players as in noncooperative games; thus, the possible coalitions, including singletons (individual players), are $(2^N - 1)$. The value of any coalition $C$, given by the characteristic function $v$, is a map from $(2^N - 1)$ to the set of real numbers, with $v(C)$ denoting the value of coalition $C$. A game in coalitional form thus has a complete description given by $(N, v)$.

For example, the three-person majority game is described by $N = \{1, 2, 3\}$; $v(\{i\}) = 0$; $v(C) = 1$ for any other $C$ (implying that the majority wins).

Similarly, consider a situation with a seller (Player 1) who has an object to sell to two possible buyers (Players 2 and 3) with valuations 90 and 100, respectively. The game can be described by $v(\{i\}) = v(\{2, 3\}) = 0$; $v(\{1, 2\}) = 90$; $v(\{1, 3\}) = 100$; $v(\{1, 2, 3\}) = 100$.

To find a solution for such games, we look for allocations (also called imputations), $x$, that are vectors $(x_1, \ldots, x_n)$ such that $\sum_i x_i = v(N)$ and $x_i \geq v(\{i\})$. Thus, allocations divide the whole benefit such that the division is individually rational.

We say that an allocation $x$ dominates another allocation $y$ through coalition $C$ if $x_i > y_i$ for all $i \in C$ and $\sum_{i \in C} x_i \leq v(C)$ (members in the coalition $C$ are strictly better off). A coalition $C$ blocks $y$ if there exists $x$ such that $x$ dominates $y$ through $C$. For example, in the three-person majority game, (½, ½, 0) is blocked by the coalition (2, 3) with an allocation (0, 2/3, 1/3).

A desirable allocation is one that is acceptable to all coalitions, that is, not blocked by any coalition. Hence, our first "solution" for these games is indeed an allocation that is not blocked. There may be many such unblocked allocations for a game. Thus, the solution is the set of undominated allocations (the allocations that no coalition can block). This set is called the core.

It can be shown that an allocation $x \in$ core if and only if $\sum_i x_i = v(N)$ and $\sum_i x_i \geq v(C)$ for all $C$. Thus, from the

above characterizing inequalities, the core is a closed and convex set. The core for some games may be empty. For example, the core is empty for the three-person majority game. The core of the seller and buyers game is given by $\{t, 0, 100 - t \mid 90 \leq t \leq 100\}$.

Another solution concept for these games is the ($vN - M$) *stable set*, named after Von Neumann and Morgenstern. This concept is based on desirable properties of a set of allocations.

A set of allocations, $V$, is called *internally stable* if for any two allocations $x, y \in V$, $x$ does not dominate $y$; that is, no two allocations in the set dominate each other. A set of allocations, $V$, is called *externally stable* if for any allocation $z \notin V$, there exists an allocation $x \in V$ such that $x$ dominates $z$ (through some coalition $C$); that is, any allocation outside the set is dominated by something in the set.

A set $V$ of allocations is called the ($vN - M$) *stable set* if the set demonstrates the two "stability" properties above—that is, if it is both internally and externally stable.

It is easy to show that for the three-person majority game, {(½, ½, 0), (½, 0, ½), (0, ½, ½)} is a stable set. Stable sets, however, may not exist for some games, as proved in a 10-person example by Lucas (1969).

## Conclusion

In this chapter, we discussed all the models and some solutions in game theory. Needless to add, there are indeed many other concepts that we have not discussed. Readers are encouraged to consult the list of textbooks in game theory below for further references. Also, there are many specific advanced topics (such as evolution and learning) and applied topics (such as bargaining, auctions) where the models and solution concepts have been used and applied. For example, alternating-offers bargaining between two parties (players) can be modeled as a noncooperative game (Rubinstein, 1982) in an extensive form and solved using the notion of subgame perfection. Sealed-bid auctions among several bidders (players) with each player $i$ having a private valuation ($v_i$) of the object can be described as a Bayesian game and solved using Bayesian-Nash equilibrium. The list below also includes some advanced texts on these specialized topics.

*Author's Note:* The author gratefully acknowledges many extremely helpful comments and constructive suggestions received from an anonymous referee, Ralph Bailey, Chirantan Ganguly, and Sonali Sen Gupta and particularly the support provided by the editor and her team.

# Economics of Strategy

Quan Wen
*Vanderbilt University*

Economic and other rational decision making involves choosing one of the available actions for the environment that the decision maker is facing, given his or her objectives. Rational decision making and the subsequent choice of action depend on these two primary factors. Economics of strategy is concerned with how a rational decision maker's behavior in choosing an action can be explained by logical and strategic reasoning. A simple decision problem can be viewed as the simplest strategic problem, when there is only one agent for a given environment. Many economic problems, however, involve multiple decision makers. Our primary goal in economics of strategy is to provide a systematic analysis of how each decision maker behaves and how the strategic logics of the decision makers interact.

The primary tool researchers use in strategic analysis is game theory. Game theory provides us with a systematic and logical method for studying decision-making problems that involve multiple decision makers. Game theory has been applied in many areas of economic studies, such as industrial organization and strategic international trade. Application of game theory has different implications, depending on the specific economic environment. To facilitate our understanding of how rational and strategic decisions are made, we focus on firms' strategic behavior in settings with different market structures. We review necessary and commonly used concepts and modeling techniques of game theory and apply them in analyzing firms' strategic behavior.

## Competitive Market and Competitive Firms

We usually do not think that an individual firm behaves strategically in a competitive market; after all, a competitive firm simply chooses a feasible action to maximize its profit. However, a competitive firm's decision problem can be viewed as a strategic problem with only one agent. In this section, we review how a competitive firm behaves in reaction to market conditions and how this reaction can be considered a simple form of strategic behavior. Some of the basic arguments we discuss in this section will help us understand more complicated strategic interactions under different market structures.

Generally speaking, a competitive firm does not have market power to influence the market price. One interpretation of this simplified assumption is that there are many similar firms in the market, and each individual firm is too small to have any significant impact on the market outcome. When making a decision, such as how much to produce in the upcoming production period, a competitive firm, however, still needs to evaluate the economic environments it will face. The main factors that dictate how a competitive firm behaves are the prices of its inputs and outputs. For example, when the price of an input increases, firms decrease output. On the other hand, when the economy grows and the price of the output increases, each individual producer will increase its output as a response to a higher price. When a firm decides how much to produce, it will weigh the benefit and cost of its primary activity. To a competitive firm, the benefit of producing one more unit of its output is its marginal revenue, which is given by the market price, while its cost for producing one more unit of its output is its marginal cost. In order to achieve the maximal profit, a competitive firm will choose to produce in such a way that its marginal cost of production is equal to its marginal revenue—that is, the market price. If a firm's marginal cost is not equal to the market price of its output, the firm could produce at a different output level to achieve a

higher profit. For example, if the market price were higher than its current marginal cost, the firm would be able to increase its profit by increasing its production. Then, how much a firm will produce is determined by the market price and the firm's reaction to the market price of its products. Alternatively, if we consider that the feasible action of an individual firm is to choose its level of inputs, then the same principle applies here but for different types of activities; the marginal benefit of a production factor is the market value of the marginal product of the factor, and the marginal cost of the factor is simply its market price.

No matter whether we consider choosing outputs or choosing inputs as the primary decision for an individual firm, the firm needs to adjust its decision for the economic environment it will be in. This adjustment can be viewed as a very simple form of strategic behavior—namely, actions in response to the environment. In other words, the behavior of a competitive firm is a plan or a course of actions conditional to economic environments and conditions; it is a strategy of the firm in this degenerated strategic environment with only one agent. We will see how this line of argument applies in more general forms of strategic setting when multiple agents interact, such as in an oligopoly market.

Another type of decision problem a firm may encounter in a competitive market is to decide whether to enter the market. The crucial factor that dictates a firm's decision to enter a market is its projected profitability. If a firm's projected profit from entering a market is more than any cost associated with entering the market, the firm will enter the market, which will lower the profitability of the other firms in the market.

## Monopoly and Monopolistic Behavior

The other extreme market structure is monopoly, in which there is only one firm that accounts for all production and sales in the entire market. In this situation, the monopolistic firm has full market power to determine how much to produce and how much to charge for its product. This is another decision problem because there is only one economic agent, namely, the monopolistic firm. Like a competitive firm, the monopolistic firm will balance the cost and benefit of its production activities in order to achieve a higher profit. In an ordinary monopoly market, the firm can choose how much to produce and let the market demand determine the price of its product. Alternatively, the firm may choose how much to charge for its product, and the market demand will determine how much the firm will be able to sell. Both models will lead to the same result for an ordinary monopoly. Researchers commonly work with the model in which the firm chooses how much to produce.

To maximize its economic profit, the firm needs to produce in such a way that its marginal cost of production is equal to its marginal revenue. The marginal cost of production is determined by the production technology of the firm, as well as the market structures of its inputs. The firm's marginal cost generally varies with respect to how much the firm produces, whether it is a competitive firm or a monopolistic firm. However, unlike in a competitive market, the marginal revenue of the firm in a monopoly varies with its output level. Producing more output has two opposite effects on the firm's profit. On one hand, additional production will generate more revenue for the firm. On the other hand, additional production will lower the price of its product, and hence, it has a negative impact on revenue. Even though the firm's marginal revenue varies with its output level, the monopolist should choose the output level at which the marginal revenue and the marginal cost are the same; this is a general principle for profit maximization. For different market structures, marginal cost and marginal revenue are determined differently, although the general principle for profit maximization is the same.

For a nonordinary monopoly, price discrimination is an important subject to investigate. There are mainly two sets of characteristics, quantity and identity, on which the monopolist may be able to discriminate in setting up different prices. In first-degree price discrimination, the monopolist charges different per-unit prices for different consumers or different groups of consumers, but this per-unit price is independent of how much the consumer purchases. Under first-degree price discrimination, we can separate the firm's profit maximization problem into different problems for different consumers or different groups of consumers, and in each separated market, the problem is equivalent to an ordinary monopoly problem with different market demands. In second-degree price discrimination, the monopolist is unable to set different prices for different consumers or different groups of consumers but can set different prices for different quantities any consumer buys. Volume discounts represent a case of second-degree price discrimination. If the monopolist can set different prices for different consumers and for different quantities, the practice is referred as to third-degree price discrimination or perfect price discrimination. With any form of price discrimination, the firm will have a higher profit than its counterpart in an ordinary monopoly.

## Static Oligopoly and Strategic Interaction

Market structure that falls between perfect competition and monopoly is known as oligopoly, in which there are a number of firms that serve the market. Unlike in perfect competition, each individual firm in an oligopolistic market influences market outcome through its production activities, but unlike in monopoly, the market outcome also depends on what the other firms in the market do. The outcome of such an oligopolistic competition depends on how all the firms compete jointly in the

market. The problem faced by each individual firm is no longer a simple decision problem, but rather a situation of strategic interaction. Recall that in a decision problem, the decision maker chooses one of the feasible actions given the environment. Although what is optimal depends on the economic environment or economic condition, the economic environment does not respond to what feasible action the decision maker chooses. In a monopoly, for example, no matter how much the firm produces or how much it charges for its product, the economic environment, which is summarized by the demand function, does not change with respect to the firm's decision. In oligopoly, however, when an individual firm decides its output or price, it is necessary to take into account how the other firms will respond to its decision, because the other firms will choose their competitive strategies based on the environments they are facing, which, in turn, depend on what competing strategy the firm under consideration will take. Because of this strategic interaction among the firms, the tool we use to analyze oligopoly problems is game theory. Before we come back to this basic static oligopoly problem, we first review some of the basic notions and concepts of game theory.

## Strategic Form Game and Nash Equilibrium

Strategic form representation, also known as the normal form representation, of a game consists of three basic and necessary ingredients: who plays the game, what each individual in a game can do, and what each individual cares about. For simplicity, we often refer to an individual in a game as a player. The interpretation of a player is rather broad. For example, a player can be an individual firm in an oligopolistic market or a country in an international trade problem. The second component in the strategic form representation of a game is the feasible actions of the players. We often interpret a strategic form game as a static game, in which all players choose their actions or strategies simultaneously. When choosing a strategy, a player does not have any information on which strategies the other players play. In this type of game model, strategies are the same as actions; a player simply chooses an action. When we discuss how to model a dynamic game, we detail the differences between strategies and actions. Given one strategy from every player, an outcome of the game emerges. Players have preferences over the set of all possible outcomes of the game, and this is the last component of a strategic game.

Because a player cares about the outcome of the game and the outcome is determined jointly by the strategies of all the players, a player cannot guarantee that a particular outcome of the game will prevail; this player must take into account the strategies used by the others. If we fix the strategies adopted by the other players, then the problem faced by the player under consideration becomes a simple decision problem, and we can derive the best action for this player to choose. Of course, what is considered optimal for this player depends on the strategies of all the other players, and this dependence is described as the best response or reaction function. This best response is a crucial step to formulating the equilibrium concept in a strategic form game.

A player's best response is stable in the sense that the player does not have any incentive to play a strategy that is not one of the best responses to the strategies chosen by the other players. Nash equilibrium is one of the widely used solution concepts in studying strategic form games. A strategy profile—that is, a list of players' strategies, one from each player, is called a Nash equilibrium if any player's strategy in the profile is a best response to the other players' strategies in the profile. There is one way to interpret this equilibrium concept: When every player decides which strategy to play, the player first forms an expectation of what the other players will play, then chooses one of the best responses to the expectation of the other players' strategies. Of course, in order for a player's expectation of the other players' strategies to be consistent, this player's expectation should be correct in the equilibrium. These two criteria in a Nash equilibrium determine what outcomes should be considered equilibrium outcomes and which should not. If an outcome, or the strategy profile that induces the prescribed outcome, is not a Nash equilibrium outcome, then there must exist at least one player who has incentive to deviate to one of the other feasible strategies, given what the other players would play in the strategy profile. Such an outcome is not stable, and hence, it should not be considered an equilibrium outcome.

## The Cournot Model

In the rest of this section, we review two classic static oligopoly models—namely, Cournot competition and Bertrand competition. In the Cournot model, firms compete in their outputs, firms simultaneously choose how much to produce, and then the market price is determined by the inverse market demand function. With or without product differentiation, this Cournot model can be considered a standard game in strategic form, in which the firms are players, their feasible output levels are the sets of strategies, and the firms' objectives are to maximize profits.

As in a generic strategic form game, in order to identify possible equilibrium outcomes, we must figure out each firm's best response in this Cournot model. When an oligopolistic firm decides how much to produce, it needs to have an expectation of how much the other firms will produce. Given this belief or expectation, the problem faced by an individual firm becomes a relatively simple decision problem. There is a unique correspondence between the market price and the output of the firm under consideration. The more the firm produces, the lower the market price for its product. Each oligopolistic firm faces a dilemma similar to that of a monopolist, and in choosing

how much to produce, it must balance the costs and benefits. When solving this firm's profit maximization problem, we treat the outputs of the other firms as a given. Then, the optimal output level of the oligopolist necessarily depends on how much the others produce. The relation between the optimal output of a firm and the output levels of the other firms provides us with the best response of this firm under consideration. Repeating the same process for every firm, we can identify the oligopolist's best response to the outputs of the other firms. An outcome that satisfies all the best responses of all firms is a Nash equilibrium outcome in the Cournot model, which is also commonly known as Cournot equilibrium.

We characterize Cournot equilibrium by taking account of strategic interaction among the firms. Because every firm's strategy in the equilibrium is a best response to the other firms' strategies in the profile, every firm's strategy in Cournot equilibrium is rationalizable. A strategy is rationalizable if it is a best response to the other strategies that are also rationalizable, and are the best responses of some other rationalizable strategies. Generally speaking, rationalizable strategies include all equilibrium strategies.

Another idea to highlight the strategic interaction among the firms is the dynamic adjustment process to reach equilibrium. For any strategy profile, if it is not an equilibrium, some firms may want to revise their strategies in the profile. After this revision of strategy, some other firms may want to revise their strategies, or some of the firms that revised their strategies may want to revise again. This adjustment process may or may not converge. When it does, this progress will converge into a stable equilibrium. In a nonstable equilibrium, if one firm produces a slightly different amount of output than the one given in the strategy profile, this adjustment process may diverge or converge into a different strategy profile. These arguments help us understand how firms interact when competing in a Cournot competition.

## Collusion and Prisoners' Dilemma

Taking the basic setup of the Cournot model, we can examine collusive outcomes. In a departure from the concept of Nash equilibrium, in which every firm maximizes its own profile, collusion happens when the firms form a cartel and coordinate their production strategies to maximize their aggregate profits. To maximize firms' joint profits, each firm will set its marginal cost equal to the marginal revenue of all the firms, which is the rate of change of firms' joint profit with respect to the output of an individual firm. Because the marginal revenue of the cartel is less than the marginal revenue of an individual firm, every firm may increase its profit by producing more, if all the other firms produce their quotas in the cartel. In other words, a collusive outcome is not an equilibrium outcome in this static setting because every firm has an incentive to deviate from a cartel agreement to produce more than what is supposed to be produced in the cartel.

The static Cournot model closely resembles a classic strategic game known as the prisoners' dilemma. In a prisoners' dilemma, two suspects are interrogated separately and simultaneously by the police for the crime they committed. To gather sufficient evidence for a successful conviction, the police offer leniency to the suspect who provides information, if and only if the other suspect refuses to do so. Each suspect can take one of two possible actions or strategies, either to collude by not providing any information to the police or to defect to the police. Regardless of whether the other suspect chooses to collude or defect, a suspect will always receive a lighter sentence by defecting to the police. However, the outcome in which both suspects choose to defect is the worst outcome for the two suspects, compared with the other three outcomes. The two suspects are the players of this prisoner's dilemma. To illustrate this situation as a strategic form game, we use the payoff bimatrix in Table 18.1 to summarize players' payoffs in all the four possible outcomes.

In this payoff bimatrix, the first number in each outcome indicates Player 1's payoff should the corresponding outcome occur, and the second number indicates Player 2's payoff in the corresponding outcome. For example, if both players collude, then every player will receive a payoff of 3. If both players defect, then each will receive a payoff of 1. The goal of every player in the game is to achieve the highest payoff by choosing one of two actions, given the action played by the other player. The payoffs can be ranked in order of desirability from 0 (least desirable) to 4 (most desirable). Desirability reflects the severity of the sentence. A payoff of 0 corresponds to a more severe sentence than a payoff of 4. We can illustrate that in this prisoners' dilemma, only the outcome in which both players choose to defect is a Nash equilibrium. Suppose Player 2 chooses to defect; if Player 1 chooses to defect too, Player 1's payoff will be 1, which is higher than Player 1's payoff of 0 if Player 1 chooses to collude. Applying the same argument to Player 2's strategic

**Table 18.1** The Prisoner's Dilemma as a Strategic Form Game

| | *Player 2 colludes and does not provide information to police* | *Player 2 defects by providing information to police* |
|---|---|---|
| Player 1 colludes and does not provide information to police | 3, 3 | 0, 4 |
| Player 1 defects by providing information to police | 4, 0 | 1, 1 |

NOTE: First number refers to Player 1's payoff; second number refers to Player 2's payoff.

thinking implies that Player 2 should choose to defect when Player 1 defects. In the prisoners' dilemma, regardless of which strategy the other player chooses, it is always best to defect. More specifically, when Player 2 chooses to collude, Player 1 will receive a payoff of 4 by defecting, which is higher than his or her payoff of 3 by colluding. When Player 2 chooses to defect, Player 1 will receive a payoff of 1 by defecting as well, which is also higher than his or her payoff of 0 by colluding. In this case, defection is called a dominant strategy, and collusion is a dominated strategy. The best outcome for the two players is when they collude. However, collusion requires that both players choose dominated strategies.

In the Cournot model, between collusion and Cournot equilibrium outcomes, firms face a situation similar to the two suspects in a prisoners' dilemma game. Although firms have higher profits together, it is not an equilibrium outcome, because every firm has an incentive to produce more than the amount agreed to. We will discuss how this collusive outcome may arise as an equilibrium outcome when firms interact repeatedly over time.

### Bertrand Competition

The term *Bertrand competition* refers to the strategic situation when all the firms choose what prices they would like to charge for their products. When firms' products are homogenous, consumers will purchase from the firms that charge the lowest price. Bertrand competition is also a standard strategic form game. However, the strategic situation faced by each firm is different from that in the Cournot competition. Because only the firms that set the lowest price are able to make a sale, a firm's incentive in Bertrand competition is to cut the price of its product as long as it is still able to make profit. Applying this logic, every firm in the market will continue to slash its prices until there is no profit to make. When all the firms have a common constant marginal cost and no fixed cost, they will set the price at the constant marginal cost, which is also the constant average cost in this simple setting. If all firms set their prices at the average cost and one firm sets its price lower, this firm will make a loss. On the other hand, if a firm sets its price higher than the average cost, this firm will not make any positive sale, and hence, it has zero profit. Therefore, a firm does not have a profitable deviation when the other firms set their prices at the average cost of production. This equilibrium outcome in which all the firms choose the price at the average cost and every firm has zero profit is referred to as the *Bertrand equilibrium.*

## Dynamic Oligopoly Models and Backward Induction

In a dynamic environment, the strategic interactions among firms are more complicated than in a static environment. A dynamic strategic interaction generally concerns an environment that involves sequential decision making by the agents. In a dynamic model, it is necessary to be more specific about when an agent chooses an action, what actions this agent can choose, and more importantly, what this agent knows at the time a choice of action is made. Because of this new element in dynamic strategy interaction, we must make the distinctions between actions and strategies more explicit. We first review how to model a dynamic game, as well as some widely used equilibrium concepts. Then we discuss a number of different dynamic oligopoly models to illustrate how economic agents interact in those dynamic settings.

### Extensive Form Games

Researchers model dynamic strategic interactions using extensive form games. Extensive form games provide all the necessary elements, including the agents or the players of the game, the timing of each player's choice of action, which actions each player may choose, what each player knows when choosing an action, and what each player cares about. Unlike in a strategic form game, the information available to a player when choosing an action is new in a dynamic game. As in static strategic problems, a player will choose an action based on the information available. One common way to summarize information available to a player is to introduce the history of past events up to the point at which the player chooses an action. In a dynamic game, every player needs to make a plan about which action to take after each possible event. A complete plan of action for a player, including one available action after every relevant event, is the player's strategy. In other words, a strategy of a player in a dynamic game is a contingent plan of actions, a plan contingent on the histories available to the player. In a static game situation, there are no different stages of information, so the concept of strategies is the same as that of actions.

As in a static game, any list of strategies (or a strategy profile of one strategy by each player) will induce a complete path of plays, which can be considered as an outcome of the game. When choosing which strategy to play, a player evaluates strategies based on the outcomes that the strategies induce, given the strategies adopted by the other players.

Depending on how well a player knows what has happened, a dynamic game can have either perfect information or imperfect information. Perfect information refers to dynamic strategic situations in which every player knows exactly what has happened, including the actions taken by the players in the past. Many dynamic games in real life have perfect information, such as the game of chess, in which every player technically observes all the past steps. The formulation of extensive form games, however, does not exclude the possibility of some players choosing actions simultaneously, in which case the information structure is imperfect. Technically, we can collect the set of players, players' strategies, and their payoffs to form a

strategic form representation of a dynamic game. However, a strategic form representation of a dynamic game loses its dynamic information structure.

## Nash Equilibrium and Subgame Perfect Nash Equilibrium

We can represent any dynamic game with a strategic form game. Any Nash equilibrium in the strategic form representation of a dynamic game is also a Nash equilibrium in the dynamic game. Because strategic representation of a dynamic game loses its information on dynamic structure of the model, applying the concept of Nash equilibrium in a dynamic game has been criticized because Nash equilibrium may involve some unreasonable behaviors, referred to as noncredible threats. Noncredible threats are the actions that are not one of the best responses given the history and what players will play in the future. Noncredible threats can be part of a Nash equilibrium strategy profile when they occur after histories that are unreachable for the given strategy profile, and hence, they are irrelevant to players' payoffs. However, if those histories were reached, noncredible threats would not be carried out because they are not the best response given how the rest of the game will be played.

Applying the concept of Nash equilibrium in dynamic games oversimplifies the strategic reasoning. In a dynamic game, when any player chooses an action, this player should choose the best action available given the history and how the rest of the game ought to be played when the same reasoning is applied. In dynamic games with a finite horizon, this line of reasoning leads to the method known as backward induction. Backward induction analyzes the last stage of the game first. In games with perfect information, the problem in the last stage of the game is a simple decision problem; the active player simply chooses one of best available actions during the last stage of the game, given how the game has been played. Next, we analyze players' strategic rationale in the second-to-last stage of the game, given how the game has been played and how the game will be played in the last stage of the game.

The problem faced by the active player in the second-to-last stage of the game is a well-defined decision problem induced by what will happen in the last stage of the game after every action of the players in the second-to-last stage. Accordingly, the active player will choose the best action induced by what will happen during the last stage. After identifying what will happen in the last two stages of the game, we then analyze the third-to-last stage and so on, and eventually we will solve a subgame perfect Nash equilibrium of the model. Backward induction eliminates noncredible threats so that any strategy profile resulting from backward induction does not suffer the criticism we discussed for applying the concept of Nash equilibrium in a dynamic game. In a dynamic game of perfect information, strategy profiles resulting from backward induction form a special class of Nash equilibria known as subgame perfect Nash equilibria.

There may not be well-defined stages in a dynamic game with imperfect information, so we cannot directly apply the backward induction technique used for games with perfect information. Instead, researchers first identify all situations in which the rest of the game can be viewed as a dynamic game itself. These situations are called the subgames of the underlying dynamic game. In fact, each stage of a dynamic game with perfect information is a subgame. After identifying all the subgames, we first derive Nash equilibrium outcomes in every subgame that does not include any other subgame—the class of smallest subgames. We then analyze subgames that contain only these smallest subgames, and the Nash equilibria that induce a Nash equilibrium in each of the smallest subgames it contains. Repeating this process leads to a Nash equilibrium of the entire game that induces a Nash equilibrium in any subgame. Accordingly, such a Nash equilibrium is subgame perfect Nash equilibrium. The concept of the subgame perfect Nash equilibrium is a widely adopted refinement of Nash equilibrium in economic research because of its simplicity. Many other refinements of the Nash equilibrium concept have been introduced and studied. The References and Further Readings section provides some useful sources on the details of equilibrium refinements in extensive form games.

## Stackelberg Model

The Stackelberg model refers to situations in which firms in oligopoly markets compete in their output, but firms do not all make their decisions at the same time. Naturally, the underlying strategic situation is a dynamic game. For simplicity, we discuss the Stackelberg model with two firms. One firm, called the quantity leader, chooses and commits to how much to produce. The other firm, called the quantity follower, first observes the amount of output by the quantity leader and then decides how much it will produce. In this subsection, we focus on this simple Stackelberg model and illustrate how various concepts and ideas for dynamic games are applied.

The Stackelberg model is a two-stage dynamic game with perfect information. To the quantity leader, there is a unique history when it makes a decision on how much to produce. Because the quantity follower observes how much the quantity leader has chosen to produce, each output level chosen by the leader is a history to the follower when it makes its decision about how much to produce. This difference sets the Stackelberg model apart from the Cournot model.

To apply the backward induction technique to find the subgame perfect Nash equilibrium in this Stackelberg model, first consider the second stage of the model in which the quantity leader has already committed to its output level. The strategic problem faced by the quantity

follower simplifies to an ordinary monopoly problem with the residual demand, which is the difference between market demand and the amount of output committed to by the quantity leader. Applying exactly the same argument as in the Cournot oligopoly model, we can find the quantity follower's best response to the amount of output by the quantity leader. The follower's best response naturally varies with respect to the quantity leader's output level and can be considered as the Nash equilibrium outcome in the subgame induced by the output quantity committed by the quantity leader.

When the quantity leader decides how much output to produce during the first stage of this Stackelberg model, it should able to anticipate how the quantity follower will respond. Taking the best response of the quantity follower into account, the problem faced by the quantity leader reduces to a decision problem because the amount of output by the quantity follower is uniquely determined by how much the quantity leader produces, and hence, the profit of the quantity leader is also uniquely determined by its output level. Any solution to this induced profit optimization problem for the quantity leader's strategy is a subgame perfect Nash equilibrium of the Stackelberg model. The best response correspondence of the quantity follower is its equilibrium strategy because its best response specifies what the quantity follower should do in all possible subgames in the second stage of the model. The response of the quantity follower to the equilibrium strategy (quantity) of the quantity leader is what would happen in this subgame perfect Nash equilibrium, which is the equilibrium outcome. All other subgames in the second stage will be not reached, according to the equilibrium strategy of the quantity leader.

## Repeated Strategic Interaction

In many economic and other strategic problems, players often interact repeatedly over many time periods. Because the strategic situation during each time period is the same, a repeated game model provides a relatively simple framework to study players' long-term strategic behavior. People change their behavior when they consider the future as well as their immediate well-being. A well-known phenomenon in repeated interaction is the folk theorem; repeated interaction introduces many new equilibrium outcomes.

To illustrate how repeated interaction differs from its static counterpart, we revisit the Cournot model with two firms. Recall that the collusive outcome is not a Nash equilibrium in the static environment, even though both firms have higher profits than in the static Cournot-Nash equilibrium. Collusion cannot be sustained in equilibrium in the static Cournot model because every firm has an incentive to produce more. Nevertheless, when both firms value their future highly enough, collusion is possible when it is highly likely that the two firms will be involved in the same Cournot competition in the future. Collusion can be sustained in a repeated Cournot model by a class of simple strategies known as *grim trigger strategies*. A grim trigger strategy profile calls for each firm to collude at the beginning of the repeated game and to continue to collude as long as both firms have colluded in the past, and as soon as either or both firms deviate, both firms will choose their Cournot-Nash equilibrium strategies forever. Any deviation from collusion triggers the Cournot-Nash equilibrium in the future, which serves as a punishment to the deviating firm. First observe that if a cartel breaks down, it is in each firm's best interest to follow its Cournot-Nash equilibrium strategy. Now the question is what incentive each firm has to continue to collude if they have colluded in the past. Consider the following two possibilities: If a firm deviates away from the collusion outcome, its profit in the current period will be higher. However, such a deviation will trigger the static Cournot-Nash equilibrium forever. On the other hand, if it does not deviate, collusion will continue. Applying the same reasoning in every period, each firm is facing two sequences of profits when deciding whether to continue to collude: collusion forever or a higher profit in the current period followed by a lower profit from Cournot-Nash equilibrium forever. When it is highly likely that the two firms will be involved in the same situation again and again, and when every firm values the future highly enough, a firm will find it beneficial to forgo short-term gain in exchange for collusion in the future. Here we discuss only one particular subgame: perfect Nash equilibrium outcome in the infinitely repeated Cournot model. As matter of fact, all outcomes in which every firm has a profit may arise as an equilibrium outcome in the infinitely repeated Cournot model. This result is known as the folk theorem.

## Conclusion

In this chapter, we took competition among oligopoly firms as a background to discuss a number of key concepts and model ideas in analyzing strategic interactions. We first considered how a perfectly competitive firm, and then a monopolistic firm, behaves, to pave the road for oligopoly problems. The key message is that firms make decisions in response to any change in the economic environment. In the rest of this chapter, we focused on oligopoly markets and analyzed how firms compete in various markets. We started with the Cournot model, in which firms compete in their outputs and make decisions simultaneously. This problem was formalized as a strategic game, and we applied the concept of Nash equilibrium to this model. Borrowing the idea of individual incentives, we have argued the collusive outcome in the Cournot model is not an equilibrium. We also discussed the Bertrand model, in which firms choose their prices simultaneously. We then moved to dynamic strategic interactions. We reviewed the Stackelberg model as

an extensive form game and the concept of a subgame perfect Nash equilibrium. Economics of strategy applies game theory in economics and in business. Here we provided only a brief overview of firms' strategic behaviors. Because of its versatility, game theory has been applied in virtually all areas of economics research and studies.

# Transaction Cost Economics

Christopher Ross Bell
*University of North Carolina at Asheville*

Economics is the study of human interactions involving trade. In addition to the costs of production and distribution, every trade has associated with it the costs of the trade itself: of locating trading partners, of negotiating the terms of the trade and adapting those terms as economic conditions change, of monitoring and enforcing the terms of the trade, and so forth. These costs are called *transaction costs,* and traders' attempts to limit them explain why many economic, political, and social institutions have evolved the way they have.

Transaction cost economists seek to understand how transaction costs influence the design and evolution of the institutions used to coordinate economic relationships. Friedrich Hayek (1945) has written of the "marvel" of the spontaneous coordination of the market in a world of flux and change: It aggregates and makes efficient use of information no one person could ever know, it is flexible and capable of responding quickly to changing economic conditions, and it avoids undue concentrations of economic and political power (p. 527). But there is an alternative to market coordination: *hierarchical coordination,* defined as coordination through deliberate choices made by managers or central planners. All modern economic institutions embody varying degrees of these alternative coordination mechanisms.

Though most modern economies rely heavily on market coordination, it is easy to find hierarchical coordination in even the most market-oriented economies: Significant portions of our private sectors are composed of vertically integrated firms, firms in which internal flows of physical materials are coordinated by orders from superiors rather than by independent responses to price signals. Further, families, schools, religious groups, social organizations, nonprofit organizations, and governments all engage in economic activities, and all are coordinated through nonmarket means.

Examples of questions undergraduates can (and have) address using the tools of transaction cost economics include the following: Have the rules guiding trades on eBay changed over time, and if so, have they changed in a manner consistent with the principles of transaction cost economics? Are the rules guiding trades on massively multiplayer online role-playing games consistent with the principles of transaction cost economics? Are there patterns to which services particular universities own and operate themselves and which they contract out? (Who operates your bookstore? Your dining hall? Your library?) Are there patterns to which services hotels provide themselves and which they contract out? Restaurants? Minor-league baseball teams? When services are contracted out, how are the contracts structured? Why do tattoo artists frequently rent space in shops owned by others but always own their own tattoo machines? Are the relationships and patterns of asset ownership found between tattoo artists and the shops from which they rent space similar to those between hairdressers and beauty shops? Mechanics and garages? Doctors and hospitals? Are the similarities and differences consistent with the predictions made by transaction cost theory?

Transaction cost economics is particularly well suited for study by undergraduates. First, it is one of the few economic subdisciplines whose key concepts are better expressed in words than equations. This means that students can read almost its entire corpus—from its classic works to its cutting edge—without the need for mathematics any more advanced than that required for their introductory economics course. If they read the key works in

chronological order, they can watch the economic frontier expand before their eyes, enabling them to understand the often halting process of economic inquiry in a manner unattainable through reading textbooks and later works written with the benefit of hindsight and reflection. Second, many students find transaction cost economics interesting because its study crosses disciplinary boundaries, relaxes assumptions, and explores subjects frequently left unaddressed in other economics courses. Thus, it challenges their views of what economics is, what it is not, and how it relates to other disciplines. Third, the tools and techniques of transaction cost economics are easily applied to real-world situations about which students have firsthand knowledge and interest. This makes it relatively straightforward for them to conduct research projects testing its fundamental propositions.

This chapter provides an introduction to transaction cost economics, with a focus on the classic works in the field. The first section lays the theoretical foundation, describing its origins, defining its key concepts, and deriving its central testable hypothesis. After discussing and illustrating its archetypical application, the make-or-buy decision, this section concludes with a discussion of the broad array of institutional arrangements that lie between spot markets and vertical integration. The second section applies the theory laid out in the first section and examines the empirical evidence supporting it. The focus of the second section is on early applications that highlight the key concepts and principles laid out in the first section and on early tests of the theory that exemplify approaches from which students writing term papers may draw inspiration. Much of the interest in transaction cost economics is policy driven. The third section examines these policy implications. The fourth section summarizes the key points made in the rest of the chapter and suggests directions for future research. This chapter closes with suggestions for further reading.

## Transaction Cost Theory

### Origins

Ronald Coase's (1937) "The Nature of the Firm" is the key work in transaction cost economics. It is a remarkable treatise for many reasons, not the least of which is that it was conceived when its author was just 21 years of age (Coase, 1988a). Coase became interested in the questions of vertical and lateral integration while studying for his bachelor of commerce degree at the London School of Economics. Why, he wondered, if the invisible hand of the price system was as wonderful as his professors made it out to be, did firms intentionally replace the spontaneous coordination of the market with the deliberate coordination of the manager? Coase spent the academic year 1931–1932 exploring this intriguing question in a series of visits to U.S. businesses and industrial plants—the happy coincidence of the necessity for an additional year of study after completing the courses required for his degree with his receipt of a scholarship that allowed for travel abroad (Coase, 1988a).

Coase (1988a) first laid out his answer to his question in a letter written in October 1932, describing a lecture he had just given at the Dundee School of Economics and Commerce (p. 4). Following reflection on what he had observed and discussed with plant managers, Coase noted that there were costs to using the price system, costs we now know as transaction costs. Coase reasoned that firms emerge when the transaction costs associated with coordinating particular exchanges using markets exceeded those of coordinating the same exchanges using managers. In the absence of transaction costs, Coase (1988c) wrote, "The firm has no purpose" (p. 34).

Coase published his explanation in 1937. As he was to write in 1972, for close to 35 years, "The Nature of the Firm" was "much cited and little used" (Coase, 1988b, p. 23). One explanation may be that Coase's observation that vertically integrated firms exist because the advantages of replacing the costs of market exchange with those of command and control is fundamentally tautological: Any and every substitution of one means for organizing economic activity for another can be explained as the outcome of a desire to reduce transaction costs. Because Coase's theory was not fleshed out enough to predict in advance which exchanges would be the most likely candidates for vertical integration, it explained both everything and nothing (Fischer, 1977, p. 322; Williamson, 1979, p. 233).

Oliver Williamson was one of the first to recognize that Coase's fundamental insight represented the beginning of a research agenda, not the end. Beginning in the early 1970s, Williamson, his students, and others who have been inspired by his and Coase's work have produced a flourishing body of research that has grown into a rich and powerful set of intellectual tools, tools amenable to those hallmarks of science, prediction, and test. Especially important have been the works that formed the basis of Williamson's *Markets and Hierarchies: Analysis and Antitrust Implications* (1975), *The Economic Institutions of Capitalism* (1985), and *The Mechanisms of Governance* (1996).

### Key Concepts

One of the more frustrating aspects of taking up a new subject is learning its jargon. Six concepts central to transaction cost economics are *transaction, transaction cost, governance structure, bounded rationality, opportunism,* and *asset specificity.*

*Transaction.* Trade requires transactions, that is, transfers of goods or services across "technologically separable interface[s]" (Williamson, 1981, p. 552). Note that while trade between businesses, individuals and businesses, governments and businesses, and so forth necessarily results in transactions, transfers of goods or services across

technologically separable interfaces are almost certainly at least as common within businesses, families, social organizations, and governments. Thus, just as the transfer of a six-pack of beer from your local convenience store's shelves to your refrigerator represents a transaction, so does the transfer of aluminum cans from a brewer's aluminum-can-manufacturing operations to its brewing operations.

*Transaction cost.* Transactions have costs associated with them: locating trading partners, negotiating the terms of trade, writing explicit contracts prior to the commencement of trade, monitoring compliance with the contracts and enforcing them as trade progresses, adapting the terms of trade to address changing circumstances, and observing, quantifying, and processing the information required to do all of the above. It is noteworthy that these transaction costs differ from those economists ordinarily emphasize—production costs—in that it is assumed "the former can be varied by a change in the mode of resource allocation, while the latter depend only on technology and tastes" (Arrow, 1969, p. 60).

*Governance structure.* What Arrow referred to as "mode[s] of resource allocation" (1969, p. 60) are now called governance structures. The term was coined by Williamson in his 1979 paper, "Transaction-Cost Economics: The Governance of Contractual Relations." Governance structures are examples of *institutions,* defined as sets of laws, rules, customs, and norms that guide human behavior (North, 1994). Thomas Palay (1984) provided an unusually clear definition of the term, writing that "governance structure" is "a shorthand expression for the institutional framework in which contracts are initiated, negotiated, monitored, adapted, enforced, and terminated" (p. 265). Examples of governance structures include spot markets (your purchase of gasoline at a convenience store while driving to spring break) and vertical integration (an oil company's production of the crude oil it will later refine into gasoline). Although the reasons different governance structures generate different transaction costs will be dealt with in greater detail later, in defining the rules of the game (customers are required to pay in advance for the gas they pump, and convenience stores are required to maintain accurate meters on their gas pumps), well-designed governance structures create incentives for transactors to cooperate with each other.

*Bounded rationality.* As a step toward understanding why the choice of governance structure matters, one must abandon the fiction of the all-knowing economic man. Transaction cost economists assume that economic decision makers are subject to bounded rationality; that is, while their actions are "intendedly rational," cognitive limitations render them "only limitedly so" (Simon, 1957, p. xxiv).

The cognitive limitations that give rise to bounded rationality come in many forms. First and foremost, we live in an incredibly complex and ever-changing world. Even if we could fully comprehend all those parts of the world critical to the economic decisions we face, what we know today may no longer be relevant when we wake up in a new world tomorrow. Worse, what we will need to know tomorrow may well be unknowable today. Governance structures differ both in regard to the amount and depth of the information individuals need and in their ability to adapt to changing information. Remember what Hayek (1945) found marvelous about the governance structure we call the market: its ability to aggregate and make efficient use of information no one person could ever know, including its ability to aggregate and make efficient use of new information.

Second, even if we could know everything there is to know about those parts of the world most important to us—past, present, and future—we would still be hampered by our ability to make sense of what we know. Herbert Simon (1972) emphasized the difficulties faced by people who must process large amounts of information. Consider, Simon (1972) suggested, writing out a decision tree for a chess game and then using this tree to decide which moves to take. Although doing so would reveal the optimal move in any given situation, no one, not even a grand master, could construct and make efficacious use of such a tree. Instead, chess players husband their limited cognitive resources by relying on relatively simple strategies that they know from experience will guide them to favorable—though not necessarily optimal—outcomes (pp. 165–171). Similarly, governance structures differ with regard to their demands on economic actors' ability to process information; assigning activities to alternative governance structures in a transaction-cost-economizing way requires strict attention to the differences in cognitive demands alternative governance structures make.

John McManus (1975), Douglass North (1981), and Yoram Barzel (1982) emphasize yet another cognitive limitation with implications for institutional design: the difficulty, and at times impossibility, of quantifying the information needed to make, monitor, and enforce agreements. Barzel and Roy Kenney and Benjamin Klein (1983) offer the diamond sights arranged by the DeBeers group, in which dealers are offered mixed lots of presorted diamonds on a take it or leave it basis, as an example of an economic institution that has evolved to reduce the costs incurred when cognitively limited human beings must quantify information.

*Opportunism.* Opportunism is self-interest taken to its limit. To be opportunistic is to act in ways that combine "self-interest seeking with guile" (Williamson, 1975, p. 26). As Williamson (1985) wrote, "This includes but is scarcely limited to more blatant forms, such as lying, stealing, and cheating. Opportunism more often involves subtle forms of deceit." These subtle forms include, "the incomplete or distorted disclosure of information, especially calculated efforts to mislead, distort, disguise, obfuscate, or otherwise confuse" (p. 47). Recognition of our proclivity for opportunism deepens our understanding as to why the choice

of governance structure matters. Just as the assignment of activities to alternative governance structures requires strict attention to the differences in cognitive demands alternative structures make, so too does the assignment require strict attention to the abilities of alternative governance structures to discourage opportunism.

*Asset specificity.* Some transactions require investments in durable (i.e., long-lived) assets that have little or no value except in support of the transaction for which the investment has been made. For example, auto racks—the railcars railroads use to transport finished automobiles—are useful only for transporting automobiles and are built in custom configurations to carry specific models produced by specific manufacturers (Palay, 1984, p. 269). Williamson (1979) used the term *idiosyncratic transaction* to refer to transactions supported by transaction-specific assets; a number of synonyms are used to describe the investments themselves, including *idiosyncratic investments* (and assets) and *transaction-specific investments* (and assets).

There are many sources of asset specificity. Investments in auto racks exemplify the term *physical asset specificity:* They represent an investment in physical capital in a custom configuration with little value in any but the transaction for which they are designed. Investments in transaction-specific human capital (e.g., the value of the time a mechanical engineer spends mastering the technical details of products unique to his or her employer and of value to no one else) represent the term *human asset specificity.* Other sources include *site specificity* (e.g., an investment in physical capital located at a specific site that is costly to relocate and has little value except when located in close proximity to the transaction it supports), *dedicated asset specificity* (e.g., an investment in physical capital that increases capacity that is not needed except in support of the transaction it was made to support), and *brand-name capital specificity* (e.g., an investment developing, promoting, and maintaining the goodwill associated with a specific branded good or service).

Two important points about transaction-specific investments cannot be overemphasized. First, the investments of interest are indeed transaction specific. Consider the investment in time and money a student makes learning to be a mechanical engineer. This investment is specific in the sense that it trains the student to be a mechanical engineer, but it is not transaction specific because there are many alternative transactions requiring general mechanical engineering skills. Second, transaction-specific investments are not made for the sake of making transaction-specific investments but because they stimulate final sales or reduce production costs (Williamson, 1981, p. 558). Thus, it may make sense to make transaction-specific investments in dies designed to stamp uniquely appealing auto bodies because doing so stimulates sales or to make transaction-specific investments in custom auto racks because doing so reduces the cost of transporting automobiles from the manufacturer to the dealer, but it would not make sense to do so in the absence of benefits like these.

## A Testable Hypothesis

The central testable hypothesis of transaction cost economics has come to be known as the *discriminating alignment hypothesis.* It rests on three propositions:

*Proposition 1: The transaction costs associated with particular transactions depend on the governance structures within which the transactions take place.* This is a restatement of Arrow's (1969) observation that transaction costs "can be varied by a change in the mode of resource allocation" (p. 60). The reasons for believing this proposition will be discussed in greater detail later, but remember that governance structures can be viewed as defining the rules of the game, and as James Buchanan (1975) had so often argued, changing the rules of the game can change outcomes—including the transaction costs associated with the play of the game.

*Proposition 2: Transactions tend to be matched to alternative governance structures in ways that reduce the sum of production and transaction costs.* The matching may be due to conscious choice or it may be the outcome of evolutionary processes (e.g., survival in a competitive world). This proposition is a restatement of Coase's (1937) seminal insight that vertically integrated firms exist because of the advantages of replacing the costs of market exchange with those of managerial coordination.

As noted earlier, however, Proposition 2 is, by itself, tautological: Any and every substitution of one governance structure for another can be explained as the outcome of a desire to reduce transaction costs. Williamson in "The Vertical Integration of Production: Market Failure Considerations" (1971) and "Transaction-Cost Economics: The Governance of Contractual Relations" (1979), and Benjamin Klein, Robert Crawford, and Armen Alchian in "Vertical Integration, Appropriable Rents, and the Competitive Contracting Process" (1978) broke the tautological nature of Coase's argument with proposition three:

*Proposition 3: Alternative governance structures differ in their abilities to economize on particular types of transaction costs; likewise, exchanges differ in their proclivity to generate particular types of transaction costs.* This proposition implies that researchers should, after identifying the appropriate characteristics of exchanges and of governance structures, be able to predict ex ante which types of exchanges will be matched to which types of governance structures. The ability to do so allows Coase's proposition to be tested.

## The Archetypical Application: The Make-or-Buy Decision

The classic application of transaction cost economics is to the make-or-buy decision: Should a firm make an input itself, or should it buy it from an outside vendor? The discriminating alignment hypothesis suggests a three-step

approach. First, assess the production and transaction-cost-reducing advantages and disadvantages of the competing governance structures. Second, identify the critical dimensions with respect to which transactions differ from each other in their proclivity to generate particular types of costs. Third, choose the governance structure whose cost-reducing advantages and disadvantages are the best match to the types of transaction costs the transaction in question is likely to generate.

Consider as Williamson did (1979, p. 245) the potential advantages to a firm of buying the input from an outside vendor. Looking first at the transaction costs, if the market for the input is competitive, the interaction of demand and supply will determine the terms of trade, present and future. This reduces the transaction costs associated with negotiating the initial terms and adapting them to changing economic conditions. The existence of alternative buyers and sellers, should either party try to take advantage of the other, encourages both to do what they have agreed to do. This reduces the transaction costs associated with enforcing the terms of trade. Finally, larger firms are more difficult to manage than smaller firms because of the difficulties bureaucracies have preserving the high-powered incentives provided by markets (Williamson, 1985, chap. 6). All else equal, by choosing to buy rather than to make, the firm will be a little smaller and easier to manage.

There are two reasons buying the input from an outside vendor may lead to lower production costs. First, if by meeting the needs of multiple customers, an outside vendor can achieve greater economies of scale, the vendor's production costs will fall, a cost savings that in a competitive market will be passed on to the vendor's customers. Second, if demand fluctuates over time, by combining production for customers whose demand for the input is less than perfectly correlated, the vendor can reduce the variability in his or her production runs in the same way an investor holding a diverse portfolio can reduce the variability in his or her returns. This too lowers production costs.

Given the many advantages of buying from outside vendors, why would a firm ever want to make the input itself? Like markets, hierarchies have their own distinctive strengths and weaknesses. With vertical integration, both sides to the transaction become part of a common team. This encourages the pursuit of a single goal—the success of the team—rather than the opportunistic pursuit of the separate goals of the parties on either side of the transaction. Further, when conflict arises, higher-level managers have access to financial, market, and technical information that can help settle disputes in ways they do not when negotiating with independent suppliers or customers. Finally, if a higher-level manager's access to lower-level information is not by itself sufficient to settle a dispute, the higher-level manager can simply declare the terms on which the dispute will be resolved. Such management by fiat is in general a more effective and less costly means of conflict resolution than third-party arbitration or litigation.

By reducing the incentives for opportunistic behavior and by increasing the options for dispute resolution, vertical integration can be especially attractive for transactions that require frequent adaptations to changing economic conditions and in which competition from rival traders cannot be relied on to discourage opportunistic behavior. Rather than write an initial contract spelling out the terms of trade for every future contingency (the better to avoid opportunistic renegotiation of the terms of trade as the future becomes the present), the vertically integrated firm can replace extensive contingent contracting and its demands on the transactors' limited cognitive powers with adaptive, sequential decision making.

Against these strengths, the weaknesses of vertical integration must be weighed. First, by vertically integrating, the firm gives up the potential production cost savings available to an input supplier meeting the needs of multiple customers. Second, as already discussed, vertically integrated firms are larger firms, and all else equal, larger firms are more difficult (read more expensive) to manage than smaller firms.

Thus, in answering the question, should we make or should we buy? the firm must weigh the distinctive strengths and weakness of vertical integration against the distinctive strengths and weakness of market procurement. Ordinarily, we would expect the weight of the comparisons to favor market procurement (Williamson, 1979). Note, however, that the advantages of market procurement hinge on the related assumptions that the market for the input is competitive and that the outside vendor can realize cost savings by meeting the combined needs of multiple customers. To the extent that these conditions are not met, the advantages of buying over making decrease, the disadvantages increase, and alternatives to market contracting begin to look more attractive. An important reason these conditions may not be met is that the transaction in question is supported by transaction-specific investments.

It is time to turn to the second step of the discriminating alignment hypothesis: What are the critical dimensions with respect to which transactions differ from each other? Williamson (1979) identified three transaction characteristics that in combination make vertical integration more likely: the frequency with which a transaction recurs, the degree of uncertainty associated with the transaction, and the specificity of the assets supporting the transaction.

Frequency matters for several reasons, one of which is that greater frequency implies that the extra costs associated with creating more complex governance structures can be spread over a greater number of transactions. This reduces the marginal cost of bringing the transaction under the direct control of the firm's managers, which, when combined with uncertainty and asset specificity, makes vertical integration more likely.

Uncertainty is important because it makes contracting over markets more complex and increases the likelihood that both sides of a transaction will find it in their interest to renegotiate the transaction's terms as economic conditions change. As an example of both uncertainty and the incentives firms have to adapt their contracts as conditions change, consider the relationship between a commercial

aircraft manufacturer designing a new plane and the vendor from which it buys engines. An airliner's engines are among its most important components. Many aspects of the design and performance of the new design will depend on the specific characteristics of the engines used, engines that are designed in tandem with the new plane so that both can take advantage of the most recent technological advances. Because the technology used is so new, however, the actual characteristics of the engines—including the cost to produce them—may not be known with certainty until the engine is in production. The fate of both the aircraft manufacturer and its engine vendor can be tied to their willingness to renegotiate the terms of their relationship as technological and market conditions unfold. This example is based on the experiences of the Boeing Company and the Lockheed Aircraft Manufacturing Company and the difficulties they experienced bringing the Boeing 747 and the Lockheed L-1011 to market; Lockheed's struggles brought it to the brink of bankruptcy. Boeing is today experiencing similar troubles bringing their 787 Dreamliner to market, due in part to the uncertainties associated with building the first large commercial airliner whose wings and fuselage are constructed out of fibers held together with epoxies rather than aluminum held together with fasteners.

It is worth noting that the importance of uncertainty in the make-or-buy decision is directly related to bounded rationality: If not for their cognitive limitations, traders should, at least in theory, be able to write contracts specifying the terms of trade under every possible future state of the world. Given their cognitive limits, however, both the expense and the ultimate impossibility of conceiving and enumerating all possible future states of the world prevent them from doing this. One alternative is to write contracts that are intentionally incomplete, then adapt them to the conditions that emerge as the future becomes the present. However, in the presence of the third transaction characteristic that makes vertical integration more likely—asset specificity—incomplete contracting opens the door to opportunistic behavior.

Asset specificity can lead to contracting problems because investments in transaction-specific assets lock the parties to transactions into bilateral (i.e., one-to-one) relationships in which each party is dependent on the other and competitive forces cannot be depended on to quickly, easily, and impartially determine the terms of trade. Because of this dependency and lack of competition, an environment ripe for opportunistic gamesmanship is created each time the terms of trade are renegotiated: If the first party owns the transaction-specific asset, the second party can threaten to withdraw from the relationship if the first refuses to renegotiate the terms in the second's favor. The gamesmanship and the transacting problems it can lead to have become known as *the hold-up problem.*

Klein et al. (1978) were the first to describe the hold-up problem in detail, introducing the concept of the *appropriable quasi rent* to do so. An appropriable quasi rent is the difference between the net revenue ownership of an asset generates for its owner when deployed in support of its current transaction at the current terms of trade and the net revenue it generates when deployed in support of its next best alternative transaction. In the absence of asset specificity, the appropriable quasi rent is zero: If the first party refuses to renegotiate and the second party withdraws from the relationship, the first can redeploy his or her assets with a third party at the original terms of trade and no loss in net revenue. At the other extreme, if the asset owned by the first party is uniquely suited to the transaction with the second party, there will be no third party to which the first can turn, and the entire difference between the net revenue at the current terms of trade and the salvage value of the asset is potentially in play.

Note that even in cases in which markets are competitive before investments in transaction-specific assets are made, after the investment, the parties are locked into the noncompetitive bilateral relationship that can lead to the hold-up problem. This shift from a competitive to a noncompetitive situation after the specific investments are made is called *the fundamental transformation.* When answering the make-or-buy question, firms must consider the possibility that the fundamental transformation will occur, and if so, whether they can devise a nonmarket governance structure that will encourage cooperative behavior without placing unrealistic demands on their limited cognitive capacities and forcing them to give up the production cost savings associated with market provision.

Two final points before moving on to an illustration: First, transaction cost economics is an explicitly comparative institutional endeavor. Williamson (1975, p. 130) reminded us that all institutions have associated with them characteristic strengths and weaknesses. Finding that market procurement in a particular situation has hazards associated with it is not the same as finding that vertical integration is necessarily the superior alternative. The challenge for businesses (and the economists studying their decisions) is to match troublesome transactions to imperfect institutions in a discriminating way.

Second, the matching of transactions characterized by frequency, uncertainty, and asset specificity to more complex governance structures—up to and including vertical integration—rests on a crucial assumption. This assumption was first clearly and unambiguously stated by Klein et al. (1978), who wrote,

> The crucial assumption underlying the analysis of this paper is that, as assets become more specific and more appropriable quasi-rents are created (and therefore the possible gains from opportunistic behavior increases), the costs of contracting will generally increase more than the costs of vertical integration. (p. 298)

Combined with Williamson's (1979) insight that asset specificity alone is not sufficient to tilt the scales away from market contracting and that frequency and uncertainty are

required to create the conditions in which asset specificity matters, it follows that the greater the degree to which frequency, uncertainty, and asset specificity are combined, the more likely it is that the answer to the question, should we make or should we buy? will be to make.

## An Illustration: Adam Smith's Pin Factory

The prevalence of opportunism combined with bounded rationality creates interesting problems for our political, economic, and social institutions to overcome. Consider, for example, the trading hazards faced by people working together to produce a simple product. In his *Wealth of Nations,* Adam Smith (1776/1974) described the manufacture of pins circa 1776:

> One man draws out the wire, another straights it, a third cuts it, a fourth points it, a fifth grinds it at the top for receiving the head; to make the head requires three distinct operations; to put it on is a peculiar business, to whiten the pins is another; it is even a trade by itself to put them into the paper; and the important business of making a pin is, in this manner, divided into about eighteen distinct operations. (p. 110)

Imagine the problems faced by any two of Smith's pin makers if the manufacture of pins is organized along entrepreneurial lines, that is, if the governance structure used to coordinate flows of semifinished pins rests on repeated market exchanges between independent entrepreneurs at each of the 18 separable stages in a pin's manufacture. Because the pin makers are only boundedly rational, they will have difficulty foreseeing and then writing a contract covering all the possible contingencies over which disagreements could occur in the future. Because each has reason to suspect the other may on occasion be opportunistic, each will be concerned that his or her trading partner may on occasion try to take advantage of him or her. This means that neither can place complete faith in a contract that says, "I will always negotiate in good faith when unforeseen contingencies arise and always provide accurate and timely information." Further, their physical proximity locks them into a bilateral trading situation; this reduces the role competitive forces can play in guaranteeing harmonious exchange. So they may look for alternatives to market organization, alternatives that realign the incentives they face to act at cross-purposes. In particular, they may choose to form a vertically integrated firm.

Note something important: By choosing a different governance structure, the formerly independent entrepreneurs have altered their incentives to cooperate with each other. That is, through careful manipulation of their trading environment, they have sought to make mutually desired outcomes (harmonious adaptation to changing circumstances) more likely. Doing so may well entail some costs: bias in information flows, additional information-processing costs, bureaucratic inertia, and so forth, but in an imperfect world, some transaction costs are unavoidable; the trick is to find that governance structure that economizes the transaction costs associated with a particular exchange. In Smith's pin factory, this has been accomplished by (in Arrow's, 1969, words), replacing "the costs of buying and selling on the market by the costs of intrafirm transfers" (p. 48).

## Beyond the Make-or-Buy Decision: Governance as a Continuum

Although the make-or-buy decision may be both the original and the archetypical application of transaction cost economics, a moment's reflection on the incredible diversity of trading arrangements in our economy leads to the conclusion that most of the action is neither in the sorts of spot markets that dominate principles of economics texts nor in vertical integration. From the beginning of the revival of interest in Coase's work, transaction cost economists have devoted much of their attention to governance structures that lie between spot markets and vertical integration. Williamson (1979) identified four general types of governance structures, ranging from market governance (or classical contracting) at one end of a rough continuum to unified governance (or vertical integration) at the other. In between are trilateral governance (or neoclassical contracting) and bilateral governance (or relational contracting).

In *trilateral governance,* moderate to highly specific investments may be made—creating an incentive for the parties to work together because punishing opportunism by leaving a relationship is costly—but the transactions are so infrequent that the costs of creating a specialized governance structure exceed the benefits. In such cases, the parties to a transaction may rely on a third party to serve as an arbitrator to encourage cooperative behavior and settle disputes. Most construction projects, for example, are managed by a general contractor who hires, coordinates the actions, and settles disputes between the various subcontractors and between the client and the subcontractors.

*Bilateral governance* is arguably the most interesting case. It occurs in situations that combine frequency with moderate amounts of uncertainty and asset specificity. It also occurs in cases that combine significant amounts of frequency, uncertainty, and asset specificity with significant production cost savings realized when the demands of multiple buyers are aggregated. In such situations, highly idiosyncratic long-term contractual, social, and cultural relationships may be crafted to ensure cooperative behavior. For example, bilateral governance structures often include contractual provisions—like the requirements that buyers pay for a minimum quantity of a good, service, or input even if they choose not to accept delivery of the entire minimum order (take-or-pay requirements)—that are hard to square with traditional economic models but make sense when viewed as means to align incentives and

promote cooperative behavior in long-term relationships that might otherwise be problematic.

## Applications and Evidence

A considerable body of evidence exists in support of transaction cost economics' central testable hypothesis: As transaction frequency, uncertainty, and, especially, asset specificity increase (the independent variables), the governance structures used to support transactions become increasingly complex, moving out the governance continuum toward relational contracting and vertical integration (the dependent variable). This body of evidence, which includes case studies, econometric studies, and combinations of the two, overwhelmingly supports Williamson's (1996) assertion that "transaction cost economics is an empirical success story" (p.55). "Indeed," wrote Paul Joskow (2008), "it is hard to find many other areas in industrial organization where there is such an abundance of empirical work supporting a theory of the firm or market structure" (p. 16).

The empirical research on transaction cost economics has been summarized numerous times. Two works in particular stand out: "Empirical Research in Transaction Cost Economics: A Review and Assessment" (Shelanski & Klein, 1995) and "The Make-Or-Buy Decision: Lessons From Empirical Studies" (Klein, 2008). Rather than summarize these summaries, the focus of this section will be on a handful of case studies and empirical tests that highlight key concepts and exemplify approaches from which students writing term papers may draw inspiration.

Palay's (1984) "Comparative Institutional Economics: The Governance of Rail Freight Contracting" has inspired many student papers. There are four reasons for this. First, Palay did an excellent job translating the often idiosyncratic language in which transaction cost theory was developed into language students can understand. Note Palay's definition of governance structure and illustration of physical asset specificity from the theory section of this chapter. Second, he finds ways to break down the theory's key concepts—many of which are both abstract and complex—into smaller, more understandable, measurable pieces. An example of this is his identification of five characteristics of governance structures (how agreements are enforced, how they are adjusted, the types of adjustments made, whether information necessary for long-term planning is exchanged, and whether information necessary for structural planning is exchanged), each of which can be evaluated on scales running from least to most complex (i.e., from what one would expect to see in a spot market to what one would expect to see in relational contracting). Third, the strategy Palay employed to test the relationship between asset specificity and governance—creating a series of tables, one for each of his five governance-structure characteristics, in which the columns represent increasing degrees of governance complexity, the rows represent increasing degrees to which transaction-specific investments have been made, and the numbers in the individual cells represent the number of transactions characterized by particular combinations of governance complexity and asset—is simple, intuitive, and does not require a course in economic statistics to apply: Look to see if the expected pattern between asset specificity and governance emerges (the greatest numbers of observations should form diagonals down the tables, with cells in the upper left, center, and lower right of each table most full). And fourth, collecting the raw data can be fun—it is done by conducting a series of interviews about specific transactions, asking questions that allow the interviewer to characterize each transaction in terms of governance-structure complexity and investments in transaction-specific investments, uncertainty, and frequency. Parents, employers, college administrators, and local business owners can all be interviewed, depending on the student's research project.

One criticism some students have of the classic works in transaction cost economics is their focus on heavy industry: commercial aircraft producers and their subcontractors (Bell, 1982), rail freight contracting (Palay, 1984), natural gas producers and pipelines (Masten & Crocker, 1985), coal and electric utilities (Joskow, 1987), steel producers and source of iron ore (Mullin & Mullin, 1997), and so forth. There are good reasons for reading these works. The significance of Palay's work was discussed above, and that of Joseph Mullin and Wallace Mullin's will be discussed in the section of this chapter on policy implications. The extensive reliance on subcontracting in the production of commercial aircraft described by Bell reminds us that high frequency, uncertainty, and transaction-specific investment need not lead to vertical integration if the benefits of achieving economies of scale and smoothing production by aggregating less than perfectly correlated demand in different end markets are high. Scott Masten and Keith Crocker (1985) did a great job describing the sort of odd contractual provisions (take-or-pay requirements, in their case) that are difficult to explain when one views the world as a series of spot markets but are the hallmarks of relational contracting. Of the many virtues of Joskow's (1987) article, one is that his discussions of site and physical asset specificity (mine mouth power plants built next to coal mines and power plants specially built to efficiently burn coal with the specific metallurgical properties of the coal unique to a colocated mine) help remind us that asset specificity is not chosen for its own sake but rather for its demand-enhancing or production-cost-reducing benefits. But are the only applications of transaction cost economics to heavy industry? Thankfully, the answer is no.

Examples of applications and empirical tests of transaction cost economic outside heavy industry include academic tenure (McPherson & Winston, 1983), fiscal federalism (Bell, 1988, 1989), marketing and distribution in the carbonated beverage industry (Muris, Scheffman, & Spiller, 1992), franchising in the fast food industry

(Kaufman & Lafontaine, 1994), and even marriage (Hamilton, 1999). Applications by students have added to the variety, as demonstrated by the list of term paper topics in the introductory section of this chapter.

## Policy Implications

The roots of the revival of interest in what we now call transaction cost economics were policy driven. Both Arrow (1969) and Williamson (1967) conducted research on government contracting in general and defense contracting in particular just as the revival was getting under way, exploring many of the same issues Williamson in particular would soon explore in greater depth in the context of commercial contracting. Just as an awareness of the issues raised by bounded rationality, opportunism, the fundamental transformation, and the potential for contractual provisions in long-term contracts that realign incentives in a way that promotes cooperative adaptations to changing economic conditions are important to businesses transacting with other businesses, they are important to governments transacting with businesses. The issues involved should play an important part in the ongoing and increasingly important debate over the future of the U.S. health care system. But historically, interest in the policy implications of transaction cost economics has been strongest in the area of antitrust.

Significant portions of two of the key early works on transaction cost economics, Williamson's *Markets and Hierarchies* (1975) and his *The Economic Institutions of Capitalism* (1985), are devoted to the antitrust implications of transaction cost economics, and many of the key early papers were published in law journals. This is no coincidence. Before the advent of transaction cost analysis, the default assumption in the antitrust community was that odd contractual provisions, that is, provisions that differed much from what one might expect to see in a spot market, were suspicious. Transaction cost economics provided an alternative explanation: Rather than mechanisms for the enhancement and exploitation of market power, these odd contractual provisions promoted economic efficiency. Examples cited by Williamson (1985) in the first chapter of *The Economic Institutions of Capitalism* included "customer and territorial restrictions, tie-ins, block booking, franchising, vertical integration, and the like" (p. 19).

The motivation for much of the interest in transaction cost economics has thus been to distinguish between contractual provisions most likely used to enhance market power (which is illegal) and those most likely used to promote economic efficiency (which is not illegal, can be used as a defense in an antitrust case, and in general should be encouraged). Mullin and Mullin's (1997) "United States Steel's Acquisition of the Great Northern Ore Properties: Vertical Foreclosure of Efficient Contractual Governance?" provided an interesting illustration. Mullin and Mullin revisited a historic antitrust case, one in which U.S. Steel stood accused of vertical foreclosure (creating an illegal barrier to entry into a market by eliminating a potential rival's access to a critical input) through their negotiation in 1906 of a long-term lease of ore properties owned by the Great Northern Railway. This relationship, called the Hill Ore Lease, is particularly interesting because its structural characteristics are consistent with both the market power and transaction-cost-reducing explanations for its existence. The two interpretations have different implications, however, for the postcontractual profits and stock prices of U.S. Steel's largest customers at the turn of the last century—the railroads. Mullin and Mullin used ordinary least squares, the capital asset pricing model, and railroad stock prices to see with which interpretation returns on railroad stocks over the period the lease was in effect were consistent. Because these returns were abnormally high, Mullin and Mullin concluded that the primary effect of the lease was the promotion of economic efficiency, not market power.

## Conclusion

Transaction cost economists believe that either through decision makers' conscious choices or by doing what is necessary to survive in a competitive world, economic institutions evolve in ways that reduce the sum of production-plus-transaction costs. When the exchanges between the various technologically separable steps required to bring a good or service to market are simple, spot markets tend to do this best. However, as the exchanges become more complex, the transaction costs associated with the use of spot markets begin to rise, and alternatives to spot-market contracting become more appealing. One alternative is vertical integration. Just as spot markets have transaction costs associated with their use, however, so does vertical integration. For this reason, comparisons of the costs and benefits of the various institutional alternatives generally result in pairings of particular transactions to governance structures that lie between the extremes of spot-market contracting and vertical integration.

To test transaction cost theory, one must identify those factors that lead to greater transaction complexity. Theory predicts that complexity increases as the combination of transaction frequency, uncertainty, and the presence of transaction-specific investments increases, all else equal, including the production-cost benefits associated with capturing economies of scale and smoothing production by aggregating demand in less than perfectly correlated end markets. This theory has been tested using case studies, econometric studies, and combinations of the two. The overwhelming weight of the evidence is in support of transaction cost theory.

A number of important reminders emerge from these tests and applications, including the frequency with which real-world governance stops short of vertical integration and the consequent prevalence of relational contracting

and its odd contractual provisions. These provisions have historically been viewed with suspicion by antitrust authorities. With the advent of transaction cost reasoning, they are seen in a new light—as means to reduce transaction costs and promote efficient adaptations to changing economic conditions rather than as mechanisms by which to exploit and enhance market power.

# Asset Pricing Models

Peter Nyberg
*Helsinki School of Economics*

One of the central questions in financial economics is how to assign a correct value to an asset that provides a stream of uncertain future cash flows. At the most general level, the solution is simple: The price of the asset today equals the expected discounted value of its future payoffs. This discounting—the assignment of a (usually) lower present value to future cash flows—reflects the time and risk dimensions of the payoffs offered by the asset. First, most investors value a dollar received today more than they value a dollar received tomorrow. Consequently, they are willing to pay less than one dollar today for a dollar that they will receive in the future. This is the time dimension of asset pricing. Second, because investors dislike uncertainty and demand a compensation for bearing extra risk, the rate at which the payoffs are discounted should reflect how risky these payoffs are. Riskier payoffs are discounted more heavily than payoffs that are less risky. This is the risk dimension of asset pricing. The variation in riskiness across assets gives rise to variation in their expected returns: Because of higher discounting, assets with a riskier payoff pattern should have a lower price and hence, provide higher expected returns than assets that are otherwise similar but have less risky payoffs. This higher expected return is the reward that investors demand so that they are willing to include the risky asset in their portfolios. In equilibrium, then, the rate of return on an asset should be aligned with its riskiness in order for demand by risk-averse investors to meet supply. Hence, the interplay between risk and return—the search for the fundamental sources of risk and the quantification of this risk—lies at the heart of asset pricing research.

Asset pricing theory provides guidance on how assets optimally should be priced and how investors optimally should invest under some assumptions specified in the theoretical models. On the other side of the coin, asset pricing research also aims to understand how assets actually are priced on real financial markets. Thus, there is a close interplay between theory and practice. For investors operating in the financial markets, it is of fundamental interest to know the fair price of any given financial asset and the return they can expect to get from their risky investments. Furthermore, using the tools of modern portfolio theory, investors can quantify the trade-off between risk and return to construct optimal portfolios that suit their own risk preferences. Hence, asset pricing theory has vast practical implications and applications. Considering this, it is not surprising that the advent of modern portfolio theory and asset pricing models revolutionized Wall Street and the field of investment management. See, for example, Peter Bernstein (2005), who provides a historical account of the interplay between theory and practice of financial economics.

This chapter proceeds as follows: First, the general framework for understanding risk and return is reviewed. Then, some specific asset pricing models, the capital asset pricing model, the intertemporal capital asset pricing model, and the consumption-based asset pricing model, are described. This is followed by a brief review of the empirical performance of the asset pricing models. This chapter concludes with some practical implications, some guidelines for future research, and a summary section. A list of further readings is also provided.

## Understanding Risk and Return

We start the analysis by assuming a single-period economy, starting at Date 0 and ending at Date 1. For simplicity, we refer to Date 0 as today and Date 1 as tomorrow. The

analysis can easily be extended to multiple periods, but the simplified valuation framework considered here is sufficient for deriving the general asset pricing results.

A representative[1] investor living in our simplified economy is faced with the problem of choosing how much of his or her wealth he or she will allocate for consumption today and how much he or she will save and allocate for consumption tomorrow. The allocation of consumption between today and tomorrow is facilitated by the existence of an asset market. An asset is a financial contract that requires a cash outlay today from the buyer and that provides a payoff to the buyer in the future. The payoff provided by the asset can then be used for consumption—that is, for buying some units of a consumption good in the future.

The investor makes his or her investment decisions today, at Date 0, and receives a payoff from his or her investments tomorrow, at Date 1. The fact that the investment is made today and the payoff is obtained in the future reflects the time dimension of asset pricing. However, to generate some relevant predictions for asset prices, we must also incorporate uncertainty about the future into the analysis. This can easily be done by assuming that there are different states of nature that can occur tomorrow. It is also assumed that the payoffs from the assets are state contingent in the sense that the payoff for a given asset might vary over the possible states of nature, but once we know what state will occur, we also know with certainty the payoff that the asset will provide. We also assume that we can assign probabilities to these mutually exclusive states of nature so that these probabilities for the different states sum to 1. For example, with two possible future states of nature, the economy tomorrow might be in a recession with a probability of $\pi$ or in a boom with a probability of $(1 - \pi)$. Risk in this framework is then captured by the fact that the investor, making his or her investment decisions today, will not know with certainty the state of nature and, consequently, the associated payoffs from his or her assets that will be realized tomorrow.

Having described the basic framework, the investor's consumption-portfolio problem can now be stated.

Start by assuming that there are $S$ different states of nature that can occur tomorrow, indexed by $s = 1, 2 \ldots, S$. Associated with each of these states is the probability that the state will occur, $\pi_1, \pi_2, \ldots, \pi_S$, with these probabilities summing to 1. The investor now has to choose how much he or she wants to consume today, $c_0$, and how much he or she would want to consume in each of the mutually exclusive states of nature tomorrow, $c_1, c_2, \ldots, c_S$.

Now, the question becomes how the investor can decide on an optimal allocation of consumption. Clearly, we need a decision rule with respect to which optimality can be defined. One such decision rule is given by the expected utility theory, developed by John von Neumann and Oskar Morgenstern (1947). Thus, we assume that the investor is choosing his or her consumption levels today and in the alternative states of nature tomorrow so that his or her expected utility from these consumption levels is maximized. Furthermore, we also assume that the investor always prefers more consumption to less consumption, and that he or she is risk averse. Technically, these two conditions imply that the utility function $u(c)$ that describes the preferences of the investor always increases when the consumption level grows larger (the function has a positive first derivative) but that the rate of increase in utility for a fixed increase in consumption gets smaller as the level of consumption grows larger (negative second derivative).

The investor's choice problem can now be stated as follows. He or she should choose the consumption levels $c_0$, $c_1, c_2, \ldots, c_S$ so that his or her expected utility

$$U(C) = u(c_0) + \theta \sum_{s\ 1}^{s} \pi_s u(C_s), \tag{1}$$

subject to the budget constraint

$$c_0 + \sum_{s\ 1}^{s} p_s c_s = W, \tag{2}$$

is maximized. In Equation 1, $\theta$ is a time-discount factor, usually assumed to be less than one ($\theta < 1$). This parameter captures the time preferences of the investor: The utility that the investor gains from a given amount of consumption tomorrow is less than the utility that he or she would gain from the same level of consumption today. In Equation 2, $W$ denotes the investor's current wealth. The variable $p_s$ is the current price (measured today) of one unit of consumption in the possible state of nature $s$ that can occur tomorrow. Alternatively, $p_s$ can be viewed as the current price of a security that offers as a payoff a claim to one unit of consumption if state $s$ is realized and nothing if any other state is realized. In the literature, such securities are often referred to as *primitive securities*,[2] and $p_s$ is the associated state price for the given state $s$. Furthermore, the price of one unit of consumption today is normalized to be 1. Consequently, the budget restriction states that the current wealth of the investor is used for consumption today and for buying contingent claims to consumption in the future.

The optimization problem presented in Equations 1 and 2 can be solved by using the method of Lagrange multipliers. For the purposes of this chapter, it suffices to show the first-order conditions of the optimization—that is, the conditions that must hold when consumption is allocated optimally so that the expected utility is maximized. These are

$$u'(c_0) = \lambda, \tag{3}$$

and

$$\theta \pi_s u'(c_s) = \lambda p_s, \tag{4}$$

for all $s = 1, 2 \ldots, S$, where $\lambda$ is the Lagrange multiplier and $u'(\bullet)$ denotes the first derivative of the utility function.

Equations 3 and 4 offer important intuition about the interpretation of the state prices $p_s$. We shall later see that these state prices are important determinants of the prices and expected returns on all financial assets. Note that by combining the two equations, the state prices can be written as

$$p_s = \theta \pi_s \frac{u'(c_s)}{u'(c_0)}. \tag{5}$$

The relationship presented above shows that there are three major factors that determine the state prices. First, we have the time preference of the investor captured by the effect of the time-discount factor $\theta$. Second, the probability of a state occurring, $\pi_s$, also affects the state prices. The smaller the probability that the claim to a unit of consumption in a future state can be used, the less valuable the claim will be. Finally, the third determinant—the ratio of marginal utilities between state-contingent consumption tomorrow and consumption today—turns out to be the most important one for asset pricing purposes. Recall that we assumed that the investor was risk averse. This is captured by the fact that the second derivative of his or her utility function is negative, implying that the first derivative, the marginal utility, is a decreasing function of consumption. Consequently, states with high aggregate consumption are characterized by low marginal utilities, whereas states with low aggregate consumption are characterized by high marginal utilities. This implies that state prices, everything else equal, are low for states where aggregate consumption is high and that they are high for states where aggregate consumption is low. A claim to one unit of consumption is more valuable and has a higher price when this claim can be used in a state of economy where resources are scarce and aggregate consumption is low.

## The Pricing of Individual Assets and the Risk-Free Rate

We now turn the discussion to the valuation of individual assets. As mentioned earlier, in this framework, we view a financial asset as an instrument that offers payoffs that are contingent on the state of nature that will occur. Consider an asset that provides state contingent payoffs $D_{i,s}$, where $i$ is an asset-specific subscript and $s$ denotes the state. For example, if there are two possible states of nature, recession (State 1) and boom (State 2), then the payoffs offered by some asset indexed by 1 could be $D_{1,1} = 3$ and $D_{1,2} = 6$. This implies that the asset offers a payoff of three claims to consumption in a recession and six claims in a boom. The asset can now be valued using the state prices. Note that the state price $p_s$ is the price today for a payoff of one unit received in state $s$ tomorrow. Thus, the current value of the payoff offered by the asset in state $s$ must be equal to the state price (value of a unit payoff) multiplied by the units of payoff that the asset offers in the given state. Consequently, any financial asset can be assigned a price today simply by taking a sum of the current values of its payoffs across all states, or

$$P_i = \sum_{s=1}^{s} p_s D_{i,s}, \tag{6}$$

where the capital letter $P_i$ denotes the price of the asset today, $p_s$ is the state price for state $s$, and $D_{i,s}$ is the state-contingent payoff provided by the asset. Using Equation 6, it is also straightforward to calculate the expected return on the asset. The state-contingent rate of return on any given asset is defined as the payoff of the asset in a given state tomorrow divided by its current price. Denote this state-contingent payoff return by $r_{i,s}$, that is,

$$r_{i,s} = \left( \frac{D_{i,s}}{P_i} - 1 \right). \tag{7}$$

The expected return on the asset can then be calculated as a probability-weighted outcome of the state-contingent rate of returns. In symbols,

$$E(r_i) = \frac{\sum_{s=1}^{s} \pi_s D_{i,s}}{P_i} - 1 = \sum_{s=1}^{s} \pi_s r_{i,s}. \tag{8}$$

The asset pricing framework described here makes it also easy to characterize a risk-free asset. A risk-free asset is an asset that gives the same state-contingent payoff in all possible states of the economy. Such an asset is risk free because it promises a payoff that does not vary over the states. If we normalize the payoff from such an asset to be one unit in all possible states tomorrow, the current price of the risk free asset is given by

$$P_{rf} = \sum_{s=1}^{s} p_s, \tag{9}$$

and the risk-free rate of return can be written as the reciprocal of the sum of the state prices,

$$r_{rf} = \frac{1}{P_{rf}} - 1 = \frac{1}{\sum_{s=1}^{s} p_s} - 1. \tag{10}$$

## Stochastic Discount Factors and Risk Premiums

Having reviewed the general framework for pricing assets, we now turn to the important question of what determines the risk premiums on different assets. One of the important research themes in empirical asset pricing is to understand why some assets provide higher average returns than some other assets. Intuitively, we would expect that the differences in returns between assets should be driven by the riskiness of their payoffs. Because investors are risk averse, they are willing to invest in riskier assets only if the risks of these assets are compensated through a higher expected return. But what do we mean when we say that one asset is riskier than another asset, and how is the expected return on the asset connected to its riskiness? This section uses the general framework

presented in the previous sections to formalize the relationship between risk and return on financial assets.

We start the analysis by rewriting the general pricing Equation 6 slightly.

$$P_i = \sum_{s\_1}^{s} p_s D_{i,.s} = \sum_{s\_1}^{s} \pi_s \frac{p_s}{\pi_s} D_{i,s} = \sum_{s\_1}^{s} \pi_s M_s D_{i,s} = E(MD_i), \quad (11)$$

$$\text{where } M_s \equiv \frac{p_s}{\pi_s} = \theta \frac{u'(c_s)}{u'(c_0)}. \quad (12)$$

In the second equality of Equation 11, we have simply multiplied and divided the pricing expression with $\pi_s$, the probability of a given state occurring tomorrow. This enables us to write the pricing formula in the form of an expectation, illustrated in the last equality of Equation 11. The price of an asset is given by a probability-weighted average of the product across all states between the probability-deflated state price ($M_s$) and the state-contingent payoff of the asset.

The variable $M$ plays a central role in modern asset pricing. Depending on the application in which it is used, it is often called a stochastic discount factor, state-price deflator, state-price density, or pricing kernel in the literature. In the remainder of this text, we refer to $M$ as a stochastic discount factor because it appears to be the most common name used. The definition presented in Equation 12 shows that the stochastic discount factor carries the interpretation of an intertemporal marginal rate of substitution. It obtains high values in states of the economy where consumption is low and marginal utilities are high.

Note that Equation 11 can be expressed in terms of returns instead of prices. To see this, divide both sides of the equation with the current price of the asset.

$$\frac{P_i}{P_i} = E\left(M \frac{D_i}{P_i}\right) \quad (13)$$
$$1 = E(MR_i),$$

where $R_i = (1 + r_i)$ is the gross return on the asset.

Equation 13 lends itself to further manipulation. In what follows, we are going to use a well-known result from basic statistical theory. Recall that the covariance, a measure of the tendency of two random variables $X$ and $Y$ to move together, can be written as $\text{Cov}(X,Y) = E(XY) - E(X)E(Y)$. Rewriting this expression slightly, we obtain $E(XY) = E(X)E(Y) + \text{Cov}(X,Y)$. Using this relationship on the variables involved in Equation 13 yields the result presented below.

$$1 = E(MR_i) = E(M)E(R_i) + \text{Cov}(M, R_i) \quad (14)$$

Using the expression for the risk-free rate presented in Equation 10 together with the definition of the stochastic discount factor implies that the gross risk-free rate can be written as $R_f = 1/E(M)$. Equation 14 then implies that

$$E(R_i) - R_f = -R_f \text{Cov}(M, R_i) \quad (15)$$

Alternatively, starting from $P_i = E(MD_i)$ and using the same covariance decomposition as above leads to an equivalent expression for prices.

$$P_i = \frac{E(D_i)}{R_f} + \text{Cov}(M, D_i). \quad (16)$$

It is important to understand the intuition underlying Equations 15 and 16. We see that the risk premium on an asset, defined as the difference between the asset's expected return and the return on a risk-free investment, is given by the negative of the covariance between the asset's return and the stochastic discount factor. Assets that deliver high returns when the stochastic discount factor is low and low returns when the stochastic discount factor is high have a negative covariance with the stochastic discount factor. Such assets demand a positive risk premium, and the stronger the negative association between the returns and the stochastic discount factor, the higher will the required risk premium be.

A higher expected return, everything else equal, implies a lower current price for the asset. Equation 16 demonstrates that the current price of the asset can be decomposed into two parts. The first part is the expected payoff that the asset delivers tomorrow, discounted at the risk-free rate. If investors did not care about risk, or if the payoffs of the asset were risk free, then the current price of the asset would be given by the first term on the right-hand side of Equation 16. The second term, the covariance of the asset's payoff with the stochastic discount factor, is a correction for the riskiness involved in the asset's payoffs. The more negative this covariance is, the lower the current price of the asset and the higher its expected return will be.

Recall from Equation 12 that the stochastic discount factor $M$ has the interpretation as the intertemporal marginal rate of substitution. This allows us to give more structure to the argument above. Because $u(\bullet)$ is assumed to be a concave function, the marginal utility $u'(\bullet)$ is high when the quantity of the variable from which the investor derives utility is low. In bad states of the economy, characterized by low aggregate consumption or low aggregate wealth, marginal utilities tend to be high, leading to high values of the stochastic discount factor. These are exactly the states of nature where an investor values an extra payoff more than he or she would value it in states where marginal utilities are lower. Everything else equal, assets that provide high payoffs in states of high marginal utility—that is, assets that have a positive covariance with the stochastic discount factor, will thus be more attractive to the investor than assets that have a negative covariance with the stochastic discount factor and thus tend to provide these high payoffs in states where marginal utilities are low. For demand to meet supply, these latter assets, due to their unattractive payoff pattern, must provide higher expected returns (Equation 15) and have lower prices (Equation 16) so that investors are willing to include them in their portfolios. In equilibrium, the higher expected return on these assets will offset their unattractive payoff pattern, and

investors will, at the margin, be indifferent in their choice between different assets.

### Systematic and Unsystematic Risk

Maybe somewhat surprisingly, the expression for the risk premium presented in Equation 15 does not involve the variance of the asset's return. Instead, it is the covariance of the asset's return with the stochastic discount factor that determines the risk premium. This covariance term captures the amount of systematic risk involved in the asset's payoffs: Only the part of the asset return that is correlated with the stochastic discount factor matters for the investor. Conversely, the part of an asset's return variance that is unconnected to the stochastic discount factor represents unsystematic risk that does not affect the risk premium on the asset.

We can again understand this prediction by recalling that the stochastic discount factor is a function of the investor's marginal utilities in the different states of nature. An investor cares about how the asset behaves in good and bad states of the economy, where the marginal utility of the investor reflects the state of the economy. An asset with a payoff variation that is completely unconnected to the variation in marginal utilities behaves like a risk-free asset: Its payoff pattern is not directly connected to the well-being of the investor in the different states of nature tomorrow.

The distinction between systematic and unsystematic risk carries over to all asset pricing models. In the general asset pricing framework studied here, where marginal utility is a function of consumption, an asset that is uncorrelated with the stochastic discount factor is also uncorrelated with the investor's consumption stream. That the asset's payoffs are uncorrelated with consumption implies that if an investor adds such an asset to his or her portfolio, the payoffs from the asset will not, at the margin, affect the variance of his or her total consumption stream. In models in which the marginal utilities are a function of the returns on well-diversified portfolios, such as the capital asset pricing model described in detail later on, the same argument carries through. In this case, adding to a portfolio a slight amount of an asset that is uncorrelated with the portfolio returns will not, at the margin, affect the variance of the investor's wealth. The distinction between systematic and unsystematic risk implies that assets cannot be evaluated in isolation, but the evaluation must always be based on how the asset, in combination with other assets, affects the overall well-being of the investor.

## Description of Specific Asset Pricing Models

Having reviewed the general framework for pricing assets, the discussion now turns to some specific asset pricing models. The first model to be reviewed is the capital asset pricing model. Then, the intertemporal capital asset pricing model and the consumption-based asset pricing model will be briefly described.

### The Capital Asset Pricing Model (CAPM)

The CAPM, derived by William Sharpe (1964), among others, can be viewed as the first formal model that quantifies the relationship between expected return and systematic risk for financial assets. The model lays out the equilibrium implications of the portfolio selection models of Harry Markowitz (1952) and James Tobin (1958) that are briefly reviewed below.

Markowitz (1952) was the first to formalize how diversification—the combination of several risky assets in a portfolio—affects the expected return and variance of the portfolio. Because individual asset returns are not perfectly correlated with each other, the standard deviation (the square root of variance) of a portfolio consisting of individual assets is less than the weighted average of the individual assets' standard deviations. The weights here are taken to be the relative proportions of the total value of the portfolio that are invested in each one of the assets. On the other hand, the portfolio's expected return is simply a weighted average of the expected returns on the individual assets. Thus, by diversifying, one can reduce the risk of a portfolio without changing its expected return.

One of the key elements of Markowitz's analysis is to characterize the portfolios that for each given level of expected return have the lowest variance. Figure 20.1 shows a graphical depiction of the investment opportunity set available for an investor in a mean-standard deviation space.

The dots inside the hyperbolic region are individual assets, each of them characterized by its mean and variance. For each level of expected portfolio return, the minimum variance that can be obtained by combining these assets into portfolios is represented by the hyperbola in the figure. This is the minimum-variance frontier. If investors have mean-variance preferences[3]—that is, they want to maximize their portfolio returns but they dislike variance because it constitutes risk—they will choose portfolios on the efficient part of the frontier. The efficient frontier is the part of the frontier that lies above the global minimum variance portfolio that is situated at the left-most part of the frontier. Investors with a high risk aversion will choose mean-variance efficient portfolios that have a relatively low expected return and low standard deviation. Investors with less risk aversion, who are willing to take on more risk to get a higher expected return, will choose optimal portfolios that lie further up on the efficient frontier.

Tobin (1958) extends Markowitz's analysis by adding a risk-free asset to the investment opportunity set. The inclusion of the risk-free asset leads to a concept known as the two fund separation theorem: For an investor with mean-variance preferences, it is optimal to divide the investable wealth between the risk-free asset and the

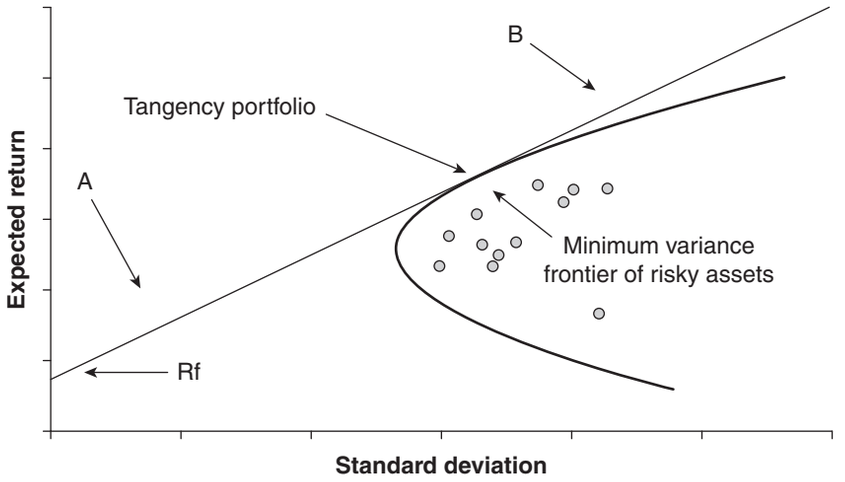

**Figure 20.1** Mean-Variance Opportunity Set

tangency portfolio, located at the point where the line starting from the risk-free asset intersects the efficient frontier. An investor can move up and down on this capital allocation line by varying the weights that he or she invests in the risk-free asset and the tangency portfolio. For example, investor A, who is more risk averse, invests some fraction of his or her wealth in the risk-free asset and the remaining fraction in the tangency portfolio. Investor B, who is willing to take more risk, can borrow money (putting a negative weight on the risk-free asset) and invest more than 100% in the tangency portfolio. Every point on the capital allocation line dominates all other investments in the sense that it is not possible to obtain a lower variance for a given expected return using any other investment strategy.

The CAPM describes an equilibrium in a world where all the investors follow the portfolio advice given above. If there exists a risk-free rate that is the same for all investors, if each investor has an identical holding period, if they all are mean-variance optimizers, and if they all have the same expectations about the probability distribution of asset returns, then they will all identify the same tangency portfolio as their optimal risky portfolio. This tangency portfolio, chosen by all investors, will thus be equal to the market portfolio[4] of risky assets.

While there are many ways to derive the relationship between risk and expected return for individual assets implied by the CAPM, it suffices to state that such a relationship can be obtained by solving a simple portfolio optimization problem. Suppose there are $n$ individual assets and a risk-free asset. The aim is to construct an efficient portfolio by minimizing variance subject to a given target return $E(r_p)$.

$$\begin{aligned} &\min_{w_i} \; Var(r_p) = \sum_{i\ 1}^{n} \sum_{k\ 1}^{n} w_i w_k \mathrm{Cov}(r_i, r_k) \\ &\text{subject to} \sum_{i\ 1}^{n} w_i E(r_i) + (1 - \sum_{i\ 1}^{n} w_i) r_f = E(r_p). \end{aligned} \tag{17}$$

In the equations above, $w_i$ is the weight invested in risky asset $i$, $E(r_i)$ is the asset's expected return, and $\mathrm{Cov}(r_i, r_k)$ is the covariance between assets $i$ and $k$. The first equation is simply the variance of a portfolio of risky assets. This variance is to be minimized by choosing the optimal weights for the individual risky assets. The second equation is a constraint stating that the linear combination of the risky portfolio's expected return and the risk-free rate must equal some target return $r_p$ that lies on the capital allocation line.

By using the Lagrange multiplier method for solving the optimization problem presented in Equation 17 and rearranging terms, one obtains an expression for the expected return on individual assets.

$$E(r_i) = r_f + \beta_{i,\,p}(E\,(r_p) - r_f), \tag{18}$$

where

$$\beta_{i,\,p} = \frac{\mathrm{Cov}(r_i, r_p)}{\mathrm{var}(r_p)}. \tag{19}$$

For each chosen level of expected return, the optimization carried out in Equation 17 gives a portfolio variance that plots on the capital allocation line in Figure 20.1. Thus, the relationship presented in Equation 18 must hold when $E(r_p)$ is the return on any portfolio on the capital allocation line. Setting the weight of the investable wealth invested in the risk-free asset to zero, implying that

$$\sum_{i\ 1}^{n} w_i = 1 \tag{20}$$

gives the expected return and variance on the tangency portfolio. Because of the assumptions of the CAPM, the tangency portfolio is the optimal risky portfolio identified by all investors. Consequently, the tangency portfolio will be equal to the market portfolio. This implies that the relationship in Equation 18 must hold for the market portfolio as well, and we can set $r_p$ to be equal to $r_m$, the return on the market portfolio, in the equations above.

Equation 18, known as the security market line (SML), is the central prediction of the CAPM. It states that the expected return on a security can be divided into two components. The first component is the risk-free rate of return. It corresponds to the rate of return that investors require to switch consumption from this period to the next period. The second component is a correction for risk. The expected risk premium on an asset is given by the product between the asset's beta, $\beta_{i,p}$, and the expected market risk premium $(E(r_p) - r_f)$.

The beta parameter measures the asset's sensitivity to movements in the market portfolio. Assets with a high beta have returns that move in close connection with the returns on the market portfolio. Conversely, assets with a low beta have returns that follow the market portfolio less closely. In line with the general framework studied earlier, we can view the risk premium implied by the CAPM as a compensation for how the asset behaves in the different states of the economy. Assets with a high beta offer high payoffs when the marketwide return is high and low payoffs when the market is doing badly. According to Equation 18, investors require a high-risk premium from these assets. Assets with a low, or even negative, beta enable the investor to diversify away some of the risks connected to market movements. Hence, these assets are more desired, and a smaller risk premium is required from them.

One of the fundamental insights offered by the CAPM is that only a part of the total risk of an individual asset, where total risk is measured by the standard deviation of the asset's returns, should be compensated with a risk premium. This follows because the total risk can be decomposed into a systematic and an unsystematic part. The unsystematic risk of a security, the part of the return variation that is uncorrelated with market movements, can be diversified away in large portfolios. On the other hand, under the assumptions of the CAPM, the systematic risk of an asset is related to its covariance with the market portfolio. This covariance is the part of an asset's total risk that the investor cannot diversify away. Only the systematic risk that investors are forced to bear should be rewarded with higher expected returns in market equilibrium. Hence, in market equilibrium, investors should not be rewarded for holding risks that they can easily diversify away.

### *Roll's Critique*

Note that in the pricing Equation 18, the return on the factor portfolio is denoted by a subscript $p$, instead of using the subscript m that refers to the market portfolio. This choice of notation is intentional. In fact, the pricing Equation 18 holds for any tangency portfolio. To state this in more general terms, a necessary and sufficient condition for finding a perfect relationship between beta and average returns is that the factor portfolio $p$ against which betas are measured is mean-variance efficient—that is, that the factor portfolio's average return and standard deviation plot on the hyperbolic region in Figure 20.1. Such a relationship between betas and expected returns can thus be derived without any need for economic motivations.

It can be argued that the only economic content of the CAPM is that it ex ante identifies that the market portfolio should be mean-variance efficient. The main result of the CAPM, the relationship between beta and expected returns, then follows from the mean-variance efficiency of the market portfolio.

Richard Roll (1977) argues that this has implications for empirical tests of the CAPM. Viewed in this light, a test of the CAPM is a test of the mean-variance efficiency of a market portfolio proxy that we use in our empirical tests. Of course, in every sample there will always exist efficient portfolios. If the proxy happens to be efficient, we obtain a perfect fit between betas and average returns—if it is inefficient, there might be no fit at all. However, even if we should by chance happen to use an efficient stock market proxy, there is no way of knowing whether it corresponds to the true market portfolio.

The only real test of the CAPM would be to test the efficiency of the true market portfolio. However, the true market portfolio is unobservable. It should, in theory, contain all the wealth in the economy and not be limited only to stocks, as is often assumed in the empirical tests. Thus, the CAPM may never be a testable model.

## The Intertemporal CAPM

The original CAPM is a one-period model: It is assumed that investors are trying to maximize the utility of their end-of-period wealth and that they make their portfolio choices without any consideration for what might happen in the next period. This assumption is relaxed in the intertemporal CAPM (ICAPM) derived by Robert Merton (1973). By assuming that investors can trade continuously in time, Merton shows that the expected returns on assets are driven not only by their covariance with the market portfolio but also by the assets' capability to hedge against shifts in future investments opportunities.

A simplified example can illustrate the thrust of Merton's argument. Assume that there is time variation in expected stock market returns and that these returns are predictable to at least some extent. Such time variation could, for example, reflect changes in marketwide risk premiums. If the current prediction were that the stock market returns would be low in the next period, a sufficiently risk-averse investor would like to hedge his or her position against the deterioration in investment opportunities that this implies. One way to hedge the reinvestment risk is to own assets that provide high returns when future stock market returns are predicted to be low. In that case, the investor will have more wealth to allocate to stock market investments at the beginning of the next period, and it is more likely that he or she will achieve some target level of wealth or consumption at the end of the period, in spite of the lower return on the stock market during the period. If the marketwide intertemporal hedging demands are

strong enough, investors will have a high demand for assets that hedge the reinvestment risk—assets that do well when there is an unfavorable shift in future investment opportunities—and this will drive up the price of these assets and decrease their expected returns.

Variables that forecast the conditional distribution of asset returns, or more generally, changes in the investment opportunity set, are called *state variables* in the literature. The ICAPM predicts that the market beta is not enough to describe the expected returns on assets, but we also need to take into account how the returns on the asset covary with the state variables. The betas measured against the state variables indicate the asset's ability to hedge against shifts in investment opportunities. The end result is a multifactor model, where the state variables work as additional factors on top of the market factor.

### Consumption-Based CAPM

Recall the section of this survey that described the general framework for understanding risk and return. The section demonstrated that the consumption–investment problem faced by the representative investor leads to many important asset pricing implications. In fact, as emphasized by John Cochrane (2005), all of the asset pricing models surveyed in this chapter can be seen as specializations of the consumption-based framework. Thus, it is interesting to see how the model can be specified to empirically relevant cases.

The theoretical development of the consumption-based capital asset pricing model (CCAPM) is accredited to Mark Rubinstein (1976), Robert Lucas (1978), and Douglas Breeden (1979). The CCAPM can be derived by considering the intertemporal maximization problem of an investor who can freely, at time $t$, trade asset $i$ that gives a payoff $D_{i,t+1}$ in the next period. The first-order condition for his or her choice is

$$P_{i,t}u'(c_t) = E_t[\theta u'(c_{t+1})D_{i,t+1}]. \tag{21}$$

The left-hand side of Equation 21 is the utility loss faced by the investor if he or she buys the asset and thus forgoes some of his or her consumption today. The right-hand side is the expected utility increase in the next period that he or she gains from his or her increased consumption owing to the extra payoff he or she get will from the asset. At the optimum, the right- and left-hand sides of the equation should be equal. If the investor, at the margin, gained more (discounted) expected utility from his or her increased consumption tomorrow than the utility he or she loses from his or her forgone consumption today, it would be beneficial for the investor to invest more in the asset and move some more of his or her consumption to the next period.

Rearranging the first-order condition slightly, we see that prices are given by

$$P_{i,t} = E_t\left[\theta \frac{u'(c_{t+1})}{u'(c_t)} D_{i,t+1}\right], \tag{22}$$

whereas, in correspondence to the arguments made earlier, returns obey

$$1 = E_t\left[\theta \frac{u'(c_{t+1})}{u'(c_t)} R_{i,t+1}\right]. \tag{23}$$

These results above, and the intuition behind them, are, of course, equivalent to results of Equations 11 and 13, which were derived using the state-preference framework. Furthermore, by specifying a utility function that investors are trying to maximize and using time-series data on consumption and asset returns, Equation 23 is also applicable for empirical testing.

Breeden (1979) derives a version of the CCAPM where the expected return on an asset is linearly related to a single beta. This beta is the sensitivity to the asset's return measured against the growth rate in aggregate real consumption. Thus, in Breeden's CCAPM, consumption growth replaces the return on the market portfolio that was the relevant factor in the CAPM. Furthermore, Breeden also demonstrates that in an intertemporal framework, the single consumption beta captures all the implications of Merton's (1973) multibeta model. This provides a significant simplification of intertemporal asset pricing theory: Whereas an application of the ICAPM requires an identification of all the relevant state variables describing the evolution of the investment opportunity set, the CCAPM needs as an input only the aggregate growth rate of consumption.

## The Empirical Performance of Asset Pricing Models

The previous sections have reviewed the relevant theory and described some asset pricing models. The next step is to assess whether the predictions made by the asset pricing models can match the properties that are observed in real asset return data. The empirical literature on asset pricing models is enormous, and only a brief review of some of the most enduring works can be given.

There are a variety of ways to test the implications of the linear factor pricing model, both in the time series and in the cross section. For example, in a time-series regression, the CAPM, assuming risk-free lending and borrowing, implies that the regression intercept $\alpha_i$ in Equation 24 should be zero for all test assets.

$$r_{i,t} - r_{f,t} = \alpha_i + \beta_i(r_{m,t} - r_{f,t}) + e_{i,t}. \tag{24}$$

Furthermore, a cross-sectional prediction is such that when the average returns on the test assets are regressed against their estimated market betas, the intercept $\lambda_0$ should equal the average risk-free rate, and the slope $\lambda_1$ should equal the expected market risk premium.

$$\bar{r}_i = \lambda_0 + \lambda_i\beta_i + e_i. \tag{25}$$

Fischer Black, Michael Jensen, and Myron Scholes (1972) and Eugene Fama and James MacBeth (1973) are among the earliest testers of the CAPM. Already their tests were able to find some empirical weaknesses in the CAPM. For example, the intercepts $\alpha_i$ in time-series tests were too high (positive) for portfolios having low market betas and too low (negative) for portfolios having high market betas. These problems were also reflected in the cross-sectional tests: The intercept $\lambda_0$ was found to be higher than the average risk-free rate and the slope $\lambda_1$ lower than the average market risk premium. Nevertheless, in spite of these problems, the tests found evidence supporting the main hypothesis of the CAPM that market betas are linearly and positively related to average returns.

Strong empirical evidence against the CAPM started to build up in the 1980s. Rolf Banz (1981) documents that when firm size is measured by market capitalization, investments in a portfolio consisting of stocks of small firms tended on average to yield much higher returns than can be explained by these firms' market betas. This became known as the *small-firm anomaly.* Furthermore, empirical tests have also shown that when firms are assigned to portfolios based on their book-to-market equity (B/M) ratios, portfolios containing high B/M stocks (called *value stocks*) have yielded much higher returns than portfolios with low B/M stocks (called *growth stocks*), and these differences in returns cannot be explained by the portfolios' market betas. This is the value anomaly. In a highly influential paper, Fama and Kenneth French (1992) show that these two variables, size and B/M, characterize the cross section of average stock returns. Even more important, they show that the relationship between market beta and average return is flat. The results imply that the CAPM is unable to explain the average returns in postwar stock market data.

Fama and French (1993) develop a multifactor model that adds two additional factors to the market factor. The first factor is the return difference between a portfolio consisting of high B/M stocks and a portfolio consisting of low B/M stocks. This factor is often denoted high-minus-low (HML). The second factor is the return difference between a portfolio consisting of firms with a small market capitalization and a portfolio consisting of firms with a large market capitalization (small-minus-big, SMB). In the time series, the empirically testable form is

$$r_{i,t} - r_{f,t} = \alpha_i + \beta_{i,MKT}(r_{m,t} - r_{f,t}) + \beta_{i,SMB} SMB_t + \beta_{i,HML} HML_t + e_{i,t}. \quad (26)$$

The model is known as the Fama-French three-factor model. Fama and French (1993) show that the model gives a good description of the average returns on 25 test portfolios that are created by sorting stocks into portfolios based on their B/M ratios and market capitalization. Thus, the model captures the value and size anomalies in the data. Fama and French (1996) show further that the model can also capture some other anomalies in average stock returns. However, the model fails in one aspect: It is unable to explain the short-term momentum in stock returns that was first documented by Narasimhan Jegadeesh and Sheridan Titman (1993). The momentum anomaly refers to the empirical finding that stocks with high past returns (during the previous 3–12 months) continue to offer higher returns during the next year than stocks with low past returns. The momentum anomaly remains as one of the biggest challenges for asset pricing models that are derived under the assumption of rational investor behavior.

The promising empirical performance of the Fama-French three-factor model has made it a benchmark model, against which new asset pricing models developed in the literature are compared. However, the model is not without its criticism. Recall that the factor SMB is the return difference on small and large firms, and HML is the return difference on value and growth firms. Thus, the factors are closely connected to the anomalies they were constructed to explain. One is curious to know what, if any, systematic risk sources these factors are acting as proxy for. There is now a large body of literature that attempts to explain why the betas relative to the Fama-French factors are priced in the cross section of stock returns, but so far, no clear consensus has emerged.

Fama and French (1996) argue that their model can be understood as a form of Merton's (1973) ICAPM. However, because the identity and number of state variables characterizing the evolution of the investment opportunity set are undefined in the theoretical derivation of the ICAPM, it is difficult to evaluate this claim. This ambiguousness involved in choosing the factors for a multifactor representation of asset pricing leads to the danger of data snooping, where researchers, having searched over different data sets, identify variables that appear to be related to the cross section of stock returns in one particular sample. However, there is no guarantee that the variable will work in other time periods or using other test assets. This is a point emphasized strongly by Fama (1991).

Campbell (1996) emphasizes that for tests of the ICAPM, researchers should look for factors that actually forecast the conditional distribution of asset returns, rather than simply choosing any factors that appear to capture common variation in returns. In his empirical tests of an intertemporal asset pricing model, Campbell uses variables that have some forecasting power for future stock market returns. He finds that these variables indeed appear to be priced in the cross section of stock returns.

We saw earlier that the consumption-based CAPM overcomes the problem with selecting factors because only one variable, some function of consumption growth, is enough to theoretically explain asset returns. Unfortunately, so far, the CCAPM has faced problems in explaining the properties observed in real asset return data. Lars Hansen and Kenneth Singleton (1982) assume that investors are described by a power utility function that they are trying to maximize. They then set out to test Equation 23 directly using aggregate consumption data and applying a statistical

method known as the generalized method of moments. Their results imply that the CCAPM cannot simultaneously explain the returns on a stock market index and the risk-free rate. Douglas Breeden, Michael Gibbons, and Robert Litzenberger (1989) find that consumption betas from the CCAPM show a performance comparable to the market betas from the CAPM in explaining stock returns.

What is even more daunting for the consumption-based framework is that in its simplest form, it gives wildly counterfactual predictions about the quantities that it is trying to explain. Rajnish Mehra and Edward Prescott (1985) show that in a simple consumption-based framework, where investors are assumed to have a time-separable power utility function, the predicted difference in stock market returns and the risk-free rate of return is much lower than what is observed in the data. This is the *equity premium puzzle:* The only way to generate the observed equity premium in the simple CCAPM framework is to assume that investors are unreasonably risk averse. However, it must be emphasized that this problem is not unique to the CCAPM. Because most asset pricing models can be viewed as specializations of the basic consumption-based framework, the equity premium puzzle lies hidden in all these models also (see Cochrane, 2005, for a thorough analysis of this issue).

Because of its disappointing performance, the standard version of the CCAPM has been modified in many directions, both in the theoretical and in the empirical research. One of the theoretical modifications has been the development of new utility functions that appear to produce a better match between the theory and empirical findings. On the empirical side, Martin Lettau and Sydney Ludvigson (2001) allow the consumption betas to be time varying in response to different states of nature that they substitute with a well-chosen indicator variable. Their empirical results indicate that value stocks are more highly correlated with consumption growth in bad times, represented by their indicator variable, than in good times, thus leading these stocks to have high expected returns as a compensation for their risks. Furthermore, they also document that these conditional versions of the CCAPM and the CAPM perform almost as well as the Fama-French three-factor model in explaining the returns on the 25 portfolios sorted on book-to-market equity ratios and size that were used as test assets by Fama and French (1993).

## Practical Implications

The previous section described that in the past, value stocks, small stocks, and stocks with high past returns have provided higher returns than their counterparts. Furthermore, these return patterns are left unexplained by the traditional asset pricing models such as the CAPM. Academic research, working under the paradigm that higher returns should arise only as a compensation for higher systematic risk, has mainly interpreted this finding as an indication that the CAPM does not capture all the priced sources of risks in stock returns. However, it is also possible to view these results from an opposite angle. Maybe the CAPM does capture the relevant sources of risk that investors care about. In this case, the returns on value stocks, small stocks, and momentum strategies are not aligned with their riskiness, and consequently, they constitute bargains to investors: By investing in these stocks, investors could historically have achieved high returns without having to take a corresponding high exposure to systematic risk. Perhaps not surprisingly, there are nowadays mutual funds that aim to capitalize on these anomalies and advertize themselves as, for example, following various value strategies.

Thus, if we really believe in the predictions of a specific asset pricing model, then observed deviations from the model can produce valuable investment advice. However, if one is willing to follow such a strategy, it is important to remember some caveats. First, it is possible that the asset pricing model, such as the CAPM, is not well specified and does not capture the priced sources of risk. Second, if such deviations from the risk-return paradigm really do exist, then these deviations are likely to quickly dissipate because of the actions of other market participants who are also trying to capitalize on these anomalies. In line with this argument, the value and size anomalies have weakened considerably in the data since they were made public by academic research. Third, past high returns on a trading strategy do not necessarily imply that the strategy will be profitable in the future. This last point becomes even more significant if the high past returns on a trading strategy cannot easily be explained by an asset pricing model that would indicate that the high returns are compatible with a capital market equilibrium.

## Future Directions for Research

While our understanding of the determinants of risk premiums on various assets has significantly improved since the 1960s, when the CAPM was developed, the picture that the large body of research paints before our eyes is still far from completely clear and coherent. For example, the value anomaly tells us that there is large variation in average returns between value stocks and growth stocks, whereas the momentum anomaly implies that prior winners (stocks with high returns in the past) continue to provide higher returns than prior losers (stocks with past low returns). Asset pricing theory tells us that these high returns should be a compensation for the riskiness of value stocks and prior winners. The asset pricing literature has proposed several new risk factors that aim to explain these return patterns, and these propositions have often received support in the empirical tests that the authors have subjected their models to. However, because many of the proposed models appear to have little in common with each other, each building on its own set of economic arguments, one is still hungry for a coherent

story that would produce a synthesis of the large field of explanations. Furthermore, Jonathan Lewellen, Stefan Nagel, and Jay Shanken (in press) demonstrate that many of these proposed models do not work as well as originally thought when the set of test portfolios is expanded to include returns on portfolios that were not included in the original tests. Ideally, a well-defined asset pricing model should be able to explain the return on any economically interesting portfolio of assets. Thus, much important work remains to be done before we can fully understand the determinants of asset prices.

## Conclusion

This chapter has discussed how financial economists view the relationship between risk and return and how this relationship is reflected in different asset pricing models. The review started with describing the general framework for asset pricing. It was demonstrated that many important asset pricing implications can be derived from an investor's optimal portfolio–consumption choice. An important implication of the analysis was that higher risk should be connected to higher expected returns in market equilibrium and that it is the systematic risk of the asset that matters for pricing purposes. Furthermore, there was an introduction to the important concept of the stochastic discount factor that assigns prices to different assets. Then, there was discussion of some specific asset pricing models and a brief review of their empirical performance. Finally, this chapter offered some practical implications and future directions for research.

## Notes

1. The assumption that there exists a representative agent makes it possible to study the actions of only one agent and use his or her actions to derive some general market-wide asset pricing implications.
2. These securities are also known as Arrow-Debreu securities, contingent claim securities, state securities, and pure securities.
3. Tobin (1958) shows that mean-variance preferences can be motivated if the investors have a quadratic utility function or if the returns are normally distributed.
4. The market portfolio is the sum of all individual holdings of risky assets.

# Portfolio Theory and Investment Management

Thomas W. Harvey
*Ashland University*

The objective of this chapter is to help readers understand theories of portfolio management. Investment, as opposed to consumption, is the commitment of funds that the investor believes will appreciate in value over time and will provide a return that is sufficient for assuming risk and for exceeding the effects of inflation.

## Portfolio Theory

This chapter begins by reviewing theories of investment and portfolio management that have been prevalent throughout the twentieth century. First, it reviews the firm foundation theories of Benjamin Graham and David Dodd, developed in their seminal book, *Security Analysis,* published in 1934. Following Graham and Dodd was John Burr Williams's (1938) theory of investment value, which added further sophistication to the Graham and Dodd calculation and which became one of the more common contemporary valuation techniques for equity securities. And then, the work of Harry Markowitz (1952) on expected utility theory, modern portfolio theory, and diversification theory furthered the analytics of Graham and Dodd and the valuation methods of Williams. Together, they became the dominant investment techniques in the twentieth century.

Second, the chapter examines Dow theory, which is the basis of technical analysis, or the reading of stock price charts to derive patterns of price movements (Schannep, 2008). Charting price movements has its roots in eighteenth-century Japan, when Munehisa Homma, a commodity merchant from Sakata, created a futures market for rice and used the charts to determine the ways in which he thought future prices would move. Homma's use of the charts is the subject of Steve Nison's (2001) book, *Japanese Candlestick Charting Techniques,* which is considered "the bible of candle charting" and contributed to the increased popularity of chart use in the latter part of the twentieth century.

The third theoretical approach is the random walk, as described by John Maynard Keynes in 1936, refined by Eugene Fama in 1965, and made popular by Burton Malkiel (1973/2003) in his landmark book, *A Random Walk Down Wall Street.* Keynes, Fama, and Malkiel postulated that stock prices were simply functions of investor decisions, and study of financial statements or examination of price charts was a waste of time. Keynes believed that all the investor had to do was find an opportunity before the market discovered it. The assumption was that the market would find it eventually, which would increase the price, creating wealth for those who had purchased it first.

Finally, the emerging field of behavioral finance as presented by Daniel Kahneman and Amos Tversky (1979), Hersh Shefrin (2002), and John Nofsinger (2008), among others, maintains that psychology should be brought into the dialogue about investments. Whether investors believe in fundamental analysis, technical analysis, or the theory of the random walk, they react to some kind of information as they make their resource allocation decisions. Personal

bias, emotion, experience, and even mood influence the way decisions are made as investors move into and out of the market.

## Firm Foundation Theory and Fundamental Analysis

Traditional finance, which was grounded in the rationality of investors, was significantly influenced by Graham and Dodd's (1934) *Security Analysis.* This work established the principles of fundamental analysis for making resource allocation decisions and became the foundation for investment portfolio management for much of the twentieth century.

Graham and Dodd recognized the difference between speculation, which focuses on when to buy or sell a security, and investment, which allows investors to determine what to buy or sell. They prescribed fundamental analysis, the centerpiece of the firm foundation theory, as a thorough study of the strengths and weaknesses of individual companies, primarily concentrating on a review of past financial results, which can then be used to develop a projection of future performance. Those estimates of future earnings became what Graham and Dodd (1934) called the intrinsic value of the firm. The idea was to find companies whose fundamental, or intrinsic, value was more than the current market price of the stock, which, thus, represented a buying opportunity.

To calculate the intrinsic value of a prospective investment meant studying such factors as past earnings and operating margins and making assumptions about expected growth rates to arrive at a projection of future earnings. Specifically, Graham and Dodd studied companies with high earnings-to-price ratios, low price-to-earnings ratios, high dividend yields, prices below book values, and net current asset valuations. They tried to find earnings trends that would represent the underlying value of the business that could be carried into future years.

That data, along with information about the economy and evaluation of the firm's management, could result in a complete understanding of the past performance and future prospects that, then, became the basis for the investment decision. If those prospects were promising, investors would buy the stock; if those prospects were not promising, they would not commit their resources.

Williams (1938) took the concept of intrinsic value a step farther. He agreed with Graham and Dodd (1934) that asset prices should reflect the basic, or fundamental, value of the firm but used different factors in his calculations. Whereas Graham and Dodd focused on historical earnings per share that they projected into the future, Williams devised the discounted cash flow model in order to determine the present value of those earnings as represented by dividends. The intrinsic value, then, was the present value of the firm's future dividends. In 1938, when Williams wrote *The Theory of Investment Value,* most if not all publicly traded companies paid dividends, which made the model most useful. In the latter part of the twentieth century, many firms omitted dividends, preferring to reinvest their earnings for future growth, thus limiting the use of the Williams model. However, the model was modified in the late 1990s to discount future free cash flow instead of dividends to derive the intrinsic value for any firm, which makes it applicable to all firms (Gray, Cusatis, & Woolridge, 1999). The theories of Graham and Dodd (1934) and Williams (1938) suggest that if the market price is less than the intrinsic value, investors will bid the price up to meet that value. Conversely, if the intrinsic value is lower than the market price, investors will bid it down.

As the firm foundation theory and fundamental analysis gained prominence in the middle of the twentieth century, Markowitz (1952) published "Portfolio Selection" in the *Journal of Finance.* In this work, Markowitz presented the mathematics of diversification that had been introduced in 1738 by Daniel Bernoulli. Bernoulli described the nature of the risk associated with a collection of assets (Rubenstein, 2002). Markowitz realized that Williams did not address the issue of risk inherent in assets because Williams believed in the mitigating factor of diversification. That is, holding a variety of assets that were not correlated with each other would eliminate the risk entirely. Further, Markowitz saw that the Williams model was problematic because the future dividend of the firm could not be known for certain. The critical factor, he understood, was the expected return of the investment (Fabozzi, Gupta, & Markowitz, 2002; Varian, 1993).

Thus, Markowitz suggested that investors should construct their portfolios based on the trade-off between risk and reward. This view is grounded in expected utility theory (EUT), which reflects the concept of *homo economicus,* or the economic man who makes financial decisions completely rationally, using all of the information that is available at the time. This is known as modern portfolio theory, and Markowitz suggested that the more risk that was taken, the greater the return the investor should require. That is, investors should try to determine the potential return for their portfolios given the amount of risk that they are willing to assume. The expected return (reward) and the volatility (risk) of a portfolio could be calculated, allowing investors to make more educated decisions about the allocation of their assets (Fabozzi et al., 2002; Graham, 1973; Rubenstein, 2002). A fundamental component of behavioral finance, however, is that investors can have different perceptions of the risk of a potential investment as well as of its expected value.

Markowitz explained that different classes of assets have different amounts of risk associated with them. The theory suggested, for example, that small company stocks would have higher average annual returns than large company stocks, corporate bonds, and government bonds, but they also would have the greatest amount of overall risk. The history supports the theory, as shown in Figure 21.1. Small companies are higher risk, but they also have higher returns. In sum, Markowitz argued that a balance of risk

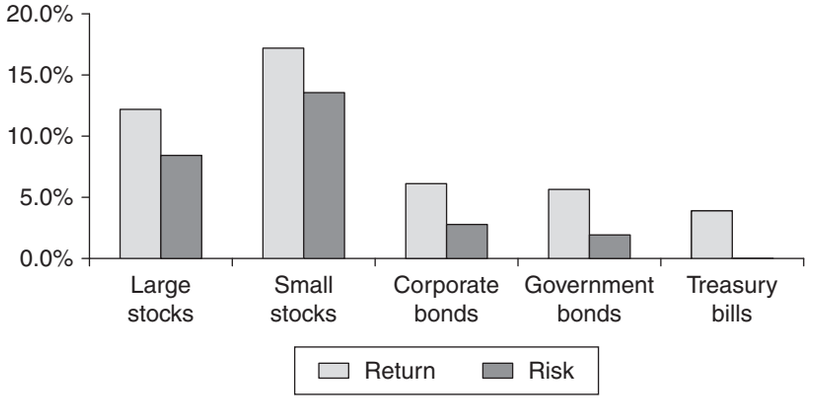

**Figure 21.1** Average Annual Returns and Risk Premiums: 1925–1996

SOURCE: Jordan and Miller (2008, p. 15).

and reward could be struck according to investors' expectations for reward, balanced against their tolerance for risk. Investors could reduce the risks associated with individual stocks, depending on the total amount of risk being assumed, by diversifying their portfolios with 20 to 30 stocks (Markowitz, 1952, 1976).

Traditional finance, then, was based on Graham and Dodd's (1934) concept of intrinsic value; Williams's (1938) theory of investment value and the present value calculation; and modern portfolio theory, diversification theory, and expected utility theory of Markowitz (1952).

## Dow Theory and Technical Analysis

In addition to conducting fundamental analysis of the firm, studying the price charts—or technical analysis—is a way to evaluate potential investments as well. Technicians believe that prices are the results of all the factors in the market, including earnings releases, economic data, investor emotions and biases, and especially the result of previous price changes. Fundamental analysis is useful for technicians, but price momentum is the key. While the use of charts was originated by the 1700s by Munehisa Homma in the prediction of the future price of rice (Nison, 2001), Charles Dow laid the groundwork for the use of charts early in the twentieth century. While Dow did not fully document his theory in a book or published article, he did document his ideas about stock price movements in *The Wall Street Journal,* of which he was editor in the last decade of the nineteenth century. Several years later, William Peter Hamilton formalized Dow theory in *The Stock Market Barometer* in 1922, which was followed by the definitive *Dow Theory,* written by Robert Rhea in 1932 (Schannep, 2008).

Dow theory maintained that past price movements could signal future price movements (Schannep, 2008). It centered on the primary trend, secondary patterns, and daily fluctuations and theorized that the primary trend would last for a long period of time while secondary patterns and daily price changes were important only when they impacted the primary trend. Charting the price movements allowed investors and speculators to identify those trends that they believed provided clues as to the next price change. Investors bought and sold according to what they saw.

Stock prices anticipate earnings, and Dow understood that when business is good, the price of the firm's stock would reflect it and vice versa. That is, the market would gauge a firm's future prospects, and if the future were promising, the price would start to advance. A pattern would start to develop as the price continued upward, for example, which would signal a buying opportunity. However, on the other hand, it might also be a signal to sell if the trader thought a reversal is imminent. The decision-making process is one of human judgment.

By looking at the charts, technicians can see the lowest price at which a particular stock has traded over a specified period of time, which is known as the support level (Schwager, 1996, 1999). That tells the analyst that there is a strong likelihood that future prices will not go below it. Conversely, the highest price at which the stock has traded can also be seen and is known as the resistance level. That price is the one that will not, in all likelihood, be exceeded. However, there are no guarantees when dealing with stock prices. Prices can break through the resistance level if the market senses pending improvement in future earnings, or there can be a break through the support level if those future prospects become clouded.

The trend line for a particular stock can be compared to the Dow Jones Industrial Average, NASDAQ (the National Association of Securities and Dealers Automated Quotation), or S&P (Standard and Poor's) 500 to gauge performance over a period of time, whether it be 5 days, 5 years, or somewhere in between. That comparison shows whether the stock has done better or worse than the index, which will have an influence on the investor's decision. Comparisons can also be made to competitors so that the analyst can

evaluate the strength of the trends of the competitive prices. Analysts can also compare the price trend to moving averages of its performance (50 day or 200 day), its relative strength index (RSI), or the volume of shares being traded as they try to discern the direction in which prices will move.

There are many different technical analytics that technicians use, such as bar charts, candlestick charts, point and figure charts, head and shoulders diagrams, saucers, double tops, double bottoms, and fulcrums (Schwager, 1996, 1999). Because there are so many applications and uses of technical analysis, most technicians have a select few methods that they use. Just as with fundamental analysis, technical analysis requires great discipline. Historical patterns and momentum can be useful to determine future direction; however, the future does not always correspond directly with the past.

## The Random Walk and the Efficient Market Hypothesis

Eugene Fama (1965) instructed that "stock price changes have no memory—the past history of the series cannot be used to predict the future in any meaningful way. The future path of the price level of a security is no more predictable than the path of a series of cumulated random numbers" (p. 56). Thus, the theory of the random walk is another way to look at asset pricing.

Fama (1965) wrote that the "techniques of the chartist have always been surrounded by a certain degree of mysticism" (p. 55). Thus, analysts, Fama argued, would turn to fundamental analysis and the concept of intrinsic value. But he conceded that there could be different estimations of intrinsic value that would affect actual prices, a concept that is at the foundation of behavioral finance. Price movements, then, could be considered random.

Malkiel (1973/2003) and other proponents of the theory of the random walk believe that there is no relationship between past and future price movements. That is, future prices cannot be predicted. "Random walkers claim that the stock market adjusts so quickly and perfectly to new information that amateurs buying at current prices can do just as well as the pros" (p. 175). That suggests that fundamental analysis and technical analysis are of no value in the attempt toward investment success.

The theory of the random walk is related to the castle-in-the-air theory, which was originated by the British economist John Maynard Keynes (1936/1965) in the 1930s and simply emphasized analyzing the behavior of the market. Under this theory, investment decisions should be made in response to what the crowd is going to do. Keynes maintained that if he could identify an investment opportunity before the rest of the market did, he could take advantage of that opportunity when other investors began to see it as well. Castles in the air are representations of "herd mentality," wherein investors purchase assets because they see others doing the same and do not want to be left out. As such, prices continue to increase when there may be no rational reason for it (Malkiel, 1973/2003).

It should be noted that many investors have done quite well building castles in the air. The tulip craze in Holland, the South Sea bubble, the dot-com bubble, and most recently, the housing run in the first decade of this century were such instances where crowd watchers earned significant returns. But eventually, all bubbles burst. The ideal strategy is to buy early, enjoy the price appreciation, and then sell before the bubble bursts because history has shown that after each major market craze, prices almost always stabilize between their normal support and resistance levels.

Malkiel also presented the concept of market efficiency, in the form of the efficient market hypothesis (EMH). EMH proposes that current market prices incorporate and reflect all relevant information about a company or a stock as soon as that information is known. The theory maintains that stocks always trade at a fair value, so fundamental and technical analyses are useless for finding undervalued equities or predicting market trends. It does not claim that a stock's price reflects future financial performance; rather, the stock price is a function of investor reaction to information that has come into the market.

Malkiel (1973/2003) wrote, "Efficient-market theory . . . [is] built on the premise that stock-market investors are rational" (p. 216). However, the recent development of behavioral finance has produced a strong argument for investor irrationality. Malkiel acknowledged that many investors were influenced by psychological biases and thus may make irrational decisions, but he also believed that investors are balanced by rational market participants. In the long term, the market is expected to continue upward. However, short term, market behavior is completely random. "Even if investors are irrational in a similar way, efficient-market theory believers assert that smart rational traders will correct any mispricings that might arise from the presence of irrational traders" (p. 217).

## Behavioral Finance

No one who has ever experienced or observed the capital markets can deny the evidence that psychology is a prominent issue in the pricing of securities. Shefrin (2002) maintained, "Psychology is hard to escape; it touches every corner of the financial landscape, and it's important" (p. 309). The study of the effects that psychological factors have on investment decisions and thus on the financial markets has been termed *behavioral finance.*

Those who ascribe to the tenets of behavioral finance do not reject the foundations of traditional finance, which holds to the theories of Graham and Dodd (1934) and Williams (1938). Further, they do not eschew technical analysis (Nison, 2001; Schannep, 2008; Schwager, 1996, 1999) or even the castles-in-the-air theory of Keynes (1936/1965). However, the field of behavioral finance

does maintain that psychological influences cause prices to deviate from their fundamental values (Shefrin, 2002).

Robert Olsen (1998) suggested that there is increased interest in behavioral finance because of empirical studies that show that traditional theories of finance have become deficient and because of the work of Kahneman and Tversky (1979) in the area of prospect theory. Kahneman and Tversky offered prospect theory as an alternative to expected utility theory as the field tried to understand, and then to explain, the ways in which investors make decisions, as opposed to the way in which the purest view of traditional finance sought to explain it. Traditional finance was, indeed, based on the concept of *homo economicus,* who in Olsen's (1998) view, was a decision maker who had unlimited amounts of information and who was able to process all of that information logically and rationally in the attempt to maximize utility.

Meir Statman (1995) provided a relatively simple distinction between traditional finance and behavioral finance. In the view of behaviorists, traditional finance is based on how human beings should behave, and behavioral finance focuses on how people actually do behave (Baker & Nofsinger, 2002; Barber & Odean, 1999; Curtis, 2004). If, in fact, investors were rational, the bubbles (like the tulip craze in Holland in the 1600s, the escalation of the NASDAQ in the late 1990s, and the housing run-up of the early part of the first decade of the twenty-first century) would not have occurred. The panic of 2008 would not have happened either. However, as Louis Lowenstein (2006) pointed out, investors can strive to be as rational as possible.

Behavioral finance is based on the use of heuristics, which Hubert Fromlet (2001) defined as the use of experience and practical efforts to answer questions or to improve performance. But that raises the question of the differences in the experiences of individual investors and their psychological reactions to those experiences that shape and influence their thinking about opportunities that might be available in the market. In sequence, then, two investors with different experiences and reactions to those experiences might view the same opportunity totally differently because of their biased views. Edgar Peters (2003) instructed that the use of heuristics might outweigh the use of statistics because the speed of investment management has increased because of the Internet.

## Investment Management

Management of an investment portfolio is accomplished by first establishing the investor's objectives.

### Objectives

Understanding the difference between speculation and investment is critical to the way in which potential alternatives for resource allocation are evaluated. Speculation occurs in the very near term and is based on price movements as traders try to take advantage of even the narrowest of spreads between the bid and the ask prices. The analysis is intuitive because the speculators see a price movement and act on it. There is little time, usually, for more thorough analysis in the evaluation process. Investment, on the other hand, is for the long term where price appreciation and dividends matter.

### Investment Decision

Investors adopt a range of strategies, depending on their objectives. Investments can be made in government securities, bearing minimal, if any, risk of default and earning a low rate of interest. Investors could also put resources in certificates of deposit in the local bank, which will be insured by the Federal Deposit Insurance Corporation (FDIC) and which will earn a low rate of interest as well.

A second strategy is to build a diversified portfolio of stocks, bonds, and cash. Depending on the investor's risk tolerance, this portfolio could be weighted more toward bonds than stocks or vice versa. The investor would also determine whether the strategy would be to have a growth portfolio, where price appreciation is the goal, or a value portfolio, which stresses the importance of dividends. On the other hand, Warren Buffett advises that investors should seek out a select group of well-managed companies instead of diversifying as prescribed by Markowitz (1952).

Bonds represent a claim on the issuer's assets and are a contract with the issuer, as opposed to stocks, which represent ownership that is not contractual. The bond contract, called the indenture, states the terms and conditions of the issue, especially the timing and amounts of the interest payments and principal repayments. Generally, for most corporate and government bonds, interest is paid semiannually.

The first step in creating a bond position is to determine the type of bond to be included in the portfolio. Bonds are issued by the federal government, agencies of the federal government, state and local governments, foreign governments, and corporations. Government bonds are backed by the full faith and credit of the United States, which means that there is very little chance of default. Those issued by states and municipalities are supported by the taxing power of the governmental unit issuing them, which also means little or no risk. Or these entities can issue revenue bonds, which are supported by the income that is generated by specific projects. Another option is the acquisition of bonds of foreign governments, which have considerably more risk associated with them.

Corporate bonds are backed by the earning power of the company issuing them, and the decision to include them in the investor's portfolio is generally based on the credit quality of the issue. In most cases involving corporate

bonds, investors choose a credit rating that is at least investment grade, as shown in Table 21.1. The rating of the bond is not the agency's assessment of the overall quality of the company issuing the bonds. Rather, it is the evaluation of the particular bond issue as supported by the company's financial strength, the quality of its management, and its current position in its markets. Bonds with the highest ratings represent the highest creditworthiness of the issuer and will have the lowest interest rate because they have the lowest risk.

Other characteristics of a bond are the coupon rate (the rate of interest that will be paid over the life of the bond); the maturity date when the bond will be redeemed; the call provision, which allows the issuer to redeem the bond prior to maturity; and any conversion provision, which enables the issuer to convert the bond into shares

**Table 21.1** Rating of Corporate Bonds

| *Rating Agency* | | | |
|---|---|---|---|
| *Moody's* | *Duff & Phelps* | *Standard & Poor's* | *Credit Rating Description* |
| | | | **Investment-Grade Bond Ratings** |
| AAA | 1 | AAA | Highest credit rating, maximum safety |
| Aa1 | 2 | AA+ | |
| Aa2 | 3 | AA | |
| Aa3 | 4 | AA– | |
| A1 | 5 | A+ | |
| A2 | 6 | A | Upper medium quality, investment-grade bonds |
| A3 | 7 | A– | |
| Baa1 | 8 | BBB+ | |
| Baa2 | 9 | BBB | Lower medium quality, investment-grade bonds |
| Baa3 | 10 | BBB– | |
| | | | **Speculative-Grade Bond Ratings** |
| Ba1 | 11 | BB+ | Low credit quality, speculative-grade bonds |
| Ba2 | 12 | BB | |
| Ba3 | 13 | BB– | |
| B1 | 14 | B+ | Very low credit rating, speculative-grade bonds |
| B2 | 15 | B | |
| B3 | 16 | B– | |
| | | | **Extremely Speculative Bond Ratings** |
| Caa | 17 | CCC+ | |
| | | CCC | |
| Ca | | CCC– | |
| C | | CC | Extremely speculative |
| | | C | |
| | | D | Bonds in default |

SOURCE: Jordan and Miller (2008, p. 607).

of common stock. Corporate bonds have varying maturity dates and coupon rates and typically have a face value of $1,000.

As with any investment, the potential return can be calculated and then compared against competing assets. The formula for calculating the present value of a bond is

$$V = \sum_{t\ 1}^{n} \frac{CT}{(1+i)^{t}} + \frac{Pn}{(1+i)^{n}},$$

where

*V* = the market value or price of the bond
*n* = the number of periods
*t* = each period
*Ct* = Coupon rate or interest rate for each period
*Pn* = Par value or maturity value
*i* = interest rate in the market

The price of any bond represents the present value of the interest payments over the maturity of the bond and the present value of the par value when the bond matures.

If a bond has a par value of $1,000, pays 6.00% interest for 15 years, and the current interest rate in the market is 8%, what is the value of the bond?

Using present value tables or a financial calculator,

n = 30 (interest on bonds is paid semi-annually)

Pn = $1,000

i = 4%

C = 3.00% (interest is paid semi-annually) or $30

Present value of the bond

$827.08

The first step in the calculation is to compute the interest that the bond will pay. Because interest is paid semiannually, divide the annual rate (6%) by 2. The result is 3%. Taking 3% of the par value of $1,000 yields interest payments of $30 every 6 months. Similarly, the current interest rate in the market is 8%, but that also has to be halved because the calculation is really dealing with 6-month intervals.

So the bond is worth $827.08 today and will provide the investor a steady income stream, but what is the current yield that will allow for comparisons of competing investments to be made?

$$CY = \frac{C}{V}$$

$$CY = \frac{\$30}{\$827.08}$$

$$CY = 3.63\%$$

In this circumstance, the current yield is 3.63%, which allows the investor to compare it to competing alternatives. Using this analysis, developing a bond portion of the portfolio can assist in reducing the amount of risk that the investor assumes in consideration with the objectives that have been set.

Mutual funds are another possible investment for the portfolio, and they, too, must coincide with the investor's objectives. The Investment Company Institute (ICI, 2008) categorized mutual funds as the following:

- Stock funds
- Hybrid funds
- Taxable bond funds
- Municipal bond funds
- Taxable money market funds
- Nontaxable money market funds

In addition, ICI reported that, as of September 2008, these funds held $10.631 trillion of investor assets.

Mutual funds may be open-ended, which means that shares of the fund can be traded at any time. Or funds may be closed-ended, which means that the number of shares in the fund is fixed and can be traded only if the investor can find another investor who wishes to engage in a transaction, either buying into the fund or selling out of it.

In addition to incurring management fees, investors in mutual funds may incur fees for purchasing the fund, called loads; reimbursing the fund for marketing expenses, called 12B-1 fees; and trading within the fund.

The investor can also purchase index funds, which as the name implies, are funds that mirror an index like the S&P 500 or the Wilshire 5000. These funds rise and fall as the index moves up and down and have the same amount of risk as the index. Exchange-traded funds (ETFs) are also available. These are funds that resemble closed-end mutual funds and index funds but can be more specialized. That is, there are numerous ETFs that consist of stocks of companies in a particular country, industry, sector, or commodity.

Another investment alternative is to purchase preferred stock in some of the larger companies being traded on the New York Stock Exchange and on NASDAQ. Preferred stock is a hybrid between common stocks and bonds, with the dividend being senior to the common dividend, but the claim on the company's assets is subordinate to the bondholders and other creditors. Preferred stock represents ownership in the company, but it is nonvoting, which means that the preferred shareholder has no say in the management of the organization, unlike common stockholders.

The final investment alternative in this discussion is common stock, which is traded around the world on various exchanges every day, most notably in the United States on the New York Stock Exchange and on NASDAQ. Common stock represents voting ownership, which means that the common shareholder is consulted

on matters affecting the corporation as a whole, such as merger and acquisition activity, the membership of the board of directors, or the selection of the independent auditing firm.

As was shown in Figure 21.1, common stock represents the most risk of any of the alternatives that have been presented, with the exception of derivatives, and stockholders demand a higher return for taking that risk, called the equity risk premium. The greater the risk of a common stock, the higher the equity risk premium demanded by the investor.

The formula for calculating the return on common stock is as follows:

$$\text{Percentage return} = \text{Capital yield gain} + \text{Dividend yield gain}$$

$$\text{Percentage return} = (Pt + 1 - Pt) / Pt + Dt + 1 / Pt,$$

where
$Pt$ = stock price at the beginning of the year
$Pt + 1$ = stock price at the end of the year
$Dt + 1$ = annual dividend paid on the stock

The purchase price of ABC Corporation was $90 per share. At May 31, the stock was selling for $106 per share. ABC paid a quarterly dividend of $0.75. If the investor had purchased 1,000 shares at $90 per share, what was the total percentage return?

R = (Pt + 1 – Pt) / Pt + Dt + 1/ Pt

R = ($106 - $90) / $90 + $3 / $90

R = $16 / $90 + $3 / $90

R = .1778 + .0333

R = .2111

R = 21.11%

Calculating the historical and expected return allows the investor to compare the stock's performance with the same returns on other investment alternatives so that a more educated decision can be made.

To understand the nature of the volatility involved with securities, there are two types of risk associated with every share of common stock. First, there is the risk of the market, which is called systematic risk. This is the risk that every stock faces, such as interest rate increases and decreases or changes in the money supply. And then, there is unsystematic risk, which is that associated with a specific company. As Markowitz (1952) noted, by diversifying the portfolio with 20 to 30 carefully chosen stocks, that risk can be mitigated and even eliminated if the movements in the stock prices that are in the portfolio are not correlated.

Systematic risk is measured with beta. Stocks with a beta of 1 have just as much risk as the market. Those with a beta of greater than 1 are riskier than the market. That is, if the beta is 2, that stock is twice as risky as the market. Similarly, if the beta is 0.5, the stock is half as risky as the market. Portfolio beta is measured by the weighted-average beta of the entire portfolio, as follows:

$$\beta p = Xa\beta a + Xb\beta b + Xc\beta c + \ldots Xn\beta n,$$

where
$\beta p$ = portfolio beta
$X$ = percentage of assets allocated to each stock
$\beta$ = beta associated with each stock

To measure the actual return on the portfolio, we use Jensen's alpha, which is the return on the portfolio less the expected portfolio return, as follows:

$$\alpha = Rp - \{Rf - [E(Rm) - Rf] \times \beta p\},$$

where
$Rp$ = actual return on the portfolio
$Rf$ = risk-free rate
$E(Rm)$ = expected return on the market
$\beta p$ = weighted average beta of the portfolio

Before the alpha can be computed, a portfolio is constructed according the investor's objectives. If the investor is a risk taker, the portfolio would be directed toward growth and would have a fairly high beta. On the other hand, if the investor is risk averse, a value portfolio would be constructed with beta being 1 or less.

## Recent Changes in Market Behavior

The subject of portfolio theory and investment analysis has taken on new meaning as the United States endured the financial crisis of the latter portion of the first decade of the twenty-first century. In 2007 through 2009, the country experienced a financial collapse that saw the demise of the investment banking industry, unprecedented housing foreclosures, significant job losses, and the drastic decline in the stock market.

The collapse of the nation's financial sector and the unprecedented sell-off in equity markets was partly a function of the speed with which financial information arrived and the creation of sophisticated derivative securities, which added significant volatility to the market (Lewis, 2004). Trading volume soared as the result of computerized institutional trading systems and online trading systems for individuals. The average volume of

stocks listed on the Dow Jones Industrial Average in September and early October 2008 was 7.2 billion shares per day, almost double the amount from the previous January. Not only was there more stock being traded, but the holding period for stocks decreased as well, further adding to volatility. Internet-based financial systems enable individuals to trade quite easily, but 57% of the respondents to a recent survey reported that they conducted no transactions using the Internet during the previous 12 months (ICI, 2008). That result suggests that it is the institutions, such as pension funds, trust companies, banks, and hedge funds, that are driving the volume volatility and potentially the price.

## Conclusion

The purpose of this chapter has been to trace the development of dominant theories of investment management. Investment theory has moved from traditional finance and its emphasis on *homo economicus* to behavioral finance, which brings elements of psychology and emotion into the human decision making associated with balancing risks and returns in financial markets.

Behavioral finance recognizes that biases, emotions, backgrounds, and experiences influence investor decision making. These human traits may skew the ability to make rational and logical resource allocation decisions as theorized in traditional finance. Thus, there is room for the elements of rational study and examination of various investment alternatives prior to making those decisions.

# Externalities and Property Rights

Mahadev Ganapati Bhat
*Florida International University*

The private market is a common economic mechanism for allocating scarce economic resources in an efficient manner. Imagine a situation where all decisions (when, where, how much, and at what price) relating to producing and consuming every good or service in the society are made by government or a group of individuals. Under such a system, one can expect much wastage, time delay, and lack of coordination among decision entities, which would hamper the smooth and efficient delivery of goods and services. In an ideal world, perfectly competitive private markets are means to achieving the most efficient way of making goods and services available to people, of exactly the quantities they need, at prices they can afford, and at a time and place they need.

However, it is rare to find such a perfect competitive market. Many conditions are necessary for the smooth functioning of the private market (McMillan, 2002). They are as follows: (a) Side effects of production and consumption are limited, or there are no *externalities* in production or consumption; (b) there are well-defined *property rights* to resources, products, and production technology; (c) there exists widely available information about buyers, sellers, and products; (d) enforceable private contracts are present; and (e) the conditions of competition exist. More often than not, one or more of the above conditions are violated in private markets, leading to suboptimal market performances, in terms of product quantity, quality, and prices and consumers' and producers' satisfaction. In this chapter, we focus on the first two assumptions of markets: absence of externalities and well-defined property rights. We will first narrate these two concepts and their nuances and then discuss how these concepts are related to one another. Later, we will present the adverse effects on the market system of violating the above two assumptions, as well as regulatory and market means to correct these adverse effects.

## Theory

### Externalities

Many economic decisions that people make in their day-to-day lives have economic consequences beyond themselves. We can find examples wherein certain people may bear costs or gain benefits from the actions or decisions taken by others, even though they had no role in making those decisions. A profit-maximizing entrepreneur normally takes into account only those out-of-pocket costs that she pays for (i.e., the costs of inputs used in the production process) while deciding how much, how, what, and when to produce goods and services. Such costs are called private costs. To increase profits, the entrepreneur always looks for ways and means—via cheaper technology and inputs of production—to keep the production costs low. It makes no economic sense for her to consider any likely costs of this economic decision inflicted on people or entities other than herself or her firm.

For instance, a farmer has to plow his land to maintain proper tilth of the soil and apply chemicals to kill weeds and pests. Excessive plowing of land with poor soil condition causes soil erosion from his land and contaminates downstream water bodies with soil sediments. The deposition of soil sediment may decrease the water storage capacity of the downstream lake and suffocate fish and other aquatic creatures. Residues from chemical application on the farmland may also end up in the lake, making that water body unsuitable for fish. Both of the above

actions on the part of the farmer might mean increased costs of lake water storage and loss of fish production. In the absence of any legal, social, or moral obligation, the farmer upstream has no incentive to reduce soil erosion or chemical application as long those actions bring him economic profits. Nor does the farmer feel responsible for paying for those costs or income losses to downstream water users. Such costs or negative income impacts are called *negative externalities* or *external costs.*

Consider another example. There is a private company selling cell phones to customers. The amount of profit the company makes from this product depends on the price and the number of phones sold in the market. The buyers are looking forward to buying a phone at as cheap a price as possible. The price that any given buyer is willing to pay equals the marginal value that he derives from the phone. This marginal value accounts for only his personal (private) value that he derives from it. Note that there could be other buyers who may have already bought this product. When this buyer makes the purchase, he becomes the newest member of the existing network of cell phone users. Each new user enhances the utility or value of the phones owned by all the existing customers. The larger the number of users of a given product is, the greater the ability of all users is to stay in touch with each others. As in the case of negative externality, this private buyer would consider only his private benefits when he makes his purchasing decision. There is no incentive for him to worry about what others might gain from his decision. The other network members are no part of his decision. The benefits that he brings to all other network members are an example of *positive externality* or *external benefit.*

In both these examples, when a particular economic decision imposes economic costs on, or generates economic benefits to, a third party, the behavior of the decision maker in the market does not include the costs to, or the preferences of, those who are affected. This means that the *private costs* borne or *private benefits* enjoyed by a decision maker are much different (normally lower) from the *true costs* or *true benefits* of that decision. The true costs and true benefits are also called *social costs* and *social benefits,* respectively. The difference between the social costs and private costs are negative externalities (external costs), and the difference between the social benefits and private benefits are positive externalities (external benefits).

### *Definition of Externality*

Now we are ready to define externality in a more precise fashion. According to Baumol and Oates (1988), an externality is an unintentional effect of an economic decision made by persons, corporations, or governments on the consumption or production by an outside party (person, corporation, or government) who is not part of the original decision. It is evident from this definition that externalities can be present in both production and consumption activities. Also, for an externality to exist, there needs to be a direct connection between the parties through real (nonmonetary) variables. Let us revisit the earlier examples of negative and positive externalities. For instance, it is easy to understand that in a production process, the quantity and quality of a good produced is dependent on the quantities of various inputs produced. In addition, there may be external inputs that, although not chosen by this producer but by someone else, may have a negative or positive impact on the production of the subject product. As in the example of negative externality from farmland cultivation, the total fish production in the downstream lake is not only dependent on fishing inputs employed by the lake users. The fish production is also affected, in this case negatively, by the levels of sediments and chemical residues deposited through the water runoff from the upstream farm. Similarly, the consumption utility or value derived by each cell phone user in the network depends on the number of phones purchased by other users.

Another important aspect of the externality that can be ascertained from the above definition is that the spillover or side effect of one person's action on the other is *not deliberate* or is *unintentional.* An economic agent who is responsible for a given externality has no intention of causing harm or doing good to the other party. The original action is undertaken for one's own personal gain (e.g., appropriating profit or income from crop production or enjoying certain utility from using the cell phone). The negative or positive spillover effect of such action is strictly unintentional.

Suppose that you are sitting in a room or a restaurant next to a person who is smoking. You may feel uncomfortable with the smell or aesthetic of the smoke. You may also develop a health problem if you are exposed to that smoke over a long time. As long as smoking is allowed in the room, the smoker is engaged in a legally acceptable activity. However, the secondhand-smoke effect inflicted on you is a negative externality. There is physical connection between the smoker and you. On the other hand, let us say every time when you sit near that smoker, he turns around and deliberately blows a puff of smoke right on your face. The effect of this action may be the same as in the first case. This deliberate action, however, would not constitute an externality because it is unintentional. Instead, we would call this behavior a nuisance or even a crime if that person does it every time he sees you.

The above definition covers a specific type of externality. These are external effects that fail to transmit through the market system in the form of prices. When a producer does not account for the external costs she inflicts on a third party, the price that she is willing to accept does not reflect the social costs of production but only her private costs of production. The market prices of such products will be cheaper than otherwise. This is because *no* private market contract exists between this producer and those affected by external effects that would have required the producer to pay for such external costs. This applies to our

cell phone market example also. When a new buyer buys a cell phone, he enhances the value of phones in use for all the existing network users. The seller does not have any ability to go back to the existing customers and to ask for a cut in the additional value accrued to each of them. The seller normally may increase the price on future cell phones sales, knowing that her product is more valuable to customers than before.

In both the examples above, the externalities are caused by real variables (e.g., sediments or phone), the economic (monetary) effects of which fail to transmit through the market process. In the case of negative externality, the full economic effects (costs) of production do not reach the intended buyers (i.e., consumers of farm products) in the market. Instead, a portion of the total costs (i.e., off-farm pollution effect) is felt by a third party (i.e., lake users). Such externalities are called technological or *nonpecuniary externalities*. In economics, the inability of the market to capture the full social costs and social benefits, therefore sending the right price signal to producers and consumers of a given commodity, is referred to as *market failure.*

The following modified definition of externality (Lesser, Dodds, & Zerbe, 1997) captures the essence of the above discussion. A technological externality is *an unintended side effect of one or more parties' actions on the utility or production possibilities of one or more other parties, and there is no contract between the parties or price system governing the impact.*

The above definition excludes economic side effects that manifest through market prices. For instance, a city municipal government builds a landfill in one of its neighborhoods. The noise and the ugly look of trucks carrying the city solid wastes daily around the landfill disturb the residents. The foul smell from the landfill may become a constant reminder of the landfill's presence. Those homeowners who can afford to buy houses in better neighborhoods elsewhere may want to sell their homes. As more and more homes start appearing in the market and new buyers may not prefer to purchase a house near the landfill, the home prices in the area will decline. This loss of home value is certainly an unintended economic side effect caused by the city's decision to build the landfill. However, this effect is carried through the housing market price. Such external effects are referred to as *pecuniary externalities.* While some people may argue that the loss in the property value is unethical or an injustice, this loss does not represent a *market failure* problem. In fact, in this case, the housing market seems to have done its job. That is, the market accurately has reflected the lower preference that the new buyers have for homes near the landfill, or that the buyers are willing to pay lower prices.

### *Effects of Externality*

As hinted earlier, the presence of externalities causes a private market to fail. When all the conditions of a perfectly competitive private market are fulfilled, the market is assumed to deliver most efficient results. Profit-maximizing producers allocate their scarce resources in a most efficient fashion. That is, the total quantity of their output meets the condition of marginality: The marginal benefit (i.e., the market price in the case of perfect competition) is exactly equal to the marginal costs of production. Similarly, the amount that consumers are willing to pay (the marginal willingness to pay) balances with the market price offered to them at the margin. This is the market equilibrium level. At such point, the market equilibrates in the sense that the producers' marginal costs of production are identical to consumers' marginal willingness to pay (marginal benefit), which is further equal to the market price. At this point, the combined net surplus of producers and consumers is maximized. Both producers and consumers are assumed to have made their resource allocation decisions in a most efficient fashion. This point of market equilibrium is therefore called *socially efficient* equilibrium.

The above market outcome is based on certain assumptions. The marginal costs of producers (i.e., supply curve) must represent the total or social costs of production. The marginal willingness to pay of consumers (i.e., market demand curve) must represent the total benefit that they derive. That is, the market supply curve should have taken into account both private costs (representing the opportunity costs of all production inputs and the production technology used) and all the potential external costs. On the other hand, the market demand curve should reflect consumers' private benefits (their own preference and taste) and the external benefits. As we discussed earlier, if there exist external costs and benefits, the private market is not going to capture these additional effects. The resulting market outcome (equilibrium quantity and price) does not reflect the social (full) costs and benefits either. It only captures the private costs and benefits and therefore can only be viewed as a *private market efficient* equilibrium.

Going back to the problem of agricultural runoff, let us assume that the private farmer faces a downward-sloping market demand, $D$ (Figure 22.1[a]). The demand curve represents the aggregate marginal willingness to pay of all consumers in the market, *MWTP.* The farmer has a marginal private cost function (supply curve), *MPC.* Assume that every unit of agricultural output imposes certain marginal external costs, *MEC*, on the lake users. Thus, the agricultural production comes at marginal social costs, *MSC*, to society. Note that

$$MSC = MPC + MEC.$$

In the private market, where she has no obligation to consider the external costs, the farmer produces $Q_m$ units of output at a unit price of $P_m$ (i.e., at a point where $MPC = MWTP$). This is efficient only from the view of the private producer, and therefore we call this level private market efficient equilibrium ($Q_m$, $P_m$).

The above equilibrium, however, is not socially efficient because the underlying cost function does not include the external costs. The socially efficient equilibrium ($Q_*$, $P_*$) should occur at a point where $MSC = MWTP$. It is interesting to note two points here. The socially efficient equilibrium quantity is lower than the private market efficient equilibrium quantity. Also, the socially efficient equilibrium price is higher than the private market efficient equilibrium price. The private market oversupplies the good. That is, $Q_m > Q_*$ and $P_m < P_*$. A production in excess of socially efficient production means larger pollution loading downstream. Because the external costs are left out of the producers' cost equation, consumers will enjoy a lower market price.

Now, consider the cell phone example that involves external benefit. Assume that the cell phone company faces a supply or marginal private cost function, *MPC* (Figure 22.1[b]). We assume that there is no external cost resulting from the phone production. All cell phone users face a combined private marginal willingness-to-pay curve, $MWTP_p$. That is, this relationship includes only the private benefit portion of all network users. We know that the each user (or phone) adds certain external value to all customers, $MWTP_e$. Thus, the (total) social marginal willingness to pay of each additional cell phone is $MWTP_s$:

$$MWTP_s = MWTP_p + MWTP_e.$$

We can see that in this case, the private market produces only $Q_m$ at a private market equilibrium price of $P_m$. However, because of the presence of external benefits, the socially efficient market equilibrium occurs at $Q_*$ and $P_*$. Note that, unlike in the case of external costs, when there are external benefits, the market underproduces goods and services (i.e., $Q_m < Q_*$). Because the consumers' true preference or value is not fully revealed in the marketplace, the private market equilibrium price is lower than the socially efficient equilibrium price (i.e., $P_m < P_*$). One might argue here that consumers are better off with lower market price. That is true; however, the network as a whole will end up getting a smaller number of cell phones than what is socially optimal if the producer is not in a position to capture the full value of each marginal phone supplied in the market. This is particularly a problem in a special class of market goods, called *public goods,* which we will discuss later.

### *Causes of Externality*

The question that naturally arises is why externalities exist in the market. In the previous examples, we see that the producer has no incentive to compensate the victims of downstream externalities, nor do cell phone consumers have an incentive to pay for the external benefits they enjoy from each additional network user. In other words, the economic decision makers in each case have no incentive to *internalize* the external costs or benefits. The two most fundamental reasons of externalities are (a) nonexclusivity and (b) high transaction costs.

First, externalities are often associated with nonexclusion or nonexclusivity characteristic of a resource or an economic asset. Consider again the example of our upstream–downstream agricultural pollution problem discussed earlier. There are no legal, social, or technological barriers that prevent the farmer from loading sediment and chemicals into the downstream lake. That is, the farmer has

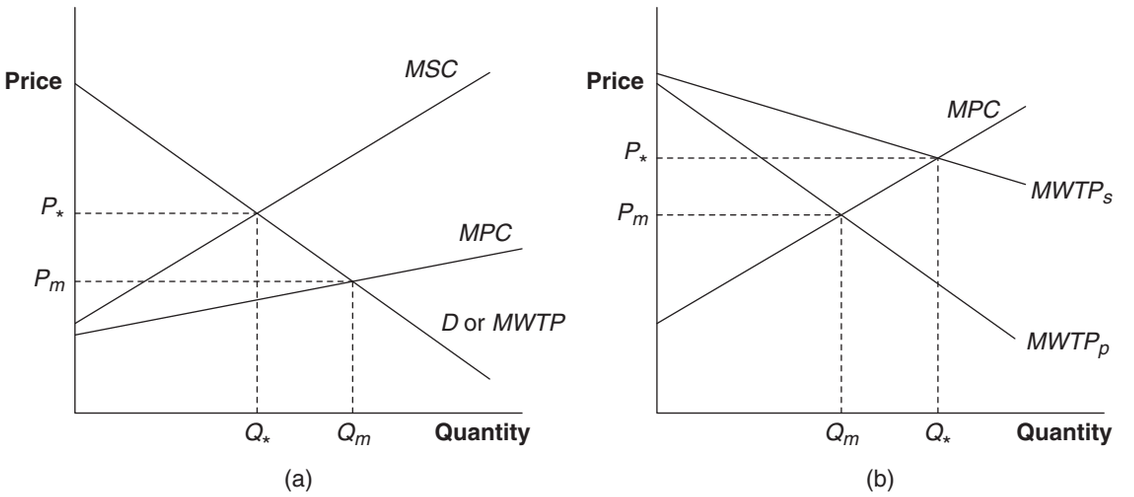

**Figure 22.1** Private and Socially Efficient Market Equilibria: (a) The Case of Negative Externalities; (b) The Case of Positive Externalities

uncontrolled access to the lake. Under the existing legal or social norm, the lake users cannot exclude (nonexclusivity feature) the farmer from dumping pollutants into the lake. The ownership of the lake is not clearly defined. Similarly, in the case of the cell phone example, as each new buyer enters the market, the existing customers benefit from the additional network sociability or social interaction. There is nothing in the marketplace that prevents the existing customers from enjoying that extra benefit unless the phone company decides to switch off their connectivity. However, such practice might be too costly for the phone company. Again, this is a case of nonexclusivity.

This brings us to the second condition of efficient markets, mentioned in the beginning of the chapter: *well-defined property rights.* The degree to which the users of a resource or property can exclude others depends on the nature of *property rights.* The right to own and use a property, including the right to exclude others from using it, influences whether and how much the external costs and benefits are internalized and transmitted through the market price. In the next subsection, we will explore the role and significance of property rights in more detail. At this point, it is enough to note that one of the reasons the lake users are forced to bear the burden of the negative externality is that they lack a well-defined property right to the lake and, therefore, lack the right to exclude upstream farmers from dumping pollutants to the lake.

The second reason externalities exist is the high *transaction* costs. According to Arrow (1969), transaction costs are *the costs of running the economic system.* Even when the right of exclusion exists, the property owners may not be able to exercise that right due to high costs of transaction. The transaction costs include the costs of gathering necessary information, costs of reaching an agreement with the other decision makers in the market with regard to one's right, and the costs of enforcing such agreement. For instance, in the case of lake users, the costs of proving that the pollution loading originates from the upstream farmer may be high. This is especially true if the pollution problem is not from just one particular farmland (a point source pollution) and, instead, from a large number of farm lands (a non–point source pollution). There are additional costs of reaching a private agreement with the upstream farmers and making sure that they bear the full costs of the pollution or take action to abate pollution. Basically, the transaction costs are the costs of exclusion. The lack of, or ill-defined, legal right to exclude upstream farmers means that the downstream lake users have high transaction costs of exclusion. These costs may be too high for downstream users to try enforcing their right against upstream farmers.

The amount of transaction costs depends on the technical and physical nature of the externality and the number of parties involved in a given market transaction. In many cases involving negative or positive externalities, there may be technical or physical barriers in reaching an agreement. Certain pollution may be hard to detect with the available technology for measurement. The external costs of such pollution may not show up in the short term but only in a distant future. A precise estimation of such costs is often difficult. External benefits may pose similar problem. Putting a value on the network-wide aggregate incremental benefit is not easy in the case of the cell phone example. Obviously, the larger the number of parties involved on either side of a market transaction, the higher the transaction costs of gathering information, reaching the agreement, and enforcing the agreement.

Whether a producer who is responsible for certain external costs is willing to bear or *internalize* the externality depends on whether she is able to transfer that extra cost on to her consumers. For her to do so, the market price that the consumers are willing to pay must be higher than the private costs of producing the good and the external costs. If the market price is not high enough to cover both the private costs and external costs, the producer has no option but to ignore the latter, which she can easily do because she enjoys nonexclusive access to the downstream environment. Thus, the externality comes into existence when the costs of internalization exceed the gains from internalization.

## Property Rights

According to Demsetz (1967), property rights are an instrument of society that accords rights to an individual to own, use, dispose, sell, and responsibly manage certain property or economic assets. These rights may be expressed through laws, social customs, and mores. The rights give its owner an uncontested privilege to appropriate benefits from the designated property or asset. The rights also protect the owner from other individuals of the society from encroaching on this asset. The bundle of rights normally comes with certain responsibility so that the owner may not put the property to legally and morally unacceptable uses.

A clearly defined property right lends its owner the ability to appropriate full benefit from its use or management. For a private market to operate efficiently, this is a key requirement. When a producer makes his decision to invest in factors of production (land, labor, and capital), he forms an expectation that he gets the full reward for his effort. One of the necessary conditions that make this possible is that he possesses full rights to all the factors and the final product until he decides to dispose his right to that product in the marketplace for a due compensation (i.e., a reasonable market price). Such a guarantee of right gives the owner an incentive to invest in the asset, manage it in a most efficient fashion, and dispose of it only when he thinks it is the best time. Therefore, the conventional economic wisdom holds that privately owned resources are put to most efficient uses. If all privately held scarce resources are used efficiently, the society as a whole benefits from that process as well.

In order for property rights to serve their function well in the market, the following requirements must be met:

Property rights must be *well defined.* There should be no ambiguity as to who owns a given economic asset. The clear identification of ownership gives its owner a right to make decisions relating to the asset's growth, maintenance, use, and disposal. The ownership can be *private, communal,* or *state.* A private owner may be an individual or a firm. The car you legally own is an example of private property rights. The farmland owned by the farmer is another example of private property rights. A patent right owned by a private firm to a certain technological innovation or product is also a private property right. A communal ownership is normally a group of owners, each member of which will have certain use and access rights and responsibilities. Communal ownerships are common among traditional societies in the case of forests, grazing land, water, rivers, and other natural resources. A state ownership puts the resource or asset in the control of a government agency. The state may own and use the resource exclusively or may share a portion of the rights with its constituents or citizens. For instance, a national park in the United States is owned by the U.S. government and managed by the National Park Service. The parks' certain uses (recreation, research, or mining in the park) may be open to the general public, subject to certain rules and regulations.

Property rights must *exclusive.* The owner of the property rights must be able to exclude others from using it. This exclusivity lends the owner an ability to enjoy the full benefit from it and be able to recover the entire costs of operating it. As discussed in the earlier sections, exclusivity also prevents an external individual from causing harm to the owner (i.e., externality).

Property rights must be *enforceable.* There must be clear legal or social guidelines as to how the society deals with a violation of one's property rights. If somebody encroaches upon the farmland, the farmer must be able to bring the violator to justice, meaning that the latter is evicted from the property and made to pay the cost of evictions and any economic damage associated with the encroachment.

Property rights must be *transferable.* The owner must be able to dispose the property whenever he wants and at a price that he can reasonably get from the market, without much restrictions. If the property is divisible and the owner can dispose any portion of it as needed, such property right represents full transferability. The owner can more effectively manage his or her resource.

### *The Case of Weak Property Rights: Open-Access Resources and Public Goods*

We will find many instances in the market system where economic resources do not operate under strict private property ownerships. In fact, we already have introduced several examples of these resources. When the property rights are ill defined, weak, or absent, multiple users will claim ownership or access rights to such resources. For instance, both upstream farmer (though unintentionally) and downstream lake users can access the lake and have competing uses for the same. Cell phone network users can enjoy the additional benefits generated by each additional phone buyer. The network provides a certain value component (increased sociability) that is open to all users to enjoy without excludability. Thus, when the property rights cannot be assigned or defined, the problem of nonexcludability arises. As we said earlier, nonexclusivity is one of the determinants of externality and market failure.

Two types of natural and economic resources and services suffer the problem of nonexcludability: *open-access resources* and *public goods.* These two resource types differ in the way their users interact with each other. We will discuss each of these resource types individually and the unique problems they pose for their owners and society in general.

An open-access resource is that resource to which users have uncontrolled access, leading to competition among users. That is, the consumption or extraction of the resource by one user reduces the quantity available for others. Thus, the resource is *divisible* and *subtractable.* In other words, you will find *rivalry* among its users. Thus, open-access resources are nonexclusive, rivalrous in nature. Fishery resources in open international waters are a good example of open-access resources. You may not find many strictly open-access resources today. A large number of resources are placed under government or community control. However, for all practical purposes, their users may have open and unlimited access to them. Such resources do suffer to some degree the problem of nonexclusivity and competition among users. Grazing lands, rivers, government forests, fishing grounds, national highways, and public parks are some examples.

Users of an open-access resource basically lack incentives to exercise caution or restraint in its use. Because other users cannot be excluded, a given user trying to conserve or enhance the resource may not realize the full benefit of his action. Therefore, the common motive you observe among the users of open-access resources are "use the resource while it lasts," "grab the resource as quickly as you can," and "grab as much of the resource as you can." Such competitive behavior will lead to overexploitation of the resource. This overexploitation problem is what Hardin's (1968) famous expression, the "tragedy of the commons," refers to. Each user will try to maximize his or her own self-interest (i.e., to the point where the private gains from the additional unit are equal to the private costs of the additional unit). In this process, each user may negatively affect the productivity of the resource or costs of extraction of the resource for all other users. The impact of each user's action on oneself may be insignificant, but the

effect of one user's action on all users combined could be quite substantial. In Hardin's words, the "freedom in a commons brings ruin to all."

To illustrate the above problem, let us consider a common-pool ground water aquifer. Farmers who own land on the ground directly above the aquifer can easily access the aquifer and extract water. Because it is accessible by only those who own land above it, the aquifer is normally considered as a common-pool resource (i.e., a resource owned by a definite community of people) and is not strictly an open-access resource. However, those land owners will have uncontrolled freedom of access to it and therefore could construct as many wells as they need.

Suppose that each well can serve two acres of land and generate a total gross return of $1,000, net of all other but the pumping cost. The cost of pumping is an increasing function of the pumping depth, which in turn is an increasing function of the number of wells on the aquifer. That is, as the number of wells increases and more water is withdrawn, the water table goes down and the pumping lift and the cost increase. See Table 22.1 for the costs of pumping per well. Looking at the net revenue column, you will see that the net revenue per well gradually declines and reaches zero when the number of wells is 60. The aggregate net revenue from all operating wells combined, though, is maximized at 30. This level can be considered the socially efficient level of extraction ($Q_*$). However, because the landowners have uncontrolled access to the aquifer, their tendency is to dig wells as long as each additional well brings a positive net profit (i.e., 60 in this example). This level can be considered the private market solution ($Q_m$). Note at the market equilibrium level, the aggregate profit earned from the resource is zero, an indication of most inefficient economic overexploitation.

Now we will turn to the case of public goods. Like open-access resources, *public goods* also suffer a nonexcludability problem. The difference is that there is no rivalry among the users of public goods. The same quantity of the good made available to one person is automatically available to all users. That is, users jointly consume or enjoy the good. This refers to the *indivisibility* quality of the good. In the words of economist Paul Samuelson (1954), "Each individual's consumption of such a good leads to no subtractions from any other individual's consumption of that good" (p. 387). Common examples of public goods are clean air, open landscape, biodiversity, public education, national security, a lighthouse along the beach that the mariners use, flood protection services, and ecological services. The word *public* here means that it is available to all users (the public) at the same time and at the same quantity.

There can be privately provided public goods. For instance, radio signals or network television services provided by private companies are also public goods, although they are paid for by private companies. Who (private or public entity) pays for a good does not make it a "public good," but that it is made available for the general public in lump sum does.

An important feature of public goods is that they possess a large degree of external benefits. A few mariners may decide to invest in building a lighthouse so that they can safely navigate around the coast. However, this lighthouse can be easily used by those mariners who may have not paid for it. Thus, the efforts of those invested in the lighthouse are yielding external benefits to noninvestors also. The nonexclusivity problem makes it difficult for the original investors to recover compensation from the noninvestors. The costs of excluding the latter may be exorbitant.

The nonexcludability (lack of property rights) and the presence of external benefits pose a unique problem in the case of public goods: the problem of *free riding.* Free riding refers to enjoying the benefits of others' efforts without paying for them. Once a public good or service is provided, users have no incentive to contribute toward the cost of the service. In a private market, you may not be able to find a sufficient number of buyers who can pay enough to make such services or goods available at socially efficient levels—that is, the problem of undersupply as discussed in the case of positive externality (Figure 22.1[b]), $Q_m < Q_*$. Again, this is another case of market failure, caused by the presence of weak property rights and positive externalities.

**Table 22.1** Income and Costs From an Open-Access Groundwater Aquifer

| *Number of Wells* | *Revenue per Well ($)* | *Pumping Costs per Well ($)* | *Net Revenue per Well ($)* | *Total Net Revenue From the Aquifer ($)* |
|---|---|---|---|---|

| 20 | 1,000 | 200 | 800 | 16,000 |
| 30 | 1,000 | 400 | 600 | 18,000 |
| 40 | 1,000 | 600 | 400 | 16,000 |
| 50 | 1,000 | 800 | 200 | 10,000 |
| 60 | 1,000 | 1,000 | 0 | 0 |

## Policy Implications

The presence of externality and ill-defined property rights lead to market inefficiency (i.e., either undersupply or oversupply of certain goods and services). There are several policy options for correcting this problem. These policy options fall under two broad categories: property right solutions and government interventions.

### Property Rights Solutions

We had argued that one of the reasons for the presence of externalities was the absence of well-defined property rights and the attendant nonexclusivity. So to resolve the externality problem, economists suggest that we directly target the weak property rights. This approach is a private market solution or property right method. Nobel laureate economist Ronald Coase (1960) articulated this approach, which is now popularly known as the Coase Theorem. The essence of the theorem is simple: If a clear property right over an environmental asset involving externality is specified, a negotiation between the two private parties (originator and the victims of the externality) will emerge and eliminate the externality. Irrespective of who originally has the property right over the environmental asset, a private market for trading the externality will evolve.

With the lake example, the private right over the lake may be given to either the upstream farmer or downstream lake users. If the farmer has the right, it makes sense for the lake users to enter an agreement with the farmer to have her cut back the pollution. Lake users will have to compensate the farmer toward the pollution control costs. This of course is based on the assumption that such monetary compensation is lower than the gains from the avoided damage to the lake via pollution control. Similarly, if the lake users have the property right, the farmer will have to pay suitable compensation to the lake users to accept a certain amount of pollution and associated damage. Thus, in either case, a more efficient private market outcome will result, with reduced pollution and lower external costs. What is happening here is that the clearly defined property right forces the parties involved to *internalize* the externality.

The above market solution will work only under certain conditions (Field & Field, 2009). The transaction costs of establishing and enforcing the market agreement between the parties must be reasonably low. A higher transaction cost might discourage either party from entering into an agreement. If the number of parties involved is large or it is too hard to prove the pollution damage impacts, the transaction cost is normally high. With a large number of parties involved, there is also a possibility of a free-rider problem. Furthermore, for technical, social, and political reasons, in some cases it may be hard to establish clear property rights.

Political scientist Elinor Ostrom (1990), who received a Nobel Prize in economics in 2009, argues that communal property rights can also eliminate overexploitation and reciprocal externality in the case of open-access resources. The *Ejidos* system of community forest management system in Mexico is a good example of a communal property right system. Almost 8% of the country's forest lands are owned and managed by community organizations. Rules of access and profit sharing are formed and enforced by the communal body and recognized by the government. Community-managed *sacred groves* found in other countries serve a similar role but on a more informal basis. A similar group or community approach is possible in the case of public goods. For instance, home owners form an association or club to manage common facilities in their residential area (e.g., playgrounds, recreational facilities, lake). Homeowners will then be required to pay for these common services with a monthly fee or on a pay-per-use basis. Such public goods and services now become *club goods*.

Finally, government may take open-access resources into its control and place full or partial restrictions on access and use rights. The goal here is to eliminate competition among users and possible externality imposed on each while consuming the resource. In the case of public goods, in the overall interest of the society, the government may bear the full cost of supply and operation instead of relying on private markets. National defense, public radio and television services, and public education are some examples of this approach.

#### *Government Interventions*

Privatizing open-access resources and government provision of public goods may not work effectively in all situations. We saw a number of reasons why it may be hard to establish property rights over resources and thereby internalize externalities. In those cases, the government can directly intervene into private markets using a variety of policy instruments, to influence the production and consumption behavior of economic agents. There are two types of government interventions: command-and-control policies and market-based policies.

The command-and-control policies will impose legal restrictions on producers' and consumers' behavior. Formal legislation may be enacted by local, state, and federal governments specifying whether and how much pollution is allowed. Private factories spitting smoke into the atmosphere and discharging waste into water bodies may be asked to install certain pollution abatement devices at their site. These are called *technology standards.* Or, the government may set a maximum limit or performance standard on the quantity of emissions leaving their plants during each time period, which may be achieved through any means of the polluters' choice. These are called *emission standards.* In the case of open-access resources such

as fisheries, ground water aquifers, and forests, the government may put legal restrictions on quantity extracted, timing of extraction, and nature of extractions. Automobile owners may be required to install certain emission control devices on their cars. These command-and-control policies require proper enforcement mechanisms, including provisions for a penalty on those who fail to comply with the law. This approach is justified on the *polluter pay principle* and is viewed as a fair approach by many, including environmentalists. While this method is easy to administer from the government agency point of view, it may work out to be a more expensive way of internalizing externalities.

Market-based approaches to internalizing externalities may overcome some of the limitations of command-and-control approaches. Again, there are several options: taxes, subsidies, and tradable permits. These approaches give economic agents higher decision flexibility, make them weigh the costs of creating an externality (e.g., an emission tax) and the costs of not doing so (e.g., emission abatement), and help them choose the most cost-effective means of internalizing the externality. Under taxes, producers responsible for a certain externality will be required to either pay a tax on every unit of pollution (emission tax) or production output (output tax) causing that externality or invest money in pollution control. Under this policy, the producer will have internalized the externality either by lowering the emission and therefore bearing the costs of abatement or by paying taxes on uncontrolled emission, which may be used to compensate the victims. A subsidy is another approach whereby government will encourage socially desirable behavior (pollution control or reduced resource harvesting) among private economic agents.

Tradable emission permits and harvest quotas are more recent and innovative market approaches that create private rights over emission or resource consumption. The popular cap-and-trade system for greenhouse emissions or sulfur dioxide emission is an example of this policy. Under this policy, each polluting firm will have a certain number of permits, each permit being equal to the right to emit a unit of pollutant. The firm can use all the allotted permits, save some and sell the unused permits in the market, or purchase some permits from other permit holders. Each firm will compare its own marginal costs of abatement with the market price of the permit. Those firms whose marginal costs of abatement are higher than the permit price can save money by purchasing permits in the market and, therefore, by not having to lower the emission as much. On the other hand, firms whose marginal costs of abatement are lower than the permit price can make a profit by lowering their emissions and by selling the unused permits at a price that is higher than their marginal abatement costs. After trading, all the firms in the market (buyers and sellers of the permits) will have adjusted their respective emission levels such that their marginal abatement costs are made equal to the permit price and, therefore, are balanced across all sources. This phenomenon is called the *principle of equimarginal costs.* In this process, the permit trading system will have moved the emission control responsibility in the market from high-cost (less cost-efficient) firms to low-cost (more cost-efficient) firms. As a result, the overall costs of emission control (i.e., costs of internalizing the externality) will be minimal.

Individual transferable quota programs for fisheries and water trading between urban and agricultural water users are other examples that fall under this category. A long-term advantage of this policy approach is that the economic agents will have an incentive for technological innovation. The permit or right system induces them to invest in innovative and cost-effective means of pollution control or harvest methods. Those who innovate find that they do not require all the allowed permits and rights and can sell the unused ones in the market for a price.

## Conclusion

In this chapter, we learned that the presence of externalities and weak property rights renders private markets inefficient. When economic agents cause negative externalities, the market will produce above what is socially optimal or efficient, leading to wastage of production resources, excessive output, and undesirable external impacts. Negative externalities associated with production or consumption will go unpriced in the market. On the other hand, in the case of positive externalities, the market will underproduce because consumers may not pay for the external benefits created as a result of someone else's action.

Externalities and property rights are related concepts. The primary reasons for externalities are nonexclusion and high transaction costs. Nonexclusion arises from weak or absent private property rights over resources or market services. Open-access resources and public goods are two common examples where weak property rights prevail and externalities emerge.

The presence of externalities and weak property rights calls for government intervention. One approach is to fix the weak property rights, which of course may not be possible in all cases. Properly defined property rights will force private agents to internalize externalities, moderate their consumption and production levels, remove undesirable conflict among users (open-access resources), and eliminate free-riding incentives (public goods). Direct government intervention, with different degrees, is another popular means to correcting externalities. No one size fits all.

# Public Choice

Peter T. Calcagno
*College of Charleston*

Public choice economics is the intersection of economics and politics. It uses the tools of economics to examine collective decisions. Public choice economics reflects three main elements: (1) methodological individualism, in which decision making occurs only with individuals; (2) rational choice, in which individuals make decisions by weighing the costs and benefits and choosing the action with the greatest net benefit; and (3) political exchange, in which political markets operate like private markets, with individuals making exchanges that are mutually beneficial (Buchanan, 2003). It is this last element that makes public choice a distinct field of economics.

Using the basic tools and assumptions of economics on collective decisions provides many insights. Economists assume that individuals are rationally self-interested in private decision making. However, this assumption is not always applied to the realm of collective decision making. In fact, for the first half of the twentieth century, it was argued that collective choices are made based on what is best for society. This view is referred to as *public interest theory*. Early public choice scholars called this dichotomy of behavior into question, arguing that individuals are rationally self-interested regardless of which sector they operate in. The public interest theory does not allow for someone operating in the public sector to make decisions based on what would benefit solely him or her. However, the public choice theory, properly understood, does acknowledge that when an actor in the public sector acts in his or her own self-interest, it may be consistent with the public's interest. In this regard, the public choice view is a more encompassing theory.

Assuming that individuals are rationally self-interested and applying the laws of supply and demand provides a unique understanding of political decision making. (For the purposes of this chapter, the terms political and collective decision making are used interchangeably.) Voters can be thought of as demanders or consumers of public policy; as such, they are concerned with having policies enacted that will benefit them. Politicians act as suppliers of public policy. Just as businesses in the private sector compete for consumers, politicians compete for voters. If businesses want to maximize profits, then politicians want to maximize votes. Unlike in private markets, public sector decision making has a third party involved in the decision making process: bureaucrats or civil servants. These are the individuals who run government and carry out the public sector choices and policies on a day-to-day basis. Bureaucrats are not elected, which means they do not directly serve a group of constituents. The public choice view of bureaucrats is that they maximize power, prestige, and perks associated with operating that bureau. To accomplish this goal, bureaus maximize their budgets.

Public choice theory provides a way to evaluate collective decision making that not only allows for positive analysis but also addresses some of the normative issues associated with policy making. The rest of the chapter provides an overview of the origins of public choice theory and the contributions it has made to the discipline of economics.

## Origins of Public Choice

Public choice economics emerged from public finance, which is the analysis of government revenues and expenditures. According to James Buchanan (2003), it was

evident by the end of World War II and the early 1950s that economists did not have a good understanding of public sector processes. Economists began to realize that the naive public interest view did not reconcile with the reality of politics. Buchanan made his first endeavor into this issue in 1949. Around that same time, two other scholars began to examine a similar question. Duncan Black (1948) began examining the decision-making process of majority voting in committee settings. Kenneth Arrow (1951) was examining whether choices of the individual could be aggregated to create an overall social ordering of preferences. Arrow concluded in what is now known as his *impossibility theorem* that it is not possible to aggregate preferences to develop a social welfare function. The only way the preferences of individuals could be consistent with those of society is if a dictatorship existed and the preferences of society were those of the dictator's. Arrow's theoretical contributions served to inspire public choice theorists, but his contributions formally developed into what is now known as *social choice theory.* Social choice theory is focused on the concern of social welfare and the public's interest. It examines how collective decisions can be made to maximize the well-being of society. Further analysis of social choice theory is beyond the scope of this chapter (see Arrow, Sen, & Suzumura, 2002, for more on social choice).

Public choice theory was developed primarily on the work of Buchanan, who was awarded the Nobel Prize in Economics in 1986. Buchanan was inspired by Swedish economist Knut Wicksell, who can be considered a precursor to public choice theory. Wicksell's focus on the role of institutions led Buchanan and Gordon Tullock (1962) to write *The Calculus of Consent: Logical Foundations of Constitutional Democracy.* This seminal work is considered the origin of the public choice revolution (Gwartney & Wagner, 1988).

The public choice revolution that began in 1962 with *The Calculus of Consent* called into question not only how political decisions are made but also the role of government in the private sector. Prior to the development of public choice theory, many economists argued that there are instances when private markets will fail to allocate resources efficiently: externalities, public goods, and monopolies. The conventional view was that government intervention could improve the allocative efficiency through taxes, government production, or regulation of the market. Public sector officials were thought to make decisions based on the public's interest and the improvement of the overall welfare of society. However, this view is at odds with the economic and political reality of public sector outcomes. While most economists do not favor policies such as price controls, tariffs, and regulatory barriers that impede competition, these types of policies are common public sector outcomes. More specifically, public choice economists started asking why, if government intervention is the means to correct market failure, does government enact policies that often increase economic inefficiency. Public choice's concept of all individuals acting in rational self-interest provided an answer to this question. It reminded us that government is not an entity that is seeking social welfare but is merely a set of rules under which decisions are made. While self-interest leads individuals to socially enhancing outcomes, via Adam Smith's invisible hand, these same motivations under government institutions can actually create outcomes that are not beneficial to society. The conclusion that emerges from this field of economics is that if one is to acknowledge that market failure exists, one must recognize that government failure exists.

## Voting in a Direct Democracy

The issue of voting and majority rule was at the forefront of the development of public choice theory, and it is still the subject of much of the literature written today. The numerous aspects of voting addressed by public choice scholars are too vast for this chapter; therefore, the focus is on the seminal work in this area.

### Majority Voting Cycles

Beginning with the work of Black (1948) and Arrow (1951), the idea emerged that if preferences are not single peaked when individuals vote for two candidates, referendums, or policies, majority voting can result in a cyclical voting pattern. This concept can be illustrated with Table 23.1. Three voters, Gordon, James, and Anthony, are represented across the top of the table, with each voter's ranking of preferences represented by the order in the column. Thus, column 1 shows that Gordon ranks his preferences as A, B, and C. Similarly, columns 2 and 3 show the preferences of the other two voters. Based on the preferences of these three individuals, there is no decisive winner when these options are voted on in pairs. Option A paired with B will result in A winning. Option B will defeat Option C, and similarly, Option C will defeat Option A. The outcome will be determined by the number of elections that will occur and in what combination the options are paired. There is not a single option that wins the majority of votes. Two further concepts regarding voting, developed in light of voting cycles, are the median voter model and agenda manipulation.

#### *Median Voter Model*

The median voter model arises out of the need to assume single-peaked preferences. Single-peaked preferences exist when voters prefer one option above all other options. If single-peaked preferences exist, then cycling is no longer a concern. In addition, the option must be a single-dimensional issue, for example, measuring government expenditures from left (less) to right (more) on an x-axis. With these assumptions, a majority rule will lead to the median voter's position always winning. The median

**Table 23.1** Preference Analysis for Three Voters

| *Gordon's Preference Ordering* | *James's Preference Ordering* | *Anthony's Preference Ordering* |
|---|---|---|
| A | B | C |
| B | C | A |
| C | A | B |

voter model has several applications for evaluating voting decisions: committees, referenda, and representative democracies.

Figure 23.1 demonstrates the median voter model. Imagine that Figure 23.1 represents spending on education to be voted on by a committee. The price axis (P) represents the amount of education spending. Committee members Gordon, James, and Anthony all pay the same tax price (T) $500. The difference is the quantity they would like to receive for that tax price. The horizontal or quantity axis (Q) represents the amount of education each voter prefers. Gordon prefers quantity $Q_1$, which is less than James, who is the median voter and desires $Q_M$, and Anthony prefers the largest quantity, $Q_3$. Given the voters' single-peaked preferences, the single dimension of the issue, and either a greater or lesser quantity of education at T, then in a majority vote, $Q_M$, the quantity preferred by James (the median voter), will always win. In a committee environment, Gordon would suggest $Q_1$, his most preferred outcome; then James, the median voter, would counter with $Q_M$, his most preferred outcome. Gordon would vote for $Q_1$, while James and Anthony would vote for $Q_M$, and $Q_M$ would win by a vote of 2-to-1. If Anthony proposes $Q_3$, then James would propose $Q_M$, and this quantity would again win by a vote of 2-to-1, Gordon and James having voted for $Q_M$ and Anthony having voted for $Q_3$. Any pairing with $Q_M$ will result in $Q_M$ winning because $Q_M$ would be preferred by Gordon and Anthony over $Q_3$ and $Q_1$, respectively (Holcombe, 2005).

This proposition will also hold for a referendum, where the government would propose a quantity of education (still referring to Figure 23.1). If the referendum were to fail, another one would be proposed until the amount $Q_M$, which could win by a majority, was on the ballot.

The median voter model, when applied to selecting a candidate, is a slightly different analysis. Voters decide on a candidate who will represent their preferred position on a multitude of issues—that is, a party platform. Figure 23.2 demonstrates the median voter model in the context of a representative democracy. Candidates for office can position themselves based on party platforms on the horizontal axis from left (liberal) to right (conservative). The vertical axis measures the number of voters that identify with that political position. One additional assumption is that the distribution of voters is normal across the population so that the most voters exist at the median (M).

The median voter model in this context was first presented by Harold Hotelling (1929). Hotelling argued that businesses and politicians, in a two-party system, would locate at the median to attract the most customers and voters. It was Anthony Downs (1957) who first suggested that political parties are strategic in their adopting of policies. According to Downs, "Parties formulate policies in order to win elections, rather than win elections in order to formulate policies" (p. 28). Politicians, as rationally self-interested actors, are concerned with winning elections and will therefore run on policies that will appeal to the decisive median voter. In Figure 23.2, candidate $L_1$ and candidate $R_1$ will both move toward M, where the greatest numbers of voters reside, in order to maximize their vote shares. Thus, candidates want to present policies that appear as centrist or "middle of the road" as possible. This will allow the candidate to attract all the votes to the left of his or her position for $L_1$ (or right for his or her position for $R_1$) plus M—and possibly voters to the right of M if he or she is closer to M than $R_1$ (or left of M if he or she is closer to M than $L_1$). One conclusion from this application is that extreme candidates to

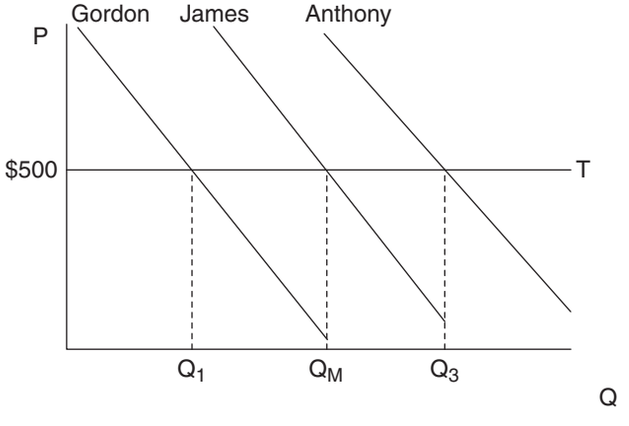

**Figure 23.1** Median Voter Model for a Committee

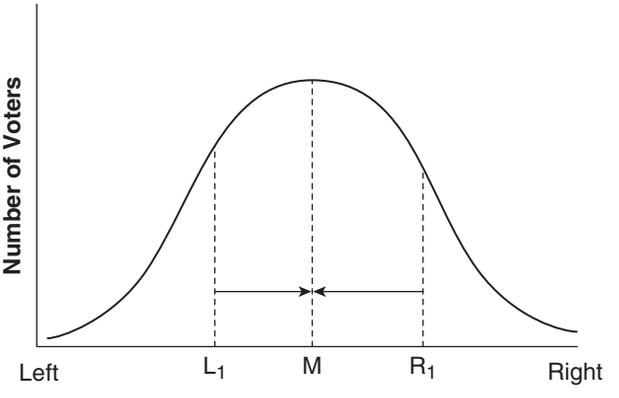

**Figure 23.2** Median Voter Model in a Representative Democracy

either the right or left cannot win elections dominated by a two-party system.

*Agenda Manipulation*

In the presence of voting cycles, the agenda setter has significant power over the final outcome. With a committee structure, in the presence of cycles, the rules that dictate how the agenda will be set matter in determining the end result. An agenda setter, a committee chair, for example, who desires to have his or her preference be the outcome, can structure the votes to achieve this end. Following the example from Table 23.1, suppose that committee members are all voting sincerely for their preferences. Suppose that Gordon is the agenda setter and prefers Option A to B and C. He would pair Option B with C, knowing that B would win, and he would then propose Option A versus Option B. Option A would defeat Option B, and at that point, the agenda setter could suspend all further voting, and the result would be Option A. Joseph Harrington (1990) argues that even when the agenda setter is selected at random, in the presence of voting cycles, that individual has the advantage of acquiring his or her desired outcome over the other members of the committee. Public choice scholars have noticed that despite the focus on voting cycles, there appears to be stability in congressional committee voting (Tullock, 1981). Committees rely on a particular set of rules that allows an agenda setter to avoid these cycles.

*Logrolling*

Economists argue that voluntary exchange is always mutually beneficial, presumably without imposing costs on others. When an opportunity exits for parties to gain from exchange, it is in an individual's rational self-interest to engage in that trade. Political decision making is no exception. One reason that voting may appear stable in the context of cyclical voting is the ability of politicians to exchange votes. Casting a vote does not indicate any intensity of preference. The congressperson from Michigan's vote counts the same as the congressperson from South Carolina's vote. However, the intensity of the preference associated with a piece of legislation may be greater for one congressperson than for another. While the actual buying or selling of votes is illegal, this process has been occurring as an informal practice since the beginning of legislatures. Vote trading or *logrolling* can be described as a "you scratch my back; I will scratch yours" process. Logrolling helps to explain why redistributive polices that benefit only a small segment of the population can be passed, and can continue to be passed, with regularity.

Suppose a congressperson from Michigan would like to pass a tariff that would protect the domestic automobile industry. This tariff will benefit the citizens of Michigan who work for that industry while citizens across the country bear the cost of the tariff. Why would a congressperson from South Carolina support this legislation if his or her constituents would not directly benefit from this policy? If the congressperson from South Carolina would like to receive votes for an infrastructure project, such as a bridge, he or she may vote for the tariff in exchange for the Michigan congressperson's vote. The citizens of Michigan and the other states are unlikely to directly benefit from the building of a bridge in South Carolina in the same way that most citizens will not benefit from the tariff. These types of redistributive policies that benefit a specific congressperson's district or state are known as *pork barrel legislation.*

One can argue that logrolling, especially in the case of pork barrel legislation, is simply tyranny of the majority, because these types of policies benefit one group of citizens at the expense of another. Overall, although trade occurs, there is no increase in net benefit for society, but the congresspeople from Michigan and South Carolina and their constituents may be better off. In the public sector, these benefits come at the expense of others. One conclusion, then, is that majority voting where logrolling occurs will always increase government spending on redistributive policies (Tullock, 1959).

## Public Choice Applied to Representative Democracy

Thus far, the focus has been on direct democracy, where citizens or committees directly vote for some policy, but what about voting for representatives? In the United States, most citizens do not directly vote to pass legislation, although that is possible in the cases of referendums. Rather, they vote for politicians, who will in turn represent them at some level of government.

### Paradox of Voting

Unlike private markets, where an equilibrium outcome exhausts the gains from trade, the costs and benefits associated with voting provide a different outcome. Voting for a representative presents a scenario where the costs outweigh the benefits. Economists argue that individuals will not participate in activities that will not provide a net benefit. If voting does not provide a net benefit, no one should vote, and yet people do vote. This paradox of voting can be better understood by further examining the theory of the rational voter.

*Rational Voter Hypothesis: Instrumental Voting*

The rational voter hypothesis was first developed by Downs (1957) and then further developed by Tullock (1967a) and William Riker and Peter Ordeshook (1968). This topic has generated scores of articles by public choice scholars and continues to be a topic of interest

(see Aldrich, 1993). Here, the simple economic application of cost-benefit analysis is demonstrated. Instrumental voting is simply the voter weighing the expected benefits and costs of voting. The expected benefit of a voter's preferred candidate's win must be greater than the costs associated with voting. For an individual to vote, conditions must be such that $PB - C > 0$. $B$ is the expected benefit that a voter receives if his or her candidate wins the election. $P$ is the probability that one's vote is decisive in determining whether the desired candidate wins the election. In its simplest calculation, one can think of $P$ as $1/N$, where $N$ is the total number of voters participating in the election. Thus, as $N$ gets large, the probability of being the decisive vote for one's candidate becomes infinitesimally small. Dennis Mueller (2003, pp. 304–305) provides a more detailed calculation of $P$. Thus, the probability of one's being the decisive vote for one's preferred candidate is $PB$. $C$ is the cost of voting: the opportunity cost of one's time to actually go the poll and the time one may spend learning about the candidates. Given that the probability of a voter being decisive is perceived as nearly zero (in large elections), even a small cost of voting should keep the rational voter away from the polls.

To complicate matters, if Down's hypothesis regarding candidates' behavior and the median voter is correct, then candidates will quickly move to the center to capture the median voter and win the election. However, if both candidates position themselves at the median, how does the voter perceive a difference between the two candidates? As the candidates move to the middle, the benefit, $B$, one sees for voting for candidate $L_1$ over $R_1$ (to use the notation from Figure 23.2) becomes smaller. Thus, $PB$ may be very small even in cases where $P$ is not infinitesimally small. According to this logic, no one should ever vote, and yet millions of people turn out to vote in elections, hence the paradox. In an attempt to rescue the rational voter hypothesis, Tullock (1967a) and Riker and Ordeshook (1968) included an additional component in the voter's calculation. They suggested that the calculation is $PB + D - C > 0$, where $D$ is a psychic benefit from voting. This psychic benefit can be perceived as a desire to vote or to fulfill one's civic duty. Therefore, if a voter participates in an election, then $D$ must be larger than $C$.

### *Rational Voter Hypothesis: Expressive Voting*

A further development of the rational voter hypothesis is expressive voting. The expressive voting hypothesis picks up where the instrumental hypothesis leaves off. The term $D$, or the psychic benefit one receives from voting, now includes the utility that one receives from being able to express one's preference. Geoffrey Brennan and Buchanan (1984) and Brennan and Loren Lomansky (1993) took a slightly different view of expressive voting, suggesting that voters are still rational in turning out to vote—but not because their votes are decisive. In fact, the hypothesis now assumes that voters understand that they will not cast a decisive vote but instead find value in being able to express their preferences for particular candidates, even if they know that their votes will not change the outcome. Expressive voting has been likened to cheering for one's team at a sporting event. One knows that cheering louder will not change the outcome of the game, but the fan wants to express his or her support for the team.

## Rent Seeking

Perhaps Tullock's (1967b) greatest contribution to the field of public choice is the concept of rent seeking, a term coined by Anne Krueger (1974). In a market economy, economists argue that firms seek profits. These profits (total revenue – total economic cost) provide necessary signals to entrepreneurs regarding how to direct resources. Industries that are earning profits will see increases in resources, and those that are experiencing losses will see resources leave the industry. The profit and loss signals are necessary for the existence of a well-functioning market economy. In all market activities, a business can profit only if it is in fact providing a good or service that is valued by consumers.

Rent seeking is the process of businesses, industries, or special interest groups attempting to gain profit through the political process. Politicians can supply policy that provides an economic advantage to a particular group, in the form of granting them monopoly power or regulation that creates barriers to entry. The policy would benefit this group at the expense of the existing or potential competitors. These rents from the creating, increasing, or maintaining of a group's monopoly power involve payoffs large enough that groups are willing to expend effort to acquire them. More important, the process of rent seeking, unlike profit seeking, results in costly and inefficient allocation of resources.

Suppose Figure 23.3 represents the market for cosmetologists (hair dressers). D is the demand for these services, and $S_C$ is the supply in a competitive market. A simplifying assumption is made that the marginal cost of serving one more customer is constant; hence, $S_C$ is horizontal. If this market operates competitively, the consumers will pay a price of $P_C$ and be supplied a quantity of $Q_C$. Now suppose that the existing members of the cosmetology industry hire lobbyists to persuade government officials to impose new regulations on the industry that create higher barriers to entry, giving existing members greater monopoly power. After the regulation is imposed, the costs of becoming a cosmetologist increase, causing the supply curve to shift from $S_C$ to $S_M$. Consumers now pay the higher price of $P_M$, and the cosmetologists will reduce the quantity to $Q_M$.

In a traditional monopoly analysis, the area labeled A would be known as the welfare transfer. The suppliers

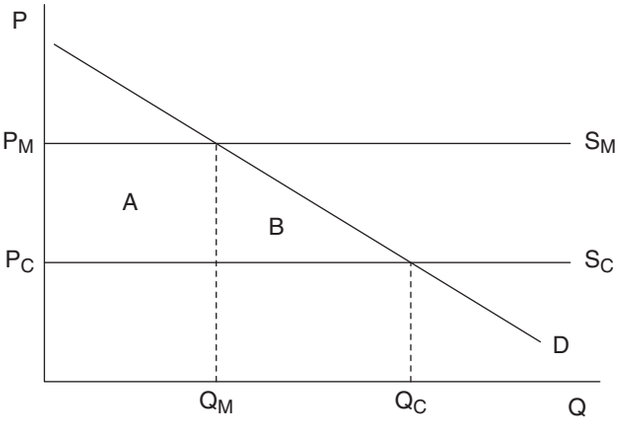

**Figure 23.3** Rent Seeking in the Cosmetology Market

gain Area A at the expense of the consumers in this market. These are the rents that the cosmetology industry is seeking through the political process. Area B is the deadweight loss, the loss of consumer and producer surplus. However, Tullock (1967b) argued that both Areas B and A are deadweight losses. Area A is the rents that can be extracted by the group through the use of government power. In this example, the cosmetology industry is willing to pay up to the amount of A to receive these rents. Real resources must be used to acquire these rents. The industry would hire lobbyists, lawyers, and consultants to meet with government officials. It may engage in a media campaign to justify the new regulations. In addition, there are other groups, perhaps consumers or a competing interest group, that may spend resources in an attempt to prevent this regulation. These are costs above and beyond what may be gained by the cosmetology industry. In the end, Area B is a deadweight loss because real production is lost from $Q_C$ to $Q_M$. Area A is a deadweight loss, or wasteful spending, because real resources are used to acquire these rents rather than to produce more real goods and services, and this creates regulation that promotes inefficiency in the market.

### *Rational Ignorance*

If economists (and presumably government officials) realize that rent seeking is wasteful, why does it occur so often? To answer this question, we return to the supply and demand for public policy. Politicians can supply policy to different groups of voters: large, unorganized groups such as the working poor, the middle class, or college students; smaller, well-organized groups such as unions; industry-specific groups such as automobile manufacturers; or groups organized by occupation such as farmers. The unorganized groups are generally classifications of citizens that have only their individual votes. The organized or special interest groups provide contributions and often a large bloc of votes to a politician.

We know from our discussion of the rational voter hypothesis that the benefits from voting are extremely small, and the cost of voting may outweigh these benefits. More important, the costs of voting do not simply include the costs of voting on the day of the election but also the costs of knowing who or what is on the ballot. Being a well-informed voter is extremely costly. Voters have to research candidates' records and policy positions, which are often not fully provided by the media or in the candidate's literature. Citizens have to be aware of the goings-on within in their legislative body. The problem is that being a well-informed voter does not change the probability or benefit of voting. Well-intentioned and informed voters might participate only to see none of their proposals or candidates win. Thus, there is little benefit to being a well-informed voter. Therefore, the self-interested voter is rationally ignorant.

Voters focus on the few policies that matter to them and become aware of only whether the politician supports their view. It is rational for voters to remain ignorant of most issues and incur only the costs associated with the issues that are most important to them. A consumer shopping for a new car will not test-drive every make and model before purchasing the car. At some point, the additional information that can be gained from driving another car will be less than the cost associated with that test-drive. The same idea applies to voters: Beyond a certain point, trying to gather more information about a candidate will prove too costly for the benefit, and voters choose to be ignorant.

It is this rational ignorance of voters that allows wasteful rent-seeking policies to occur. Most citizens remain unaware of the regulations surrounding a particular industry and the motivations for imposing them. It is also important to realize that well-organized special interest groups have the incentive to be well informed. The benefits to the special interests are large, relative to the dispersed costs imposed on the taxpayers.

## Legislatures, Bureaucracies, and Special Interest Groups

If politicians want to maximize votes to win elections, they can appeal to rationally ignorant voters in ways that convince the citizens to vote for them. For example, a politician campaigning on a college campus may speak on issues of affordable higher education. Rationally ignorant voters now know that this candidate will promote a policy that will benefit college students. These students may not seek any additional information on the candidate and may proceed to vote for him or her. Building on the concepts developed in this chapter, we can see that legislators will supply public policy to special interest groups in addition to broad groups of voters. Legislators using logrolling and relying on the rational ignorance of voters will allow special interest groups to rent seek in an effort to win or remain in office.

Special interest groups are typically organized based on industry, occupation, or a political cause. Mancur Olson (1965) argued that when these groups form to promote the interests of the group, they take on the characteristics of public goods, which means they suffer from the free-rider problem. Therefore, he argued that these groups will be more effective when they are relatively small, and if they are large, they require what Olson referred to as *selective incentives* to minimize the free-rider problem. An example of a selective incentive is a union's requiring that members have dues deducted from their wages so that members cannot receive the benefits of the union without incurring the costs. Public choice economists have made two arguments regarding why special interest groups contribute to elections: (1) in an effort to (re)elect politicians and (2) to influence the way a politician votes on a public policy relevant to the special interest group.

Political action committees (PACs) are the legal or formal method by which special interest groups make contributions to legislators. The empirical literature on the influence of PACs on elections and legislation is numerous. James Kau and Paul Rubin (1982, 1993), Michael Munger (1989), Kevin Grier and Munger (1991), and Thomas Stratmann (1991, 1992, 1995, 1996, 1998) find evidence that PACs give to a legislator, with the hope of influencing the legislator's votes and not merely to improve his or her chance to win office. For a brief review of this literature, see Mueller (2003). Calcagno and Jackson (1998, 2008) argue that PAC spending increases roll call voting, the voting on legislation, for members of the U.S. Senate and the House of Representatives. Thus, public choice economists argue that special interest groups have more influence on political decision making for three basic reasons: (1) Politicians want to win elections, and special interest groups (PACs) can offer money and votes to improve the odds of winning; (2) voters are rationally ignorant of the policies that special interest groups are lobbying for or against; and (3) these policies offer concentrated benefits to special interest groups and widespread costs on individual voters.

Bureaucrats run the government on a day-to-day basis and include everyone from the clerk at the Department of Motor Vehicles to the head of the Food and Drug Administration. These individuals are primarily appointed and are not subject to the same accountability as politicians. These individuals cannot be voted out of office and many remain in these positions long after the politicians that appointed them have left office. William Niskanen (1971) was one of the first economists to examine bureaucracies from a public choice perspective. If bureaucrats, like everyone else, are rationally self-interested, what is it that they are maximizing? Niskanen argued that bureaucrats are budget maximizers. Larger budgets signal greater political power, prestige, and job security. Bureaucracies are difficult to monitor. This allows the bureaucrat to extract these nonpecuniary benefits. The model of bureaucracy is based on the monopoly model. The bureau is the only one producing a particular good or service for the public. Bureaucracies present to congress and the citizens an all-or-nothing demand curve. That means they can either produce the goods or services for a specific budget or not at all. This perception is in part due to the difficulty of monitoring bureaus. Beyond that, the output of bureaucracies is often difficult to measure, making it easier to present to the public a level of output that requires a specific budget.

Unlike the private sector, where managers have the incentive to improve production and are rewarded for their efficiency by higher profits, bureaucrats do not receive any such reward. Thus, the incentive to improve efficiency is not part of the bureaucracy's institutional structure. Bureaucrats will seek larger and larger budgets under the guise of satisfying citizens. In addition, bureaus can appeal not only to satisfying the citizenry as a whole but also often provide a good or service that is specific to a special interest group. In an effort to expand the bureau's patronage, bureaucrats make the special interest group aware of the goods or services they provide that benefit the group. Providing these goods or services encourages special interest groups to pursue rent-seeking behavior—that is, more benefits for the special interest group. Providing more goods or services allows bureaus to expand in size, scope, and budget.

### *Government as Leviathan*

If politicians are maximizing votes, bureaucrats are maximizing budgets, special interest groups are dominating the political process, and voters are rationally ignorant, then the logical conclusion is the theory of government as Leviathan. Rather than a benevolent government, which seeks to aid the public's interest, the theory of Leviathan suggests government is a monopolist with the sole interest of maximizing revenue. Government officials use cooperation—or whatever means they are constitutionally permitted—to generate as much revenue as citizens will allow. This view of government is at odds with traditional public finance, which suggests that there are optimal levels at which to tax citizens and that government officials are constrained by their accountability to citizens. If citizens (voters) are uninformed, government officials with the power to tax, spend, and create money are uncontrolled. Even with constitutional limits, rationally ignorant voters will not understand the amounts they are being taxed, the size of deficits and debt, and the impact of expanding money supplies. When government exceeds its constitutional limits, citizens may realize that they must monitor government more closely. However, these attempts to constrain government are often short lived. Voters attempted to constrain government with tax revolts in the 1970s and with the Contract with America (Mueller, 2003) in the early 1990s. Brennan and Buchanan (1980) provide a complete analysis of the theory of government as Leviathan.

*Political Business Cycle*

Although public choice is primarily a microeconomic field, it examines the macroeconomy through the prism of business cycles. Business cycle theories can be broadly categorized by their causes: (a) large declines in aggregate demand, (b) expansionary monetary policy, and (c) technological shocks to the economy. While business cycle theories may suggest that government policy may play a role in the creation of the business cycle, public choice scholars take this view one step further. Business cycles are the result of government policy, primarily through monetary expansion, and these cycles coincide with election cycles. Political business cycle economists argue that politicians will attempt to improve economic conditions prior to elections so as to win reelection. Focusing on a simple trade-off between unemployment and inflation, politicians will pursue policies that will reduce unemployment and generate positive economic conditions. Monetary expansion and fiscal policy are used to reduce unemployment. Only after the election does the inflationary effect of the policy emerge, and the boom becomes a bust. At this point, the politicians start the cycle again. This opportunistic political business cycle in part relies on the rationally ignorant voter, but one wonders if voters are fooled over and over again by such policies. An alternative explanation is that voters are selecting politicians that they believe will benefit them. If unemployment is a concern for a voter, he or she may vote for a politician who reduces unemployment because it will specifically benefit the voter.

According to Jac Heckelman (2001), the first term of the Nixon administration provides anecdotal evidence of a political business cycle, and Heckelman suggested that it was Nixon's administration that inspired early theoretical models:

> Keller and May (1984) present a case study of the policy cycle driven by Nixon from 1969–1972, summarizing his use of contractionary monetary and fiscal policy in the first two years, followed by wage and price controls in mid-1971, and finally rapid fiscal expansion and high growth in late 1971 and 1972. (p. 1)

Similarly, Jim Couch and William Shughart (1998) find evidence that New Deal spending was higher in swing states than in states with greater economic need, suggesting that the spending was motivated by Roosevelt's desire to be reelected. The empirical evidence of an opportunistic political business cycle has mixed results in the economics literature. In a recent study, Grier (2008) found strong support for the political business cycle. He found evidence that the real gross national product (GDP) rose and fell between the years 1961 and 2004, in conjunction with presidential election cycles.

## Normative Public Choice

### The Importance of Institutions

Like most economics, public choice is primarily positive economic analysis, which means it is used to explain what is or what will happen. However, because public choice examines the world of political decision making and these decisions affect factors such as economic growth, taxation, and individuals' standards of living, it seems appropriate that it ventures into the realm of normative analysis, or the way things should or ought to work. The use of normative economics in public choice has focused on the role of institutions. It is not enough to understand why voters may chose a particular candidate under majority rule, but one must ask whether majority rule is the best institution to select elected officials. Gwartney and Wagner (1988) argued that if individual actors are going to generate outcomes that benefit society, then

> success rests upon our ability to develop and institute sound rules and procedures rather than on our ability to elect "better" people to political office. Unless we get the rules right, the political process will continue to be characterized by special interest legislation, bureaucratic inefficiency, and the waste of rent-seeking. (p. 25)

*Constitutional Economics*

The normative aspect of public choice can be seen as the overlap with social choice theory. One major normative analysis that emerges from public choice theory is constitutional economics. As in social choice theory, the fundamental question addresses the best way for a society to be organized so as to maximize the welfare of its citizens. It is precisely this question that Buchanan and Tullock (1962) tried to answer in *The Calculus of Consent.* Constitutional economics can be thought of as both a positive and a normative analysis. In normative analysis, the argument for a constitution is similar to other social choice theories that address the concept of a social contract. Public choice theory starts with the first stage, a convention being called, to establish a constitution under uncertainty. The difference in these theories is the degree of uncertainty for the actors in this first stage of decision making. Buchanan and Tullock argue that in this first stage, collective decisions are really individual decisions in which each individual follows his or her own self-interest.

The constitutional convention requires unanimity to have a successful outcome. If everyone agrees to the constitution, everyone is agreeing to abide by the rules, even though some of those rules may ban or restrict their behaviors in the future. It is in this way that the uncertainty comes into play. The actors know that certain actions will reduce the utility of individuals in the future, but they do not know at that point whether they will be one of the individuals affected. A first-stage decision may be the voting rule used in future

elections: simple majority rule, a two-thirds majority, or a three-fourths majority. By having unanimity in the first stage, everyone is agreeing to that rule without knowing whether they will be in the majority in the future. It is not until the second stage when individuals are actually voting on policies and candidates that they will know to what degree they will be affected by the first-stage decisions.

One contention in this theory is whether constitutions are contracts or conventions. The contract theory views constitutions as contracts agreed on and actually signed by the originators to signify their commitment. The convention view suggests that constitutions are devices by which social order and collective decisions are made. The convention view treats constitutions as self-enforcing, because all parties understand the convention or device by which decisions will be made and chose a convention in the first stage that maximizes social welfare. Thus, the second-stage decisions are easily agreed on, and no one has an incentive to violate the convention. The constitution-as-contract view requires an outside enforcement mechanism, such as a police force or a court system, to ensure that individuals do not violate the contract. Both views recognize that at the first stage, the rules need to be constructed to create an incentive structure consistent with individuals' rational self-interest. Otherwise, in the second stage, individuals will generate outcomes that will not maximize social welfare. Constitutions possess characteristics of both contract and convention. Although the self-enforcing feature of conventions is desirable, one potential problem is that constitutions can evolve over time, and these decisions may be out of the citizens' control. When a constitution is a contract, it is harder to change, but because the government enforces it, conflicts between the state and the citizen can arise.

### *Anarchy*

It is precisely the idea of the state as a neutral party that has some public choice scholars asking whether constitutions are the right means of organizing society. As has been noted throughout this chapter, individuals, in the absence of sound institutions, will create outcomes that are inefficient. Instead of a constitutionally limited state, some economists argue that the logical conclusion of a public choice perspective is anarchy. Beginning in the 1970s, public choice economists began to examine the issue of anarchy. The initial results were pessimistic views that a state is still necessary to prevent individuals from plundering their neighbors. However, a younger generation of public choice economists has a more optimistic view (Stringham, 2005). The absence of government does not mean the absence of rules or laws but rather the form that they take. Private institutions, through voluntary exchange and contracts, will create a set of rules that individuals agree to abide by. This research is being revisited, and this question is being asked: Why not consider anarchy in the realm of possible choices?

Peter Boettke (2005) pointed out that public choice economics presents a puzzle. He argued that Buchanan suggested there are three potential functions for government: (1) protective, in which the state is protector of private property rights; (2) productive, in which the state improves inefficiency where warranted; and (3) redistributive. The first two features, many economists will argue, are desirable, but the third, the redistributive power of the state, is the one that exists but should be avoided. How do you create a state that will generate the first two and not the third? Boettke suggested that there is a fine line between opportunism and cooperation in individuals' self-interested behavior. Does this require the state's intervention, or can markets solve this puzzle? This issue provides an interesting area for future research in public choice.

## Conclusion and the Future of Public Choice

It has been said the framers of the U.S. Constitution were the original public choice economists. Somewhere between the eighteenth century and the first half of the twentieth century, this view of politics and institutions changed. Beginning in the 1940s and taking hold in the 1960s, public choice economics emerged to return us to this original vision. Using economic tools to examine political choices provided new insights into the field of public finance. The dichotomy of private decision making as self-interested and public decision making as altruistic was confronted with a single vision of economic humanity. Individuals, whether they are buying a car or deciding for which congressperson to vote, are now seen as behaving rationally self-interested.

Over the last half-century, the field of public choice has examined every aspect of political decision making from voting to politicians' behavior and from campaign financing to the running of bureaucracies. The field of public choice has questioned whether political behavior drives our macroeconomy, debated the proper origins of the state, and asked whether the state can be contained and whether the state should even exist. Public choice economics has been integrated into the field of public finance and neoclassical economics to such an extent that not treating both private and public actors as rationally self-interested may be viewed as an incomplete analysis, perhaps even naive.

Public choice has tackled many of these issues, empirically finding strong evidence of rationally ignorant voters, rent seeking, vote-maximizing politicians, and the existence of an opportunistic political business cycle. It has ventured in the normative arena, asking what type of institutional arrangements will generate the greatest prosperity and maximize social welfare.

What has emerged from this field is an understanding that if market failure exists, so does government failure. Public choice economics presents a means by which market-based outcomes can be compared to public-sector

outcomes and economists can decide which institutional arrangement, even if flawed, will likely lead to greater economic efficiency (Gwartney & Wagner, 1988).

Public choice theory continues to examine these issues, both empirically and from a normative perspective. Public choice theory continues to make contributions to the field of economics, analyzing every type of collective decision. With the government taking a larger and larger role in the economy, public choice will continue to prove a useful field of analysis.

# Taxes Versus Standards

## *Policies for the Reduction of Gasoline Consumption*

Sarah E. West
*Wesleyan College*

Fossil fuel consumption and greenhouse gas emissions from the personal transportation sector promise to be key challenges facing the next generation of policy makers. In 1999, transportation became the largest end-use producer of carbon dioxide from fossil fuels in the United States. Gasoline-powered vehicles are responsible for about 60% of the carbon from the transportation sector. They also emit the majority of carbon monoxide, as well as substantial proportions of oxides of nitrogen and volatile organic compounds (Davis, 2004).

The transportation sector became the largest producer of carbon dioxide for two reasons. First, with the exception of 2007 and 2008, when gas prices reached new highs and the U.S. economy slumped into recession, households increased the number of miles they drove (Federal Highway Administration, 2009). Second, the vehicle fleet has become less fuel efficient so that in 2005, households on average used more gasoline per mile driven than they used per mile in 1987 (Davis, 2007). This is a stunning statistic, given that, overall, the U.S. economy uses far less energy per unit of output now than it did 30 years ago.

Why did the transportation sector become less fuel efficient? After all, passenger cars sold now get about 7 or 8 more miles per gallon, on average, than those sold in 1978. And light-duty trucks, the category that includes pickups, vans, and sport-utility vehicles (SUVs), experienced an increase in fuel efficiency of about 3 miles per gallon since 1978. But the market share of light-duty trucks, which are less fuel efficient than cars, increased dramatically over that time period, rising from less than one third of vehicles purchased in 1988 to more than half by 2000. Increases in SUV purchases were primarily responsible for the increase. The increase in the number of these less fuel-efficient vehicles, relative to the number of passenger cars, brought down the overall fuel economy of the U.S. vehicle fleet.

At the same time, problems related to traffic congestion and dependence on foreign oil intensified, and awareness of the likely impacts of climate change increased. Policy makers have therefore directed their attention toward policies for the reduction of gasoline consumption.

This chapter summarizes the current state of economic knowledge on whether government intervention in gasoline and fuel economy markets is justified, and if so, what form policies should take if they are to efficiently and effectively reduce gasoline consumption. It begins by defining market failure due to the presence of externalities and by describing the kinds of policies generally used to address such market failures in the United States. It then quantifies the external costs associated with gasoline consumption, concluding that the presence of a number of externalities in gasoline markets justifies government intervention in those markets. Following discussion of the relative efficiency of various policies that may correct failures in the gasoline market, this chapter considers the possibility that not only do consumers fail to internalize the costs they impose on others by consuming gasoline but they also fail to fully account for the fuel

savings that can be had by buying a more fuel-efficient vehicle. If consumers are fallible in this way, then not only is intervention in gasoline markets justifiable on efficiency grounds, but so is intervention in the market for fuel economy. The same is true if automakers fail to provide a sufficiently broad and varied selection of fuel-efficient vehicles. The chapter concludes with a discussion of distributional considerations of policies for the reduction of gasoline consumption and with suggestions for directions for future research.

## Justifications for and Types of Government Intervention

When consumers decide how much gasoline and the kind of vehicle to buy, or producers decide how much to sell, they weigh the private costs of their activities against the benefits. For example, consumers evaluate the prices of various vehicles, the costs of operating such vehicles, the price of gasoline, and the prices of alternative modes of transport. Producers compare the revenues that they expect to earn with the costs of refining and distributing gasoline or of producing various types of vehicles. Without proper incentives, however, consumers and producers will not include the costs that they impose on the environment and others in their decisions of how much and what to consume and produce. This failure to include these external costs in decisions results in a market failure: Drivers buy and use and producers sell too much gasoline and vehicles that are too inefficient. When market failure occurs, usually a case can be made for government intervention (West & Wolverton, 2005).

Governments have typically used both command-and-control (CAC) regulation and market-based incentives to resolve market failures. Prior to 1990, virtually every environmental regulation in the United States and elsewhere took the form of CAC regulations, and they are still commonly used. These regulations are so named because they command that emissions be controlled to meet a given minimum or maximum standard. As such, they tend to be either technology based or performance based.

Technology-based regulations mandate the control technology or production process that producers must use to meet the emissions or fuel economy standard set by the government. Such a standard might take the form of a requirement that a particular kind of vehicle, an electric vehicle for example, be adopted by all state and local governments. One problem with this type of CAC regulation is that it applies a one-size-fits-all policy to producers and consumers that may face very different costs of reducing gasoline consumption. Thus, while gasoline is reduced to the desired level, it is accomplished at a higher cost than might have occurred if firms and consumers were allowed to determine the most cost-effective means for meeting the standard. Alternatively, if more flexible policies were used, more gasoline reduction or higher environmental quality and fuel efficiency could be achieved at the same cost. Technology-based CAC policies do not encourage vehicle manufacturers or consumers to find new and innovative fuel-saving strategies, nor do they provide an incentive to reduce consumption beyond the set level.

Performance-based regulations are more flexible CAC policies; they mandate that a standard be reached but allow producers and consumers to choose the method by which to meet the standard. Still, once they have reached the level specified by the standard, producers and consumers face little incentive to increase fuel economy or reduce gasoline consumption any further.

Market-based policies, on the other hand, are regulations that encourage behavior through price signals rather than through explicit instructions or mandates (Stavins, 2000). Many market-based instruments function as follows: A firm or a consumer faces a potential penalty in the form of a tax or permit price per unit of gasoline, emissions, or fuel inefficiency. The firm or consumer can choose to pay for existing gasoline or low fuel economy via the tax or permit, or can instead reduce gasoline consumption or increase fuel economy to avoid paying the penalty. Other market-based policies might subsidize fuel economy. For example, the federal government subsidizes hybrid vehicles until manufacturers reach a specific production volume, and several states provide similar incentives.

Market-based policies give consumers and automakers more flexibility than most CAC policies. First, the method for reducing gasoline consumption is not specified, giving drivers or manufacturers with heterogeneous costs the flexibility to use the least costly fuel-saving method. Second, because market-based incentives force producers and consumers to pay taxes, buy permits, or forgo subsidies when they sell or drive fuel-inefficient vehicles, they provide an always-present incentive to take measures that reduce gasoline consumption. Such incentives, therefore, also promote innovation in fuel-saving technologies (for discussion of the effects of incentives on innovation, see, for example, Jaffe & Stavins, 1995; Laffont & Tirole, 1996: Parry, 1998).

Only in a very narrow set of circumstances could such market failures be addressed without government intervention. In a seminal article, Ronald Coase (1960) lists three conditions that must be met for an externality problem to be resolved without government intervention. There must be (1) well-established property rights, (2) a willingness of affected parties to bargain, and (3) a small number of parties affected. Although it might be possible to legislate rights for, say, fuel economy or a stable climate, it is less likely that oil companies, automakers, and those affected by the external costs of driving would be willing to bargain effectively. And as the number of parties affected by climate change includes the global population, Coase's third condition is clearly violated.

## Failures in the Market for Gasoline

Think about the last time you drove or rode in a car. Did you consider the fact that your car pollutes the air with hazardous emissions, adds greenhouse gases to a warming atmosphere, increases congestion and the likelihood of accidents on the road, and exacerbates reliance on oil imported from areas prone to war and dictatorial regimes? More important, if you did think about these external effects of your gasoline consumption and driving, did you drive or ride in a car less than you would have had gasoline consumption been harmless, and did you opt for a more fuel-efficient vehicle? Maybe you did. But do most Americans? Probably not. This means that even if you are paying $4.00 per gallon for gasoline, you are paying too little. That $4.00 covers the costs of oil, refining, distribution, marketing, and state and federal gas taxes. But as we shall see below, the taxes per gallon fall far short of covering external costs.

### Quantifying the External Costs of Gasoline Consumption

The external costs related to gasoline consumption are substantial, which implies that in the absence of government intervention, the gasoline market fails to operate efficiently. Ian Parry, Margaret Walls, and Winston Harrington (2007) divide these costs into two categories: per gallon externalities and per mile externalities.

Per gallon externalities involve costs imposed on others when gasoline is burned, regardless of how many miles were driven when it was burned. Parry et al. (2007) suggest that a reasonable estimate for the costs of greenhouse gases per gallon of gasoline is 6¢, while the estimate of costs due to increased oil dependency is 12¢ per gallon (both in 2007 U.S. dollars).

Of course, uncertainty in the science of climate change and its effects, not to mention uncertainty about the relationship among gasoline consumption, oil dependency, and terrorism, imply that the true magnitude of these costs is itself extremely uncertain. But even if the per gallon external costs of gasoline consumption are much higher than the best guesses in Parry et al. (2007), it is very likely that the per mile external costs swamp per gallon costs. Traffic congestion in the United States causes drivers to lose billions of dollars per year of one of their most valuable resources: time. For this reason, external costs due to congestion are estimated to be a whopping $1.05 per gallon (in 2007 dollars). Costs from increases in accidents due to increases in gasoline consumption when more miles are driven, plus costs from local pollutants such as carbon monoxide and ozone, add up to another $1.05, for a total of $2.10 per gallon in per mile external costs of gasoline consumption.

In addition to the per mile costs discussed by Parry et al. (2007), an increase in miles driven also involves a more subtle but sizable cost. The argument goes like this: Because they face a tax that depends on how many hours they work, workers work too little, which implies that labor markets operate inefficiently. Any policy that further reduces the number of hours worked will exacerbate this inefficiency. It turns out that making either gasoline or miles cheaper, and thereby increasing miles driven, also reduces hours worked. If it costs a worker less to drive, for example, he or she might be more likely to take work off early on a Friday to drive to a weekend retreat. Sarah West and Roberton Williams III (2007) find that because labor markets are so large, small reductions in hours worked that occur when miles driven increase involve potentially large efficiency losses, with the costs of reduced work hours amounting to about a third of the sum of the external costs estimated by Parry et al. (2007).

The magnitude of these external costs, when taken together and when compared to each other, has two important complications. First, existing federal and state gasoline taxes, which sum to an average of 40¢ per gallon, do not cover external costs. Second, because the costs associated with driving a mile far exceed the costs of burning the gasoline in isolation, any policy that increases miles driven is likely to be quite costly in terms of its effects on congestion and accidents.

### Policies to Correct Failures in Gasoline Markets

It seems clear that gasoline markets will be inefficient if left to themselves. What should be done, then, to induce gasoline producers, automakers, and drivers to internalize the costs they impose on others? Any policy that does this successfully must induce consumers to use less gasoline. Mindful of the relatively high per mile costs of congestion and accidents, one can place policies that reduce gasoline consumption into two categories: those that also reduce miles driven and those that increase miles driven.

In the absence of an additional market failure (e.g., a failure in the market for fuel economy, discussed at length below) or political or administrative constraints, a policy that also reduces miles driven—or at least one that does not increase miles driven—will be preferable to policies that reduce gasoline consumption but also increase miles driven.

Policies that increase the price paid per gallon or the price paid per mile can be expected to reduce both gasoline consumption and miles driven. Such policies include a tax per gallon of gasoline, a carbon tax or cap-and-trade program, a direct tax on vehicle-miles driven, or a pay-as-you-drive (PAYD) insurance premium (see Parry et al., 2007, for general discussion and Parry, 2004, 2005, for a more specific treatment of the PAYD insurance premium).

The gasoline tax has the advantage of being easy to administer, and in terms of per gallon externalities, it internalizes costs perfectly. It efficiently encourages drivers to consider their effects on the climate, because the amount

of carbon released by a gallon of gasoline is independent of the manner in which it is combusted. The same is true for the effects on oil dependency. It is important to note that a gasoline price floor, which would set a minimum price for gasoline, would not attain the same efficient outcome as would a gasoline tax. Such a policy, which has been discussed in the U.S. Congress, would likely lead to inefficient gasoline shortages, when binding, and inefficiently low gasoline prices, when not binding.

When faced with a tax on gasoline, drivers will choose the most cost-effective method of reducing consumption. Consumers that live near work may opt to walk, bike, or take public transportation. Others might choose to change air filters more often, to monitor tire pressure more vigilantly, or to reduce highway driving speed. An increased tax on gasoline would also induce consumers to change their vehicle purchasing behavior. They might buy a Toyota Camry with a four-cylinder engine when they would have otherwise purchased one with six cylinders. Or they may replace a less efficient car with an established hybrid, such as a Toyota Prius, or with one of the newly emerging vehicle technologies. Advances in battery technology have now moved electric vehicles off the drawing board. High-end electric vehicles are currently available from Tesla Motors, and General Motors's Volt electric car is scheduled to go on sale in 2010. Low-end, inexpensive golf-cart type vehicles are being upgraded to meet crash protection standards. Plug-in hybrids are being readied for production. Gasoline taxes would increase the demand for these vehicles and reduce the demand for conventional gasoline-powered cars and trucks.

A tax on gasoline would also induce consumers to seek cheaper fuel alternatives for their conventional vehicles. About 49% of the gasoline in the United States is already E10 (gasohol), which is 10% ethanol. Brazil has completely freed itself from foreign oil dependence, with virtually all its cars running on E85, which is 85% ethanol. There are already 6 million "flex-fuel" vehicles in the United States that can run on E85 right now. Used conventional cars can be converted to flex-fuel for about $100 in parts, including replacing the computer chip that controls the air mixture, attaching new fittings to the fuel lines, and replacing the rubber seals with nonrubber seals. Wal-Mart is working out the details with Murphy Oil Company to make E85 available at Sam's Club and Wal-Mart gas stations throughout the United States.

Switching to corn-based E85 is likely to reduce the per gallon costs of oil dependence, but it is also likely to result in higher greenhouse gases and greater health costs due to increases in particulate matter. Ethanol from sugar cane, however, is much more efficient than ethanol from corn, and ethanol from cellulose is another promising and rapidly developing alternative (see Hill et al., 2009, for more on the differences among various sources of and processes for producing ethanol).

However they respond to a gasoline tax, consumers will choose the cheapest of the set of all behaviors that reduce miles driven or increase miles per gallon. The same would be true if they were faced with a carbon tax or if producers were required to pay a fee for a carbon permit. Direct taxes on miles driven or PAYD insurance would also reduce miles driven and lead to reductions in gasoline consumption. While these mileage fees could efficiently internalize the per mile externalities discussed above, they have been challenged by some who suggest that consumers may tamper with their odometers or that calculating miles driven using GPS technology may infringe on civil liberties.

On the other hand, any policy that acts only to increase fuel efficiency involves the undesirable incentive to drive more miles. Increases in fuel economy reduce the cost per mile, because they increase the number of miles that can be driven per gallon. As with any good, the law of demand holds here—as the price of miles drops, the quantity of miles driven rises.

The United States' main policy to increase fuel economy is Corporate Average Fuel Economy (CAFE) standards. It also assesses so-called gas guzzler taxes, but only on the most inefficient passenger cars, which are exclusively luxury sports cars. CAFE standards mandate that each vehicle manufacturer attain a specific average fuel economy in the cars it sells, and another applies for light trucks. At the time this book went to press, the federal government was in the process of overhauling these rules. The new rules will almost certainly impose more stringent (higher) fuel economy requirements.

CAFE is a CAC regulation. In particular, CAFE is a performance-based standard that allows manufacturers to choose the method by which to meet the standard. As such, performance-based standards are more flexible than a technology standard, which mandates that all manufacturers supply specific technologies (such as electric vehicles).

Still, once automakers have reached the level specified by the standard, they face little incentive to increase fuel economy any further. And CAFE applies a one-size-fits-all policy to firms that may differ widely in size and cost structure. Thus, while fuel economy is increased to the level desired by policy makers (which may be inefficiently low or high), it is accomplished at a higher cost to firms and consumers than might have occurred if different firms were allowed to attain different levels of average fuel economy. If firms for whom innovation in fuel economy technology is easier were induced to sell more vehicles than firms for whom such technology is more difficult, fuel economy goals could be attained at lower overall costs to society.

Feebates, which subsidize the purchase or manufacture of fuel-efficient vehicles and tax fuel-inefficient vehicles, would solve this problem, because manufacturers could choose exactly how to respond to the policy. Those who innovate cheaply would respond more than those for whom innovation is costly. A tax on fuel-inefficient vehicles would also be efficient, but the feebate has the potential advantage of being inherently revenue neutral, so any tax revenues taken in by the program would be rebated in the

form of subsidies to fuel efficiency. Such revenue neutrality is generally more attractive to policy makers in the United States, who risk damage to their popularity when they increase the overall tax burden placed on their constituents.

Both CAFE and feebates, however, increase miles driven by reducing the price per mile. This is the rebound effect, where gasoline consumption rebounds because driving is cheaper, and offsets some of the reduction in gasoline made possible by higher fuel economy. Ken Small and Kurt Van Dender (2007) estimate this effect is about 10% of the initial reduction in gasoline consumption due to more stringent CAFE standards. Unless consumers fail to buy or producers fail to offer the efficient amount of fuel economy for reasons other than the existence of the external costs discussed above, then gasoline taxes, carbon taxes, or carbon cap-and-trade programs are almost certainly more efficient than policies that increase fuel economy but also increase miles driven.

## Failures in the Market for Fuel Economy

The conclusion that a gasoline tax is an efficient (and thus preferable) policy instrument for the reduction of gasoline consumption rests on an economic model in which consumers make fully informed, rational decisions regarding both how many miles to drive and what vehicle to buy. It also requires that automakers provide consumers with an efficiently varied set of vehicles from which to choose. There are reasons to think that these conditions may not hold. In particular, there is evidence that consumers may not sufficiently value fuel economy when making the decision about what car to buy, and logical arguments suggest that producers offer fewer than the optimal number of choices of fuel efficiencies.

### Possibilities for Market Failure Due to Consumer Fallibility

Consumers may undervalue fuel economy because they do not fully and correctly calculate the present discounted value of the flow of future operating costs, which depend on driving behavior, fuel economy, and the future price of gasoline. That is, when choosing between a more fuel-efficient and a less fuel-efficient vehicle, a consumer may not correctly calculate or perceive the difference in what he or she will pay for gasoline in the one vehicle versus the other over the entire period during which he or she will own the vehicle.

This implies that in the absence of a corrective policy, consumers will buy too little fuel economy. It also implies that consumers will underreact to a greenhouse gas policy that raises the value of fuel economy by increasing the price of gasoline. As such, an additional policy, such as the CAFE standard, or a feebate, which subsidizes the purchase of fuel-efficient vehicles and taxes the purchase of inefficient vehicles, can be welfare improving, even when carbon emissions have been priced optimally via a gasoline tax, a carbon tax, or a cap-and-trade program (see Fischer, Harrington, & Parry, 2007; Greene, Patterson, Singh, & Li, 2005; National Research Council, 2002; Train, Davis, & Levine, 1997, for discussions of the possibility that CAFE or feebates may be efficient in the presence of such consumer fallibility).

A growing body of evidence suggests many reasons to think that consumers may make systematic mistakes regarding the value of fuel economy. First, experimental evidence suggests that consumers are confused by the nonlinearity of cost savings in miles-per-gallon-rated fuel economy (Larrick & Soll, 2008). For example, an increase in fuel economy from 15 to 16 miles per gallon implies a greater cost savings than an increase from 30 to 31 miles per gallon, but consumers tend to think these changes result in the same cost savings. Second, qualitative evidence from surveys of new car buyers suggests that most consumers are unable to articulate the key building blocks required for a present discounted-value analysis, including typical mileage, fuel economy ratings of their current vehicles, and a discount rate (Turrentine & Kurani, 2007). Third, analysis of data from the Michigan Survey of Consumers produces several results that are difficult to explain in a model of infallible consumers. Each month, the survey asks a sample of households whether it is a good time to buy a vehicle and why. Even when controlling for the real price of gasoline (the price that consumers pay, adjusted by inflation to account for the changes in purchasing power over time), consumers are more likely to cite gasoline prices and fuel economy as important when nominal gasoline prices (the price that is posted on gasoline station signs) are high and when prices have just changed. They also appear to respond more strongly to gasoline price increases than decreases (Sallee & West, 2007). There is also evidence that consumers act the same way when buying other durable goods, such as refrigerators and air conditioners—they do not fully account for the differences in energy costs when deciding between buying a more expensive but more fuel-efficient appliance and a cheaper but less fuel-efficient appliance (Dubin & McFadden, 1984; Hausman, 1979).

Skeptics, however, point out that of a vehicle's many characteristics, consumers probably understand fuel economy better than most of its other characteristics (Kleit, 2004). After all, a vehicle's fuel economy rating appears in large type on a window sticker placed on every new vehicle sold in the United States. And other researchers have found that consumers buying used cars do seem to fully account for differences in future operating costs across vehicle models (Dreyfus & Viscusi, 1995).

Part of the reason that economists have yet to reach an agreement on the existence or magnitude of consumer myopia or fallibility is that until recently, data and computing requirements were too onerous. To properly identify consumer fallibility, one must isolate consumer

responses from a whole host of other factors, including broad economy-wide movements and a multitude of production and pricing behaviors on the part of automakers. Work that measures the effects of changes in gasoline prices in used-car markets is promising, because it can more easily control for the confounding effects of vehicle manufacturers' pricing decisions. Such work finds that consumers internalize a surprisingly small proportion of operating costs when deciding which used car to buy (see Kahn, 1986; Kilian & Sims, 2006; Sallee & West, 2009) and provides preliminary support for the notion that consumers are fallible.

### Possibilities for Market Failure Due to Producer Behavior

It is also possible that market failures exist on the producer side. But even less is known about producer behavior, especially because (quite understandably) automakers are hesitant to share information about their production and pricing strategies.

Portney, Parry, Gruenspecht, and Harrington (2003) list a number of reasons why producers may undersupply fuel economy. First, the vehicle industry is oligopolistic, in that a relatively small number of firms dominate the market. This may imply that these firms do not face the same incentives to provide fuel economy as firms in more competitive markets. Instead, these companies may engage in strategic behaviors that result in a lower-than-optimal amount of innovation.

Second, although engineering studies indicate that it is in the interest of automakers to supply vehicles of greater fuel economy, such studies may not capture the full costs of developing and implementing a new technology. Third, if automakers are unable to reap the full returns of investment in fuel-saving technologies because of copycat activity on the part of competitors, they will invest in less technology than is socially optimal.

However, it may simply be the case that consumers are unwilling to forgo the performance attributes, such as acceleration, that would likely be lost if automakers were to sell models that are more fuel efficient. Automakers may simply be responding optimally to consumer demands. After all, as Portney et al. (2003) remind readers, there is already a wide variety of fuel-efficient models from which consumers can choose.

### Policy Implications if the Market for Fuel Economy Is Inefficient

Findings of consumer fallibility or inefficient producer behavior have the potential to shake the world of environmental policy making, because they imply that a policy that sets a price on carbon will not be sufficient to efficiently reduce gasoline consumption, and therefore greenhouse gases, from the personal transportation sector.

If consumers or producers do not buy or supply an efficiently high amount of fuel economy, then to attain the efficient amount of gasoline consumption, a tax or fee on carbon or a tax on gasoline must be paired with another incentive that induces further improvements in fuel economy. If consumers are fallible or producers provide too little fuel economy because of strategic behavior, the increases in miles driven that come about from increases in fuel economy will be warranted.

For the reasons discussed above, a feebate—or even just a tax on fuel-inefficient vehicles—would be more efficient than making CAFE standards more stringent. If consumers are myopic enough, disregarding part or all of the future fuel cost savings from choosing a more fuel-efficient vehicle, making CAFE more stringent might increase efficiency. The same is true if producers' supply choices are sufficiently constrained by strategic or other considerations.

## Distributional Concerns

Because the extent and the magnitude of externalities in gasoline markets are so clear, most economists focus their attention on the potential efficiency-improving characteristics of policies that internalize such externalities. Equity, or distributional, implications of a tax on gasoline or carbon, however, are often cited as one of the strongest arguments against increasing or imposing such taxes. Many worry that poor households will bear a greater burden because expenditure on gasoline tax would be a larger proportion of their incomes than it would be for wealthy households. That is, they worry that a gasoline tax is regressive, as opposed to progressive, where the amount paid in tax as a proportion of income increases as income increases. They also worry that households will bear more of the burden than producers.

As explained in West and Williams (2004), an ideal measure of tax incidence would begin with a calculation of all of the changes in prices that would occur throughout the economy in response to the change in the tax rate and proceed with a calculation of the effects of those price changes on households' well-being. The obvious effect of an increase in the gasoline tax is a rise in the consumer price of gasoline, imposing a burden on gasoline consumers. But an increase in the gasoline tax could also lower the producer price of gasoline, imposing a burden on the owners of gas stations, gasoline producers, and perhaps in turn, through lower wages, on workers in those industries. It could also affect the prices of other goods that use gasoline as an intermediate input.

However, calculating such effects requires a great deal of information, most notably the demand and supply elasticities for all relevant industries and the distribution of ownership of firms in those industries. A few papers either hazard a guess on the relative burden on producers and consumers (e.g., Congressional Budget Office, 2003) or

estimate the relative burdens explicitly (e.g., Skidmore, Peltier, & Alm, 2005). But most incidence studies assume that the supply of consumer goods is perfectly elastic. This implies that the imposition of a tax on a consumer good does not affect the producer price of that good and thus that the entire burden of the tax falls on consumers.

These studies find that the gasoline tax is indeed quite regressive, one of the most regressive taxes in the economy (see Poterba, 1991; West, 2004; West & Williams, 2004). This is not surprising, because gasoline, like all energy, is a necessity—as income increases, so does consumption of gasoline, but not by enough to make wealthy households spend more on it as a proportion of their income than do poor people.

But West and Williams (2004) suggest a simple way to mitigate or even completely overcome the regressivity of the gasoline tax. By using the revenues from the gasoline tax to reduce taxes on work, the policy can be made significantly less regressive. And by using the revenues to give rebates of the same amount to all households, the policy can actually be made progressive. Such rebates do not reduce the efficiency of the gasoline tax, because the tax still provides the incentive to reduce gasoline consumption. Indeed, if gasoline tax revenues are used to reduce labor taxes, the overall efficiency of the gas tax policy is improved.

In part because such regressivity-reducing revenue rebate schemes are available, but more importantly because the externalities from gasoline use are substantial, economists do not rule out taxes on gasoline because of equity concerns. Indeed, more often, they operate on a general principle that it is best to use environmental policies to internalize externalities, regardless of their distributional implications, while relying on the income tax system to attain equity goals.

Unfortunately, very little is known about the equity implications of CAFE standards. When CAFE standards are binding, making automakers do something they would not have otherwise done, they increase the price of new vehicles because they force automakers to incur costs when investing in fuel-saving vehicle technologies. Because wealthy households are more likely than poor households to buy new vehicles, one might posit that wealthy households would pay the higher prices for new vehicles. In this case, CAFE standards would be progressive. But autoworkers are likely to bear some of the burden of binding CAFE standards, and used-car markets are also likely to be affected by CAFE, making the overall incidence of CAFE uncertain.

Feebates, on the other hand, would make new fuel-efficient vehicles cheaper. Both consumers and producers might be expected to reap some of the benefits of such a subsidy, and those selling and those buying gas guzzlers would share the costs of the tax portion of the policy. To the extent that wealthy households buy more fuel-efficient vehicles than poor households and therefore are more likely to receive a government subsidy, a feebate might be expected to be regressive.

## Conclusion and Future Directions

If consumers are making fully informed, rational decisions about what kind of vehicles to drive and producers both reap the full benefits of investment in fuel-saving technologies and act competitively when supplying fuel economy, then policy makers can rely on a gasoline tax, a carbon tax, or a carbon cap-and-trade program to efficiently reduce greenhouse gases from the personal transportation sector. In such a context, it is very unlikely that CAFE standards, now the primary policy used to encourage fuel saving in the United States, can be efficient alone or in conjunction with a tax on gasoline or carbon policy. The primary problem with CAFE is that it reduces the price of driving, thereby inducing consumers to impose greater congestion and accident costs on others. Because a feebate also reduces the price of driving, it too can be expected to be inefficient.

Only if some additional imperfection causes the market for fuel economy to fail, if consumers are short sighted, or if automakers are restricted or restrict themselves in supplying the optimal variety of fuel efficiencies, can we expect for CAFE or a feebate to improve efficiency. If the market for fuel economy fails, economic theory tells us that the one-size-fits-all nature of CAFE, at least as the policy currently stands, renders it less preferable than a feebate.

To determine whether a tax on gasoline, a carbon tax, or a carbon cap-and-trade program is sufficient to induce the optimal amount of gasoline consumption and greenhouse gas emissions from the transportation sector—and how to best implement such policies—researchers must now focus on three main areas. First, they need to identify and quantify potential failures in the market for fuel economy. Second, they should refine estimates of the external costs of gasoline as new information on the potential effects of climate change becomes available. Third, they should gain a greater understanding of the potential distributional effects of any policy designed to increase fuel economy.

# Public Finance

Neil Canaday
*Wesleyan University*

Public finance, commonly referred to as public economics, is the field of economics that examines the role of the government in the economy and the economic consequences of the government's actions.[1] A notable exception to this definition is the study of the government's effects on the business cycle, which is usually considered to be a part of macroeconomics rather than public finance. Public finance is concerned with both positive and normative economic issues. Positive economics is the division of economics that examines the consequences of economic actions and thus includes the development of theory, whereas normative economics brings in value judgments about what should be done to analyses and often gives recommendations for public policy. Normative economic issues, in fact, are discussed and debated more often in the public finance literature than in the literatures of most other fields in economics.[2]

Public finance covers a wide range of topics, many of which are central to the economics discipline. The public finance literature examines theoretical as well as empirical topics. Some studies focus on macro-issues, and others examine specific economic issues. Notwithstanding this diversity in coverage, most questions addressed by the public finance literature fall into one or more of the following three categories: (1) Under what scenarios should governments intervene in the economy, (2) what are the economic consequences of government interventions in the economy, and (3) why do governments do what they do?

Our present knowledge of public finance is the result of more than 200 years of scholarly contributions. Although originally published in 1776, *The Wealth of Nations* by Adam Smith popularized many notions about the proper role of the government that are still very much relevant to today's world. Adam Smith discussed the following three duties that the government should perform: (1) protect its citizens from foreign invaders by providing national defense; (2) protect members of society from injustices from each other through the provision of a legal system; and (3) provide certain public works, such as bridges, roads, and institutions, including elementary level education (but not secondary and university education).[3] Most people, including economists, would agree with Adam Smith that the government should perform these three tasks. Of course, many people believe the government should do even more. Many readers of this chapter may strongly believe the government should provide for the education of students at universities and colleges.

As the role of the government in the economy has changed over time, the focus of the public finance literature has similarly evolved. In the 1950s and 1960s, the emphasis of public finance was largely on issues of taxation. Now, with the government significantly involved in many aspects of the economy, the public finance literature has expanded its focus to include virtually all facets of government spending, as well as taxation. Many advances have been made within the field of public finance over the past several decades, and public finance economists have made substantial contributions to many other fields in economics. For example, the economics of aging, a relatively new economic subfield, has benefited greatly from public finance economists who have provided analysis and policy recommendations for issues pertaining to government entitlement programs for retirees. Many of these topics are of particular importance to Americans. How will the approaching retirement of the baby boomer generation affect the overall level of economic activity? And how will this growth in retirees

strain government entitlement programs such as Social Security and Medicare, and what should the government do, if anything, to these entitlement programs as a result?

## Public Finance Theory

### The Theory of the Government

When the proper role of the government is under consideration, it is often useful to think about under what circumstances the government can do a better job than private markets. If reliance on private markets' carrying of economic activities always results in economically efficient outcomes and people are, for the most part, content with the distribution of income and wealth, then there is little or no need for a government role in the economy. However, there are many circumstances where the private market fails to achieve an efficient outcome or the private market outcome results in a distribution of income or wealth that is considered by most people to be very unjust. Sometimes there are market failures. In these situations, society may be better off when actions are conducted by the government, rather than letting economic activities take place solely in private markets.

One task the government can likely do better than private markets is the provision of so-called public goods. The theory of public goods was to a large extent developed by the economist Paul Samuelson.[4] To economists, public goods are not the same things as goods provided by the public sector. Rather, public goods are goods that have the following two qualities: (1) nonrivalry and (2) nonexcludability. In comparison, private goods have both rivalry and excludability. Nonrivalrous goods are goods for which consumption by one consumer does not prevent or diminish simultaneous consumption by other consumers. On the other hand, a good has rivalry if consumption by one consumer prevents or diminishes the ability of other consumers to consume it at the same time. A slice of pizza is clearly a rivalrous good. Nonexcludability means it is not possible to prevent people who have not paid for it from enjoying the benefits of it. Air is an example of a nonexcludable good. National defense is a public good, because it has both nonrivalry and nonexcludability in consumption. Although the government provides many public goods, it also provides many private goods, such as health care, school lunches, and Social Security.

The free-rider problem is a primary cause of private markets' failure to efficiently provide public goods. Because people benefit from public goods regardless of who in society pays the costs of providing them, people have an incentive to spend too little on public goods themselves and instead take a free ride on the contributions of others. Therefore, when private markets provide public goods, too little is often spent on their provision. The government can correct this market inefficiency by taxing members of society and using this tax revenue to provide an efficient amount of public goods. On the other hand, taxes also cause market inefficiencies, a matter that is discussed later in this chapter.

The problems associated with the provision of public goods can alternatively be discussed in the framework of private and social costs and benefits. The marginal private benefit is the incremental benefit of an activity for private individuals or businesses engaged in that activity, whereas the marginal social benefit measures the incremental benefit of an activity for society. Marginal private costs and marginal social costs are similarly defined. Therefore, the demand and supply curves are the same as marginal private benefit and marginal private cost curves, respectively. Public goods create a positive externality, which is to say that public goods provide external benefits. The external benefit or positive externality is measured by the amount to which social benefits exceed private benefits. In other situations, there are negative externalities. A negative externality exists when the social cost exceeds the private cost.

Figure 25.1 illustrates the case for a positive externality. When the provision of the public good is left to private markets, individuals will purchase units of the public good until their marginal private costs are equal to their marginal private benefits. In other words, marginal private cost is the supply curve, and marginal private benefit is the demand curve. For the overall market, the quantity of the public good provided, $Q^c$, at the competitive equilibrium is not economically efficient. More specifically, too little of the public good is provided by the private market. Notice that at the competitive equilibrium (where supply equals demand), the marginal social benefit still exceeds the marginal social cost. The economically efficient outcome, $Q^*$, occurs where the marginal social benefit is equal to the marginal social cost. There are potential social gains to government intervention if the government's actions result in an increase in the quantity of the public good that is closer to the economically efficient outcome than the competitive equilibrium. For example, $Q^G$ in Figure 25.1 is one possible outcome of government intervention that results in a more economically efficient outcome than the competitive equilibrium.

Under certain circumstances, government intervention is not needed to correct the externality problem because the private market will be able to solve the externality problem on its own and provide an economically efficient outcome. The Coase Theorem, attributed to Ronald Coase, provides the conditions where the market may work efficiently even if externalities are present. The Coase Theorem states that when property rights are well defined and the transaction costs involved in the bargaining process between the parties are sufficiently low, the private market may provide an economically efficient outcome even though externalities are present.

How the Coase Theorem works can be illustrated with a simple example. Suppose Jack and Jill live next door to each other and Jack is contemplating planting a flower garden in his front yard. The flower garden will cost Jack $50 to plant (because of seeds, water, fertilizer, and labor) and

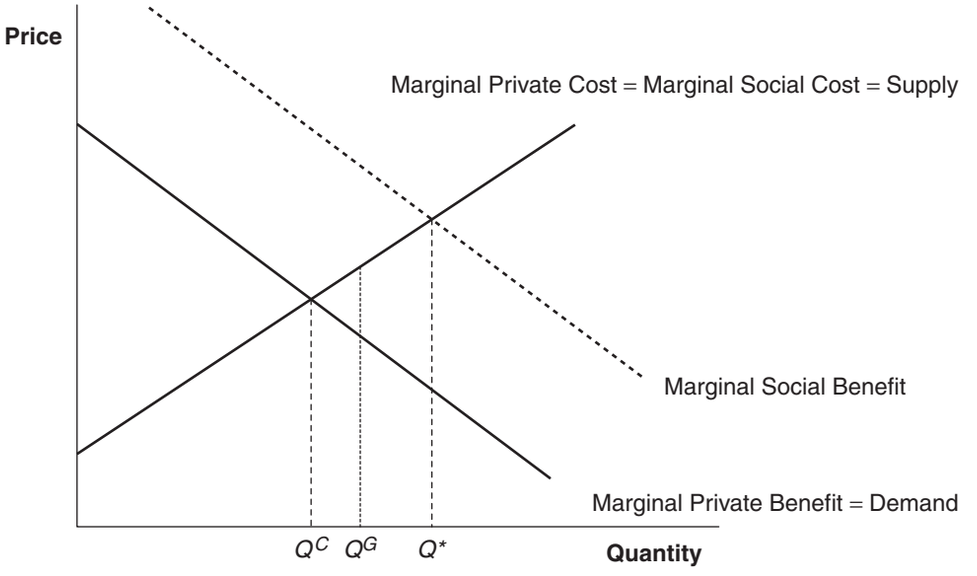

**Figure 25.1** Effects of a Tax

will provide him a benefit equal to $40 because of its beauty. The flower garden will also provide an external benefit to Jill equal to $20. This positive externality arises because Jill will get to enjoy the beauty of the flower garden even though she does not own it. Clearly, from a social viewpoint, the flower garden should be planted, because it has a total social benefit of $60, which exceeds its total social cost of $40. Nonetheless, Jack will not plant the flower garden if he has to rely solely on his own funding, because his private benefit of $40 is less than his private cost of $50. The first condition of the Coase Theorem—that property rights are well defined—is met, because Jack has the property rights over whether to plant the flower garden. Suppose further that Jack and Jill can bargain over the planting of the flower garden at zero cost. With this assumption, the second condition of the Coase Theorem—that the transaction costs of bargaining are sufficiently low—is also met.

Now, let us see the Coase Theorem in action: Jill would be willing to pay Jack an amount that is sufficiently high to induce him to plant the flower garden. As a result of this side payment, both Jack and Jill would be better off, because the flower garden will be planted and the efficient economic outcome will arise. For example, if Jill pays Jack $15 to plant the flower garden, her total benefit of $20 exceeds her total cost of $15. Similarly, for Jack, his total benefit would be $55 ($40 from getting to enjoy the flower garden and $15 from Jill), which exceeds his total cost of $50.

When only a few parties are involved in situations of externalities, the transaction costs of bargaining may very well be sufficiently low, like in the above example, and private markets may be able to correct the problem of externalities on their own, providing an economically efficient outcome. In fact, judges and legal scholars sometimes use the Coase Theorem as a guide for thinking about proper solutions to tort cases involving public nuisances.

Unfortunately, many serious situations of externalities involve many parties, and the costs of bargaining are prohibitively high. For example, situations where companies are polluting the air or water often involve many victims, and bargaining between all the parties involved would be a very costly and complicated process. It is farfetched to think that private markets can solve problems of externalities and achieve economically efficient outcomes on their own in situations of industrial pollution. In these cases, government intervention in the marketplace could improve on the private market outcome. In fact, government intervention in situations where there is degradation of the environment is common.

So far, the discussion of the government has focused on what the proper role of the government should be and how the government can improve on outcomes left solely to actions of private markets. However, economists are also interested in why governments do what they do. The subdiscipline of public finance called public choice tries to explain how democratic governments actually work, rather than how they should work. *The Calculus of Consent: Logical Foundations of Constitutional Democracy,* coauthored by James M. Buchanan and Gordon Tullock (1962), is considered by many economists the landmark text that founded public choice as a field in economics. Although public choice shares many similarities with political science, public choice economists assume that voters, politicians, and bureaucrats all act predominately in their own self-interest, rather than in the interests of the public good.

## The Theory of Taxation

A natural starting point for examining the modern theory of taxation is Richard Musgrave's 1959 textbook, *The Theory of Public Finance.* Musgrave's public finance text

was the first to look like a present-day economics textbook, using many algebraic equations and graphs to illustrate the economic effects of government policy. Musgrave's textbook provides a thorough partial equilibrium analysis of taxation. Partial equilibrium analysis examines the equilibrium in one market without factoring in ripple effects on other markets. In comparison, general equilibrium analysis examines the entire economy, and therefore, it takes into account cross-market effects. Two important economic questions of taxation are (1) what is the incidence of the tax and (2) how large is the loss in economic efficiency from the tax? The deadweight loss of the tax is another term for the economic efficiency loss of the tax. Tax incidence measures how the burden of a tax falls on different members of society. In practically all cases, taxes create economic inefficiencies through the distortion of incentives.

Figure 25.2 illustrates the concepts of tax incidence and deadweight loss within the partial equilibrium framework. Without a tax, the competitive equilibrium occurs where the demand equals supply at a price of $P^*$ and a quantity of $Q^*$. The equilibrium with no tax is economically efficient because the marginal social cost is equal to the marginal social benefit. Now, suppose a tax is imposed. The tax shifts up the supply curve vertically by the amount of the tax per unit.[5] The equilibrium quantity with the tax, $Q^T$, is below the equilibrium quantity without the tax, $Q^*$. The tax distorts market behavior in an inefficient manner, which is evident because the units between $Q^T$ and $Q^*$ are not being bought and sold when the tax is imposed, even though the marginal social benefits of these units exceed their marginal social costs. The deadweight loss of tax is represented by the triangle shaded in gray. Notice that the tax puts a wedge between the price consumers pay, $P^C$, and the price sellers get to keep net of the tax, $P^S$. The tax revenue per unit that the government receives is measured by the difference between the consumer price and seller price $(P^C - P^S)$.

The tax incidence is examined by comparing how much of the tax falls on consumers and how much falls on sellers. The dollar amount of the tax per unit falling on consumers is equal to the price consumers pay, with the tax subtracted from the price they pay without the tax $(P^C - P^*)$. Similarly, the dollar amount of the tax per unit falling on sellers is equal to the price sellers receive, without the tax subtracted from the price sellers receive with the tax $(P^* - P^S)$. The addition of the dollar amount of the tax per unit falling on consumers to the dollar amount falling on sellers equals the amount of the tax per unit $(P^C - P^S)$. In the example illustrated in Figure 25.2, the tax burden falls disproportionately on consumers.

It is important to note that how much of the tax collected from consumers, as opposed to sellers, has absolutely no effect on either the incidence or the deadweight loss of the tax. In Figure 25.2, the tax is levied entirely on sellers, as is evident by the tax raising the marginal cost exactly by the amount of tax per unit. Alternatively, if the tax were levied entirely on consumers, the demand curve would have shifted vertically downward by the amount of the tax per unit. In both cases, the consumers' net price, the sellers' net price, and the size of the deadweight loss are all exactly the same.

The elasticity of demand and the elasticity of supply are the factors that determine the incidence and deadweight loss of a tax. Some generalizations can be made about how the elasticity of demand and supply influence the tax incidence and the size of the deadweight loss of a tax. The more inelastic the demand or the supply, all else equal, the larger the share of the tax burden that falls on consumers and the smaller the share that falls on sellers.

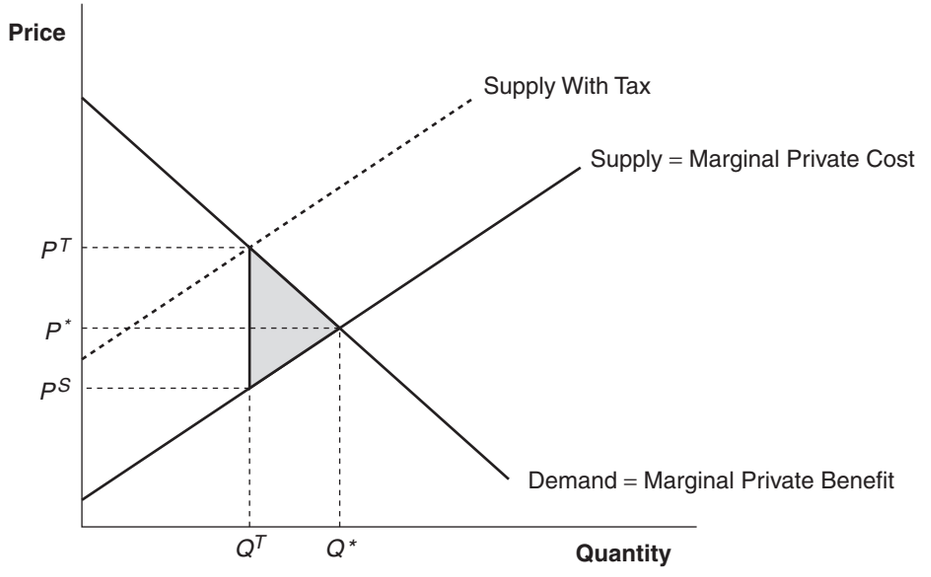

**Figure 25.2** External Private Benefits

Additionally, the more elastic the demand or the supply, the larger the deadweight loss of the tax will be. For example, suppose a tax is imposed on gasoline, a product with a relatively inelastic demand. The burden of this tax will fall primarily on consumers of gasoline, even though governments collect this tax from sellers. Furthermore, because the demand for gasoline is relatively inelastic, the deadweight loss of the tax will be relatively small because there will be a relatively small change in the quantity of gasoline bought and sold.[6] Although partial equilibrium analysis is helpful for understanding many issues of taxation, it is inadequate for providing profound insight about some important economic issues surrounding taxation. For instance, partial equilibrium analysis often cannot adequately describe the incidence and deadweight loss of taxes for situations where there are multiple products and multiple sectors of the economy. Additionally, partial equilibrium analysis is not useful, in most cases, for determining the optimal tax structure of the tax system (e.g., how much of the tax rates should be on wages, savings, and different products). To examine these issues of taxation, public finance economists rely on general equilibrium models.[7]

The scholarly work by Arnold Harberger shows how the techniques used to measure the incidence and deadweight loss of taxes in the partial equilibrium framework can be extended to situations with multiple products and sectors, including the case of the corporate income tax. The deadweight loss resulting from a tax or some other type of distortion, such as a price floor or a price ceiling, is often referred to as Harberger's Triangle. In Figure 25.2, Harberger's Triangle is the triangle shaded in gray.

The incidence of a tax may differ widely depending on whether the economy is opened or closed (i.e., whether the economy, for the most part, freely trades with other economies).[8] Harberger (1962) examines the corporate tax incidence with a general equilibrium model of a closed economy that has two sectors (corporate and noncorporate) and two factors (labor and capital). Harberger (2008) has recently revisited his work on the incidence of the corporate tax. For the interesting case where product demands and the production functions in both sectors conform to the commonly used Cobb-Douglas functional form, the entire burden of the corporate income tax falls on capital. In comparison, models that assume the economy is opened often find that much of the burden of the corporate income tax is shifted to labor.

Economic theories have addressed the design of an optimal system of taxation, a topic related to the measurement of the deadweight loss of taxes. Although taxes create losses in economic efficiency by distorting people's behavior, they are needed to generate revenues for a society to pursue its social objectives. Theories of optimal taxation look for the system of taxes that minimizes the economic efficiency costs of taxes, subject to constraints, such as the types of taxes and information that are available to the government. Theoretical inquiries into optimal taxation fall into one of the following three categories: (1) the design of the optimal system of commodity taxes; (2) the design of a general system of taxation, including nonlinear taxes on income, with a focus on the role of taxes for addressing concerns about inequality; and (3) the role of taxes to address market failures. The first strand began with the work by Ramsey (1927) and has been added to, most notably, by Peter Diamond and James Mirrlees (1971a, 1971b). The Ramsey tax rule says that under a tax system composed only of commodity taxes, the optimal tax rates are higher for commodities with more inelastic demands. Thus, the optimal tax rate is higher for gasoline than for pretzels, assuming that gasoline is more inelastically demanded than pretzels. The work by Mirrlees (1971) was the first in the second strand of theory. Finally, the seminal work by Arthur Pigou (1947) provides the foundation for work in the third strand of theory. A Pigouvian tax is levied to correct a negative externality. For example, suppose that the production of widgets has a constant $1 external cost. The government can fully correct this negative externality by imposing a constant $1 tax per widget. When this tax is imposed, widget producers will act as if their private costs are equal to the social costs, and the economically efficient outcome will prevail.

The extent to which economic inputs into production, such as labor and capital, are mobile has significant implications for taxation as well as for many other aspects of public finance. Economists have developed theoretical models to examine the effects of tax competition—a situation where governments lower taxes or provide other benefits in an effort to encourage productive resources to relocate within their borders—on tax rates, tax incidence, and on the distribution of resources across regions. Tax competition can occur between countries, states, or smaller units of government.

Also related to factor mobility is the Tiebout model, developed by Charles Tiebout (1956). Tiebout's insight is that the free-rider problem pertaining to public goods is different in the context of local governments because they offer bundles of goods and services and taxes to potential residents because people are able to take into account, when deciding where they want to live, the governmental amenities and disamenities offered by the various localities. In the Tiebout model, competition among local governments and people's ability to vote with their feet effectively solves the free-rider problem and results in an economically efficient provision of public goods by local governments. When people have different tastes for amenities, the Tiebout model predicts that there will be locational sorting based on individuals' preferences. For example, people with children will choose to live in locations with high tax rates for schools and well-funded public schools, whereas people without children, such as retirees, will choose to live in locations with low school tax rates and poorly funded public schools.

## Applications and Empirical Research

The empirical public finance literature has made significant strides over the past several decades. Several factors, including advances in computer technology, econometric techniques, and software, have contributed to improvements in both the quality of research and to the exploration of new avenues of research in public finance. Additionally, new data sets containing valuable information at the individual and household levels have been created, and this has allowed researchers to better examine empirical phenomenon. Some of the significant findings in the empirical public finance literature are discussed below, although because of the great breadth of the empirical literature, it is not possible to highlight every important area of empirical research.

Public finance economists have exploited changes in tax policy and individual and household-level data, such as the public use tax model files generated by the Internal Revenue Service's Statistics of Income Division, to measure how work incentives are distorted by tax policies. Empirical studies typically have found that the overall number of hours worked by men is not very responsive to changes in income tax rates. The high degree of inelasticity of the male labor supply implies that the burden of the income tax falls squarely on male workers, rather than employers, and that small increases in income tax rates are unlikely to create large deadweight losses from distortion of the incentives to work.

Even though, overall, the policy of income taxation may have a negligible effect on the aggregate supply of labor, income tax policy may significantly influence the labor supplies of specific groups of individuals and in specific markets. The labor supply of women, particularly married women, has been found to be much more elastic than the labor supply of men. Therefore, increases in income tax rates may cause significant numbers of married women to focus on household production instead of working in the workplace. Some studies have found that high marginal tax rates may induce some workers to leave legitimate occupations for work in the underground economy to avoid paying taxes. Also, the income tax policy pursued by a particular state may affect the labor supply of that state via migration. Some evidence suggests that workers tend to migrate from states with high income tax rates to states with low income tax rates.

Besides influencing labor supply, tax policy affects many other types of economic activity. Of particular interest is the effect of tax policy on savings decisions. Some economists have argued that lowering the tax rate on capital income increases savings because it increases the after-tax rate of return on investing. However, the theoretical and empirical evidence of the effect of tax rates on capital income and savings has been ambiguous. For example, if someone is saving with the explicit goal of accumulating $50,000 in 3 years for a down payment on a house, a reduction in capital income taxes will lower the amount this person needs to save now, because he or she can achieve the savings goal by saving less. Along these lines, more specific literature has examined how changes in tax policy that have given preferential treatment to retirement savings through contributions to IRA, 401(k), and other retirement plans have influenced aggregate retirement savings. Although some empirical evidence has indicated that this preferential tax treatment has had a positive influence on retirement savings, additional empirical analyses are still needed to develop a clearer understanding of this relationship.

Over the past 50 years, the role of the government in the economy has greatly expanded in terms of scope and magnitude, particularly regarding government spending on nondefense items. Nondefense spending by the federal and state governments in real 2007 dollars has increased almost fivefold between 1960 and 2007, from $686 billion in 1960 to $3,256 billion in 2007.[9] Spending by local governments has similarly swelled over this time period. This large expansion of the government has motivated public finance economists to examine the empirical effects of spending on a wide range of government programs.

Social insurance programs have been the recipients of much of the growth in government spending. A vast number of empirical studies have examined the economic issues for a host of social insurance programs, including Social Security; government health care programs for the elderly and poor, such as Medicare and Medicaid; unemployment insurance; worker's compensation; programs that provide subsidies to the poor, such as Temporary Assistance to Needy Families (TANF) and the Earned Income Tax Credit (EITC); and many other programs. Empirical research has found that social security programs in the United States and in other countries have reduced aggregate savings and produced early retirements. Studies have also examined the general equilibrium effects of Social Security reform, which would switch the current pay-as-you-go system to a system at least in part based on investment accounts similar to private retirement savings accounts. Many empirical studies on Medicaid and Medicare have focused on issues of adverse selection and moral hazard. Other studies have examined the potential fiscal impacts of continued growth in spending on Medicaid and Medicare.

The economic effects of government antipoverty programs have been the focus of many empirical studies. TANF is the primary welfare program in America today. In 1997, it replaced its predecessor, Aid to Families with Dependent Children (AFDC). In contrast to AFDC, TANF has strict time limits for assistance and places a strong emphasis on vocational training, community service, and the provision of childcare. Although more empirical work is still needed to sort out all of the economic impacts of TANF, one finding without controversy is that the switch to TANF has undoubtedly caused a large reduction in welfare caseloads. In terms of enrollment, EITC is the largest

government antipoverty program. EITC supplements the earnings of low-wage workers with a tax credit. This program may reduce the total hours worked of some workers and cause others to switch to lower-paying but more enjoyable occupations so that they can qualify for the tax credits. Notwithstanding these negative effects on labor supply, many empirical studies have found that EITC has increased the overall rate of labor force participation, particularly among single parents, by increasing the marginal benefit of working.

The structure of many government programs, such as public education, involves a complex interrelationship among the several tiers of government: federal, state, and local. Fiscal federalism is the subfield of public finance that examines the economic effects of having public sector activities and finances divided among the different tiers of government. A central question addressed by fiscal federalism is what aspects of the public sector are best centralized and what functions are best delegated to lower tiers of government.

Many empirical studies related to fiscal federalism have examined the economic effects of intergovernmental grants. The federal government gives grants to state and local governments for a variety of governmental programs, including those for public education, welfare, and public roads and highways. Many types of earmarks, such as the earmarking of state lottery revenues for educational funding, conceptually have the same economic effects as grants. According to standard economic theory, a lump-sum amount of intergovernmental aid given to a lower tier of government for an activity should have the same effect on spending for this activity as an increase in private incomes (Bradford & Oates, 1971). For example, a federal grant increase of $50 per taxpayer given to states for education should, theoretically, increase educational spending in the same manner as an earnings increase of $50 per taxpayer per year.[10] Therefore, grants and earmarks should have a minimal impact on total spending. Many empirical studies, however, have rejected the fungibility of intergovernmental aid, finding instead that the money given to lower tiers of government "sticks where it hits." As a result, this phenomenon is referred to as the *flypaper effect,* a term attributed to Arthur Okun. The findings in the empirical literature, however, are mixed. Some recent studies have found that local and state funding is substantially cut in response to funding from federal grants, particularly after time has elapsed since the federal aid was first received.

The Tiebout model outlined previously has spawned a rich empirical literature. Many empirical studies have built on Tiebout's work, using people's processes in choosing where to live to estimate the demands for local public goods, such as public education, and to measure how property values reflect local amenities and taxes. Empirical research has also used the Tiebout model as a foundation for explaining that the prevalence of restrictive zoning laws in many urban communities is a device to prevent free riding: buying inexpensive homes with low property tax assessments in areas where most residents own expensive homes with high property tax assessments. Additionally, the Tiebout model has influenced the fiscal federalism literature; many empirical studies have examined the proper roles of the different tiers of government.

## Public Policy Implications

It is not surprising that public finance has a wide array of implications for public policy, given that the focus of public finance is on the government's role in the economy and the economic effects of its actions. Much of the theoretical and empirical public finance literature has direct relevance for issues of public policy. Public finance economists work in all levels of government. They carry out a variety of important administrative functions and provide crucial advice and analyses to government decision makers. Public finance economists perform important public policy roles at all federal government agencies, including the Joint Committee of Taxation, the Congressional Budget Office, the United States Department of Agriculture, the Department of Defense, and the Department of Homeland Security. All state governments, and many county and city governments, also employ public finance economists, largely for their advice and analyses on issues of public policy. Even the public finance economists that are not directly employed by the government, working instead at universities and public policy institutions, directly influence debates of public policy through their research, writings, and consulting activities.

In their endeavors, public finance economists are influencing how to best address the key public policy issues of today. Here are just a few of the questions in the current debates over public policy that public finance economists are now trying to answer: What is the best way to keep Social Security sustainable without inducing severe distortions on work incentives? How should the federal government expand the coverage of heath care? How can federal and state governments best support local governments in their efforts to improve underperforming public schools? Should a state government lower corporate taxes to induce new businesses to relocate to their state?

Of course, public policy makers do not always heed the advice of public finance economists, nor do they always properly take into account the findings of economists when deciding on a course of action. In other situations, public policy makers receive conflicting advice from public finance economists, a result of vehement disagreement among economists over the proper course of action for issues of public policy. Nonetheless, the large number of public finance economists actively working with elected officials and other policy makers indicates that the field of public finance often does effectively influence public policy.

## Future Directions

In recent years, empirical research has flourished in the field of public finance. Every indication suggests that empirical research in public finance will continue to thrive in the near future. Advances in computer technology and econometric software will likely continue. New rich data sets will be created. Additionally, many new topics ripe for empirical analysis will surely arise. Governments will continue to tinker with tax policy. Reform and expansion of government social security programs will remain hotly debated topics. And the multiple tiers of government will continue to work together for providing many government programs, such as public education.

Many issues related to globalization will likely receive a lot of attention from public finance economists in the near future. By lowering the costs of capital and labor mobility across international borders, globalization has significant implications for many aspects of public finance, particularly for tax policy. Historically, some actors and rock stars have moved from one country to another, seeking lower taxes. Globalization has made this a viable option for a much larger segment of the world population. Internationally, capital is even more mobile than labor. Tax competition to induce businesses and residents to locate somewhere is no longer merely a local issue but an international one. Future research topics involving globalization will likely include how changes in tax policy induce international movements of labor and capital and how countries coordinate tax policy with each other.

The international financial crisis and federal financial bailout approved in the fall of 2008 will surely provide fruitful opportunities for future research in public finance. Many public finance issues are directly related to the federal bailouts. The federal financial bailout has important ramifications for issues related to tax burden and tax incidence, particularly if taxpayers are not fully reimbursed by the bailed-out industries. The federal bailout also involves many short- and long-run budgetary concerns. Another implication of the federal bailout is further expansion of the role of the government. Bailouts are already under way for the automobile industry. Will bailouts for other industries follow? Public finance economists will certainly examine the effectiveness of cooperation between the private sector and public sector officials.

## Conclusion

Public finance is the field of economics concerned with the role of the government in the economy and the economic consequences of the government's actions. Both positive and normative economic issues are discussed and debated in the public finance literature. Normative issues receive more attention in the public finance literature than in many other economic fields. Public finance theories examine taxation and government spending. Many theoretical advances have been made in public finance over the past 50 years. Theories of taxation examine tax incidence, economic efficiency costs of taxes, and the optimal design of systems of taxation. Issues of income inequality are sometimes taken into account by theoretical studies of the optimal design of taxation. The development of general equilibrium models has made important contributions to our theoretical understanding of taxation. Theories of government spending fall under two broad categories. First, some theories of government spending focus on the proper role of the government, examining the circumstances in which society is made better by government intervention in the economy. Second, some theories of government spending are more interested in why the government does what it does. In particular, the subfield of public choice is interested in why governments behave as they do. More recently, the empirical public finance literature has made great strides that have significantly added to our understanding of public finance. The empirical public finance literature has flourished, largely because of advances in computer technology, econometrics, and the creation of data sets with information at the household or individual level. A vast empirical literature now covers virtually every facet of taxation and government spending.

In the coming years, public finance economists will likely continue to advance our knowledge of the field and play an important role in influencing key debates over public policy issues. Globalization and the federal financial bailout that began in the fall of 2008 are two topics that surely will receive a lot of attention from public finance economists in the near future. It is to be hoped that public policy makers will rely on the advice and analyses offered by economists, many of whom specialize in public finance, to make wise decisions about the role of the government in the economy and to get us through the difficult economic times we now are experiencing.

## Notes

1. Sometimes public finance is defined more narrowly than public economics, with an emphasis primarily on issues of taxation and government expenditures.

2. The relative importance of normative issues in public finance is evident by the title of the popular textbook *Public Finance: A Normative Theory* by Richard W. Tresch (2002), which examines government economic policy.

3. Musgrave (1985) provides an excellent discussion of the history of fiscal doctrine.

4. See Samuelson (1954).

5. Because the supply curve with the tax is parallel to the original supply curve, the tax is constant per unit. Many taxes, such as sales taxes, are levied as a percentage of the products' prices. Nonetheless, the main economic findings are the same in either case.

6. This result assumes there are no negative externalities associated with the consumption of gasoline, particularly in relation to environmental degradation. Assuming there are negative externalities associated with gasoline consumption, then imposing a tax on gasoline could actually improve economic efficiency. See the discussion on Pigouvian taxes.

7. The general equilibrium models that were first used to examine incidence and deadweight loss of taxes were adopted from the economic literature on international trade. Harry Johnson (1974), an important figure in the early development of general equilibrium models for issues of international trade, provides a nice discussion of simple general equilibrium models in his *Two-Sector Model of General Equilibrium.*

8. The closed economy case is also useful for thinking about the situation in which many countries raise or lower their tax rates at about the same time.

9. Budget totals are calculated using the budgetary figures given by the Office of Management and Budget (1960, 2007).

10. Because education is a normal good, an increase in incomes would result in additional spending on education.

# Regulatory Economics

Christopher S. Decker
*University of Nebraska at Omaha*

Economic theory establishes that in a free and unfettered market, characterized by intense competition between many well-informed buyers and sellers, where resource mobility is possible, a socially efficient allocation of an economy's resources is generated. Characteristic of perfectly competitive markets, this social efficiency is measured as the maximization of total market surplus—that is, the sum of consumers' and producers' surpluses is maximized at a market-determined equilibrium price. For the individual firm, the consequence of this intensely competitive market is that price for the seller is determined within the market, and the only profit-maximizing mechanism available to the firm is to set production levels such that profits are maximized. This occurs when the firm's marginal cost of production equals the market price. Any deviation from this price will generate a reduction in market surplus, commonly referred to as a *deadweight loss.*

When a deadweight loss occurs, a market failure is said to result. This, then, becomes an economic justification for governmental intervention in the market place. History is replete with instances of government imposing restrictions on market outcomes and business behavior. For instance, for most of the nineteenth century, the government of the United States levied significant tariffs on imported goods in an effort to protect certain fledgling domestic industries from international competitive forces. Although there are many rationales, both noneconomic and economic, for governmental intervention in the marketplace, the focus of this chapter is specifically on economic rationales for governmental intervention.

In the United States (the primary focus in this chapter), there are two primary methods that government has adopted to impact business behavior and market outcomes. The first is referred to as *competition policy,* or *antitrust policy.* Competition policy tries to promote economic efficiency through rules, or codes of conduct, for firm behavior that are designed to restore the market to a competitive, or near competitive, outcome. It is not so much that monopolies are deemed illegal under competition policy, but rather it is more the attempt by a firm or group of firms to monopolize an otherwise competitive market that tends to trigger a government response. In many respects, competition policy tends to be reactive, in that it is prompted by legal challenges to a firm's observed behavior designed to garner market power when competition would otherwise exist. Competition policy is a vast field in economics and is beyond the scope of this chapter. This chapter focuses primarily on *direct regulation.*

Direct regulation is more preemptive in nature. Rules for market outcomes are established by the government. Prices are set, capital investments are subject to oversight, market entry is limited, and often certain types of production processes are mandated. Such regulation tends to override market outcomes that would have arisen without any such rules. From the perspective of most economists, who would generally prefer that the market allocate resources, the fact that regulation substitutes for market outcomes can be justified only if the market is indeed subject to failure.

After a brief review of the regulatory history of the United States, the economic reasons for regulation as well as common types of regulation are reviewed. However, because the economic prescriptions for market failures have not been followed closely in practice, a more formal review of the incentives of regulators to regulate is considered. Finally, with regulatory incentives more clearly understood, a review of deregulation is offered with an eye toward future industry regulatory efforts.

## A Brief Regulatory History of the United States

There are essentially four major periods in the regulatory history of the United States. The first occurred in the late nineteenth century. Article I, Section 8 of the U.S. Constitution grants the U.S. Congress the power to regulate commerce among and between states. This power is tempered by the Fifth Amendment to the Constitution, which asserts that the federal government shall not deprive any person the right to life, liberty, and property without due process. The first major test of government's authority to intervene in the marketplace was *Munn v. Illinois* in 1877. In a landmark decision, the U.S. Supreme Court upheld an Illinois law that regulated the prices that grain elevator operators could charge farmers. This case ultimately led to the passage of the Interstate Commerce Act in 1887 and the establishment of the Interstate Commerce Commission (ICC), which was initially set up to regulate the railroad industry.

The second major period was the progressive era and the New Deal, spanning the early twentieth century through the end of the 1930s. Regulation during this period was expanded dramatically. Industries such as electric utilities, telecommunications, trucking, air transportation, and financial securities were all subject to substantial regulatory rules and oversight. For instance, the Securities and Exchange Commission was established in 1934, and the Federal Energy Regulatory Commission was formed in 1930. Much of this regulation was focused on specific industries where prices, entry, capital investments, and quality of product and service were controlled.

The third major wave of regulation was in the 1960s and early 1970s. Rather than focusing on specific market outcomes such as prices and entry, these regulations were set up to address problems associated with product safety and the environment. For instance, the Consumer Product Safety Commission was established in 1972, and the U.S. Environmental Protection Agency was formed in 1970.

The fourth major period started in the mid-1970s and lasted through the early 1990s. During this period, many of the regulatory structures established in the 1930s were reversed, leading to substantial deregulation. Air transportation, rail and trucking industries, telecommunications, and financial markets were largely deregulated during this period. As we enter the twenty-first century, this last period of deregulation is prompting some reconsideration, at least in certain sectors of the economy. Addressing the motivations for both regulation and deregulation is clearly in order.

## Market Failure

As stated above, a market failure exists when the market, left to it its own devices, fails to efficiently allocate an economy's resources. Under such circumstances, market prices for goods and services will either be too high or too low, and production will either be too low or too high. There are several sources of market failures. For instance, a firm that enjoys limited competition, such as a monopolist, is in a position to select a profit-maximizing price in excess of the marginal cost of production. The general result is higher price, lower output, and the generation of a deadweight loss.

Another common form of market failure results from the presence of externalities in the market. An externality is a cost (or benefit) that is created as a result of market transactions that do not accrue to either producers or consumers. The classic example of an externality that generates a cost is pollution. The production of paper generates air and water pollution, thus degrading the surrounding natural environment. Residents located near the paper plant may not be employed by the paper plant and may not purchase any paper products produced by that plant. Yet they bear the cost of that pollution through potential respiratory problems and reduced quality of life. If the paper company does not compensate for this harm done, its marginal cost of production is lower than the social marginal cost of production (i.e., the cost that includes the harm done to the local residents). As a result, production levels will be too high and paper prices too low.

There are other types of market failure as well, the root cause of which has much to do with the very nature of the good (or service). Goods (or services) can be categorized based on their excludability and rivalry characteristics. A good is considered nonrival if consumption of the good by one person does not preclude other people from also deriving benefit from that good. Examples include radio signals, stadium lighting, an uncongested road, and national defense. A good is considered nonexclusionary if, once provided, no one can be prevented from consuming the good. An open access road for which there is no toll would be an example, as would, again, radio signals, stadium lighting, and national defense.

Generally speaking, markets will efficiently allocate resources in the production of goods that are rival and exclusionary, provided there is a sufficient amount of competition. For such goods, prices can be established, but no one can enjoy benefits without purchasing the good. Hence, firms will gain in such transactions. Goods that lack either excludability and/or rivalry will generate a market failure. For instance, common property resources are goods that are rival but nonexclusionary. A free and unfettered market cannot exclude access to the resource, but each additional user of that resource reduces the benefit other individual users derive from the resource. The classic example is an ocean fishery, whereby open access to the ocean prompts too much fishing activity, resulting in dramatic reductions in fish populations and potential resource extinction (the so-called tragedy of the commons). Hence, nonexcludability generates a market externality that would justify governmental intervention.

Goods that are both nonrival and nonexclusionary are referred to as *public goods.* Given these characteristics, potential suppliers of such goods (or services) would have little incentive to actually supply such markets because there is no way for a supplier to establish a price to charge consumers to secure a profitable return on investment. The result is a severe undersupply of the market, thus justifying some governmental intervention.

## Natural Monopolies

Both common property and public goods, as well as externalities, are subject to regulation. Such regulation is often termed *social regulation.* Because these types of conditions are addressed in other chapters in this volume, they are not addressed in detail here. However, goods that are nonrival and excludable dominate this chapter because they tend to generate monopoly markets where regulatory intervention is warranted on efficiency grounds. Markets where goods are nonrival and excludable are generally characterized as *natural monopolies.* Examples include electricity generation and distribution, telecommunications, cable television services, and natural gas pipelines. These goods are excludable in that access requires paying a price. However, these goods tend to be nonrival in that one additional consumer does not impact other consumers' utility. For instance, a new cable television subscriber pays a fee for the service, but that additional subscriber does not diminish other subscribers' services.

A hallmark characteristic of these markets is that there tends to be a substantial capital (fixed) cost component to supplying the good or service, but the marginal cost of supplying an additional unit tends to be relatively small. Consider an electric utility. There is a substantial capital cost associated with the construction and maintenance of generation and distribution equipment. However, once in place, the marginal cost of generating an additional kilowatt-hour of electricity is relatively small. Many goods and services in the information technology industry exhibit similar characteristics. For example, there is significant up-front investment in the development of new computer software. However, once developed, the cost of duplication and distribution to end consumers is relatively small.

A monopoly is considered natural if one firm can supply a good or a set of goods at a lower cost than can two or more firms. A key characteristic of such costs is called subadditivity. Costs are said to be subadditive if the following condition is met:

$$C(q_1) + C(q_2) + \ldots + C(q_n) > C(Q), \qquad (1)$$

where $Q = \sum_{i}^{n} q_i$.

This simply states the cost associated with producing at a total level of production, *C(Q),* by one supplier is lower than costs associated with producing smaller levels of production by many suppliers. The implication is that the average cost of production is declining over the relevant range of production. This is depicted in Figure 26.1.

Subadditivity is likely to arise under at least two circumstances. The first is in the presence of economies of scale where it is simply cheaper on average to produce larger levels of output. These scale benefits are likely to arise in industries such as electricity generation and distribution, where there is a substantial capital cost component. Spreading these large, fixed costs over larger levels of production reduces average total cost.

A second circumstance is in the presence of economies of scope (although it is possible for there to be diseconomies of scope and subadditivity). Economies of scope and subadditivity arise if a firm is producing multiple goods. If economies of scope exist, the fixed costs of production are larger than any increase in variable cost caused by joint production. Hence, it is cost effective to avoid the duplication of fixed costs associated with operating multiple plants and simply produce multiple goods from a single plant. Placed in the context of competition, then, production by multiple producers will duplicate fixed costs. Thus, if there are economies of scope, having a single firm producing output will be cost efficient.

While a single supplier is cost efficient in a natural monopoly, there is still an allocative efficiency problem if the monopolist is left to his or her own devises. Refer to Figure 26.1. Profit maximization results in a level of $Q_m$ and a price of $P_m$, generating deadweight loss equal to Area *abc.* Because promoting competition through entry will generate cost inefficiencies, some direct regulation is justified.

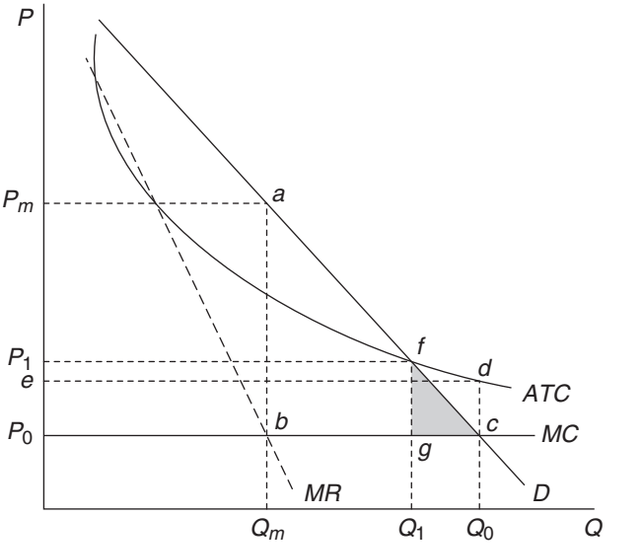

**Figure 26.1** Natural Monopoly

### Theoretical Solutions to the Natural Monopoly Problem

*Linear Marginal Cost Pricing*

The most obvious solution to the allocation problem is to regulate the price to equal marginal cost. In the figure, this would amount to setting price at $P_0$. This would result in increasing output to $Q_0$ and eliminating the deadweight loss. However, note that this will result in economic losses for the firm because at $P_0$ and $Q_0$, $P_0 < ATC$. Under such regulation, then, there would be no incentive for the firm to produce. What is necessary, then, is for the regulator to subsidize these losses by the amount $cdeP_0$, such that the firm earns zero economic profit (often referred to as a *fair rate of return*).

There are several problems with this solution. First, the regulator will likely not know the marginal cost, and the firm certainly has little incentive to provide accurate information to the regulator. Also, if the firm knows losses will be subsidized, there is less incentive for the firm to control production costs. Finally, even if all relevant cost information were known, there is an argument against this regulation on distributional grounds. Because the subsidy must come from public sources, it is not clear whether nonconsumers of this good being sold in this market should be required to subsidize producers based on economic efficiency arguments alone.

*Linear Average Cost Pricing*

In recognition that marginal cost pricing is not sustainable without subsidization, the regulator can default to average cost pricing where the price is set at $P_1$. At this price, $Q_1$ units of output are produced and the firm earns zero economic profit, another characteristic of (long-run) perfect competition. Note however, that this is a type of second-best solution to the natural monopoly problem in that there is still a deadweight loss of *cfg*.

## Government Regulation in Practice

The above discussion is largely theoretical. Implementation of regulation designed to mimic these outcomes has been the subject of substantial attention. Many means of correcting these allocation problems have been adopted. In this section, a few such policies are addressed.

### Public Ownership and Operation

Perhaps the first thought on how to correct market failure is to remove the market and allow government to supply the good. The classic example in the United States is the U.S. Postal Service. U.S. ports are also largely government owned. While relatively limited in the Unites States, public ownership and operation is more widespread in other largely market-oriented economies. In Australia, for instance, ports, electric utilities, telecommunications, natural gas distribution, and railways are nearly entirely owned and operated by the state. With state ownership, the price can presumably be set to maximize total market surplus.

Much has been written and debated about the relative merits of public versus private provision of goods and services. Many studies, such as those by Louis De Alessi (1980) and Anthony Boardman and Aidan Vining (1989), find public enterprises are less responsive to market changes, operate less efficiently, and adopt cost-reducing technologies more slowly. Other studies, such as that by William Hausman and John Neufeld (1991), find evidence in the electric utility sector (prior to rate-of-return regulation, discussed below) that publicly owned firms were more efficient than those that were privately owned. This is an issue that has been debated for years and will likely continue in the foreseeable future.

### Franchise Bidding

Harold Demsetz (1968) questions the very need to regulate utilities or other natural monopolies on efficiency grounds. His argument is that even though feasible competition in the supply of such goods is not possible, one can introduce competition by allowing firms the opportunity to bid for the right to supply the market. In essence, government auctions off the right to supply the market to the least-cost bidder. As long as there is sufficient competition—that is, a sufficient number of least-cost bidders—in the bidding process, the winning bid would be the one where the price charged to consumers would be just sufficient to ensure zero economic profit—that is, $P = P_1$ in Figure 26.1. Although this price does not eliminate the deadweight loss, franchise bidding imposes few informational requirements on a government agency. Franchise bidding, while not widely adopted in the electric utility industry, has been used rather extensively in supplying cable television services in the United States.

Although there appear to be benefits to franchise bidding, there are some potential drawbacks. For instance, if competition is over price alone, product or service quality might suffer. Offering a good (or service) at least cost may involve poorer quality inputs, little attention to manufacturing quality, poor customer services, and so forth. The duration of the franchise contract is an issue as well. If a firm is granted a franchise for a relatively long term, there must be some contractual delineations for rate changes as input costs, consumer demand, and technologies change. This may require the existence of a regulatory body to oversee such changes. If the contract is relatively short in duration, then the franchisee may, toward the end of the contract, skimp on maintenance and underinvest in new capital, leaving real problems for the next franchise owner.

## Rate-of-Return Regulation

Rate-of-return regulation is quite common and has been mostly directed at the electric utility industry. In essence, government (typically state-level government) sets up regulatory commissions. These commissions regulate the prices that the firm can charge its customers so that the firm earns a normal profit. However, it does so in a rather indirect way by regulating the rate of return the firm can earn on capital investments. For instance, maintenance and expansion of electricity generation plants and transmission lines require capital expenditures by the firm. Ideally, the firm would pass some of this cost on to consumers in the form of higher prices. To ensure that the needed price increase allows the firm only a normal rate of return on that investment (akin to what linear average cost pricing would justify), a rate hearing is convened and a new rate is agreed on. In effect, the allowed rate of return on the capital investment (i.e., the price of capital) is set. In turn, the price the firm charges consumers is then adjusted. Although this is an indirect means of attempting to achieve linear average cost pricing, it has become the most common regulatory form in the United States.

Several issues arise here as well. First, it may be that the regulatory commission allows a higher than fair rate of return if information is not complete enough to ensure an accurate cost measure. Another issue that arises is regulatory lag. Once a new fair rate of return on investment is agreed on, capital market prices (i.e., interest rates on purchased capital) can change. Before a new rate hearing can be set, there may be a significant period of time when the firm can enjoy a rate of return on its investment in excess of the fair rate of return.

The potential for the market rate of return on capital investments to differ from the regulated rate of return has caused economists to question the efficiency of rate-of-return regulation. In a seminal article, Harvey Averch and Leland Johnson (1962) show that rate-of-return regulation could lead to overcapitalization in production. Their basic model involves the regulated firm maximizing profits by choosing a level of capital, $K$, and labor, $L$:

$$\max_{K,L} \Pi = R(K,L) - wL - rK, \tag{2}$$

subject to the following regulatory constraint:

$$\frac{R(K,L) - wL}{K} = s, \tag{3}$$

where $R(K,L)$ is the firm's revenue function, $w$ is the wage rate, $r$ is the unit cost of capital, and $s$ is the allowed rate of return on $K$. Note that if $s < r$, then the firm will not produce. So we consider the case where $s \geq r$. Optimization yields:

$$\frac{MPK}{MPL} = \frac{r - \alpha}{w}, \tag{4}$$

where $MPK$ and $MPL$ are the marginal products of capital and labor, respectively, and

$$\alpha = \frac{\lambda(s - r)}{1 - \lambda}, \tag{5}$$

where $\lambda$ is the Lagrange multiplier whose value lies between zero and 1. Note that if $s = r$, then $\alpha = 0$ and the result would be the standard long-run condition for optimal input mix presented in intermediate microeconomics courses:

$$\frac{MPK}{MPL} = \frac{r}{w}. \tag{6}$$

In effect, the regulator has ensured not only a normal economic profit but also optimal input mix of $K$ and $L$. However, if $s > r$, then $\alpha > 0$. Under this condition, after some algebra, we find that rate-of-return regulation causes the following result:

$$\frac{MPK}{r} > \frac{MPL}{w}. \tag{7}$$

The condition of Equation 7 states, under rate-of-return regulation, that at the prevailing market prices for $K$ and $L$, the firm has an incentive to buy more capital. In effect, regulation has induced the firm to value capital at a higher rate than the market for that capital dictates, prompting additional purchases of $K$. This overcapitalization result prompted a series of empirical studies. Some have found support for the model, such as H. Craig Petersen (1975); others have not, such as William Boyes (1976).

The potential for resource misallocation under rate-of-return regulation can have other undesirable implications. Joseph Flynn and John Mayo (1988), for instance, find evidence that the regulated rate of return does have a significant effect on the incentives of electric utilities to invest in research and development. Indeed, they find that the more restrictive the regulated rate—that is, the lower $s$ is, the less research and development will be undertaken by regulated firms. In effect, the firm is responding to the regulatory constraint, rather than market forces, in seeking cost-efficient innovations to production and distribution. Given that rate hearings are costly and potentially infrequent, the potential implication of these results is that rate-of-return regulation can slow innovation if $s$ is low and not allowed to increase. In response to such possibilities, economists have developed incentive-based policies that allow regulated firms opportunities to respond to market conditions.

## Cross's Incentive Pricing Scheme

John Cross (1970) developed a simple pricing rule that would allow regulated firms to reap rewards for adopting cost-efficient innovations. His basic rule is

$$P = \beta + \alpha(ATC), \tag{8}$$

where $P$ is the regulated price, $ATC$ is the regulated firm's average total cost, $\beta$ is a base price below which actual prices may not fall, and $\alpha$ is a sharing rate coefficient bound between zero and 1. This sharing rate measures the percentage of $ATC$ that gets reflected in price. Recall that rate-of-return regulation ideally tries to set price equal to $ATC$ and hold it there until the next rate hearing. To see how Cross's rule works, suppose that $ATC$ is set at \$10 per unit, $\beta$ is \$5 per unit, and $\alpha$ is 0.5. Clearly, under Cross's rule, $P$ is \$10 per unit. Now suppose that the firm is able to reduce average costs to \$9 per unit. The new price $P$ is thus \$9.50. Note that consumers gain by enjoying a lower price. However, the firm also gains because average costs have fallen by \$1 per unit but price has fallen only 50¢ per unit. Hence, the firm gets to enjoy the benefits associated with its cost reduction efforts automatically.

### Price Cap Regulation

Cross's rule has not appeared to have realized much application. However, a related incentive-based regulatory scheme called *price cap regulation* has. Under this regulatory policy, a firm's price is set, or capped, at an initial regulatory hearing. After that, the regulated firm is allowed to adjust price at the rate of inflation minus the rate of productivity growth. So if inflation were running at 4% and productivity gains were averaging 1%, the firm could increase its price by 3%. Moreover, the firm is free to price at any level it chooses below the price cap. Like Cross's rule, allowing automatic price changes due to both market conditions and technology offers the firm incentives to seek productivity gains. Such regulation was adopted in the 1980s in the telecommunications industry. Alan Mathios and Robert Rogers (1989) study states with some type of price cap mechanism versus those without. They found that those states with such a price cap regulation had lower prices for long-distance service than those without.

There are many other incentive-based regulatory schemes that seem to offer results to superior rate-of-return regulation, but their adoption in policy circles is relatively slow. The natural question to ask is why. Perhaps a more formal review of the motivation for regulation is in order.

## Regulatory Behavior and Theories of Regulation

Irrespective of the type of policy adopted to regulate natural monopolies, one underlying motivation seems clear: There is a general recognition that, left to its own devices, the market will generate a higher price and a lower level of production than is socially desirable. The question, however, is whether regulators are in fact motivated to adopt policies that lower price to increase social welfare or are responding to other forces in the economy.

### Public Interest Theory of Regulation

The idea that regulators are motivated to maximize social welfare by lowering prices and reducing deadweight losses forms the foundation of a theory of regulation commonly referred to as the *public interest theory* of regulation.

The essential validity of this theory was challenged by several scholars, starting in the 1960s. In a very influential article, George Stigler and Claire Friedland (1962) study prices charged to consumers by electric utilities in states where some regulation existed and compared them with rates levied in states with no regulation. They find, contrary to what the public interest theory would predict, no statistical difference in prices between these groups of states. Although this prompted many follow-up empirical studies, some of which confirm Stilger and Friedland and some of which refute their findings, there is little doubt that this study prompted economists to reconsider the public interest theory of regulation. Indeed, in a detailed and often-cited review of regulation in the United States, Richard Posner (1974) concludes that there is little correlation between regulation and the correction of externalities or the curbing of monopoly power. Clearly, revising regulatory motivation was in order.

### Economic Theory of Regulation

Development of an alternative theory of regulatory behavior is rooted in four seminal studies: Mancur Olson (1965), Stigler (1971), Sam Peltzman (1976), and Gary Becker (1983). Stigler, building on Olson's work on the rationale for collective action, addresses these fundamental questions: Why is there regulation? How is it implemented? He then sets forth a series of general assumptions that would enable predictions as to which sectors of the economy would be subject to regulation and which would not. This analysis is formalized by Peltzman.

#### *Stilger and Peltzman Models*

The basic insight and structure of the theory is as follows. First, Stigler (1971) asserts that government is unique in its power to coerce agents in an economy to act or behave in certain ways. This basic resource—that is, the power to coerce—is in effect a tradable commodity. An interest group, such as an industry or a labor union, that can influence the government to employ its power of coercion to meet the desires of that group, stands to gain. Therefore, there is in fact a market for political influence, the supply of which is the power of coercion, and the demand for which is the potential benefits the coercion can offer an interested party. The mechanism through which political influence is exchanged can take many forms. Perhaps the most common are the securing of monetary campaign contributions and the securing of votes for

particular candidates. The outcome of the transaction may be varied as well. Indeed, regulation may be the primary avenue whereby an interest group can increase its economic gains by having the government construct rules and institutions that favor that group. By relying on market forces to dictate the structure and direction of regulation, predictions can be made regarding where regulation is likely to occur and how. In effect, any group that stands to benefit and is able to pay the price for such regulation will realize regulatory benefits.

*Types of benefits received by an interest group.* There are many types of benefits a group receiving favorable regulation can receive. One benefit is a direct subsidy from the government. The most famous example is the U.S. government land grants given to the transcontinental railroads in the 1860s. Another regulatory benefit might manifest itself in the form of an entry barrier allowing existing firms to enjoy secure market shares and profits. Since the 1930s, many large cities in the United States have limited the number of legally operating taxicabs by issuing taxi medallions (essentially, permits to operate a taxicab). Regulation can also increase the price of a substitute product for a particular industry. For instance, in the 1930s and 1940s, the ICC expanded its authority to regulate freight rates for trucking and barges, in effect increasing rates in these sectors. This benefited the rail industry, which otherwise might have faced substantial price competition from these alternative services. Finally, it is possible for regulation to favor one group of customers over another. This is a form of cross-subsidization whereby different prices are charged to different groups. For instance, it is generally accepted today that prior to deregulation of the telecommunications industry, because the rates for long-distance service were substantially higher than rates for local services, users of long-distance service were in effect subsidizing local service customers.

*Characteristics of groups that tend to garner regulatory favor.* The literature suggests at least five characteristics of groups that garner regulatory favor. The first is perhaps the most important. The size—that is, the number of members—of the interest group matters. At first glance, one might conclude that the larger the membership of the interest group, the more influence that group will wield. While this is in part the case, there is an important element to consider. In the exercise of political influence, which can be a very costly activity, there is serious potential for a free-rider effect to arise. If an interest group is sufficiently large, one member may rationally deduce that one additional player's marginal contribution to political influence is sufficiently small relative to the cost of participation and choose not to participate in the influence game, believing that the other members will engage. This is the essence of the free-rider effect—that is, attempting to secure benefits on the efforts of others without having to incur any costs. However, such a rationale is likely to be exercised by others in the group as well. As a result, there is likely to be a substantial underrepresentation of political influence by the interest group. A smaller group stands a better chance of engaging all members in political influence because it is easier to identify, and punish, free riders. Hence, in the regulatory influence realm, moderately sized interest groups are likely to have more success than very large groups or relatively small groups.

Second, groups with a strong commonality of interests tend to be more successful in regulatory influence. Many groups have divergent interests. Other groups have very well-defined interests and objectives. The voting population of the United States, for instance, constitutes a political interest group. This group clearly has a wide range of interests, and it is difficult to identify a given issue or objective that dominates this group's concerns. However, firms competing in the U.S. steel industry and facing the prospect of foreign competition due to relaxed trade quotas or lower trade tariffs have a strong common interest in hindering such legislation. As a result, they are likely to be more successful in achieving their objectives.

Third, those interest groups with a very large overall per-member benefit from a given regulatory outcome are going to have a greater incentive to engage in political influence, and they are likely to exert greater time and effort in obtaining their desired outcomes. Fourth, success often hinges on what is termed the *deep pockets effect.* Those interest groups that have greater financial resources to support political causes or candidates are likely to have greater success in the regulatory influence game. Finally, interest groups with complete information about the various ramifications of regulatory structures are more likely to succeed. The ultimate effects of many regulatory actions are often far from obvious. If a given regulatory outcome is not clearly understood by a particular interest group affected by the regulation, that group's interests will be underrepresented in the political process.

In short, then, those groups with an optimal number of highly impacted members with ready access to good information regarding regulatory outcome as well as sufficient resources available to influence regulators are likely to have success in influencing the structure and enforcement of regulations. The theory of economic regulation, in general, does not necessarily focus on an industry's ability to direct regulatory structures in its favor. Indeed, there are many interest groups that exert substantial influence on regulators. When it appears that regulation favors an industry, the term *capture theory of regulation* is often adopted.

Capture theory posits that legislators that design regulations favoring an industry are in effect captured by that industry. Many examples seem to fit well with the characteristics of this theory. Randal Rucker and Walter Thurman (1990) highlight the U.S. peanut market as an example. Since 1949, the federal government managed a program

called the U.S. Peanut Program, which had the effect, through international quota limits and other means, of limiting the number of farmers who could sell peanuts in the United States. The number of U.S. peanut farmers is relatively small, but they have enjoyed substantial profits from peanut sales. Although this program in effect kept peanut prices higher than a competitive market would generate (estimates suggest that the domestic price is about 50% higher than the world price), peanut demand is relatively broad based, and consumers, representing a very large constituency with diverse interests, are ill inclined to mobilize against a program that is estimated to cost each consumer only $1.23. Clearly, the capture theory of regulation appears to have been in operation in this market.

### *Becker's Model*

The Stigler (1971) and Peltzman (1976) models of economic regulation are essentially based on a regulator's objective of maximizing political support. Building on this basic structure, Becker (1983) focuses attention on competition between interest groups. In Becker's construct, there is a fixed amount of political influence, and interest groups compete for some portion, if not all, of this influence. Interest groups, in deciding how much political pressure to apply on the regulator, in the form of, say, direct lobbying or campaign contributions, must now consider not only the cost of such activity but also the level of political pressure their competitors are likely to exert. This approach introduces a game theoretic concept into the economic theory of regulation: the theory of best response. In Becker's model, one interest group's best response in increases in political pressure by a competing group is to itself increase its level of political pressure. Ultimately, this will lead to a political-pressure equilibrium, where political influence is, in effect, shared between groups. One interest group enjoys a greater share of political influence than another if the characteristics of that group are favorable to success (i.e., a optimal group size, sufficient resources, and complete information). Given the determination of relative influence as the outcome, however, Becker's approach focuses on relative effectiveness of interest group influence. Specifically, an interest group could succeed in gaining a substantial amount of political influence even if there is substantial free-riding behavior among its members. What is important now is that the interest group's free-riding problem is less severe than that of any competing interest group. It is the relative severity of free riding that leads to the relative distribution of political influence.

## The Deregulation Movement and Beyond

With a clear indication from academic economists, policy analysts, and general public perception that regulation was not only failing to generate social-welfare-enhancing outcomes but also appearing to favor the economic interests of regulated industry, a wave of deregulation efforts began in the mid-1970s. Although the long-term implication of mass deregulation is subject to considerable debate, there are a number of instances where evidence suggests that the immediate aftereffects of deregulation in certain sectors were quite positive.

One example is the airline industry in the United States. In 1938, the Civil Aeronautics Act was passed, creating the Civil Aeronautics Board, which effectively regulated price, routes, entry, capital investment, and scheduling of flights. However, in the intervening years, it became clear that regulation of this industry was not justified, on grounds that it exhibited characteristics of a natural monopoly. Indeed, most economists viewed the industry as a workably competitive one. Such a market is characterized by a sufficient number of firms to warrant potential competition, limited scale economies, mobile capital, and relatively frictionless entry and exit. The airline industry generally has these characteristics: There are a number of competitors, entry into viable markets is quite possible, and planes are highly mobile resources. Eventually, the industry was effectively deregulated in 1978. According to Alfred Kahn (1988), the result was that between 1976 and 1986, fares fell over 28%. Moreover, Steven Morrison and Clifford Winston (1986) estimate welfare gains to the industry of about $8 billion.

Another industry with a long history of regulation that was deregulated at this time was the railroad industry. As stated, the regulations of rates, entry, and capital investment began in 1887 with the passage of the Interstate Commerce Act. The Hepburn Act of 1906 gave the ICC the authority to set maximal rates, and the Transportation Act of 1920 gave it the authority to set minimal rates and regulate entry on rail routes. The reason for this regulation has been linked directly to the economic theory of regulation. In short, the existing railroad companies of the early twentieth century in effect wanted regulation to stabilize prices, secure market shares, and limit substitute services, such as trucking or barge transportation, from undercutting their business.

Over time, however, it became clear that regulation was preventing efficient pricing. In effect, this industry was also a working competitive one where competitive pricing was possible and allocatively efficient. In 1980, the Staggers Act was passed, effectively ending the ICC's control over the industry. The result, according to Kenneth Boyer (1987), was that freight rates fell over 12% between 1981 and 1986. Regulation was, in effect, artificially inflating prices.

## Conclusion: Is Reregulation in the Future?

This chapter offers a brief overview of the regulatory economics field. Given space limitations, a number of key subjects have been omitted. Interested readers are referred to W. Kip Viscusi, John Vernon, and Joseph Harrington

(2005) and David Kaserman and John Mayo (1995) for more in-depth study. That said, this chapter highlights the key literature in the field.

The challenges facing the U.S. economy at the beginning of the twenty-first century are quite substantial. Although this chapter has intentionally not focused on regulation of the financial markets, largely because many of the issues are macroeconomic and finance-oriented in nature, needing an entire chapter to effectively evaluate, it seems clear that dramatic deregulation of the financial markets in the 1990s may have gone too far. Some form of reregulation may be in order. Indeed, reregulation may need to be reconsidered in other sectors as well. Future policy recommendations coming from economists regarding such regulation are unknown. However, analysis is likely to build on some of the incentive regulations discussed in this chapter, with deference toward the economic theory of regulation, and focus on information asymmetries, another type of market failure that generates an inefficient price and output combination. Whether an industry is a natural monopoly or not, be it automobiles, electricity, or financial securities, sellers tend to have more information than buyers, and the incentives to exploit such informational advantages are quite powerful. Consumers could be induced to pay a higher price than a competitive market with full information would justify. Regulation is likely to focus on rules that require complete disclosure of such information. How such policies should look will require substantial scholarly attention. The regulatory economics is a fascinating subject indeed, and, with much work yet to be done, this field's future is bright.

# Cost-Benefit Analysis

Mikael Svensson
*Örebro University, Sweden*

Infrastructure, education, environmental protection, and health care are examples of goods and services that in many circumstances are not produced by competitive private companies. Instead, decision making regarding investments and regulations is often made by politicians or public sector officials. For these decisions to be consistent, rational, and increase welfare, a systematic approach to evaluating policy proposals is necessary. Cost-benefit analysis is such a tool to guide decision making in evaluation of public projects and regulations. Cost-benefit analysis is a procedure where all the relevant consequences associated with a policy are converted into a monetary metric. In that sense, it can be thought of as a scale of balance, where the policy is said to increase welfare if the benefits outweigh the costs. Cost-benefit analysis of a proposed policy may be structured along the following lines:

1. *Identify the relevant population of the project.* For a cost-benefit analysis of a single individual or for a firm, this is not a problem. But in a societal cost-benefit analysis, we need to consider how to define society. A common approach is to consider the whole country as the relevant population. This is reasonable given that most public policies are financed at the national level. Another approach is to conduct a cost-benefit analysis specifying costs and benefits using different definitions of the relevant population—for example, including benefits and costs of a neighboring country in the analysis.

2. *Specify all the relevant benefits and costs associated with the policy.* The aim with a cost-benefit analysis is to include all relevant costs and benefits with a policy. Based on the definition of the population (Step 1), every aspect that individuals in this population count as a benefit or a cost should be included in the analysis. For some benefits and costs of a policy, this may be an easy task—for example, 2,000 hours of labor input are required next year to build a road. But there are also more difficult phases in this step of a cost-benefit analysis; some examples include (a) a new infrastructure investment may have ecological consequences that are difficult to estimate and (b) regulating speed limits in a major city may have beneficial health effects due to decreases in small hazardous particles. For the economist or analyst, this step often consists of asking the right questions and gathering the necessary information from the literature, professionals, or both.

3. *Translate all the benefits and costs into a monetary metric.* A cost-benefit analysis requires that the different consequences are expressed in an identical metric. For simplicity, we use a monetary metric ($ or €, etc.). Consider the example of an investment in a new road. The costs for the labor input can be valued by the wages (plus social fees, etc.), and the use of equipment may be estimated by the machine-hour cost. For benefits of, for example, increased road safety, decreased travel time, and decreased pollution level, there are no market prices to use; instead, weights and estimates are necessary to translate these benefits into a monetary metric. If this would not be possible with all relevant consequences, they should at least be included as qualitative terms in the evaluation. In the Valuation of Nonmarket Goods section, giving nonmarket goods a monetary estimate is discussed.

4. *If benefits and costs arise at different times, convert them into present value using an appropriate social discount rate.* Most people prefer a benefit today to a benefit in one year. There are several reasons for this, one being that no one knows for sure whether he or she will be alive in a year. Another reason may be that, over a longer

time horizon, people expect their incomes to increase in the future. If an extra dollar has a larger utility benefit to a less rich individual, that individual would prefer to consume when he or she has less money (today) rather than when he or she has more (e.g., in 5 years). Also, from an opportunity-cost approach, $100 that is not consumed today can be invested in a bond, and in a year from now, it may be worth $105, implying higher consumption in one year. In a cost-benefit analysis, economists therefore (generally) do not treat benefits and costs that occur at different times as equal; rather, they translate all benefits and costs into a present value. Choosing an appropriate social discount rate is, however, a complicated task and will often have major effects on the results of the evaluation. In the Discounting section, this is discussed in more detail.

5. *Compare the net present value of benefits and costs.* When the present value of benefits ($PV_B$) and costs ($PV_C$) has been calculated, what remains is to calculate the net present value (*NPV*). The policy is said to increase social welfare if the net present value is positive—that is, $PV_B - PV_C > 0$. It is also common to express the comparison as the benefit-cost ratio—that is, $PV_B / PV_C$, which gives the relative return of the investment. If the ratio is greater than 1, the policy increases social welfare.

6. *Perform a sensitivity analysis to see how uncertain the benefit-cost calculation may be and give a policy recommendation.* A cost-benefit analysis will have several uncertainties regarding the outcome. It is most often not reasonable to show only one point estimate of the evaluation. There are often uncertainties regarding both parameter values (such as the monetary estimates of, e.g., increased safety or environmental pollution) and more technical issues, such as the economic lifetime of a new road, which is the period during which it retains its function. These uncertainties need to be explicitly modeled. The final step in a cost-benefit analysis is to give a policy recommendation based on the result of the evaluation as well as the uncertainties associated with the result.

## What Do We Mean by Social Welfare?

The aim with a cost-benefit analysis is to evaluate the welfare effect of a policy. This requires a definition of what is meant by social welfare in an economic framework. The meaning of a welfare improvement is, in its most restricted view, formulated in the Pareto criterion. The Pareto criterion states that a policy that makes at least one individual better off without making any other individual worse off is a Pareto-efficient improvement and increases welfare. However, the Pareto criterion is generally useless as a definition for welfare improvements in a real-world application, because more or less all policies make at least someone worse off. It may also be criticized on ethical grounds; consider a vaccine that would save 1 million lives in sub-Saharan Africa but required a €1 tax on someone (a nonaltruistic individual) in Europe or the United States. According to the Pareto criterion, this policy could not be said to increase welfare, but this conclusion would violate the moral values of most individuals.

As a development to the Pareto criterion, the Kaldor-Hicks criterion was formulated, and it may be seen as the foundation of practical cost-benefit analysis. The Kaldor-Hicks criterion is less restrictive than the Pareto criterion and may be interpreted such that a policy is considered to increase welfare if the winners from a policy are made so much better off that they can fully (hypothetically) compensate the losers and still gain from the policy (potential Pareto improvement). This implies that every Pareto improvement is a Kaldor-Hicks improvement, but the reverse is not necessarily true. The compensation from the winners to the losers is a hypothetical test, and the compensation does not need to be enforced in reality (which distinguishes it from the Pareto criterion). In the example above, the vaccine to save 1 million lives would pass the Kaldor-Hicks criterion, if those who were saved would be hypothetically willing to compensate the European taxpayer with a payment of at least €1. Cost-benefit analysis is a test of the Kaldor-Hicks criterion, translating all the benefits and the costs into a monetary metric. The Kaldor-Hicks criterion also implies that we need to collect information only on aggregate benefits and costs of a policy; we do not need to bother ourselves determining which individuals are actually winning or losing from a policy.

## Valuing Benefits and Costs

Performing a cost-benefit analysis of a policy requires that all benefits and costs of the policy be summed up in monetary terms. There are two principal ways of measuring the sum of benefits in a cost-benefit analysis: willingness to pay (WTP) and willingness to accept (WTA). Both WTP and WTA are meant to value how much a certain policy is worth to an individual in monetary terms. The WTP of a policy may be characterized as an individual's maximum willingness to pay, such that he or she is indifferent to whether the policy is implemented—that is, if it is implemented, utility is the same after the policy as before the policy. The WTA of a policy may instead be characterized as the lowest monetary sum that an individual accepts instead of having the investment implemented—that is, utility is the same when receiving the money as it would have been if the investment had been implemented. WTP and WTA for a policy are expected to differ (WTP < WTA) because of the income effect. Robert D. Willig (1976) shows, using plausible assumptions, that WTP and WTA should not differ from each other by more than a few percentage points. But a lot of research has

documented that WTP and WTA usually differ a lot for the same policy, with WTA being significantly higher than WTP. Several hypotheses have been put forward trying to explain this discrepancy, one frequent hypothesis being the existence of an endowment effect (Kahneman, Knetsch, & Thaler, 1990). An endowment effect states that individuals value a good significantly more once they own it, which would create a gap between WTP and WTA for an identical good. In several circumstances, it is often more problematic to estimate WTA for a good, especially in valuation of nonmarket goods, implying that it is more common to use the concept of WTP in cost-benefit analyses.

The cost of a certain policy is based on the opportunity cost concept—that is, the value of the best alternative option that the resources could be devoted to instead. The opportunity cost is derived based on companies' marginal cost curve—that is, the cost that is associated with increasing output with one unit. This should not be equalized to accounting costs, which do not necessarily tell us the economic cost of an activity. As an example, going to a 2-year MBA program has some direct costs (accounting costs), such as tuition fees, books, and travel costs to attend lectures, but also indirect costs, such as the money that one could earn in a job if not attending the MBA program. The economic cost of an activity is the sum of direct and indirect costs.

## Valuation of Market Goods

To estimate benefits and costs of a policy, the natural starting point is to examine whether market prices exist that may be used. If the market is characterized by perfect competition, or a reasonable approximation of perfect competition, and no external effects exist, the market price can give us information about the willingness to pay for a marginal change of a good. For example, if we need to use production factor $X$ for a certain investment and our demand for $X$ will not affect the market price, we can use the market price as a cost measure. The total cost of the production factor in the cost-benefit analysis is, then, the market price multiplied by the number of units used. However, if the policy will also affect the market equilibrium, we cannot simply use the market price in our analysis. Figure 27.1 shows the difference.

Initial market equilibrium is at price $P_0$ and quantity $Q_0$. Imagine that a new policy will lead to a decrease in the market price to $P_1$, which increases quantity consumed to $Q_1$. The total benefits of this policy include the increased consumer surplus for the original consumers (rectangular area $P_0P_1AC$) as well as the benefit of the new consumers (triangle area ABC). Hence, the total benefit may be represented by the area $P_0P_1AB$, which shows that when a policy has a nonmarginal effect on the market price, we cannot simply use the prepolicy market price in a cost-benefit analysis.

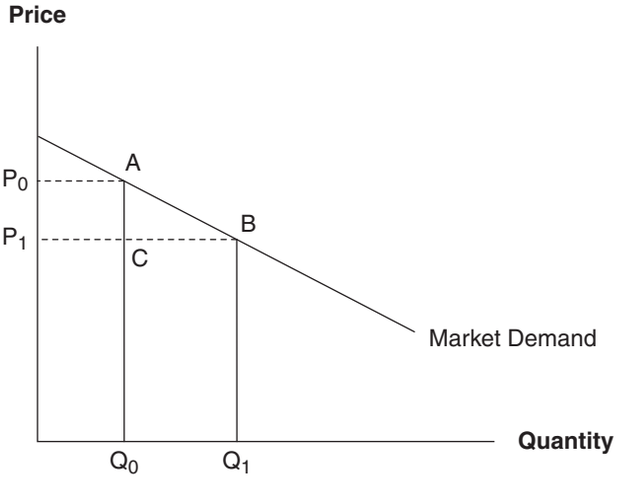

**Figure 27.1** Measuring Benefits and Costs for Nonmarginal Changes in Quantity

Other problems to note when using market data as information on prices in a cost-benefit analysis include market imperfections, such as tax distortions and externalities. The existence of taxes implies that there are several market prices, including or excluding taxes. An easy rule of thumb is to calculate prices including taxes, which implies that prices are expressed as consumer prices rather than producer prices. This implies that, for example, labor costs should be calculated as gross wages plus other social benefits or taxes that the consumer (or employer) has to pay. There is also another important effect of taxes that needs to be considered. Usually, cost-benefit analyses are performed for public projects, which often are paid for by taxes that lead to distortions in the economy. Distortions are created because not all activities are taxed, such as leisure. This implies that taxes on labor incomes change the relative prices between labor and leisure and lead to economic inefficiency. The distortion should normally be included in a cost-benefit analysis. As an example, in Swedish cost-benefit analysis, the recommendation is to include a distortion cost of 30% of direct costs (including taxes).

A final complicating note is that theoretically it may be that the correct benefit measure is the option price of a policy, which consists of the expected surplus (as outlined above) as well as the option value of a policy. Option value is the value that individuals are willing to pay, above the expected value of actually consuming the good, to have the option of consuming the good at some point in time (Weisbrod, 1964). For example, investing in a new national park includes the expected surplus of actually going to the park for the visitors. But it may also include a willingness to pay reflecting that the national park provides an option to go there, even if an individual will never actually go. In practical applications, it is common to exclude option value in the benefit calculations. There are several arguments for this; for example, it is difficult to measure and separate option values from other types of

values or attitudes that may not be relevant, such as nonuse values (non-use value refers to value an individual may place on, e.g., saving the rain forest in a specific region in South America, even if the individual knows that he or she will never go there—an intrinsic value). In addition to option value, sometimes it is also argued that a quasi-option value (sometimes referred to as *real option*) should be included in a project evaluation. The quasi-option value refers to the willingness to pay to avoid an irreversible commitment to the project right now, given expectations of future growth in knowledge relevant to the consequences of the project. It is not particularly common to include quasi-option value in cost-benefit analyses.

## Valuation of Nonmarket Goods

A common difficulty with a cost-benefit analysis is the fact that the policy to be evaluated includes a nonmarket good that is publicly provided. This implies that there are no market data to use. Examples of nonmarket goods that are common in cost-benefit analyses of public policy are values of safety, time, environmental goods, and pollution. Generally, there are two main approaches available for estimating monetary values of nonmarket goods: (1) revealed preference (RP) methods and (2) stated preference (SP) methods. RP methods use actual behavior and try to estimate implicit values of WTP or WTA. SP methods use surveys and experiments where individuals are asked to make hypothetical choices between different policy alternatives. Based on these choices, the researcher can estimate WTP or WTA.

### *Revealed Preference Method*

Revealed preference techniques can be used to elicit willingness to pay when there is market information about behavior that at least indirectly includes the good that the analyst is interested in evaluating.

One revealed preference approach is hedonic pricing (Rosen, 1974). Imagine that we would like to estimate the willingness to pay to avoid traffic noise; we may be able look at the housing market in a city to accomplish this. The price of a house depends on many different characteristics: size, neighborhood, number of bedrooms and bathrooms, construction year, and so on. But another important determinant may be the level of noise—that is, a house located close to a heavily trafficked highway will generally be less expensive than an identical house located in a noise-free environment. The hedonic pricing approach uses this intuition and performs a regression analysis where the outcome is the market value of a house including several relevant characteristics as determinants of the house price (including the noise level, measured in decibels). The results from such a statistical analysis can in a second step tell us the impact of the noise level on the market price, holding other important factors constant. For example, Nils Soguel (1994) uses data on monthly rent for housing in the city of Neuchâtel in Switzerland and included factors measuring the structure and condition of the building, several apartment-specific factors, and the location of the property. Based on a hedonic pricing approach, it shows that a one-unit increase in decibel led to a reduction in rents by 0.91%. Hence, using this approach, it is possible to estimate the economic value of noise.

Another revealed preference approach is the travel-cost method (see, e.g., Cicchetti, Freeman, Haveman, & Knetsch, 1971). This method uses the fact that individuals can reveal the value of a good by the amount of time they are willing to devote to its consumption. For example, if an individual pays $10 for a train ride that takes 30 minutes to visit a national park, we can use this information to indirectly estimate the lower bound of the value that the individual assigns the park. If the value of time for the individual is $20/hour, the individual is at least willing to spend the train fare of $10 plus $20 for the pure time cost (60 minutes back and forth) to visit the park—that is, a total sum of $30. Using this approach on a large set of individuals (or based on average data from different cities or regions), it is possible to estimate the total consumer surplus associated with the national park.

### *Stated Preference Method*

In many cases, it may not be possible to use revealed preference methods. Further, it should be noted that revealed preference methods assume that individuals (on average) have reasonable knowledge of different product characteristics for a hedonic pricing approach to give reliable estimates. In many cases, this condition may not be fulfilled. A possible option is then to turn to stated preference methods, which are based on hypothetical questions designed such that individuals should reveal the value they would assign to a good if it were implemented in the real world (Bateman et al., 2004). There are two common approaches in the stated preference literature: (1) contingent valuation (CV) and (2) choice modeling (CM). A CV survey describes a scenario to the respondent—for example, a proposed policy of investing in a new railway line—and asks the individual about his or her willingness to pay. A common recommendation is to use a single dichotomous-choice question—that is, respondents are asked whether they would be willing to pay $X for a project—and use a coercive payment mechanism (e.g., a tax raise) for the new public good (Carson & Groves, 2007). The cost of the project is varied in different subsamples of the study, which makes it possible to estimate the willingness to pay (demand curve) for the project using econometric analysis.

In a CM framework, a single respondent is asked to choose between different alternatives where different characteristics of a specific good are altered. For example, the respondent may choose between Project A, Project B, and status quo. Project A and Project B may be two different

railway line investments that differ with respect to commute time, safety, environmental pollution, and cost. Using econometric techniques, it is possible to estimate the marginal willingness to pay for all these different attributes using the choices made by the respondents.

Stated preference methods have the advantage that it is possible to directly value all types of nonmarket goods, but the reliability of willingness to pay estimates is also questioned by many economists. Problems include individuals' tendency to overestimate their willingness to pay in a hypothetical scenario compared to a real market scenario, referred to as *hypothetical bias* (Harrison & Rutström, 2008). There are also many studies that highlight the problem of *scope bias* (Fischhoff & Frederick, 1998), which refers to the fact that willingness to pay is often insensitive to the amount of goods being valued—for example, willingness to pay is the same for saving one whale as for saving one whale and one panda.

## Application: The Value of a Statistical Life

Many cost-benefit analyses concern public policies with effects on health risks (mortality and morbidity risks). Environmental regulation and infrastructure investment are two examples where policies often have direct impacts on mortality risks, morbidity risks, or both. Hence, we need some approach to monetize health risks. In the United States, an illustrative example can be found in the evaluation of the American Clean Air Act by the Environmental Protection Agency, where 80% of the benefits were made up of the value of reduced mortality risks (Krupnick et al., 2002). In a European example (from Sweden), cost-benefit analyses of road investments show that approximately 50% of the benefits consist of mortality and morbidity risk reductions (Persson & Lindqvist, 2003).

In the literature of the last 20 to 30 years, the concept used to monetize the benefit of reduced mortality risk is the value of a statistical life (VSL). It may be described in the following way:

> Suppose that you were faced with a 1/10,000 risk of death. This is a one-time-only risk that will not be repeated. The death is immediate and painless. The magnitude of this probability is comparable to the annual occupational fatality risk facing a typical American worker and about half the annual risk of being killed in a motor vehicle accident. If you faced such a risk, how much would you pay to eliminate it? (Viscusi, 1998, p. 45)

Let us assume that a certain individual is willing to pay \$100 to eliminate this risk. Using this information on WTP, the value of a statistical life is then based on the concept of adding up this total willingness to pay for a risk reduction of 1 in 10,000 to 1. Hence, in this example, it implies that the estimate for the value of a statistical life is equal to $\$100 \times 10{,}000 = \$1$ million (VSL = WTP / $\Delta$ risk). This implies that a policy that prevents one premature fatality increases social welfare as long as the cost is less than \$1 million.

What value should be used in a cost-benefit analysis? There is no market where we explicitly trade with small changes in mortality risks. Rather, researchers have been forced to turn to RP and SP methods to estimate VSL. The most common RP approach has been to use labor market data to estimate the wage premium demanded for accepting a riskier job (hedonic pricing). The idea behind these studies is that a more dangerous job will have to be more attractive in other dimensions to attract competent workers, and one such dimension is higher pay. Hence, by controlling for other important determinants of the wage, it is possible to separate the effect that is due to a higher on-the-job fatality risk. This approach has been particularly popular in the United States; see W. Kip Viscusi and Joseph Aldy (2003) for a survey of several papers using this approach.

SP approaches to estimate VSL are also frequent. Primarily, they have been performed using the contingent valuation approach. For example, a survey might begin with a description of the current state of the world regarding traffic accidents in a certain municipality, region, or country. The respondent might be told that in a population of 100,000 individuals, on average, 5 people will die in a traffic accident the next year. After this description, the respondent might be asked to consider a road safety investment that would, on average, reduce this mortality risk from 5 in 100,000 to 4 in 100,000—that is, 1 fewer individual killed per 100,000 individuals. To elicit the preferences of the respondent, the following question may be asked: Would you be willing to pay \$500 in a tax raise to have this traffic safety program implemented? The respondent then ticks a box indicating yes or no. Other respondents are given other costs of the project, which gives the researcher the possibility of estimating a demand curve for the mortality risk reduction.

In the United States, the Environmental Protection Agency recommends a VSL estimate of €6.9 million for cost-benefit analyses in the environmental sector. In Europe, for the Clean Air for Europe (CAFE) program, a VSL (mean) of €2 million (approx. \$2.7 million) is suggested (Hurley et al., 2005). Theoretically, higher income and higher baseline risk should be associated with a higher VSL (although this can hardly explain the large differences between the estimates used by the United States and the European Union). In the transport sector, there are also international differences. Among European countries, Norway recommends a VSL estimate for infrastructure investments of approximately €2.9 million; the United Kingdom, €1.8 million; Germany, €1.6 million; Italy, €1.4 million; and Spain, €1.1 million (HEATCO, 2006).

For many individuals, it is offensive to suggest that the value of life should be assigned a monetary value, and there is some critique from the research community (Broome, 1978). However, it needs to be acknowledged

that in estimating WTP for small mortality risk reductions for each individual (hence the term *statistical life*), no one is trying to value the life of an identified individual. Moreover, these decisions have to be made, and we make them daily on an individual basis. Public policy decision making on topics that have impacts on mortality risks will always implicitly value a prevented fatality. Using the concept VSL in cost-benefit analysis, economists are merely trying to make these decisions explicit and base them on a rational decision principle.

## Discounting

As stated in the introduction, benefits and costs associated with a policy that occur at different times need to be expressed in a common metric. This metric is the present value of benefits and the present value of costs. Practically, discounting into present value is calculated as $PV = B_t / (1 + SDR)^t$, where $PV$ is the present value of a benefit ($B_t$) occurring in year $t$ in the future. $SDR$ is the social discount rate. For example, with a social discount rate of 3%, a benefit of \$100 occurring in 5 years has a present value of $\$100 / (1 + 0.03)^5 = \$86.26$. Traditionally, there have been two main approaches to choosing an appropriate social discount rate: (1) the social opportunity rate cost of capital, and (2) social time preference rate. The former can be seen as the opportunity cost of capital used for a certain policy. Imagine that a road safety investment has a cost of \$100; this money could instead be placed in a (more or less) risk-free government bond at a real interest rate of perhaps 5%. This would be the opportunity cost of the capital used for the public policy. The social time preference rate approach can be formulated as in the optimal growth model (Ramsey, 1928) outlining the long-run equilibrium return of capital: $SDR = \rho + \mu \times g$, where $\rho$ is the pure time preference of individuals, $\mu$ is the income elasticity, and $g$ is the growth rate of the economy. This captures both that individuals tend to receive \$1 today rather than in a year ($\rho$), and it reflects that as individuals grow richer, each additional \$1 is worth less to them ($\mu$).

The actual discount rate used in economic evaluation often has a major impact on the result. Consider Table 27.1, which shows the present value of \$1 million in 10, 30, 50, and 100 years in the future with discount rates of 1%, 3%, 5%, and 10%. As an example, with a discount rate of 1%, the present value of \$1,000,000 occurring in 10 years is \$905,287. The present value if using a discount rate of 5% is instead \$613,913.

Table 27.1 can be used to show how important the discount rate is for the discussion regarding what to do about global warming. The predicted costs of global warming are assumed to lie quite distantly in the future. The effect of different discount rates will be relatively larger the more distant in the future the benefit or cost will take place. An environmental cost of \$1 million occurring in 100 years is equal to only \$7,604 in present value if using a discount rate of 5%. If using a discount rate of 1%, it is \$369,711. A policy that would be paid for today to eliminate this cost in 100 years would be increasing social welfare if it cost less than \$7,604 using the higher discount rate (5%) or would be increasing social welfare if it cost less than \$369,711 using the lower discount rate (1%). Hence, it is obvious that the conclusion on how much of current GDP we should spend to decrease costs of global warming occurring in the distant future will be highly dependent on the chosen discount rate used in the cost-benefit analysis.

In 2006, a comprehensive study on the economics of climate change was presented by the British government: the Stern Review (Stern, 2007). The review argues that the appropriate discount rate for climate policy is 1.4%. Stern argues that because global warming is an issue affecting many generations, the pure time preference ($\rho$) should be very low (0.1), and he assumes an income elasticity ($\mu$) of 1 and a growth rate ($g$) of 1.3; this implies $SDR = 0.1 + 1 \times 1.3 = 1.4$. This is a relatively low discount rate compared to what most governments recommend for standard cost-benefit analyses around the world for projects with shorter life spans than policies to combat global warming. The Stern Review has also been criticized by other economists, who argue that such a low discount rate is not ethically defensible and has no connection to market data or behavior (Nordhaus, 2007). Weitzman (2007) argues that a more appropriate assumption is that $\rho = 2$, $\mu = 2$, and $g = 2$, which would give a social discount rate of 6%. The debate about the correct social discount rate has been a very public question in discussions about global warming policy—that is, how much, how fast, and how costly should measures taken today to reduce carbon emissions be?

**Table 27.1** Present Value of \$1 Million Under Different Time Horizons and Discount Rates

| *Discount Percentage Rate* | *10 Years* | *30 Years* | *50 Years* | *100 Years* |
|---|---|---|---|---|
| 1 | \$905,287 | \$741,922 | \$608,038 | \$369,711 |
| 3 | \$744,093 | \$411,987 | \$228,107 | \$52,032 |
| 5 | \$613,913 | \$231,377 | \$87,204 | \$7,604 |
| 10 | \$385,543 | \$57,309 | \$8,519 | \$73 |

There really exists no consensus regarding the correct discount rate, and there probably never will. Different government authorities around the world propose different social discount rates. The European Union demands that cost-benefit analyses be conducted for projects that imply important budget consumption, and the European Commission proposes a social discount rate of 5%. In the so-called Green Book in the United Kingdom, a social discount rate of 3.5% is proposed. In France, the Commisariat Général du Plan proposes a discount rate of 4%. In the United States, there are somewhat different proposals for different sectors, but the Office of Management and Budget recommends a social discount rate of 7% (Rambaud & Torrecillas, 2006). Several of the recommendations are also indicating that the social discount rate should be dependent on the time horizon of the project; in the United Kingdom, the social discount rate is proposed to be 3.5% for year 0 to 30, 3% for year 31 to 75, and decreasing down to 1% for policies with a life span of more than 301 years.

## Sensitivity Analysis

There are often large uncertainties in a cost-benefit analysis, regarding parameter estimates of benefits and costs. It has been shown that, especially for large projects, costs are often underestimated and benefits are sometimes exaggerated, making projects look more beneficial than they actually are (Flyvbjerg, Holm, & Buhl, 2002, 2005). These types of uncertainties need to be explicitly discussed and evaluated in the analysis. One common approach to deal with uncertainty in a cost-benefit analysis is to perform sensitivity analyses. There are different approaches regarding how to conduct a sensitivity analysis. Partial sensitivity analysis involves changing different parameter estimates and examines how it affects the net present value of the policy. Examples include using different discount rates and different parameter values of the value of a statistical life. Another approach is the so-called worst- and best-case analysis. Imagine that the benefits are uncertain but that an interval can be roughly estimated—for example, the benefit of improving environmental quality will be in the interval $100,000 to $150,000. A worst-case analysis implies taking the lowest bound of all beneficial parameter estimates. A best-case analysis implies the opposite. These types of sensitivity analyses may be interesting for a risk-averse decision maker and also give information about the lowest benefit (or largest loss) for a given project.

The downside to partial sensitivity analysis and worst- and best-case scenarios is that they do not take all available information about the parameters into consideration. Further, they do not give any information about the variance of the net present value of a project. For example, if two projects give similar net present value, decision makers may be more interested in the project with the lowest variance around the outcome. This requires the use of Monte Carlo sensitivity analysis. This is based on simulations where economists make assumptions about the statistical distribution of different parameters and perform repeated draws of different parameter values, each leading to a different net present value. This can give an overview of the distribution of the uncertainty of the project. A standard approach to visually describe the results from a Monte Carlo sensitivity analysis is to display the results in a histogram that shows mean net present value, sample variance, and standard error.

## An Application

To end this overview, a cost-benefit analysis of the Stockholm congestion charging policy is described (Eliasson, 2009). The Stockholm road congestion charging system is based on a cordon around central parts of Stockholm (capital of Sweden), with a road toll between 6:30 a.m. and 6:30 p.m. weekdays (higher charge during peak hours). The aim with the charging system is to reduce congestion and increase the reliability of travel times. Positive effects on safety and the environment are also expected. The cost-benefit analysis has the particular advantage of being based on observed traffic behavior, rather than simulations and forecasts (this is possible because the charging system was introduced during a trial period of 6 months). Using the six steps in a cost-benefit analysis as outlined in the introduction:

1. The first step involves defining the relevant population. The Stockholm congestion charging policy is mainly relevant for the population in the region of Stockholm, but because the cost-benefit analysis is based on actual behavior and data, it will therefore include benefits and costs of users of the roads in Stockholm, which will include various types of visitors as well. Hence, the relevant population is all the users of the roads.
2. The second step in a cost-benefit analysis is to identify the relevant consequences associated with the policy. The following main benefits are associated with the policy: (a) reduction in travel times due to decreased congestion, (b) increased reliability in travel times, (c) reductions of carbon dioxide and health-related emissions due to the decrease in traffic volume, and (d) increased road safety due to decrease in traffic volume. It could be hypothesized that the system would have effects on decisions where to locate, the regional economy, and retail sales, but it has been judged that these effects will be very small. Negative effects are (a) investment and startup costs, and (b) yearly operation costs.
3. The third step in the cost-benefit analysis is to monetize all the benefits and costs associated with the policy. Table 27.2 summarizes the consequences and shows their monetary benefits and costs. Some of the smaller benefits and costs in the analysis are not described here; refer to the reference for a more detailed description.

**Table 27.2** Annual Benefits and Costs of the Stockholm Road Charging System

| | *Consequence* | *Value per Unit* | *Total Benefit or Cost* |
|---|---|---|---|
| **Benefits** | | | |
| Decrease in travel time | Approximately 4.4 million hours | 122 SEK/hour | 536 million SEK |
| Increased reliability in travel time | — | 0.9 × (value of time) × (standard deviation of travel time) | 78 million SEK |
| Decrease in emissions | Decrease in $CO_2$ by 2.7% | 1.50SEK/kg $CO_2$ | 64 million SEK (+ 22 million SEK for health-related effects) |
| Decrease in traffic fatalities and injuries | Decrease by 3.6% | 17 million SEK per fatality | 125 million SEK |
| **Costs** | | | |
| Operation costs | Reinvestment and maintenance | Machine hour costs and labor hour costs | 220 million SEK |
| Marginal cost of public funds | Distortionary tax effects | 1.3 × all direct costs | 182 million SEK |
| **Net social benefit excluding investment costs** | | | **654 million SEK (91 million USD)[a]** |

SOURCE: Based partially on data reported in Eliasson (2009).

NOTE: a. Based on the December 16, 2009, exchange rate: 1 USD = 7.2 SEK.

Table 27.2 shows the annual benefits and costs of the system. The magnitude of the effects on travel time, standard deviation of travel time, and so on is based on large computer estimations of the traffic measurements on 189 links to calibrate origin-destination (OD) matrices for the case with and without the charging system. The investment cost is not listed in Table 27.2 but was estimated at 1.9 million SEK.

4. The next step consists of calculating the net present value of all benefits and costs based on the annual estimates. It is not obvious which time horizon should be used for the project, but technical data and past experience indicated that it was reasonable to make a conservative assumption that the system would have an economic life span of 20 years. Hence, the benefits and operating costs in year 2, 3, . . . , 20 have to be discounted to a present value. The Swedish National Road Administration argues that the social discount rate should be 4%. Hence, the present value of the net social benefits in year 20 is $654 / (1.04)^{20} = 298$ million SEK. These calculations are performed for benefits and costs in years 1 through 20.
5. Discount all annual benefits and costs to present values, as in Step 4, showing that the total social surplus (after deducting the investment costs) is approximately 6.3 billion SEK (approx. $800 million). Expressing it as a payback estimate, this means that the policy will take 4 years before the investment costs are fully repaid. It is also explicitly discussed that some consequences were deemed too difficult to include in the calculations, such as the effects on noise, labor market, time costs for users, quicker bus journeys, and so on.
6. The sixth step in a cost-benefit analysis is to perform a sensitivity analysis. In this aspect, there is little done in the described analysis. One reason for this is that the actual estimates of the consequences as performed using OD matrices are very time consuming, which more or less implies that because of practical limitations, only one main estimation can be performed. A simple sensitivity analysis is performed assuming increasing benefits over the time horizon. But if any improvement to the cost-benefit analysis should be suggested, it would be to conduct a more detailed sensitivity analysis. The quite straightforward conclusion of the cost-benefit analysis, even though it should have included sensitivity analyses to satisfy our full requirements, is that social welfare will increase because of the charging system.

## Conclusion

How should we evaluate a proposed public policy or regulation? A cost-benefit analysis is an approach that includes all relevant consequences of a policy and compares, in monetary units, benefits with costs. If benefits outweigh the costs, the policy is said to increase social welfare. Social welfare is defined using the Hicks-Kaldor criterion, which states that a policy increases welfare if the winners from the policy can compensate the losers from the policy and still be better off than if the policy is not implemented.

To conduct a cost-benefit analysis, one must identify consequences and express them in a monetary metric so that all consequences can be compared in the same unit of measurement. If benefits and costs arise in the future, they should be discounted to present value using a social discount rate. Finally, given the uncertainties involved with estimating consequences of a policy or regulation as well as uncertainties with the monetary estimates of the consequences, a proper cost-benefit analysis should include sensitivity analyses to show how robust the result is.

Finally, considering the definition of social welfare as usually applied in cost-benefit analysis (Hicks-Kaldor criterion), the typical cost-benefit analysis of a project or regulation estimates the effect on economic efficiency. Therefore, even though a very important guide to decision making, in most applications, cost-benefit analysis is often seen as one of several guides to the decision making process. Especially in political decision making, there will be other effects of interest, such as effects on income distribution and geographical distribution of benefits.

# PART IV

## Macroeconomics

# 28

# Economic Measurement and Forecasting

Mehdi Mostaghimi

*Southern Connecticut State University*

In December 2000, within a few days after a U.S. Supreme Court decision on the result of the November presidential election, then–Federal Reserve Chairman Alan Greenspan announced a grim prediction of a downturn for the near future of the U.S. economy. To counter it, the Federal Reserve implemented a series of expansionary monetary policy actions—cutting the federal funds rate and increasing the supply of money for the ensuing 2 years. In July 2003, the National Bureau of Economic Research (NBER), a nongovernmental think tank organization consisting mostly of academicians, identified and dated a recession in 2001 for the United States with a starting date of March and an ending date of November, for a total of 7 months.

An interested person learning about macroeconomic policy decision making, after reading the preceding paragraph, curiously asks a series of questions focused on identifying economic activities, measuring economic activities, modeling information, economic forecasting, and decision and policy making. The focus of this chapter is to briefly provide answers to some of these questions without getting into the complexities inherent in their details.

A *recession* is a contraction or downturn in overall economic activity when output and employment decline, generally for a period of 6 months (two quarters) or more. A severe and long contraction is called a *depression.* A relatively mild and short contraction (less than 6 months) is referred to as a *downturn* or *slowdown.* When economic activities change at a positive rate (output and employment are rising), the economy is said to be in an *expansion* phase. When the demand for the goods and services in an economy exceeds its ability to meet them or when for some other reason prices throughout the economy rise, the economy experiences *inflation. Stagflation* occurs when an economy experiences high unemployment and inflation simultaneously.

The preceding phases of the economy reflect the business cycle (Figure 28.1). Each economy has a long-run growth rate that is dependent on its economic structure and a range of socioeconomic and technological factors. In a dynamic economy, as these factors change—for example, through technological advancements—the long-run growth rate will change. In the short run, economic growth may be rising or falling around the long-run growth rate. When the short-run growth rate is falling, the economy is in a slowdown that may lead to a recession. When the short-run growth rate is rising, the economy is in an expansion. These are the phases of the business cycle. A *business cycle* consists of an expansion and a contraction that follow each other separated by a peak and a trough. A *peak,* the high point of a cycle, is the beginning of a downturn, and a *trough,* the low point of a cycle, is the beginning of an expansion. An expansion may contain one or more downturns and slowdowns. Not all the slowdowns and downturns end up in a recession, and predicting if and when a recession will occur is difficult.

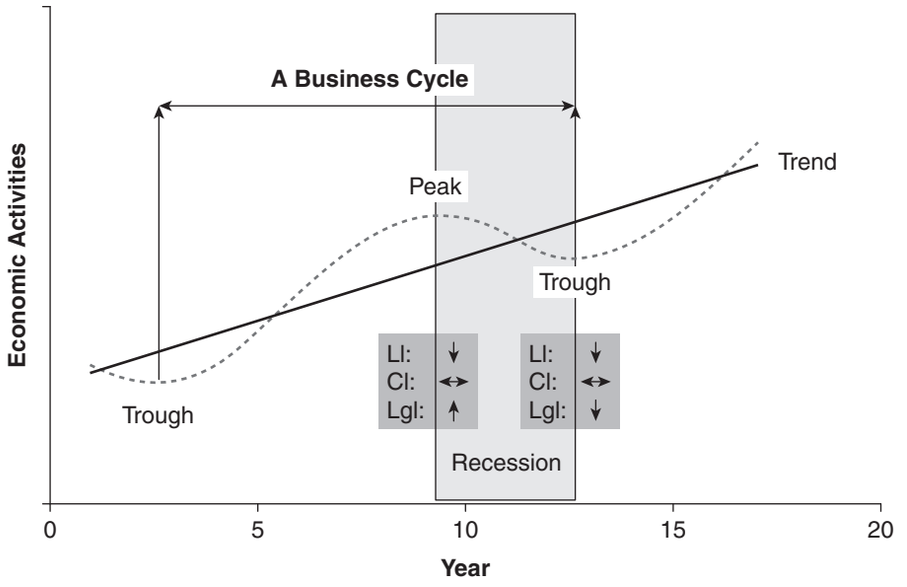

**Figure 28.1** The Business Cycle

NOTES: A *business cycle* consists of an expansion and a contraction that follow each other, separated by a peak and a trough. A *peak* is identified when the changes in leading indicators are negative, no changes are observed in the coincidental indicators, and the changes in the lagging indicators are positive. A *trough* is identified when the changes in the leading indicators are positive, no changes are observed in the coincidental indicators, and the changes in the lagging indicators are negative.

From 1959 to 2007, the U.S. economy has gone through seven business cycles with a cycle averaging 7 years, expansions averaging 6 years, and recessions averaging 1 year. From 1982 to 2007, there have been two complete business cycles ending in March 1991 and November 2001 with an average of 10 years and with expansion and recession averages of 9 years and 8 months, respectively. In this period, there were several downturns that did not turn into recessions, notably in 1987 and 1996. Longer expansion periods and shorter recession periods have been characteristics of the modern U.S. economy, reflecting the impact of advancements in predicting peaks and troughs accurately and of implementing the appropriate monetary and fiscal policies in a timely manner.

For economic policy decision making (monetary and fiscal), predicting a turning point (peak and trough) in a business cycle is very important. A main objective of economic policy is to create a stable economy that grows at a desirable rate with high employment and low inflation. Policy actions designed to bring stability in the economy are business cycle dependent. For example, to prevent an economy from overheating during an expansion period, which may result in rapid price hikes for goods and services and a high inflation rate, policy actions such as tightening the money supply and raising interest rates will cut the demand for goods and capital and cool the economy down. An example of policy action for preventing a slowing economy from entering a recession is a combination of fiscal stimulus, such as a tax cut, and easy money, such as lower interest rates, to encourage customer and business spending.

Predicting a downturn or the peak that it will follow is considered critically important for policy making because a peak is the start of a recession. If an impending recession can be predicted correctly and appropriate policy actions are designed and implemented in a timely manner, a recession and the resulting unemployment and business failures can be entirely avoided, or their severity and duration reduced.

Expansionary monetary policy actions implemented by the Federal Reserve after correctly predicting an impending recession in December 2000 did not prevent it from happening in 2001, but those actions likely reduced the potential severity and duration of that recession and maintained economic stability despite the economic shock of the September 2001 World Trade Center attack.

To formulate an effective economic policy for a country, it is critical to correctly measure the economy's performance. The parameters used to gauge the performance of the economy and their measurements are generally called *economic indicators* and *economic indexes*.

An economic system can be monitored using parameters that describe its different aspects, such as income, production, employment, inflation, and so on. For each parameter, there may be several indictors that are used to measure it. For example, both the consumer price index and producer price index are measures of inflation. As in any dynamic system, not all of the economic parameters are known a priori; they are discovered and their measurements are invented as the economy evolves.

By modeling and analyzing these indicators, it is possible to study the behavior of an entire economic system. Forecasting the future behavior of the state of an economy

in a business cycle is a projection of its past behavior onto the future. Because the future will inevitably vary from the past, no forecast is perfectly accurate, and uncertainty is associated with every forecast.

The focus of this chapter is on economic indicators and their use in predicting a downturn (or the peak that it will follow) in the United States. The next section focuses on describing and grouping economic indicators in the United States. This is followed by a section on modeling to combine the information of these indicators for predicting a turning point in the overall state of the economy. Discussions focused on forecast performance and evaluation and on economic policy decision making are also presented in this section. The final section focuses on future directions of economic indicators and on forecasting in the twenty-first century.

## Economic Indicators

An economic *parameter* describes an aspect or dimension of an economic system. An economic *indicator* is a measure of a parameter for an economy at a given point in time. A parameter may have several indicators, each measuring it differently. All the parameters of an economy together describe the overall behavior of that system. A collection of all economic indicators describes the behavior of an entire economic system at a given point in time (Burns & Mitchell, 1946).

Gross domestic product (GDP), which measures the total value of all goods and services produced in an economy, is probably the most important indicator of the performance of an economy. U.S. GDP for the first quarter of 2008 was estimated at $11.6 trillion. The change in the value of GDP from one quarter to another, in percentage form, is a measure of economic growth. When GDP is adjusted (deflated) for price changes, it is called *real GDP*. A positive percentage change in real GDP is an indication of expansion, and a negative percentage change is an indication of a downturn, or contraction. Real GDP grew by 0.9% in the first quarter of 2008, indicating a weak expansion. To study the behavior of an economy, the change in the value of an indicator is more informative than the indicator's overall value.

A few other major parameters and their main indicators for the U.S. economy are (a) inflation and price stability, measured by consumer price index and producer price index; (b) employment and labor force use, measured by the unemployment rate; (c) efficient use of the employed labor force, measured by the productivity index; (d) cost of borrowing money, measured by the prime interest rate; and (e) consumers' future economic behavior, measured by the consumer sentiment index.

In the United States, economic indicators are mostly produced by such federal government agencies as the Commerce Department, the Bureau of Labor Statistics, and the Federal Reserve Bank. The U.S. Congress compiles and publishes monthly reports on most of these indicators. A few indicators are also produced by major universities, such as the University of Michigan, and by economic research organizations, such as the Conference Board.

Each state in the United States has similar economic parameters and indicators focused on its towns, cities, and counties. State government agencies, such as state departments of labor and economic development, as well as state universities, economic research organizations, and chambers of commerce, are developers and producers of economic indicators. In the last 10 to 15 years, major advancements have been made in this area at the state and local levels.

There are many ways to group economic indicators for systematically studying an economy. Three of them are presented here:

1. Grouping by *economic category*. The broad categories of economic activity are the base for this grouping, which includes categories such as income and output, employment and wages, and producer and consumer price.
2. Grouping by *information source*. This is an indicator of an aspect of the real (production) economy, money economy, or behavioral economy.
   - Real economy indicators are measures of the actual products and services produced and of economic factors such as labor and capital. GDP and the unemployment rate are two examples of real economy indicators. Some of these measures, such as GDP, are adjusted, or deflated, for price changes and inflation.
   - Money economy indicators are measures of the availability of money in the economy and of the security market's valuations. Measures of the money supply, the Federal Funds Rate, Treasury Bill rates, and the Standard & Poor 500 Index (S&P500) are examples.
   - Behavioral economy indicators are measures of consumers' and businesses' attitudes toward the future directions of the state of the economy in terms of being optimistic, pessimistic, or in between. These attitudes will affect consumers' and businesses' decisions about purchasing goods and services and investing in new equipment and machinery. The University of Michigan's Consumer Sentiment Index and the Conference Board's Consumer Confidence Index and CEO Confidence Survey are three examples here.
3. Grouping by *business cycle timing*. There are many indicators whose values are informative in identifying the location of an economy on the business cycle. They are lagging indicators, coincidental indicators, and leading indicators.
   - *Lagging indicators* identify the location of the economy on the business cycle in the near past. The peak and trough of a lagging indicator are the confirmations of the peak and trough of the recent state of an economy. For example, when a lagging indicator peaks, it confirms that the overall economy has already peaked. Average duration of unemployment is a lagging indicator. It peaked in April 2001, a month after the start of the 2001 recession.

- *Coincidental indicators* identify the current state of the economy in a business cycle. Real GDP is a coincidental indicator measuring the current, quarterly, value of goods and services produced in the economy. Real GDP peaked as early as the third quarter of 2000 to signal the start of the 2001 recession.
- *Leading indicators* are predictors of the near future state of the economy. Slope of the yield curve, defined as the interest rate spread between the 10-year treasury bonds and the federal funds, is a leading indicator. A negative slope of the yield curve is an indication of an impending slowdown and, possibly, a recession in the economy. It happens when the financial risks in the near future exceed the ones in the long term. This slope has been negative prior to all the recessions since 1959.

The list of indicators used to study the U.S. business cycle varies from one research organization to another. For example, the American Institute for Economic Research (AIER) uses different indicators than the Conference Board. The list of indicators used by the AIER is shown in Table 28.1, and those used by the Conference Board for leading indicators are shown in Table 28.2. These lists are, however, highly overlapped for each group and are modified occasionally once the relative performances of the indicators change. For example, the Conference Board removed 3 indicators from its list of leading indicators in 1996 and added 2 new ones to cut the total number of its leading indicators from 11 to 10.

A change in percentage in the value of an indicator is used for locating the economy on a business cycle. A change consists of a sign and a magnitude. For most of the indicators, a positive sign in the percentage change is an indication of a growth. For a few, such as the unemployment rate, a positive sign is an indication of a decrease in growth. The magnitude of a percentage change is a measure of the degree of impact. A large percentage increase in real GDP is a measure of strong economic growth, and a large percentage increase in the unemployment rate is a measure of a large contraction in an economy.

Identifying a peak and a trough in the economy is critical for predicting the start of a recession and the start of an expansion, respectively. Generally, a peak is identified when the changes in leading indicators are negative, no changes are observed in the coincidental indicators, and the changes in the lagging indicators are positive. A trough is identified when the changes in the leading indicators are positive, no changes are observed in the coincidental indicators, and the changes in the lagging indicators are negative.

Not all indicators of a group show the same sign and the same magnitude percentage change in a given month. Because it is possible for the indicators of a group to show conflicting signals on both the sign and the magnitude, a consensus of them is usually used for identifying the location of an economy on the business cycle.

For example, if five coincidental indicators are used to identify the current state of an economy, two extreme possibilities are for all to be either positive or negative with both having high percentage changes in magnitude. The interpretations of these two cases are straightforward in that the economy is strongly growing and severely contracting, respectively. However, if three of the five coincidental indicators show positive percentage changes, one has zero change, and one has a negative percentage change, and for the ones with nonzero percentage changes, the magnitude of the change varies from a small to a large value, a consensus interpretation of the values of these indicators for the state of the economy is not straightforward. Because, in addition to sign and magnitude of the change, other factors

**Table 28.1** Grouping Economic Indicators by Business Cycle Timing

The Primary Leading Indicators:

- M1 Money Supply
- Yield Curve Index
- ISM Price Index
- New Orders for Consumer Goods
- New Orders for Core Capital Goods
- New Housing Permits
- Ratio of Manufacturing and Trade Sales to Inventories
- Vendor Performance, Slower Deliveries Diffusion Index
- Index of Common Stock Prices
- Average Workweek in Manufacturing
- Initial Claims for State Unemployment Insurance
- 3-Month Percent Change in Consumer Debt

The Primary Roughly Coincident Indicators:

- Nonagricultural Employment
- Index of Industrial Production
- Personal Income less Transfer Payments
- Manufacturing and Trade Sales
- Civilian Employment as a Percentage of the Working-Age Population
- Gross Domestic Product

The Primary Lagging Indicators:

- Average Duration of Unemployment
- Manufacturing and Trade Inventories
- Commercial and Industrial Loans
- Ratio of Debt to Income
- Percent Change from a Year Earlier in Manufacturing Labor Cost per Unit of Output
- Composite of Short-Term Rates

**Table 28.2** U.S. Composite Leading Indexes: Components and Standardization Factors: February 2008

| *Leading Indictors* | *Factor* |
|---|---|
| Average weekly hours, manufacturing | 0.2565 |
| Average weekly initial claims for unemployment insurance | 0.0310 |
| Manufacturers' new orders, consumer goods and materials | 0.0763 |
| Vendor performance, slower deliveries diffusion index | 0.0672 |
| Manufacturers' new orders, nondefense capital goods | 0.0186 |
| Building permits, new private housing units | 0.0270 |
| Stock prices, 500 common stocks | 0.0384 |
| Money supply, M2 | 0.3530 |
| Interest rate spread, 10-year treasury bonds less federal funds | 0.1037 |
| Index of consumer expectations | 0.0283 |
| Total | 1.0000 |

such as the relative importance of the indicators is also critical for coming up with an interpretation.

Economic research organizations use various schemes and models for generating a consensus interpretation for each group. For example, if the information used is limited to just the sign and magnitude of a change, the Conference Board produces diffusion indexes for all three groups. In addition, if the relative importance of the individual indicators is used, the Conference Board has composite indexes, such as composite leading economic indicators. AIER has similar indexes derived using different schemes. These factors are also used informally, usually by economic experts with extensive experience in economic forecasting, to produce a consensus interpretation for a group. Thus, given the high degree of subjectivity involved in this process, economists often arrive at different interpretations of the same information and produce different assessments of the state of the economy.

Another way to use these indicators to identify the position of an economy in a business cycle is to combine the information and interpretations of all three groups of indicators. If the changes in indicators of all three categories behave the same way, either positively or negatively, it is an indication that the economy is in a given state of the business cycle: expansion if the changes are positive and recession if the changes are negative. However, when the signs are different, they may point to a peak or trough of the cycle. In an expanding economy, negative changes in leading indicators, no change in coincidental indicators, and positive changes in lagging indicators are a sign of a possible peak in the economy. Similarly, in a declining economy, positive changes in the leading indicators, no change in the coincidental indicators, and negative changes in the lagging indicators are a sign of a trough in the economy. There are formal, econometric methods used for such analysis, which are briefly mentioned in the next section. However, it is the subjective interpretations of the information by the expert economists that are frequently used for decision making—a method that may result in even more conflicting interpretations!

## Combining Information and Predicting a Turning Point

In the previous section, economic indicators were described. We noticed that some of these indicators can be grouped as lagging indicators, coincidental indicators, and leading indicators. We have also noted that the values of these indicators could be used in a group to describe the overall state of an economy at a given time.

In this section, we focus on combining information from these indicators and using them to predict the near future state of an economy in a business cycle. The idea is that, for example, if there are 10 leading indicators that all individually describe the behavior of the state of an economy in the near future, a composite, a combination, of them should have a superior performance over the performance of each individual one—superior in yielding more accurate predictions and signaling fewer false alarms. A false alarm would be an indicator that signals a recession when in fact one is not likely to occur.

The question then becomes how to combine the information provided by the indicators and how to evaluate the performance of a composite indicator in identifying the state of an economy on a business cycle. Modeling and nonmodeling approaches are used in response to these questions. Both approaches are briefly described in this section. A detailed treatment of these approaches is quite mathematical, requiring a high level of understanding of mathematical and econometric modeling—something that is well beyond the scope of this introductory chapter (Lahiri & Moore, 1991). For interested readers who have a good technical grasp of economic modeling, a rather comprehensive treatment of these topics is the excellent collection of work presented in Graham Elliott, Clive Granger, and Allan Timmermann (2006).

### Modeling Overall Economic Performance

To model an economy's overall performance, several measures are used to capture different areas of economic activity. For example, because employment and production are two very important aspects of an economy, measures and indicators of these aspects, such as unemployment rate and industrial production, are both used in the analysis.

Because each measure provides information about a particular aspect of the economy, for studying an economy's overall behavior, a combination of these measures, a composite indicator, must be used.

GDP is the one indicator that is generally recognized as a good measure of the overall state of an economy. A disadvantage of GDP, however, is its low production frequency (quarterly as opposed to monthly). Other monthly indicators such as industrial production (IP), real personal income, and employment can, however, be used as proxies for GDP. These proxy indicators are not perfect, and their relative importance continually changes due to changes in the structure of an economy.

A more appropriate measure of the overall economic performance seems to be a composite measure of several indicators. The National Bureau of Economic Research (NBER) uses a combination of such measures as IP, employment, income, and sales in an informal, committee process for making decisions on business cycle dating. The Conference Board uses a formal, statistical method for combining the information of the individual indicators to produce lagging, coincidental, and leading composite indicators. There are also econometric-based models for formally combining information. These formal methods are briefly described next.

### *Statistical Modeling*

The purpose of statistical modeling is to identify a set of indicators that collectively represents all important aspects of an economy; to measure the indicators' statistical properties, such as their means, standard deviations, and correlation coefficients; and to combine this statistical information to produce composite indicators. The best-known such indicators are the Conference Board's composite lagging indicator (CLgI), composite coincidental indicator (CCI), and composite leading indicator (CLI) (Conference Board, 2001). The CLI is the most used as a predictor of the near future state of the U.S. economy.

CLI is a linear weighted-average value of 10 leading indicators of the U.S. economy whose assigned weights are standardized values of their relative variability, with standard deviation of an indicator used as a measure of variability. The higher the variability of an individual indicator (high standard deviation), the lower weight assigned to it in the composite. These weights are standardized to a total of 100% for all 10 indexes.

CLI values are produced monthly starting at a base value of 100 at a given month and year and adjusted for the changes in CLI every month after. Thus, an increase in CLI value over its previous month is considered a positive growth in the economy (i.e., increase in real GDP value), and a decrease in CLI value is considered a negative growth (i.e., a contraction). This base month and year is updated every few years. The latest update started in April 2008 by setting the CLI value for January 2004 equal to 100.

CLI's components and weights are regularly updated and revised to be current with the changing economy. Weight distribution is updated annually, reflecting the addition of new information used in statistical measures. However, more fundamental revisions happen less frequently and are made only when there is good evidence indicating a change in relative predictability of the individual leading indicators. This usually reflects a possible structural change in the economy.

The last such modification happened in 1996 when the Conference Board recognized that financial and money indicators were more accurate in predicting the near future state of the U.S. economy than the real economy indicators. A decision was made to replace three of the real economy indicators with two new money indicators. A revised distribution of the weights assigned a much higher total relative weight of about 65% to the money indicators and a much lower total weight of 35% to the real economy indicators. As a result of this revision, two money indicators of interest rate spread and money supply received over 60% of the total CLI weight.

This revision was troublesome because these two money indicators are also monetary policy instruments that, to a large extent, are controlled and influenced by the Federal Reserve Bank policy decisions. The implication is that monetary activities were to a large extent dominating CLI. In other words, CLI was less influenced by the activities of the real economy. This problem became obvious in the 2001 recession when CLI did not provide good forecasting information about the near future state of the economy. The Conference Board has, subsequently, made a revision to the definition of the interest rate spread in 2005, resulting in a reduced relative weight being assigned to it in CLI.

Criticisms of the statistical modeling of a composite indicator focus on its lack of underlying support in economic theory and on its not tracking a specific target similar to the one used by econometric modeling. However, from a practical viewpoint of being able to predict the near future state of the economy, especially in predicting and dating peaks and troughs in business cycles, the CLI has been very informative and accurate. In addition, CLI information is easy to understand and communicate to nontechnical consumers and beneficiaries (i.e., business decision makers) of such information.

### *Econometric Modeling*

Econometric modeling of composite indicators relies on cause-and-effect relationships supported by economic theory. Leading and coincidental indicators are modeled. Two approaches, factor-based modeling and Markov switching (MS) modeling, are used to model the composite coincidental indicator. For the development of the composite leading indicators, three approaches—vector autoregression (VAR)-based modeling, factor-based modeling, and MS-based modeling—are discussed next.

Econometric modeling of composite indicators is theoretical and complex, and requires a high degree of understanding of underlying technical issues. From the practical point of view of capturing and predicting the overall

behavior of the economy, the performance of these indicators is, at best, as good as that of indicators developed using statistical modeling.

The rationale behind factor-based modeling is that there are a number of common forces behind the movements of coincidental indicators. An econometric model that incorporates these common factors is developed to estimate the coincidental indicators (Sargent & Sims, 1977; Stock & Watson, 1989). The rationale behind MS modeling is the same with the exception of relaxing the assumption of a fixed dynamic behavior of the economy in a business cycle. In other words, as the economy goes through expansion and recession phases in a business cycle, the model parameters are changing or switching according to a probabilistic behavior of the Markov process (Hamilton, 1989). Justification behind MS modeling is that economic factors behave and interact differently in recession and expansion phases of a business cycle.

The rationales described here for factor-based and MS-based construction of composite coincidental indicators are also valid for the construction of the composite leading indicators (CLI). Because the main purpose of producing the CLI is predicting the near future state of the economy, the information generated from these models can be used to produce the probability of a turning point in an economy and to devise a decision rule for signaling a downturn point and a recession.

VAR is a linear model for establishing a relationship between leading indicators and coincidental indicators and their lagged values. Once a model is established, in a similar way to the other composite leading indicators' econometric models, its results can be used for business cycle predictions.

In addition to the approaches mentioned already, there are other mathematical approaches to developing leading indicators. One approach is incorporating a smooth transition to MS modeling. This approach assumes that the phases of the business cycle transition from one to another (i.e., expansion to recession) gradually rather than abruptly and suddenly. A second approach uses artificial neural networks to tap into a vast class of nonlinear models of the relationship between leading indicators and coincidental indicators. There is still another approach using binary variables in modeling expansion and recession phases of a business cycle and applying probit and logit methods for estimation and prediction. Massimiliano Marcellino (2006) is a good starting point for learning about modeling.

## Evaluation

A model is evaluated for its performance using in-sample data and out-of-sample data. In either case, this evaluation can be formal or descriptive. The purpose of the in-sample evaluation is to check for the fitness of the model to the sample data. Selection of a formal evaluation is a function of the forecasting methodology applied. For example, in cause-and-effect modeling of a target variable, such as the coincidental composite indicator as a linear function of leading indicators, standard statistical and econometric evaluative methods can be used. Formal methods for out-of-sample evaluation range from mean squared error (MSE) and mean absolute error (MAE), used if the target variable is a continuous variable such as a leading indicator, to quadratic probability score (QPS) and log probability score (LPS), used for predicting a discrete indicator such as an upturn or downturn in an economy (Diebold & Rudebusch, 1989; Winkler, 1969). A comprehensive treatment of forecast evaluation can be found in Kenneth D. West (2006).

A shortcoming of formal evaluation methods is that they are based on the information of the data series for the entire period of study, and every data point is given the same amount of weight in the analysis. In reality, data points around the peaks and troughs of a business cycle are more important for evaluating a turning point, and special attention should be given to them.

Descriptive evaluations of the models, which can be used for both in-sample and out-of-sample periods, are usually most effective in identifying the peaks and troughs of a business cycle. The goal is to measure how accurately and timely a model signals a turning point in an economy and to identify false alarms and missed signals. Descriptive evaluation methods are more informative in communicating the performance of a turning-point forecasting model.

A model that predicts a peak with a lead time is superior in its forecasting. Generally, the longer this lead time is, the better that model is. The number of consecutive downturn signals identified by a model is a measure of how persistent a model is in signaling a peak. The larger this value, the greater the likelihood that a peak will occur.

## Forecasting and Economic Policy Making

Economic climate is extremely uncertain and volatile during a slowdown, downturn, and peak period. The state of the economy, and the information about it, can change drastically in a very short period of time. A forecast is made based on the best information available at a given time, and an economic policy formulated using this forecast may become nonaccurate and ineffective to counterproductive, respectively, once the information has changed. This may create challenges for economists dealing with all stages of measuring economic indicators, of forecasting state of the economy, and of making policy recommendations. The contemporary state of the U.S. economy (2007–2009) has provided a clear example of this situation described as follows:

*2007 to 2008 Second Quarter:* Two major factors dominated the economic climate in this period.

1. Factor 1 is a substantial and continuing decline of the housing prices throughout the country after 5 years of major growth year after year. This has created two distinct problems for the economy with direct and, possibly, major effects on many economic activities. The first problem is a decline in the number of new housing construction permits and in the construction of the new houses. The

second problem, also known as the subprime mortgage rate crises, is the substantial readjustment increases of the variable mortgage rates as a result of the rise in the interest rates to the effect that a large number of these mortgages are not affordable to the homeowners. Nonaffordability of mortgage payments coupled with decline in housing prices have forced many banks to foreclose on people's houses. Because most of the mortgage contracts are securitized and sold in market to financial institutions throughout the world, it was unclear at this point how a large number of mortgage defaults could have an impact on these institutions in the coming months and years.

2. Factor 2 is the rapid increases in the commodity prices, from oil to soy beans, in the last few years, due to increase in demand from the emerging developing countries, which had put a substantial upward pressure on the prices of many goods and services from grocery products to plane tickets.

Confronting inflation in the economy is a primary policy objective of the Federal Reserve System for bringing stability in the economy. In formulating a monetary policy at that time, the Federal Reserve had to deal with the conflicting consequences of these two factors on the economy. On one side, it had to raise interest rates in order to confront inflation in the economy. On another side, it had to ease the supply of money in order to confront the economic slowdown consequences of a decline in housing construction and of instabilities in the financial institutions. The balancing policy actions of the Federal Reserve System in dealing with these problems were critical in preventing a peak in the U.S. economy in 2007 to 2008.

By summer 2008, all indications were that, of the two major factors impacting economic stability, the threat of the subprime mortgage rates effects was being diminished and inflation was going to be the main concern going forward. Therefore, what happened in the economy in late 2007 to early 2008 seemed most likely to be a slowdown, not a recession. The recommended policy action was an anti-inflationary policy of raising interest rates and reducing money supply.

*2008 to 2009:* Moving on to fall 2008, a sudden change occurred in the status of these two economic factors. It turned out that the impacts of the subprime mortgage rates on the financial institutions were so deep that they basically paralyzed the entire industry, requiring substantial governmental interventions, at the U.S. and global levels, to prevent it from collapsing. This brought slowdowns, downturns, and recessions to the countries around the world. In fact, in December 2008, NBER officially declared a recession for the United States starting December 2007. Given such a state of the economy globally, inflation did not turn out to be a concern, mainly due to a collapse in the commodity prices. The recommended policy was an expansionary policy of cutting interest rates and providing stimulus fiscal help.

## Economic Indicators and Forecasting in the Twenty-First Century

An economy, as a dynamic system, is continuously changing to incorporate technological innovations in the production processes and to satisfy the needs of an ever-evolving society. In the last 30 years, an outburst of technological innovations in the computer and in communication has moved the economy to be more global. This can clearly be seen in the formation of the global corporations in all industries, especially in financial, and in the outsourcing of production and services in the manufacturing and labor sectors. The global slowdown and recession of 2007 to 2009 has taught us that there is a strong interaction among the economic activities of all countries around the world. We are seeing that new economic powers are emerging in the developing countries, challenging the already well-established powers of the United States, the European Union, and Japan. These new powers are strong in both producing and consuming goods and services. At such a global setting, the economy of a country is very much dependent on global economic activities. This dependency needs to be incorporated in measuring economic parameters of a country, such as output, prices, employment, and so on. In addition, new parameters need to be identified and measured for the global economy. Further studies along these areas are expected in the years to come.

On the technical aspect of forecasting, one area that still needs substantial contribution is in applied forecast evaluation. Defining success in an organization and evaluating the performance of a forecast in that context is in critical need of development. For example, in predicting the overall state of the economy in the near future, is a forecast of a downturn that did not happen, due to the policy makers' effective and timely actions, a failure or a success? It can easily be argued that that forecast was a false alarm, thus, a failure. However, that predication has generated new information to alert the policy maker to act, thus it is a success. Developing objective evaluation methodologies of the performance of a forecast in the context of an organization's overall objective can be very helpful. For people interested in performing research on the technical areas of forecasting, a starting point is the excellent survey of Elliott et al. (2006).

# Measuring and Evaluating Macroeconomic Performance

David Hudgins
*University of Oklahoma*

The performance of a nation's economy actualizes as both cause and effect. The phase of the economic cycle serves as a catalyst that permeates the decisions of individuals, business firms, and government policy makers on a continuous basis. It affects the prices and yields of financial assets, the spending decisions of consumers, corporate borrowing and investment, and choices available to general public. Yet the course of economic activity is also the result of the expectations and actions of its participants. Their collective behavior works in conjunction with the state of nature, which may include favorable conditions or unfavorable conditions, such as excessive droughts, flooding, or other disasters, to guide the economy along its trajectory.

Despite the importance of assessing economic performance, its measurement and evaluation are elusive. This is true for three main reasons. First, just as beauty is in the eye of the beholder, the state of the economy depends on the evaluator. There is no one universal criterion or natural law that determines the standard by which performance is judged. The choice of standard depends on a host of factors, some of which are the relative weighting of unemployment and inflation, the definitions of boom and recession, the rate of economic growth versus environmental degradation, and the national income distribution.

Second, macroeconomic performance deals with aggregated variables, such as overall economic output or national unemployment. These aggregated variables do not directly reveal all of the components that constitute the aggregates, such as the individual composition of the output, which means that many of the details are effectively hidden from policy makers. Third, the measurement of the variables themselves is imprecise. For example, there is no universal way to capture overall inflation. Even if accurate data on all prices could be accurately determined, the relative weighting scheme for determining which goods and services should contribute the most and least to the overall index is entirely up to the individual or organization constructing the index.

The primary reason for gathering and analyzing macroeconomic data is to aid in making decisions. Although the difficulties in assessing economic performance are formidable, there are some commonly accepted concepts that can be used. This chapter integrates these concepts to form a comprehensive approach.

## Theory and Concepts Relating to Economic Performance and the Business Cycle

*Macroeconomic performance* refers to the behavior of the entire economy. Economies follow a cyclical pattern, which is referred to as the economic cycle, or business cycle. The measurement over this cycle by macroeconomic data is the result of aggregation, which means combining many individual units into one overall economic unit. Although this has the downside of hiding the measurements of the individual components, it is necessary because the data must be combined to be useful. Because most markets tend to move in unison across the business cycle, much of the data

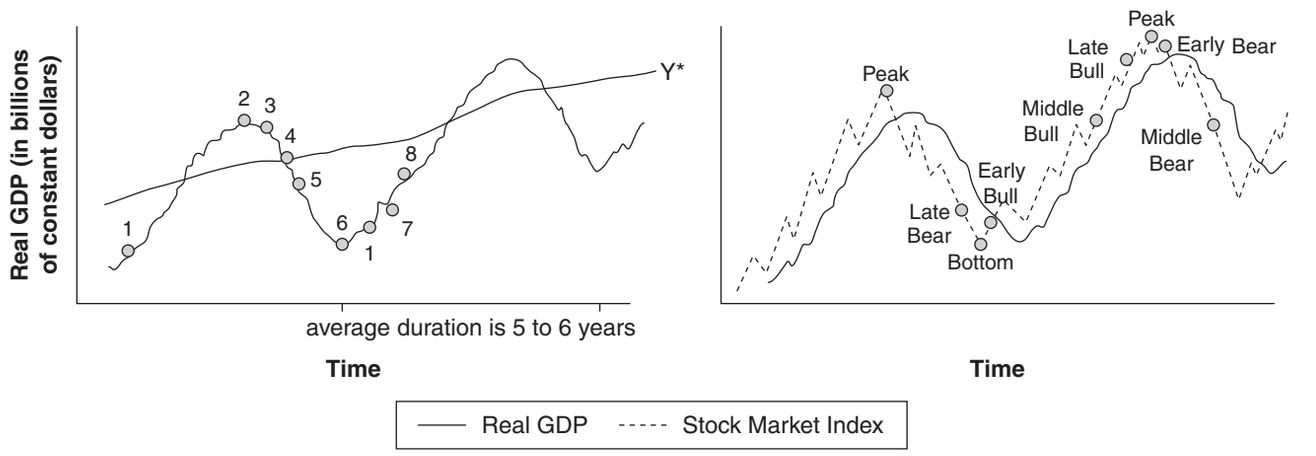

**Figure 29.1** The Business Cycle

NOTES: The first panel shows the phases of the business cycle along with Y* = potential GDP. The second panel shows the phases of the stock market cycle as a leading indicator of economic performance.

on individual markets can be relegated to the examination of economy-wide variables, which generally reflect an adequate signal of the phenomena whose measures are desired (Baumol & Blinder, 2008). The primary variables for measuring economic performance are the level and growth rate of national output (both overall and per capita), the inflation rate, and the unemployment rate.

The business cycle represents the tendency of economic activity to rise and fall over time in a cyclical pattern. It has four phases: (1) expansion (or recovery), (2) peak, (3) recession, and (4) trough (or bottom). When analyzing national output, the path of the business cycle can be traced out as in the first panel of Figure 29.1.

At Point 1, the expansion, or recovery, begins. During this phase, the growth rate of national output is high, while the national unemployment rate is falling. Once the level of economic activity reaches its peak at Point 2, it starts to decline, causing business inventories to rise around Point 3. At Point 4, a recession begins, eventually causing a high unemployment rate, a decline in interest rates, and a decline in the general level of prices, represented by Point 5. At Point 6, the economic trough, or bottom, is hit, and the economy starts on a new expansionary phase. At Point 7, consumption and investment rise, leading to a rise in interest rates and the general level of prices. Eventually, the economy reaches a new peak and will repeat the cycle again and again.

## Potential Gross Domestic Product

Notice that the cycle is not constant. Each successive peak tends to be higher than the last, so that the average level of economic output is constantly growing. This growth in the average level of economic output represents the upward long-run trend over time, and it is labeled as Y* in Figure 29.1. In the United States, this long-run trend average annual growth rate of real gross domestic product (GDP) is around 3%, with an average real per capita GDP growth rate of around 1.5% (*Economic Report of the President,* 2006; Peterson & Estenson, 1996). This is used as one benchmark for economic performance. An annual real GDP growth rate around 2% to 3% or higher reflects a strong economy, while a growth rate of less than 1% per year suggests poor economic performance.

This long-run trend value is of the upmost importance for several reasons. It represents what is equivalently referred to as potential GDP, full-employment GDP, or the natural level of output. The interpretation is that if the economy were not fluctuating due to cyclical factors, and thus, if it were always producing at its long-run sustainable rate of production, then it would be producing on this trend curve. Along this trend, the unemployment rate would consist of only what is referred to as frictional unemployment, meaning that all unemployment would result from only a small amount of normal job turnover. This trend unemployment rate is referred to as the natural rate of unemployment, or the nonaccelerating inflation rate of unemployment (NAIRU), and in the United States, it is generally assumed to lie between 4% and 5%. It is called the NAIRU because when the economy is operating on this long-run trend line, business firms are not producing at such a high level relative to current capacity that excess product demand and labor demand are causing inflationary pressures.

One final reason for the importance of this trend line of potential output is that it represents the material well-being of the economy's residents in the long run. Economist Paul Krugman (1990) stated that productivity is not everything, "but in the long run it is almost everything" (p. 9). For an economy's residents to sustain higher levels of per capita income and consumption, the economy must improve its capacity to produce output over time. Although this can be achieved in part by acquiring more of the factors of production such as capital, labor, and land, the primary means is by increasing labor productivity, which embodies both advances in technology and advancements in the skills and training of the workforce. This long-run trend curve Y* thus represents the growth rate of the economy's labor productivity, which in

turn determines the per capita consumption of the economy. Indeed, any macroeconomic policy that does not improve technology and labor productivity in the long run will not lead to any sustainable increase in the per capita income of its citizens.

One of the biggest obstacles in measuring and evaluating economic performance is that the graph in Figure 29.1 does not show all of the activity of the economy. The amalgam that is referred to as the economy does not evolve in cycles that are as clear-cut as those shown in Figure 29.1. Moreover, the economy never manifests the future values to a current observer, and the data that can be gathered, such as real GDP, generally has a lag involved in its collection and compilation. The trend curve for Y* is also only an estimation of the artificially generated concept called potential GDP and not an actually occurring phenomenon from which data can be collected.

Very few analysts ever agree on whether the economy is in an expansionary phase or a recessionary phase until the middle or even the end of the phase is reached. The term *recession* is properly defined as a period of time in which there is a marked decline in the general level of economic activity. It has commonly been defined as a decline in an economy's GDP during two consecutive quarters. The U.S. Department of Commerce's Bureau of Economic Analysis (BEA) has specifically stated that the widely used definition of a recession as a negative growth rate in GDP for two consecutive quarters is not correct. Instead, the BEA (2008) defers to the U.S. National Bureau of Economic Research (NBER) and states that

> recession is a monthly concept that takes account of a number of monthly indicators—such as employment, personal income, and industrial production—as well as quarterly GDP growth. Therefore, while negative GDP growth and recessions closely track each other, the consideration by the NBER of the monthly indicators, especially employment, means that the identification of a recession with two consecutive quarters of negative GDP growth does not always hold. (Business Cycle Dating Committee of the National Bureau of Economic Research, 2008)

The NBER has determined that during the period 1945 to 2001 in the United States, there were 10 business cycles with average duration from one trough to the next being 67 months.

## Cyclical Indicator Approach to Measurement of the Business Cycle

The business cycle is also alternatively assessed by the partially overlapping method referred to as the *cyclical indicator approach.* This approach analyzes what are called *economic indicators,* which are macroeconomic variables that are used to measure economic activity. These indicators serve as signals that represent the performance of various aspects of the economy. There are three types of economic indicators. Coincident indicators measure the current level of economic activity and turn at the same time as the business cycle turns. Leading indicators normally turn down before recessions start and turn up before expansions begin and can thus be used to forecast the direction in which the economic cycle is moving. Lagging indicators measure what the level of economic activity has been—they turn after the business cycle turns.

Rather than using just one indicator, the individual indicators are generally combined to form weighted composite indices. The Conference Board (2008) states, "These are constructed to summarize and reveal common turning point patterns in the data in a clearer and more convincing manner than any individual component, primarily because they smooth out some of the volatility of the individual components." The Conference Board, a nonprofit organization, now publishes the Index of Leading Economic Indicators (LEI) monthly for nine countries. Also called the Composite Index of Leading (Economic) Indicators, it was developed by the NBER and was formerly published by the BEA in the "chart book" section of the *Survey of Current Business.* It is supposed to forecast turns in the business cycle 3 to 6 months in advance but is often unreliable. Economist Paul Samuelson (1966) famously stated that "Wall Street indexes predicted 9 of the last 5 recessions" (p. 92), and this statement is widely applied as a criticism of the LEI as a forecasting or measuring tool. The current components of the LEI, in decreasing order of their relative weights, are as follows:

1. Interest rate spread: 10-year Treasury bond (T-bond) rate minus federal (fed) funds rate. This is a measure of the slope of the yield curve. A T-bond is a long-term coupon-bearing debt issued by the U.S. government with a maturity that is generally more than 7 years. The interest is paid semiannually and could be exempted from the local and state tax. The fed funds rate is set by the U.S. Federal Reserve System (the Fed) and is the overnight interest rate at which banks lend the federal funds to other depository institutions.
2. Real M2 money supply. M2, a proxy of money supply, is the summary of physical currency, checking and saving accounts, small denomination consumer certificates of deposit, and noninstitutional money market mutual funds.
3. Average weekly hours of production workers in manufacturing. These data are issued monthly by the U.S. Department of Labor's Bureau of Labor Statistics (BLS) (http://www.bls.gov). Both seasonally adjusted and nonseasonally adjusted data are released.
4. Manufacturer's new orders for consumer goods and materials, adjusted for inflation. These data are issued monthly by the U.S. Department of Commerce's Census Bureau. Both seasonally adjusted and nonseasonally adjusted data are released. New orders are the totals for that period, and these data are adjusted based on the calendar month variations and

trading days. Data for the semiconductor industry are not included.
5. Stock prices, measured by the Standard & Poor's 500 Index (S&P 500). The S&P 500 is the most commonly used benchmark for the U.S. equity market and includes the top 500 large-cap (large capitalization) companies, which are from different industries, such as energy, materials, industrials, consumer discretionary, consumer staples, health care, financials, information technology, telecommunications services, and utilities.
6. Fraction of vendors facing slower deliveries from suppliers, a component of the National Association of Purchasing Managers index.
7. Average weekly initial claims for state unemployment insurance (inverted). This index is issued weekly by the U.S. Department of Labor. Both seasonally adjusted and nonseasonally adjusted data are released.
8. New building permits issued. This index is issued monthly by the U.S. Department of Commerce's Census Bureau. Both seasonally adjusted and nonseasonally adjusted data are released.
9. Index of Consumer Expectations. These data are issued monthly by the University of Michigan and reflect American consumers' subjective expectation for the current and future (6 months) economic situation. This index also plays an important role in the decisions of business firms and in the public polices of government.
10. Manufacturers' new orders for nondefense capital goods, excluding aircraft. These data are issued monthly by the U.S. Department of Commerce's Census Bureau. Both seasonally adjusted and nonseasonally adjusted data are released.

The series in the LEI that are based on the Conference Board estimates are manufacturers' new orders for consumer goods and materials, manufacturers' new orders for nondefense capital goods, and the personal consumption expenditure used to deflate the money supply.

The Conference Board also publishes an Index of Coincident Economic Indicators and an Index of Lagging Economic Indicators. The four components of the Index of Coincident Economic Indicators are as follows:

1. Personal income less transfer payments
2. Manufacturing and trade sales
3. Industrial production
4. Employees on nonagricultural payrolls

The components of the Index of Lagging Economic Indicators include the following:

1. The average duration of unemployment (inverted)
2. Change in the consumer price index (CPI) for services
3. Ratio of consumer installment credit to personal income
4. Change in labor cost per unit of output
5. Commercial and industrial loans outstanding
6. Average prime rate charged by banks
7. Ratio of manufacturing and trade inventories to sales

Two other indices are also used. The ratio of the index of coincident to lagging indicators is used by some forecasters as a leading indicator. Diffusion indices, generally, analyze the degree to which the individual components of an index move with the direction of the overall index. Each diffusion index published by the Conference Board measures the proportion of the components that contribute positively to the overall index.

## Measuring the Economy Through Stock Market Cycles

The path of the stock market cycle generally precedes the business cycle, and thus, the performance of the stock market is a leading indicator. As previously mentioned, stock prices as measured by the S&P 500 are the fifth indicator in the LEI index. Because the prices of equities are determined by both the perceived underlying company fundamentals and the integration of all investor expectations, the stock market performance is symptomatic of the overall direction of the economy. A *bull market* is a sustained period of time when the broad indices of stock prices are rising, or advancing. A *bear market* is a sustained period of time when the broad indices of stock prices are falling, or declining.

As shown in the second graph in Figure 29.1, the early bull market precedes the general economic cycle trough, and the early bear market generally precedes the peak of the economic cycle. This fact provides a chief reason why the stock market is watched so closely by analysts: It signals the direction that the overall economy is likely to traverse in the near future. It is also the reason why it is so important to determine when the stock market hits a bottom after a bear market. Once the bottom is reached, the overall economy begins to pull out of a recession and begins a recovery phase.

The behavior of the stock market also partially drives overall economic performance. Standard economic analysis assumes that private aggregate consumption spending, which is the largest component of a nation's aggregate demand (about 70% in the United States), depends on both per capita income and the value of real wealth in consumers' portfolios. If stocks are in a bear market, then individuals will find that the balance in their retirement accounts and other investment portfolio accounts has dropped. As a result, consumption spending, consumer and business confidence, and business investment are all likely to fall, thus leading to an economic downturn.

Stocks tend to fall into three broad categories. They either move with the business cycles (cyclical stocks), resist these cycles (defensive stocks), or assume a long-term trend of growth despite market ups and downs (growth stocks). *Cyclical stocks* are stocks whose prices vary with anticipated company earnings, which in turn move together with the swings in the business cycle. In general, they include steel, cement, paper, aluminum, machinery, machine tools, airlines, railroads and railroad equipment, automobiles, and other industrial groups. *Defensive stocks* are stocks that present relatively low risk

in recessions because they represent corporations whose products or services are essential to consumer needs and are sufficiently low priced to be demanded at all stages of the business cycle. They include foods, tobacco, utilities, and household products. *Growth stocks* are stocks of corporations whose sales and earnings have increased faster than the general economy over a secular time span (more than one complete business cycle). They may come from all sectors, especially technology.

When a recession appears likely, many investors will shift their portfolio holdings toward defensive stocks. If the recession appears to be especially severe, investors will shift mostly out of stocks and into cash, money market assets, and bonds. When interest rates (and anticipated stock prices) have approached a bottom, and when the outlook is for economic recovery, then investors generally shift toward cyclical and growth stocks. Hence, the overall composition of financial portfolios also reflects economic conditions as well as consumers' expectations about the path that the economy will take in the near future.

One of the key determinants of the price movement of a stock is its quarterly earnings per share (EPS). If the EPS shows strong growth as compared to the same quarter in the previous year for an increasing number of stocks in a recurring pattern over several quarters, then corporations tend to show strong profits and growth. If the EPS is increasing for a large percentage of corporations, then this signals that the economy is strong, thus creating a favorable overall climate for increases in stock prices and an economic boom. A lackluster growth or decline in key corporate sectors or in a wide-ranging group of firms indicates weak economic fundamentals and an impending cyclical downturn. Thus, corporate earnings reports are watched closely by market analysts.

## Measuring the Pattern and Robustness of the Economic Cycle

In the early 1930s, the world was undeniably in the grip of the Great Depression. In 1931, U.S. President Herbert Hoover assigned economist Edward R. Dewey, chief economic analyst for the U.S. Department of Commerce, the task of uncovering the causes of the economic crash and the misery that lay behind this period of suffering. Dewey formed and became the president of the Foundation for the Study of Cycles in 1942, and this now defunct organization was superseded by the Cycles Research Institute (CRI; http://www.cyclesresearchinstitute.org) in 2004.

In over 30 years of research on cycles, Dewey and his associates studied empirical data from a huge variety of natural and human cycles, including insects, fish, mammals, man, and other natural phenomena, which were all found to be connected to sunspot cycles. Some examples included caterpillars in New Jersey, lynx and coyote abundance in Canada, salmon abundance in Canada and England, heart disease in New England, ozone content in London and Paris, pig iron prices, steel production, cigarette production, Goodyear tire and rubber sales, railroad stock prices, rainfall in London, worldwide precipitation, and the average yield of chief crops in Illinois. Dewey found cycles with periods ranging from months to hundreds of years, and several thousand cycles were recorded. One of the main cycles was one with a period of 9 2/3 years (Dewey, 1967).

Based on Dewey's analysis, one other economic assessment tool has been acquired—that of indicators from other disciplines. Because there is both theoretical and empirical evidence that economic cycles are correlated with other human and physical phenomena, the performance of the economy can also be measured by indicators from these other fields. This is obvious in a direct sense, because agricultural production depends on natural weather cycles and economic productivity depends on the stability of the social and political systems; for example, countries being devastated by war will not have strong economic performance.

Dewey concluded that four of the empirical laws of cycles are as follows:

1. Common cycle periods appear in many seemingly unrelated disciplines.
2. Synchrony is the observation that cycles of the same period often have the same phase.
3. Cycles' harmonic ratios is the observation that the common cycle periods are related by the ratios 2, 3 and their products.
4. Cycles outside the earth are often related to cycles on earth. (CRI, n.d.)

To optimally assess the performance of the economy, the driving influences and the responses must be adequately understood. Dewey concentrated on *forced oscillations,* which are externally caused rhythms that are patterns where the rhythm in the economic and other cycles is the direct result of a rhythm in some other phenomenon. Dewey (1967) concluded,

> Insofar as cycles are meaningful, all science that has been developed in the absence of cycle knowledge is inadequate and partial. Thus, if cyclic forces are real, any theory of economics, or sociology, or history, or medicine, or climatology that ignores non-chance rhythms is manifestly incomplete . . . as medicine was before the discovery of germs.

Ongoing comprehensive studies across diverse phenomena provide an increasingly clearer picture of the state of the economy, especially with the current rapid advances in data analysis, computing, and communications technology.

### Schumpeter's Waveform Analysis of the Economic Cycles

Further insight into the understanding of the measurement of the economy and its cycles was added by the well-known and respected economist Joseph Schumpeter. Similar to Dewey, Schumpeter (1938) used a variety of

empirical evidence to develop a cyclical waveform model of economic behavior. This model consisted of a combination of three cycles. The first was Nikolai Kondratieff's long-wave cycle of 50 to 60 years. The second was French medical doctor Clement Juglar's 9 to 10 intermediate-term cycle, which is in accordance with Dewey's 9 2/3-year cycle. The third was economist Joseph Kitchin's short-term minor cycle of 40 months.

Unlike Dewey, Schumpeter (1938) viewed his analysis as being very limited as a useful policy tool. He stated,

> No claims are made for our three cycle scheme except that it is a useful descriptive or illustrative device. Using it, however, we in fact got *ex visu* of 1929, a "forecast" of a serious depression embodied in the formula: coincidence of the depression phase of all three cycles. (p. 174)

This illustrates the principle of resonance in the business cycle models: When the long-, intermediate-, and short-run wave cycles all coincide in a downturn, the economy is likely to suffer an extreme depression. On the other hand, coincidence of all of the upward short-, intermediate-, and long-run cycles creates explosive growth while the economy transitions into a new, higher phase. For several decades, many economists had rejected the ideas of Dewey, Schumpeter, and others who studied these cyclic patterns. Current world developments and newfound computational tools have eclipsed this narrow-minded stance, having shown that this broad, multidisciplinary approach serves as a useful tool in both the measurement and forecasting of economic performance at the macro and micro levels.

### The New Keynesian and Real Business Cycle Views on Evaluating Performance

There are two directly contrasting views on how the economy's performance should be treated as it reacts to stimuli, or "shocks," over the course of the business cycle (Mankiw, 1989; Peterson & Estenson, 1996; Plosser, 1989). The real business cycle (RBC) approach extends the neoclassical framework and suggests that when supply shocks such as technology changes occur, or when demand shocks such as a change in consumer expectations occur, economic participants always act optimally so as to maximize their welfare. As a result, active fiscal and monetary policy have no role because all markets always clear and are in continuous equilibrium. The new Keynesian view is built on the foundation that the reason for recessionary periods is due to market failure, and thus, the economy frequently performs at suboptimal levels away from its efficient full-employment equilibrium.

When looking at the Great Depression and other major recessionary periods worldwide, especially when considering the corruption-induced contributions in the United States such as the saving and loan crisis of the 1980s, the dot-com scandals, and the subprime real estate and financial crises of the new millennium, it is not plausible for even the most ardent proponent of RBC to argue that the economy has continually followed an optimal equilibrium adjustment path. Nonetheless, just stating that the economy is following a nonequilibrium path and attempting to measure the hypothetical "income gap" is not a full solution to the measurement problem. The measurements must be augmented with the insights of the more robust analyses of the type used by Dewey and Schumpeter in order to study the nature of the shocks themselves, which are never "external" but rather part of the interconnected plethora of processes that jointly determine the level of economic performance that is to be evaluated as it unfolds over time.

## The Primary Variables and Data Used to Assess Macroeconomic Performance

National output, inflation, and unemployment are the undisputed "three kings" of the data used to gauge economic conditions. A nation's output is virtually equivalently measured by three primary measures of economic production: gross national product (GNP), which is based on ownership of the factors of production; GDP, which is based on geographical borders; and gross national income (GNI), which is based on the income earned by factors of production. Quarterly and annual data for all of these in the United States are published by the BEA in the National Income and Product Accounts, which the BEA considers to be the cornerstone of all its statistics. Some of these data are also reprinted annually in the tables section of the *Economic Report of the President.*

GDP is the sum of the money values of all final goods and services produced by the economy during a specified period of time. It includes all production inside the country's geographical borders. Nominal GDP (NGDP) is calculated by valuing the outputs at current prices, whereas real GDP (RGDP) is calculated by valuing all outputs at the prices that prevailed in some base year, which is currently the year 2000. Therefore, RGDP directly measures the quantities produced, and is a far better measure of changes in national production than is nominal GDP.

However, RGDP is a secondarily constructed measure, which can be seen by viewing the manner in which it is obtained. In the United States, for the year 2001, nominal GDP was $10,128 billion. The GDP implicit price deflator (IPD), which is the quarterly published index of overall prices, had a value of 100 in the year 2000 because it is the currently used base year. The IPD price index value for the year 2001 was 102.399, meaning that the overall level of prices was 2.399% higher in the year 2001 than in 2000. This percentage change,

which measures the overall inflation rate, is found by the following formula:

$$\begin{aligned}\text{percentage change} &= \frac{\text{new} - \text{old}}{\text{old}} \\ &= \frac{102.399 - 100}{100} \\ &= 2.399\% \\ &= \text{inflation rate for 2001.}\end{aligned}$$

RGDP is found by dividing nominal GDP by the IPD index for the corresponding year. Before this calculation is made, however, the IPD index must be taken out of index number form by dividing it by 100. In the previous example, the transformed IPD value equals 1 for the base year 2000 and 1.02399 for the year 2001. In the year 2000, nominal GDP was \$9,817 billion, so

$$\begin{aligned}\text{real GDP}_{2000} &= \frac{\text{nominal GDP}}{\text{transformed IPD}} \\ &= \frac{\$9,817 \text{ billion}}{1} \\ &= \$9,817 \text{ billion.}\end{aligned}$$

Note that values of nominal and real GDP are always equal for the base year. In 2001,

$$\begin{aligned}\text{real GDP}_{2001} &= \frac{\$10,128 \text{ billion}}{1.02399} \\ &= \$9,890.72 \text{ billion of constant} \\ &\quad (\text{year } 2000).\end{aligned}$$

The growth rate of the economy is measured by the percentage change in the RGDP. The growth rate for the year 2001 is as follows:

$$\begin{aligned}&\frac{\$9,890.72 \text{ billion} - \$9,817 \text{ billion}}{\$9,817 \text{ billion}} \\ &= 0.00751 = 0.751\%.\end{aligned}$$

This is the same growth rate that can be compared to the 2% to 3% annual growth of the trend curve given by Y* in Figure 29.1. Because 0.751% is less than even 1% annual growth, this year can be evaluated as a slow growth year.

Both internally and in cross-country comparisons, the most widely used measure of economic performance regarding the level and change in a country's economic well-being is its per capita RGDP, or RGDP per person. Per capita RGDP represents the purchasing power of the average citizen's annual income earnings. It is found by using the following formula, where the year 2001 is again used as a continuing example:

$$\begin{aligned}\text{per capita RGDP}_{2000} &= \frac{\text{RGDP}}{\text{population}} \\ &= \frac{\$9,817 \text{ billion}}{282{,}403{,}000 \text{ persons}} \\ &= \$34{,}762.38/\text{person.}\end{aligned}$$

$$\begin{aligned}\text{per capita RGDP}_{2001} &= \frac{\text{RGDP}}{\text{population}} \\ &= \frac{\$9,890.72 \text{ billion}}{285{,}335{,}000 \text{ persons}} \\ &= \$34{,}663.54/\text{person.}\end{aligned}$$

The growth rate for per capita GDP in the year 2001 was

$$\begin{aligned}&\frac{\$34,663.54 - \$34,762.38}{\$34,762.38} \\ &= 0.28\%.\end{aligned}$$

This small negative growth rate means that the average citizen encountered a fall in the real income level and would have only been able to purchase a slightly smaller quantity of goods and services than in the previous year. In years where the economy is growing according to its long-run full employment equilibrium trend growth rate, this per capita increase would be around 2% to 3%.

Real per capita GDP (or GNP) is not a full measure of a nation's economic well-being and does not provide precisely accurate cross-country comparisons because of the following reasons (Baumol & Blinder, 2008; Nafziger, 2006). First, for the most part, only goods and services that pass through organized markets are counted in the GDP calculations. International GDP comparisons are vastly misleading when countries differ greatly in the fraction of economic activity that each conducts in organized markets. The underground economy, which consists of many cash and barter transactions and illegal activities, is not counted, neither are the services of housewives or househusbands.

Another shortcoming is that GDP places no value on leisure, so GDP would understate economic well-being in this respect. Negative and destructive types of goods and those that are produced as a result of a negative stimulus also get counted in GDP, so GDP could overstate economic well-being in this respect. For example, although production might increase to clean up after an earthquake or to fight a war, the citizens would be better off without these events. Ecological costs are not netted out of GDP, either, even though environmentally adjusted measures have been proposed.

GDP is understated for developing countries, where household size is substantially larger than that in developed countries, resulting in household scale economies. Two people can live more cheaply together than separately. India's household size is 5.2 compared to the United States' 2.6. Moreover, a larger percentage of the average Indian household consists of children, who consume less food and resources than adults. Equivalent adult, equivalent household (EAEH) adjusts income based on household size and children. India's per capita income is about 10% higher when it is EAEH adjusted, and Africa's EAEH adjustment for per capita income is more than 10% because

its population growth rate and average household size are larger than India's (Nafziger, 2006).

GDP includes only what are called final goods, which are those that are purchased by their final users. It does not include intermediate goods purchased for resale or for use in producing another good; otherwise, there would be multiple counting of these intermediate goods. It has been argued that many of the final goods produced in developed countries, such as Western executives' business suits, smog eradication expenditures, and part of defense spending, should in fact be classified as intermediate goods (Nafziger, 2006). As a result, GDP may be overstated for developed countries because a number of items included in their national output are intermediate goods, reflecting the costs of producing or guarding income.

For international comparisons, the exchange rate used to convert GDP in local currency units into U.S. dollars, if market clearing, is based on the relative prices of internationally traded goods (and not on purchasing power). However, GDP is understated for developing countries because many of their cheap, labor-intensive, unstandardized goods and services have no impact on the exchange rate, because they are not traded. Many of the necessities of life, such as food—for example, cheap rice is the primary food staple in India—are very low priced in dollar terms. GDP is overstated for countries, usually developing countries, where the price of foreign exchange is less than a market-clearing price. On balance, however, the other adjustments outweigh this effect so that income differences between rich and poor countries tend to be overstated.

GDP growth is heavily weighted by the income shares of the rich. A given growth rate for the rich has much more impact on total growth than the same growth rate for the poor. In India, which has moderate income inequality, the upper 50% of income recipients receive about 70% ($350 billion) of the GDP, and the lower 50% receive about 25% ($150 billion) of total GDP ($500 billion). A growth of 10% ($35 billion) in income for the top half results in 7% total growth, but a 10% ($15 billion) income growth for the bottom half is only 3% aggregate growth. However, the 10% growth for the lower half does far more to reduce poverty than the same growth for the upper half.

## The Twin Evils of Inflation and Unemployment

Inflation and unemployment are known as the twin evils of macroeconomics. One of the key macroeconomic goals for every country is to have an inflation rate that is very stable and close to zero. *Inflation* is defined as a sustained increase in the general price level. As previously discussed, the inflation rate is measured by the percentage growth in the price index. There are three primary price indices used to measure inflation. The GDP IPD discussed previously is the most comprehensive and is published quarterly by the BEA. It is a type of Paasche aggregate price index, which means that it uses current year quantities as weights for its calculation. Thus, the IPD index shows how much the quantity of goods constituting GDP produced in a given year would have cost if those same goods would have been produced in the base year. The weights for the index thus change in every period.

The other two indices are both published by the U.S. Department of Labor's BLS. The producer price index (PPI) measures the selling prices received by domestic producers for their output. The PPI targets the entire marketed output for U.S. producers and thus excludes imports. The prices included in the PPI are from the first commercial transaction for many products and some services.

The most commonly quoted inflation measure is the consumer price index (CPI), which measures the prices paid by urban consumers for a representative basket of goods. Whereas the primary use of the PPI is to deflate revenue streams in order to measure real growth in output, the primary use of the CPI is to adjust income and expenditure streams for changes in the cost of living. The CPI index is a type of moving Laspeyres aggregate price index, which uses the base year quantities as weights. This index shows how much a basket of goods produced in the base year (say, the year 2000) would have cost in any given year of interest. The BLS publishes three major versions of the CPI. The CPI for all urban consumers (CPI-U) is a broader index than the original CPI index, and it is the most used version quoted in the media. Individual income tax parameters and treasury inflation-protected securities returns are based on all the items CPI-U. In 1978, the CPI-U was created and the original CPI was renamed as the CPI for urban wage earners and clerical workers (CPI-W). Social Security and federal retirement benefits are updated each year for inflation by the CPI-W.

The validity and optimality methods of assessing inflation through the methods employed by the BLS in computing the CPI are controversial (Greenlees & McClelland, 2008; Williams, 2006). Former chairman of the Fed Alan Greenspan and Michael Boskin put forth a substitution effect argument that stated that the CPI would overstate inflation if consumers substituted hamburger for steak when the price of steak became more expensive. The CPI does not use a variable basket of goods that allows this type of substitution; however, the original arithmetic weighting scheme was replaced by a geometric weighting scheme that now automatically gives a lower weight to CPI components that are rising in price and a greater weight to items whose prices are falling. The net effect has been a reduction in the annually reported CPI by 2.7% compared to the original arithmetic weighting scheme, and a reduction in the Social Security annual cost of living adjustment by more than a third when compounding the results from the 1990s to the present (Williams, 2006). The BLS defends the geometric weighting scheme in its formula, noting that it is widely used by worldwide statistical agencies and that it is recommended by the International Monetary Fund and the Statistical Office of the European Communities.

Another controversial aspect of the CPI formula is hedonic quality adjustment, which is one of the methods used to determine what portion of a price difference is viewed by consumers as reflecting quality differences. The BLS (Greenlees & McClelland, 2008) defines this as "a statistical procedure in which the market valuation of a feature is estimated by comparing the prices of items with and without that feature." For example, when the price of a television rises, the hedonic adjustment would assume that part of the price increase was due to an increase in the quality and part of the increase was due to inflation, so that the CPI would view the new, higher price as reflecting the higher quality or added features. This adjustment is necessary to reflect both improvements and drops in the quality of goods; however, the amount of adjustment and the range of goods for which it is applied remain subjective. If the quality adjustments are weighted too heavily, then the CPI will understate the true underlying inflation rate experienced by consumers. The chained CPI-U (C-CPI-U), introduced during the second Bush administration as an alternate CPI measure, attempts to directly measure the substitution effect, rather than an approximation based on a geometrically weighting scheme.

A final controversy lies in the short-term and seasonal adjustment procedures. When the index is seasonally adjusted for monthly repeating seasonal price swings, intervention analysis dampens the volatility of extreme fluctuations in fuel prices, especially price increases, which results in the CPI reflecting a lower inflation rate than that which is actually experienced. This problem is related to the controversial concept of the core rate of inflation (net of food and energy), which also seeks to remove the short-term (1- or 2-month) volatility resulting from extremely large fluctuations in food and energy prices. This is always be a misleading inflation gauge because food and energy account for about 23% of consumer spending as weighted in the CPI (Williams, 2006).

The third part of the trilogy of measures of performance is the unemployment rate. High unemployment has been linked to higher incidence of certain types of crimes, psychological disorders, divorces, and suicides (Baumol & Blinder, 2008; Mankiw, 2006). Unemployment may also cause a loss of job skills (or a decrease in their accumulation).

The BLS measures unemployment by surveying about 60,000 households every month. Workers are classified as being employed, unemployed, or not in the labor force. The labor force refers to the number of people holding or seeking jobs, so that the labor force = employed + unemployed. The unemployment rate is defined as the percentage of the labor force that is unemployed. For the United States in the year 2001,

$$\text{labor force} = 135.1 \text{ million (employed)} + 6.7 \text{ million (unemployed)} = 141.8 \text{ million}$$

$$\text{u} = \text{unemployment rate} = \frac{\text{unemployed}}{\text{labor force}} = \frac{6.7 \text{ million}}{141.8 \text{ million}} = 0.047 = 4.7\%.$$

Although both civilian and overall unemployment rates are computed, it is the civilian unemployment rate that is usually quoted. Unemployment rates are also computed for more narrowly defined groups—blacks, whites, men, women, and so on.

The stated unemployment rate figures actually understate the true underlying unemployment problem by ignoring discouraged workers and underemployed workers. When individuals desire to work full-time but are currently employed only part-time, they are counted as employed. The unemployment rate ignores the underemployment of these workers. The unemployment rate also does not count discouraged workers, who are unemployed persons that give up looking for work and are therefore no longer counted as being in the labor force.

Conversely, the unemployment rate overstates the true unemployment burden as the result of what is referred to as the added worker effect, which occurs when nonworking spouses or teenagers enter the labor force as the result of a primary household income earner becoming unemployed. The added worker effect smooths family income over the business cycle. In the United States, most spells of unemployment are short, and most of the unemployment observed at any given time is long-term. Thus, most of the economy's unemployment problem is attributable to the relatively few workers who are jobless for long periods of time (Mankiw, 2006).

There are four types of unemployment. *Frictional unemployment* is due to normal turnover in the labor market. It includes people who are temporarily between jobs because they are moving or changing jobs (or occupations). *Structural unemployment* occurs when workers lose their jobs because they have been displaced by automation, because their skills are no longer in demand, because of sectoral shift, or other similar reasons. *Seasonal unemployment* results when employment is of a seasonal nature, such as with lifeguarding, ski instructors, and construction work. These three are sometimes classified together as frictionally unemployed.

The last type is the one negative type, which results from poor economic performance. *Cyclical unemployment* results due to a decline in the economy's total production. It rises during recessions and falls during booms. The Employment Act of 1946 committed the U.S. government to help maintain low unemployment.

*Full employment* is a situation where no cyclical unemployment and minimal structural unemployment exists. The natural rate of unemployment is the unemployment rate that corresponds to full employment, where there is no cyclical unemployment. It is the normal rate of unemployment around which the actual unemployment rate

fluctuates over time. As explained previously, it is also called the NAIRU, and in the United States it fluctuates between 4% and 5%. So, even at full employment, some unemployment exists.

## Conclusion

This analysis has presented the data sources and methods for measuring the macroeconomic variables that determine economic performance. Over the course of the business cycle, the level of economic activity generates a slew of indicators as it waxes and wanes across the time series that are to be evaluated.

Many macroeconomic models that measure economic performance define a performance or criterion index that allows the policy maker to choose a compromising trade-off between high inflation and high unemployment (which corresponds to low output growth, especially in the short run). This inflation–unemployment trade-off is referred to as the Phillips curve relationship. Evaluation of economic performance always depends on the relative weights assigned to price stability, unemployment, and output growth. There is no global positioning system to define where the economy is and which path will most directly lead it to a desired future destination. As it proceeds, the economy's path will be evaluated differently by each individual person based on the perceived influence of its entirety on that person's experience.

# Macroeconomic Models

Christopher J. Niggle
*University of Redlands*

The term *macroeconomics* refers to study of the behavior of an economy as a whole or as a system; the phenomena explained are (1) the short-run level of economic activity—the levels of national output, income, and employment; (2) the causes of short-run fluctuation in economic activity (business cycles); and (3) the long-run growth rate of an economy. This chapter focuses on the first two aspects of macroeconomics. The models are presented in an approximate chronological order; the chapter's organizing theme is that modern macroeconomic models can be seen as based on one of two competing "visions" of the economy: (1) The economy is seen as stable, with strong market forces pushing it toward an equilibrium level consistent with full employment of labor and capital (as in the classical and new classical models), or (2) it is seen as an unstable system that grows through time in a boom–bust pattern, with its normal state being less than full employment and so less-than-potential output being produced (as in Keynes's and the Keynesians' models).

## The Beginning: Keynes's Critique of Classical Economics

Macroeconomics as a distinct field within economics emerged in the late 1930s as a response to John Maynard Keynes's *General Theory of Employment, Interest and Money* (1936/1973, referred to subsequently as GT). Keynes contrasted his views on the causes of depressions and persistent involuntary unemployment with those of his predecessors, whom he termed the *classical economists.* In Keynes's view, these economists assumed that the normal condition for a market economy is one of capital-accumulation-fueled growth with full employment of labor and capital, and that periods of high unemployment were rare and temporary deviations from the norm. Keynes wrote that this assumption is empirically incorrect because economies frequently experienced prolonged periods of high unemployment and below-potential output (recessions or depressions). He presents his model by developing a critique of three dimensions of the classical theory: (1) Say's law, (2) the quantity theory of money, and (3) continual clearing of the labor market at "full employment."

Keynes's informal model (*informal* meaning that he did not specify his model with a series of equations or represent it with a set of diagrams but, rather, mainly used verbal exposition) begins by seeing the classical economists as having all held the validity of Say's law of markets. Say's law denoted an argument that all income generated by production would be spent on purchasing the national product—either directly, as when workers' wages or capitalists' profits are spent on consumption, or indirectly, when capitalists' savings are borrowed by firms to finance purchases of new capital goods. In modern economic language, we say that the classical economists assumed that the level of *aggregate demand* (Keynes's innovative term) for products always equals the cost of producing them, including a return on their capital to the capitalists whose firms produce the products; in other words, aggregate demand is equal to aggregate supply. Because this would mean that firms would always be able to sell any quantity of goods they might produce, they would choose output levels based on their calculations of their profit-maximizing outputs. They would collectively find it profitable to employ as many workers as were willing to sell labor services at the going wage rates; full employment would

result: The only unemployed workers would be those unwilling to accept the going wage rate, who were considered to be "voluntarily unemployed." Keynes rejected this proposition; in his model, aggregate effective demand for the social product was quite likely to be less than the value of what would be produced if all workers willing to work were employed (aggregate demand could be less than aggregate supply at full employment). If the latter occurred, firms would reduce their employment and output levels until they arrived at the levels at which their sales rates equaled their production rates. So aggregate demand determines the level of actual output and employment, and significant and persistent involuntary unemployment can occur. The cause of recessions or depressions is inadequate aggregate demand. How could this occur? Keynes had a simple answer: Although workers' wage income was generally spent, creating demand for products, profits and interest might very well be saved. And if all of those savings were not borrowed to finance demand for investment goods, aggregate demand could be less than sufficient to employ all those willing to work. Depressions are caused by "too much saving"—too much in comparison with the amount of investment that firms are willing to borrow to finance

Keynes also rejected the validity of another aspect of classical economics: the quantity theory of money (QTM). The QTM argues that the exchange value of a monetary unit is expressed in the average level of prices within the economy (P), and that increases or decreases in the quantity of money (M) in circulation would cause changes in the price level P. Sophisticated versions of the theory were presented using the equation of exchange $M \times V = P \times Y$, in which V represents the velocity of circulation of the money stock and Y represents the current (and assumed full-employment level of national product). If V and Y are assumed to be constant, changes in M would lead to directly proportional changes in P. Because the QTM assumed that V and Y were fixed in the short run, changes in the quantity of money (e.g., an increase in M) would not affect the real level of output or employment. So money is "neutral" within the economy: Changes in the money stock will not cause changes in the levels of output or employment.

In Keynes's model, changes in the quantity of money could cause changes in interest rate levels that could influence aggregate demand for products (especially for investment spending on new capital goods) and thus could influence aggregate production and employment. Money is not generally neutral in Keynes's model; increases in the money stock would affect only the price level and not output in the special case of the economy already being at the full-employment, full-output level.

Finally, Keynes also rejected the validity of the classical views on the working of the labor market, using Pigou's model as an example of these views. Pigou and the other neoclassical marginalist theoreticians had argued that if wages were flexible because of competition for employment and employees, the levels of both the money and real wage (the purchasing power of the level of nominal or money wages) would adjust to "clear the market" for labor. They also argued that the equilibrium *market-clearing real wage* would be equal to the marginal product of labor. Keynes argued that money wages are usually fixed in the short run and that workers cannot bargain over their real wage that would clear the market, because neither they nor their employers can set output prices while bargaining over money wage levels.

## Keynes's Model Represented as a Set of Propositions

Keynes's theory and model attempt to describe the relationship between the amount of money in circulation, the level of interest rates, and the level of employment (his model, the GT, places financial markets and interest rates at the heart of the macroeconomy).

1. High unemployment is caused by insufficient aggregate demand for national product.
2. Insufficient aggregate demand is the result of saving in excess of business' willingness to borrow to finance investment in new capital goods.
3. Excessive saving is done by high-income earning households, who receive interest on bonds; it is the result of an "arbitrary and excessive inequality in the distribution of income" (Keynes, 1936/1973, p. 372). Low investment is caused by low profit expectations or high interest rates, or both—both of which discourage business investment in new capital goods.
4. Low levels of aggregate demand by the private sector (firms and households) can be offset by high levels of government expenditures (stimulative fiscal policy). Low levels of interest rates can also encourage more investment.
5. He argues that the rate of interest should be seen as the price of liquidity (or the price of holding financial wealth as money, as opposed to less liquid financial assets, such as bonds). He termed this the *liquidity preference* theory of money and interest.
6. The level of the rate of interest is explained as determined by the interaction of the supply and demand for money, with the supply controlled by the central bank through monetary policy and the demand determined by the level of transactions and the price level of those transactions, plus financial wealth holders' expectations regarding the future market price of bonds.
7. Another theoretical proposition advanced by Keynes was that if either government expenditures or private investment expenditures increased, total expenditures (aggregated demand) and actual output would increase by a greater amount: He termed this the *multiplier effect.*

Soon after the publication of his book, professional economists began discussing Keynes's views in professional journals, most often in the form of book reviews.

Other economists attempted to describe and interpret Keynes with more formal models. The most influential example of this is John R. Hicks's (1937) IS/LM model, which represented Hicks's interpretation of Keynes's theory with a set of equations and a two-dimensional diagram. Hicks argued that Keynes's theory rested on the validity of his assumption that money wages were fixed in the short run and would not fall if unemployment increased, so Keynes's model should be seen as valid only in the "special case" of an economy in which some institutional factors prevented wages from being downwardly flexible; ironically, Keynes had not presented a "general theory," valid for all economies. Hicks later repudiated his evaluation of Keynes's theory and argued that his model oversimplified Keynes's theory (Hicks, 1957, 1967).

Other attempts at presenting a formal model of Keynes's theory were made by Alvin Hansen (1953) and Paul Samuelson (1948). Their model became known as the Hansen-Samuelson *Keynesian cross diagram.* Given the levels of interest rates, money wages and prices, the parameters of the consumption function—that is, the relationship between personal income and personal consumption expenditures—and planned business investment expenditures, the economy finds a unique equilibrium level of output at the level where aggregated demand equals aggregate production.

## Keynesian Economics

By the early 1950s, Keynes's theory was widely seen as valid by most professional economists (especially among academics). Economists accepting the validity of the Keynesian short-run theory of output determination became known as *Keynesians.* Their published work focused on how fiscal policy could be used to prevent or end depressions, but they also developed business cycle theory and growth theory consistent with Keynes's short-run model. Toward the end of the 1950s and in the early 1960s, some of these economists began to argue that Keynes's theory of depression (inadequate demand causing involuntary unemployment) could be extended to explain price inflation (too much demand at full employment). Logically, there should be a level of unemployment consistent with stable prices and wages, and this was seen as a desirable target for macroeconomic policy. *Full employment* became defined as the lowest rate of unemployment consistent with wage and price stability. Empirical work attempting to estimate the relationship between wages, prices, and unemployment levels produced evidence of an inverse relationship between unemployment and wage or price inflation, consistent with theory. Because such a relationship is downward sloping if graphed with inflation on the vertical axis and unemployment on the horizontal axis, this curve became a part of the core of Keynesian economics (and named the *Phillips curve* after A. W. Phillips, 1958, who conducted one of the earliest econometric estimates of its parameters). Another core belief among the "original Keynesians" was that monetary policy by itself was not usually sufficient to end a severe recession; rather, a fiscal policy stimulus of higher spending by the national government was required. The increases in U.S. gross domestic product (GDP) following increases in expenditure during the 1930s and especially the dramatic increase following large increases in World War II (WWII)–related military expenditures was interpreted by the Keynesians as empirical evidence in support of their central propositions.

However, even as Keynesian economics became dominant in the academy and widely adopted as a guide to macroeconomic policy, widespread opposition to the core theory appeared within academic economics, and Keynesian economics itself divided into several quite different schools of thought, stressing different aspects of Keynes's somewhat vague and informal model in the GT, including approaches now known as *original Keynesians*, *post-Keynesians*, and *new Keynesians*.

## The Evolution of Macroeconomics Since the 1960s

The history of macroeconomics over the last 40 years can be interpreted as a struggle between competing visions of the economy and the proper macroeconomic roles of the state. One vision is exemplified by *new classical economics,* which sees the economy as essentially stable and tending toward an equilibrium characterized by high employment and an economic growth rate largely determined by the rate of technological change (the *natural rate of unemployment* and the *steady-state* rate of growth). Another, contrasting, approach taken by institutionalist and post-Keynesian economics rests on a vision of a very unstable economy, whose growth rate is the result of an open-ended transformational process taking place through economic fluctuations, characterized by excessive unemployment and inequality, and which is often threatened by incoherence and the possibility of breakdown; this approach is called *evolutionary Keynesianism* here.

The first approach implies a noninterventionist role for the state in the economy; the second argues for a strong interventionist state. A third approach, which acknowledges occasional episodes of instability and a limited role for the state in stabilization and the active promotion of growth, appears in new Keynesian economics and new endogenous growth theory, and appears currently hegemonic within mainstream economics.

New classical economics supports arguments against activist macroeconomic stabilization policy, whereas original Keynesian, new Keynesian, institutionalist, and post-Keynesian economics all support intervention. To a great extent, the debates within macroeconomics reflect a

broader and deeper philosophical division between proponents of a radical laissez-faire economic philosophy and those who advocate a strong, interventionist state with wide responsibilities for the common good. The institutionalists and post-Keynesians share a common vision and models that are similar in many respects; their approach is designated *evolutionary Keynesianism* in what follows. The primary purpose of the rest of this chapter is to delineate the important differences between the new classical (NC), new Keynesian (NK), and evolutionary Keynesian (EK) approaches. This chapter suggests that although new classical economics (NC) dominated the mainstream in the 1970s and 1980s, its influence has declined recently as new Keynesian (NK) economics has become more influential, dominating the postmonetarist "new consensus" among macroeconomists. The chapter also argues that the institutionalist/post-Keynesian approach offers a third framework for economic policy.

## The Rise of New Classical Economics: Monetarism, Rational Expectations, and Real Business Cycle Theory

The brief hegemony of Keynesian economics within academia and policy economics lasted for about 2 decades (perhaps from the late 1940s to around 1970) before being challenged by the new version of classical economics. The 1960s consensus approach to macroeconomics was represented with fixed-price, fixed-wage versions of Samuelson's (1948) and Hansen's (1953) Keynesian cross and John Hicks's (1937) IS/LM macroeconomic models of income and employment, and was based on the assumption of a stable relationship between unemployment and price or wage inflation, represented with a Phillips curve. This approach was often referred to by Paul Samuelson's term *neoclassical-Keynesian synthesis,* because its implicit microeconomic foundation was largely a form of the Marshallian price theory that Keynes had used in his GT and that then formed the core of standard neoclassical academic microeconomics, while its macroeconomics was an interpretation of Keynes's theory of effective demand.

The first generation of Keynesian economists saw national governments as responsible for economic stability, economic growth, and full employment, with the highest short-term priority to be given to full employment. Business cycles were seen as caused by fluctuations in aggregate demand, which could be offset with fiscal policy; monetary policy should be used to support fiscal policy, but monetary policy by itself was generally seen as inadequate to stabilize the economy.

Many economists and historians see Keynesian economics as one of the cornerstones of the post–WWII consensus regarding the proper relationship between the state and the economy, and as an integral component of the argument for a more interventionist role of the state. The new political-economic system that emerged in the 1940s and 1950s in most of the wealthy capitalist nations has been described with many terms including *welfare capitalism, managed capitalism, state capitalism, monopoly capitalism,* and *guided capitalism.* The counterrevolution to the Keynesian revolution of the 1940s and 1950s began in the late 1960s with the rise of monetarism, the first component of what was to become NC economics.

### Monetarism

Monetarism can be understood as a set of theoretical propositions and policy proposals focused on the macroeconomic role of money. The core theoretical propositions are as follows:

1. The economy is essentially stable and tends toward an equilibrium at a "natural rate" of unemployment that is consistent with stable wages and prices; this natural rate of employment, the stock of capital, and technology then determine the potential level of national income.

2. Disturbances to equilibrium are almost always caused by changes in the money stock or its growth rate.

3. If unanticipated, these monetary shocks can result in temporary fluctuations in output and employment, but the economy tends to return to the natural rate quickly as wages, prices, and interest rates adjust. Monetarists argue that anticipated monetary shocks are likely to change only the levels of wages, prices, and interest rates even in the short run. Changes in the money supply are neutral in the long run with respect to the real dimensions of the economy: the levels of output, employment, the composition of output, and the real wage. This proposition is described as the *classical dichotomy* between the real and nominal or monetary dimensions of the economy, and its refutation was one of the core ideas in Keynes's GT.

4. Inflation and deflation are the result of excessive or insufficient growth rates in the money stock as in the QTM.

A set of ancillary propositions agreed to by most monetarists was consistent with and supported the core distinguishing theoretical principles of their school mentioned previously.

5. Most versions of monetarism assumed that fiscal policy could not be used to stabilize an economy or otherwise improve macroeconomic performance; this was described as the "ineffectiveness" of fiscal policy in the literature. Changes in government budgets (deficits) intended to stimulate the economy that were financed by borrowing and bond issue resulted in rising interest rates and "crowded out" private investment. Deficits financed by printing money led to inflation; expenditures financed by taxes lowered private spending commensurately. In any of these scenarios, output composition and the allocation of resources would change, but not the aggregate level of

output or employment; surpluses reduced interest rates and stimulated private investment. Because the private sector usually used resources more efficiently than the state sector, expansionary fiscal policy would have detrimental effects; because the economy tended toward the natural rate of employment, countercyclical fiscal policy was unnecessary as well as ineffective.

6. The monetarists argue that the normal state of the economy is the natural rate of employment and positive economic growth as described in Robert Solow's (1956) neoclassical growth theory. A higher saving rate would lead to a higher capital–labor ratio and raise per capita income during a transitional period, but diminishing marginal returns to capital and the free flow of capital and technology across nations implied that growth rates should converge to a "natural rate" of growth determined by technological change.

The key policy proposal advanced by monetarists became known as *Friedman's rule*: Central banks should concentrate on keeping the price level constant (or inflation very low) by setting the growth rate of money at the anticipated growth rate in real output plus the estimated change in velocity. In more sophisticated versions, Milton Friedman (1968) acknowledged that some circumstances such as financial crises might warrant a temporary abandonment of monetary growth targets by the central bank, but he argued that such episodes would not occur very often if the central bank were committed to a stable monetary growth regime, which would be consistent with a stable economy. If the chief source of fluctuations in nominal GDP were fluctuations in the money supply, economic fluctuations would largely disappear under such a regime.

Monetarists also advocated flexible exchange rate systems, arguing that they would strengthen the effectiveness of monetary policy and increase its independence by doing away with the necessity to use monetary policy to peg the exchange rate. Keynes and the Keynesians favored interest rate targets, discretionary monetary policy as a supplement to fiscal policy, and fixed exchange rates to reduce uncertainty.

As increasingly formal versions of monetarism were presented, debates centered on how expectations regarding future levels of wages and prices were formed, and how changes in expectations affected the relationship between unemployment, wages, and prices, which the first generation of Keynesians had thought to be fairly stable and described with Phillips curves. Early versions of Phillips curves (Phillips, 1958; Samuelson & Solow, 1960) described a stable inverse relationship between wage or price inflation and unemployment, which would allow policy makers to choose a level of unemployment and inflation. Edmund Phelps (1968) and Friedman (1968) argued that Phillips curves shift over time, implying unanticipated changes in the natural rate, as the economic environment changes; especially important in their view were expectations of future inflation, which were largely determined by the recent past behavior of prices.

If monetary policy caused inflation by pushing unemployment below the natural rate (by "surprising" workers who did not anticipate reductions in their real wage caused by the inflation), the increase in inflation would lead to more inflation as economic actors attempted to regain their real income by raising wages, prices, and interest rates (known as the *Gibson paradox* and *Fisher effect* in the literature). Economic actors' inflationary expectations adapted to the actual rate of inflation as they looked backward into time trying to forecast economic conditions. These related propositions came to be known as the backward-looking or *adaptive expectations* model and were represented with inflation-augmented Phillips curves, which were vertical at the natural rate in the long run, as in the "neutrality of money" story.

By the late 1970s, monetarism, the natural rate hypothesis, shifting Phillips curves, and vertical long-run Phillips curves at the natural rate of unemployment appeared in all macroeconomics textbooks and were widely accepted as valid analytic concepts within mainstream economics. Support for the neoclassical-Keynesian synthesis and discretionary countercyclical fiscal policy declined. The Federal Reserve began targeting monetary aggregates in 1970 and increasingly emphasized control over monetary aggregates as its primary intermediate target for policy and low inflation as its primary ultimate objective throughout the 1970s and early 1980s; between 1979 and early 1982, it conducted an inflation-fighting monetarist "experiment," targeting the growth rate of the monetary base and the monetary aggregates M1 and M2, while allowing interest rates to increase and fluctuate widely. This episode was consistent with the wide support for monetarism within economics and is often cited to indicate the high watermark of monetarist influence among policy makers in the United States.

## Rational Expectations

A parallel development beginning in the early 1970s was the increasing insistence by some economists that Keynesian economics was not based on the proper *microfoundations* with respect to assumptions about human behavior. If economic actors are rational and utility maximizing, and markets are complete and efficient, markets should continuously clear—including the market for labor.

Persistent involuntary unemployment seems logically inconsistent with those assumptions, since the labor market should allow utility-maximizing workers and profit-maximizing firms to find each other. Many economists began to reject Keynesian models as unscientific because they ignored these issues and seemed inconsistent with the rational expectations hypothesis.

Combining aspects of monetarism (the quantity theory) and the Walrasian microfoundations critique, Robert E.

Lucas Jr. (1972, 1973, 1975, 1976), Thomas Sargent and Neil Wallace (1975), and others argued that if changes in the money stock caused inflation, and if economic actors understood the connection between money and prices—and if they were rational—they would come to anticipate inflation whenever the money stock grew (they would learn from their mistakes and change their behavior). If rational economic actors noticed that the central bank increased the money supply whenever unemployment increased, their "rational" reaction to increasing unemployment and anticipated money supply growth would be to raise wages, prices, and interest rates. Rational economic actors would be forward looking in forming their expectations regarding inflation. If so, monetary policy could not be effective in changing the real dimensions of the economy in even the short run unless the policy changes were unsystematic—irrational policy moves that rational actors would not anticipate, such as raising interest rates in a recession or lowering them in an inflationary boom.

Building on the rational expectations framework, Robert Barro (1974, 1981a, 1981b) argued that rational behavior by forward-looking economic actors would also prevent fiscal policy from stimulating the economy. For example, if the government proposes a tax cut to stimulate consumption and employment, rational consumers and tax payers will anticipate higher taxes (on themselves or their descendants) in the future to repay the increased government debt and will save more to finance those higher anticipated taxes, reducing their current consumption: Aggregate current demand cannot be stimulated with tax cuts. This proposition is known as *Ricardian equivalence* because Barro claims David Ricardo as an early proponent (although Ricardo himself seems not to have believed in the empirical validity of the proposition; O'Driscoll, 1977). The rational expectations hypothesis thus supports arguments for the irrelevance of both fiscal and monetary stabilization policy. Note that the critical assumptions supporting the ineffectiveness of intervention is that changes in the money supply will lead always to changes in the price level and not cause changes in the real dimensions of the economy (the monetarist quantity theory and neutrality of money hypotheses), and on a more fundamental level, that the economy is stable and tends toward the natural rate of unemployment, which is derived from the market-clearing hypothesis. Rational expectations economists often describe their models as *equilibrium economics.*

The rational expectations theory began to dominate economics as taught in elite graduate programs in the late 1970s, appearing in textbooks at about the same time. By the early 1980s, its radical argument against the possibility of altering the real dimensions of the economy through monetary or fiscal policy was widely accepted within the profession and became dominant by the end of the decade.

In the late 1970s, versions of the NC theories, business cycles, and inflationary episodes were mainly the result of external shocks to the economy, temporary misperceptions by workers or firms regarding the wages or prices that would clear markets (false trading), or the unintended consequences of well-intentioned but doomed attempts to stabilize the economy, and the latter were most often caused by unanticipated attempts to push the unemployment rate below the natural rate and to raise growth above the long-run trend determined by growth in resources and technological change. The resulting inflation required central banks to tighten monetary policy, forcing the economy into a recession until inflationary expectations were reduced and the economy returned to its equilibrium natural rates of unemployment and growth. The state should leave the economy alone, as in most versions of original classical economics; economic policy should be restricted to providing the proper institutional framework for a capitalist market economy and instructing the central bank to follow Friedman's rule. This view is a profound rejection of the political economy of Keynes and the early Keynesians, who held that the state can and must improve the performance of the economy through discretionary monetary and fiscal policies.

## Real Business Cycle Theory

But to many of those working within the rational expectations–Walrasian model, the "bad monetary policy" story seemed an inadequate explanation for business cycles; real business cycle (RBC) theory emerged in the early 1980s to offer an explanation consistent with both the Walrasian continuous market-clearing approach and the rational expectations theory's definition of rational behavior. In this theory, economic fluctuations are largely the result of "real" or nonmonetary factors: changes in technology and in preferences by workers for leisure versus goods, or *intertemporal substitution.* Expansions and high growth rate periods are the result of the introduction of new technology sets, as in Schumpeter's theory of economic development (and Marx's as well); recessions occur when the economy readjusts to the diminishing influence of a set of technological changes on investment. Increases in unemployment not caused by technological change are the result of workers' preferences shifting away from products toward leisure, or rational responses to changes in real wages and interest rates that alter the relative prices of goods and leisure.

Very importantly for present purposes, the RBC models denied any real effects of changes in the money stock on the economy; in fact, in an interesting twist, the money supply was seen as endogenous to the economy: The money stock increased in expansions and declined in contractions, passively reacting to cyclical changes in the demand for loans (as in the endogenous money supply theory advanced by the EK school). The RBC theory is based on a radical version of the classical dichotomy between the real and monetary dimensions of the economy.

The emerging new version of classical theory that attacked the previous Keynesian consensus began with an argument that only changes in the money stock could influence the economy (early monetarism); moved to the position that money mattered but only in the short run (the inflation-enhanced Phillips curve version of monetarism); then adopted the rational expectations position that only unanticipated, unsystematic, irrational monetary policy ("bad policy") could have even short-run effects; and then finally proposed that money did not matter at all with respect to causation in the short-run or long-run behavior of the economy in the RBC models.

The NC theory presented a view of the economy consistent with the original classical story at least in its popularized form within modern economics literature: Capitalism is self-adjusting and stable; competitive markets lead to the most desirable state of affairs; the normal state is high employment with economic growth at the highest rate possible, given time and leisure-goods preferences and the exogenously determined rate of technological change. The only policy role for the state consistent with this vision is providing the necessary institutional structure; otherwise, laissez-faire and free market fundamentalism are advised. By the late 1980s, NC dominated academic economics in the United States in the elite graduate programs and in textbooks, and was widely taught to undergraduates as well.

## Opposition to the New Classical Theory

Two strong currents questioning the validity and challenging the hegemony of NC macroeconomics developed even as NC emerged: the new Keynesians and the institutionalist/post-Keynesians or evolutionary Keynesians (EK). The new Keynesians operate within the mainstream, teaching at elite universities and publishing in the profession's highly ranked journals; many of them (e.g., Ben Bernanke, Alan Blinder, Stanley Fischer, Gregory Mankiw, Joseph Stiglitz, Lawrence Summers, John Taylor, and Janet Yellen) have held important policymaking positions in institutions such as the Federal Reserve, World Bank, Council of Economic Advisors, U.S. Treasury, and the International Monetary Fund.

Meanwhile, outside of the inner circle of mainstream economics, a radical critique of both NC and NK based on a different vision of the economy, a different set of assumptions about human behavior and economic reality, and perhaps a different set of social values and priorities was developed by the EK school.

### New Keynesian Macroeconomics

NKE emerged in the late 1970s and early 1980s in reaction to the criticism of consensus IS/LM Keynesianism mounted by the NC school; their emphasis was on explaining the causes of business cycles. The new Keynesians retained Keynes's insistence that economic fluctuations can be caused by aggregate demand changes and that aggregate demand fluctuations could be caused by factors other than monetary shocks, and they retained the early consensus Keynesian approach that held that wages and prices were downwardly inflexible in the short run and that recessions could be seen as the result of "coordination failures" and "quantity adjustments" to demand or supply shocks. They retained the Keynesian view that recessions were inherent in capitalism, undesirable, socially expensive, and preventable with correct policy. But many of them accepted the NC microfoundations argument that assuming rational utility-maximizing behavior by economic actors and some version of rational expectations was necessary and useful for economic analysis.

Although some NK economists have advocated the use of countercyclical fiscal policy in severe recessions or when the threat of deflation appears (Stiglitz, 2002; comments by Auerbach, Blinder, and Feldstein in Federal Reserve Bank of Kansas City, 2002), most of them have argued that monetary policy is more efficient and generally sufficient to stabilize the economy. And although they advocate interventionist monetary policy to stabilize the economy (money is not neutral in the short run), they generally express a preference for monetary policy rules as opposed to discretion (Taylor, 1999, 2000). "Rules" means setting targets for policy (the rate of inflation, or more often minimizing the gap between actual and *potential GDP,* defined as the level of GDP consistent with the lowest sustainable level of unemployment without accelerating price inflation—the nonaccelerating rate of inflation [NAIRU]) and designing a policy reaction function in which the central bank would increase or decrease interest rates by a given amount if GDP exceeds or falls below potential. Most of the new Keynesians see the money supply as endogenous in the sense of its growth rate being the interaction of demand for credit and the central bank-determined level of short-term interest rates, and see money as neutral in the long run with respect to its influence over the growth path of the economy (DeLong, 2000; Parkin, 2000; Taylor, 2000).

Their primary focus and contribution with respect to understanding business cycles has been to demonstrate that (a) inflexible wages and prices could lead to quantity adjustments that were destabilizing (recessions could be understood as systemic coordination failures of the economy's markets because markets do not always quickly find prices that "clear") and that (b) rigid, sticky, or slowly adjusting prices and wages could be seen as the result of rational responses by economic actors within the actual institutions of capitalist economies. Much of their research focused on the latter point; they found plausible explanations for sticky wages and prices, which challenged both the NC argument that markets clear quickly (or would in a more nearly perfect world) and the NC claim that the Walrasian equilibrium approach was useful as a description of reality. NK has been described as *dis-equlibrium*

economics, in that it explains why economies are usually not in equilibrium at the natural rate of unemployment and the potential level of output.

Inflexible wages and prices are explained by institutional factors such as monopolistic competition, menu costs, lengthy contracts, efficiency wage theory, wage and price staggering, markup pricing, bureaucratic inertia, and marketing strategy. Other NK lines of attack on NC involved skepticism regarding aspects of rational expectations, importantly including the assumption of inexpensive and complete information; the NC assumption that workers, managers, and owners actually think and behave like the NC economists' models would have them; and propositions built on rational expectations, such as the Ricardian equivalence story.

In summation, the new Keynesians argue that capitalism is often unstable due to the persistence of both demand and supply shocks, and to the ways in which the market system adjusts to such shocks. They also believe that it is both desirable and necessary to use interventionist policy to stabilize the economy; these positions put them in the Keynesian camp and in clear opposition to the views of the NC school. Their preference for monetary policy over fiscal policy—(a) because they think monetary policy is usually effective, (b) because they think that automatic stabilizers are more effective than discretionary policy due to the relatively small estimates for multipliers and the long time lags for fiscal policy, and (c) because of the political problems that make timely changes in fiscal policy difficult—and for policy rules over discretion differentiates them from the original Keynesians as well as the post-Keynesians.

The views of the new Keynesians appear to be currently hegemonic within mainstream academic macroeconomics in the United States and United Kingdom from the perspectives of who has been selected for policy advice by the Federal Reserve, the Bank of England, and recent governments in both countries; whose macroeconomics texts are most widely adopted and whose theoretical views are dominant in classrooms; and whose policy views are adhered to by the Federal Reserve.

### New Economic Growth Theory

Another interesting aspect of mainstream economics is the development of new neoclassical approaches to economic growth that go beyond the Solow growth models and lend support to arguments for government intervention in the economy. Solovian growth models are based on neoclassical and NC assumptions such as perfect competition (and continuous market clearing), diminishing marginal returns to capital, the free flow of information and technological change, and equilibrium between aggregate demand and aggregate supply (so that the economy is assumed to be always at full employment). In these models, diminishing returns to capital lead to the counterintuitive deduction that high rates of investment will have no effect on economic growth over the long run; *conditional convergence* should be obtained, in which countries with similar savings and population growth rates should converge to the same level of per capita national income and to the same rate of growth (the stationary state), while countries with different characteristics would end up with different per capita income levels but the same growth rate. The common growth rate would be determined by the exogenous rate of technological change under the assumption that technology and knowledge are mobile across countries (Solow, 1956); this leaves almost no role for the state in promoting economic growth.

The new economic growth theories (NEG) broaden the definition of *capital* to include knowledge (human capital) and also incorporate the spillover effects of investment in both human and fixed capital and the effects of increasing returns to scale. Under these conditions, countries with higher rates of savings and investment could have permanently higher rates of technological progress and economic growth. Because the growth rates of technological progress and output are influenced by the rate of investment, which is determined within these models, this approach is often termed *endogenous growth theory.*

For present purposes, the importance of the NEG models is that they present another reason for state intervention in the economy: The state can encourage economic growth (a) through its investment in human capital (education, research, and development) and in infrastructure (Aschauer, 1989), (b) by developing appropriate institutions (competitive markets, well-regulated financial systems, stable money), and (c) through policies that encourage saving and investment by the private sector.

## Post-Keynesian Economics

A radical critique of original IS/LM Keynesianism, NCE—especially its monetarist core—and new Keynesianism as well has been developed by institutionalist and post-Keynesian economists, whose separate views on macroeconomics have been merging since the late 1970s. Following the much admired Joan Robinson, the first generation of economists who referred to themselves as post-Keynesians such as Paul Davidson (1978) used derogatory terms such as *bastard Keynesianism, IS/LM Keynesianism,* and *textbook Keynesianism* to refer to what they saw as a much attenuated and misleading version of the master's views that had been developed in the 1940s and 1950s by the first generation of Keynesians. They argued that IS/LM Keynesianism ignores Keynes's stress on uncertainty and disequilibrium; it is another form of general equilibrium theory, describing a tendency toward equilibrium that does not exist in the real world (or in Keynes's theory).

These economists attempted to go beyond Keynes's work (*post*-Keynesian) by building on what they saw

as Keynes's correct ideas and insights while rejecting what they found inadequate in his work. Included in the latter category are his GT assumption of a central bank–determined exogenous money supply (although Keynes apparently held to an endogenous theory of money in his other works), his Marshallian price theory, and the lack of a theory of economic growth. The post-Keynesian project is to construct a realistic model of modern capitalism that would be useful in designing policy to encourage full employment, stability, growth, and less inequality. A strong emphasis on finding practical solutions to economic policy problems is found throughout the work of this group, which has also been a hallmark of American institutionalism. Many of the early post-Keynesians were (and some still are) sympathetic to some versions of democratic socialism; most advocate some form of incomes policy; and all advocate a powerful, interventionist state whose economic policies should give highest priority to encouraging full employment, economic growth, and less inequality—the goals proposed by Keynes in the final chapter of his GT.

The core propositions of post-Keynesian economics (the first two form their "pre-analytic vision," in Schumpeter's [1954, pp. 41–42] term) include the following:

1. The recognition of *fundamental* or *absolute uncertainty* as radically different from *statistical* or *probabilistic risk;* fundamental uncertainly does not allow us to make precise calculations of risk. Keynes observed that many of the most important economic decisions—such as whether to invest in fixed capital, purchase a bond, or hold money—are made in situations in which the information necessary to evaluate risk probabilistically will always be absent. The post-Keynesians' understanding of uncertainty is related to their stress on the importance of historical time and the irreversibility of many important decisions, and is antithetical to the NC approach to knowledge and uncertainly.

2. The economy is inherently unstable because of uncertainty and the instability of expectations, especially expectations regarding profit from investment and the future prices of assets. The classical and NC's equilibrating mechanism of flexible prices is weak (prices are not very flexible downward), and it would actually increase instability if prices could somehow be made more flexible with institutional change, because falling prices in a recession would depress profit expectations and investment. Full employment is less likely than widespread unemployment. Financial speculation and financial instability are inherent in the structure of modern financial institutions and financial markets, and can be the cause of instability in the "real" economy. Society needs to impose stabilizing constraints on the economy, including institutions that stabilize prices, wages, and interest rates. Most important, a large government sector whose expenditure can quickly increase in slumps is necessary to prevent downward instability (Minsky, 1982); small state sectors reduce stability.

3. Economic growth, economic fluctuations, and income distribution are dialectically related and mutually reinforcing: Inequality enhances instability; instability (especially recessions) reduces investment and growth, while recessions and low growth increase inequality. This centrality of demand in post-Keynesian theory leads to the proposition of *demand-led growth:* The long-run growth path of the economy is determined by its short-run behavior.

4. Economies are best understood as "complex systems" that are "self-organizing" and exhibit "emerging properties" (see Moore, 1999, for a clear statement of this proposition and its implications; it is related to the institutionalist economists' insistence that society's institutions evolve through time, so that theory must be institutionally specific to be useful).

5. Moving to another core proposition on a lower level of abstraction, the entry point into macroeconomics for the EK school is a "monetary theory of production" (Keynes, 1936/1973). Money is created (by banks) to finance an increase in production, which requires more fixed and circulating capital. Money is necessary for production to take place because production takes time and because money is the social institution that transfers and stores purchasing power over time. Because of the existence of money, interruptions in the circular flow of income and expenditure can take place (by holding wealth in the form of money), which are unlikely in a barter economy.

According to the EK school, the NC's *axiom of reals* (also held to a lesser extent by the NK school as well)—the dichotomy between the monetary and real dimensions of the economy—is misleading; capitalism must be understood as a monetary economy, in which the circuit of money is as important as the physical flow of production and circulation of goods and services. Macroeconomics must begin with an analysis of money—its nature, origin, and functions; money is never neutral with respect to the real economy. The level of interest rates (the price of liquidity and the cost of credit) is a key price within the economy, because it influences both the willingness and the ability of entrepreneurs to invest in real capital and of financial capitalists to hold nonmonetary financial assets such as stocks and bonds.

6. The levels of prices, wages, and interest rates should be understood as the result of distributional struggles that are determined by social institutions and complex processes, as opposed to their determination by the quantity theory of money as advanced by NC. Rather than determining the level of wages and prices, the quantity of money in circulation is seen as the result of changes in the level of wages and prices, reversing the quantity theory's direction of causality. In EK economics, changes in the

level of wages lead to a change in the prices of goods, because firms practice markup pricing: Prices are marked up over—primarily—labor costs of production, and estimates of average rather than marginal cost at normal output levels are used to set prices. Changes in the price level (inflation) leads ceteris paribus to an increase in the demand for working capital (credit), which banks accommodate. As more loans are made, the money supply increases (Moore, 1988).

7. The endogenous money supply theory argues that anything that increases the demand for bank credit will increase the money supply; commercial banks must accommodate most of any increase in business or consumer loan demand, because most loans are made under predetermined lines of credit (Moore, 1988).

8. Finally, although EK economists see the level of interest rates as important in influencing aggregate demand—especially business investment—their empirical work argues that spending and real output may not be very sensitive to interest rates in recessions, so that other demand-stimulating policies are necessary (Arestis & Sawyer, 2002a, 2002b; European Central Bank, 2002). Those same studies provide evidence that interest rate changes are not very effective in reducing price inflation either.

## Post-Keynesians and New Keynesians

Although the EK and NK economists agree on aspects of macroeconomics (e.g., the endogeneity of the money supply and the need for interventionist demand management), they disagree on many important points.

1. EK economists see the economy as very unstable, requiring constraints stronger than discretionary monetary policy; new Keynesians assume strong equilibrating processes in the long run, pushing the economy toward equilibrium at a socially optimal natural rate of employment and the potential level of output.

2. EK economics follows Keynes (and Kalecki) in arguing that savings does not finance investment as in the old classical, neoclassical, NC, and NK models. Rather, investment is determined by profit expectations and the rate of interest, and it is financed by bank credit (and the growth in the money supply). The level of investment coupled with the variables that determine the Keynesian multiplier then determines the level of national income. National income moves toward the level that generates enough savings to equal the exogenously determined level of investment: Investment determines savings, rather than savings determining investment.

This insight has powerful implications for many aspects of policy: Most NC and NK economists argue for policies (such as low marginal rates of taxation, high real interest rates, shrinking government, reducing the generosity of public pension systems) that should encourage higher net national savings (savings net of government budget deficits and depreciation), because in their models, this would lead to higher private investment. From the EK perspective, this is wrongheaded: Government spending—especially public investment—can increase productivity, private profits, and profit expectations, thus encouraging private investment ("crowding in" rather than "crowding out"). And the level of savings has little influence over either interest rates or investment, because interest rates are primarily determined by monetary policy and liquidity preference. In fact, *ceteris paribus,* a higher saving rate might depress investment and economic growth because it would lead to a lower level of consumption and aggregate demand growth.

3. EK economists put a higher priority on full employment than on price stability and argue that the level of unemployment necessary to keep effective downward pressure on wages and prices entails unacceptable social costs. NK economists put a higher priority on low inflation than on full employment. EK economists are skeptical of our ability to reliably estimate the level of unemployment consistent with price and wage stability—the natural rate of unemployment or the NAIRU, which determines the potential level of national income in the NK model—and use that as a target for stabilization policy. There is no natural rate of unemployment in the sense of a *strong attractor* that the economy tends toward.

EK economists argue that the important goals of full employment and both wage and price stability can be reached only by developing institutions that socially control wages, prices, and the distribution of income across the social classes (the wage–profit ratio), and that link aggregate wage and profit increases to productivity gains.

In contrast, new Keynesians argue that the NAIRU can be reliably estimated (although the range of estimates is seen by some as quite wide) and the estimates used as a target for stabilization policy; NK economists are willing to tolerate whatever levels of unemployment are necessary for price stability, disagreeing with the EK view that "non-traditional" forms of intervention such as incomes policy can be effective.

4. EK economists agree with both Keynes and Kalecki that the distribution of income is important for business cycles and growth; they are interested in both the *functional* or *class* distribution between labor and capital and the *personal* or *size* distribution across individuals, households, and families. One argument that Keynes and post-Keynesians make is that changes in the distribution of income can influence the composition and levels of aggregate demand (more profits means more investment, higher wages means more consumption). From this perspective, less inequality is preferred because it will stimulate production and employment in the short run and

thus stimulate investment and economic growth in the long run; lower interest rates both reduce inequality and stimulate investment (Keynes, 1936/1973; Niggle, 1998, surveys and assesses some recent literature discussing the relationship between inequality and growth).

Followers of Kalecki observe that a declining wage share should be expected to reduce aggregate demand, capacity utilization, and investment, and thus reduce both employment and economic growth. Proper macroeconomic policy implies paying attention to income distribution. Again, new Keynesians do not pay much attention to these issues.

5. EK emphasizes a demand-led approach to growth theory, in contrast to the NC supply-side approach, which new Keynesians and new (endogenous) economic growth theories also stress.

6. Many EK economists advocate fixed exchange rate systems constructed around an international financial institution that could issue liquid financial assets as needed by deficit countries (Davidson, 1994); most new Keynesians, such as Joseph Stiglitz (2002), accept flexible exchange rates with some important and influential exceptions.

7. EK economists favor financial market regulations and see unregulated financial markets as dangerous (Isenberg, 2000; Minsky, 1982, 1986); most new Keynesians are not concerned with financial market deregulation.

## Conclusion

In the 1970s and 1980s, NC economists developed and mainstream economics assimilated a set of propositions, models, and theories that argued against both the need for and the efficiency of Keynesian forms of state intervention in the economy to promote full employment, stability, equality, and economic growth. Aspects of this economic philosophy—NC, monetarism, RBC theory, supply-side economics, and public choice theory—offered theoretical support for neoliberalism and have been very influential both within economics and within the domains of policy and politics.

Keynesian economists rejected many aspects of the neoliberal program based on their competing NK theoretical stance. EK economists present a more radical critique of NC and offer a very different perspective on the economy. In the past decade, new Keynesian and new growth theory economics have become more influential within the mainstream. This phenomenon, coupled with the persistence of economic problems that seem intrinsic to unregulated global capitalism—such as stagnation, increasing unemployment and inequality, and recurrent financial crises—opens up the possibility for EK economics to be seriously considered by mainstream economists, because it offers coherent explanations for those problems along with plausible solutions to them.

# Aggregate Expenditures Model and Equilibrium Output

Michael R. Montgomery
*University of Maine*

*Aggregate expenditures* (AE), the total spending in an economy on final goods and services over a designated time period, is the core demand-side concept in modern macroeconomics (a *final good* is a newly produced good bought by a user who will "finally" dispose of that good by using up its services). Following the lead of John Maynard Keynes in his *General Theory of Employment, Interest and Money* (1936/1965) and early Keynesians such as Alvin Hansen (1953) and Paul A. Samuelson (1939), AE is typically broken down by major type of purchaser into consumption expenditures, investment expenditures, government expenditures, and the sum of exports less imports (known as *net exports*). The study of these categories in recent decades has been aided considerably by the development of the National Income and Product Accounts (NIPA) accounting system, which is used by governments in measuring and reporting the sizes of these categories. The sum of this spending is known as gross domestic product, or GDP. Specifically,

- *Consumption expenditures* are expenditures on final goods (excluding housing) and services by consumers, produced during the accounting period and in the economy under study.
- *Investment expenditures* are final goods and services purchased by businesses and buyers of homes, produced during the accounting period and in the economy under study. They include nonresidential structures of all types, plus all producers' durable equipment, plus residential structures, plus all inventories produced in the accounting period (some of these inventories may be *planned,* or *desired,* inventories; others may be *unplanned,* or *undesired,* inventories—unplanned inventories being acquired when sales are less than anticipated). Investment expenditures do not include financial transactions such as the purchase of stocks and bonds.
- *Government expenditures* are final goods and services purchased or produced by governments at all levels, produced during the accounting period and in the economy under study.
- *Net exports* are exports of final goods and services by the country under study (produced during the accounting period in the economy under study), minus the imports of such goods into that country.

The sum of these four spending components equals AE. AE thus equals GDP. That is, the total value of expenditures on final goods and services is equal to the total value of all that which is expended on the acquisition of final goods and services (i.e., GDP).

## Theory

### Expenditures, Planned Expenditures, and Inventory Adjustment

There are, however, two variants of the AE concept: *actual* AE, as defined previously, and *planned* AE. The latter is of particular importance in modern macroeconomics.

*Planned AE* is the amount of expenditures the economy generates when all purchasers purchase an equilibrium amount of goods and services. It describes a state where purchasing decisions are consistent with the resources and needs of purchasers. (Planned AE often is referred to as *aggregate demand.*)

By way of illustration, consider the behavior of a typical retailer. Each month (let us say), a retailer assesses the state of its business and, based on that assessment, orders a particular quantity of the goods that it is its business to sell. At month's end, any of the ordered goods that are unsold will be added to inventory. If the retailer's assessment of the market demand for its product is correct, its sales of goods will be such that, at month's end, it will be left with just the amount of inventory stocks on its shelves that is consistent with its long-run needs (needs given by relatively stable factors like how many customers the store loses if it runs out of goods its customers wish to buy, the financing costs of carrying such goods, etc.).

Suppose, however, that the retailer has overestimated the demand for its goods, so that it is left at month's end with more unsold goods than it had expected. Had the store known, at the beginning of the month, that demand would be lower, then it would have ordered fewer goods. However, because it did not know this and so did not reduce its orders, some of the goods it had planned to sell to customers that month remain on the store's shelves at month's end. The retailer's actual expenditures on new inventory for the month, then, are greater than its planned expenditures on inventory. The store's actual expenditures on inventory now exceed what it would have spent if it had predicted monthly demand correctly. As a result of its miscalculation, the retailer now has excess, or unplanned, quantities of inventories on its shelves.

As an aid to clarity, consider a simple numerical example. Suppose a T-shirt retailer orders 100 shirts, planning to sell 80 and retain the other 20 as inventory. At month's end, it turns out that the retailer has been able to sell only 70 of the 100 T-shirts that were ordered on the first of the month. It will, therefore, add the remaining unsold 30 T-shirts to its inventory, including 10 more than the 20 shirts it had planned to add. Had the store known that T-shirt demand would drop by 10 units, it would have cut its orders by 10 units, so as not to add more T-shirts than planned to its inventory stocks. Thus, had the retailer been fully informed at the start of the month about the state of demand for its product, it would have ordered only 90 T-shirts.

As things stand, the retailer has ordered 100 T-shirts when, had better information been available at the start of the month, it would have chosen to order only 90. The store's planned investment is the 20 T-shirts it had planned all along to add to its inventories. Its unplanned (or involuntary) investment is the 10 T-shirts it adds to its inventories unintentionally. (Quite likely, next month the store will reduce its orders in order to "work off" its excess stock of inventories, weakening thereby the amount of economic activity at the factories from which it orders its stock of goods.)

The same type of reasoning, but in reverse, holds when the store finds that demand for its T-shirts is greater than expected. Suppose the store has ordered 100 shirts, again expecting to sell 80 and retain 20 as inventory. Suppose demand is greater than expected, equaling 90 T-shirts. The store will then sell all the T-shirts (80) that it had ordered for sale during the month. However, in addition, it will sell 10 more units that it had been planning to add to its stock of T-shirt inventory. The store's planned investment is still 20 T-shirts, but its unplanned investment is –10 (negative 10) T-shirts, due to its unexpectedly strong sales. As a result, at month's end, the store's total investment is 10 T-shirts smaller than had been planned. (Quite likely, next month the store will increase its orders to increase its stock of inventories to its planned levels, increasing thereby the amount of economic activity at the factories from which it orders its stock of goods.)

The simple inventory problem faced by our retailer turns out to be quite important, both as a part of macroeconomic analysis and in the actual economy. The economy often behaves as suggested in the retailer example. In periods of unexpected demand weakness, the economy's retailers, wholesalers, and so on accumulate positive levels of unplanned inventories. Subsequently, retailers and other sellers of goods cut back on orders, causing less production upstream in the factories and so amplifying the initial weakening of the economy. In the reverse case, an unexpectedly strong economy causes an undesired depletion of inventories (negative levels of unplanned inventories), causing increases in orders at the factories and so amplifying the initial strengthening of the economy.

Another reason why the simple inventory problem is particularly important to macroeconomics stems from a characteristic of NIPA accounting. Consider consumption expenditures. How much of the spending that consumers do is truly intended or planned, and how much of it is mistaken (i.e., with full knowledge, particular consumers might have bought more, or less, product than they did in fact buy)? Because of the inherent impossibility of making such a determination, NIPA accounting simply assumes that all of the spending carried out by consumers is planned spending. Similarly, all government spending is considered to be planned spending, and the same convention is applied to net exports. However, for the case of investment spending, as we have already seen, planned expenditures and actual expenditures do differ. In fact, it is in the investment spending accounts that all of the gap between AE and planned AE is found. When consumers, governments, or "net exporters" unexpectedly reduce their expenditures, all of the goods they have chosen not to purchase wind up being held as inventory by merchants who were unable to sell these goods (and vice versa if spenders unexpectedly increase their expenditures). The distinction between planned and unplanned

inventory stocks, therefore, is the mirror image of unexpected changes in expenditures by others in the economy.

## Planned AE and Inventory Adjustment: The Keynesian Cross

The preceding analysis suggests a simple visualization of macroeconomic fluctuations, based on firms' inability to consistently predict demand and the resulting accumulation or reduction of inventory stocks on the firms' aggregate balance sheet. Consider a substantial and unexpected reduction in planned AE in an economy that has grown accustomed to a higher level of such expenditures. As a result, sales fall, and unplanned inventories accumulate on firms' shelves and in their warehouses.

How will retailers, wholesalers, and so on react to the undesired swelling of their inventory? There are two possibilities, in principle. One is for them to immediately lower their prices by enough to induce buyers to quickly clear out their excess inventory by taking advantage of these "fire sales." However, because these firms will likely take a sizeable capital loss on their inventory stocks if they eliminate them in this way, they are often reluctant to lower their prices by enough to sell off very much of their excess inventory stock. The alternative strategy is to hold prices more or less unchanged and to reduce the size of their orders from the factories. This way, firms allow their excess stocks of goods to be worked off slowly over time (because business has slowed, this second strategy usually also involves laying off a portion of the firms' workforce).

To an extent, firms will pursue both of these strategies. However, it is a common observation that firms primarily respond to excessive inventories by laying off workers, cutting orders, and working off inventory stocks slowly over time. This strategy, however, transmits weaker sales "upstream" to wholesalers and factories as described previously, triggering weaker economic activity in these sectors too and causing a lessening of activity and layoffs in those sectors. These layoffs, in turn, reduce demand by consumers in still other sectors where these consumers purchase items, triggering still more unplanned inventory buildup and layoffs in those other sectors, and so on (in a dynamic sequence commonly known as the *multiplier process*). Thus, the initial decline in planned AE that had initially led to firms' accumulation of unplanned inventory investment can, through the preceding sequence, become a general decline in economic activity.

The standard graphical model used to illustrate this process is known as the *Keynesian cross* (after John Maynard Keynes, who founded this line of thought). Sometimes it is instead called the *45-degree line diagram* (after the graph's most notable visual feature). Before discussing this diagram, however, we need to clarify an important relationship in our simple model. One of the core principles of national income accounting is that, allowing for a couple of side issues, the production of a given dollar amount of GDP generates an equal dollar amount of income for the factors of production that participated in the production of that GDP. In fact, this statement is only an approximation of the true state of affairs, due to the side issues of depreciation expenditures and indirect business taxes. In the actual economy, before counting our new production this year, we must replace the equipment we used up (or depreciated) last year due to our productive activities then. Also, in the actual economy, there are indirect business taxes that tax away some business receipts before they can be distributed to the factors of production. However, in our simple illustrative economy, we ignore these two factors. An alternative treatment uses net national product (NNP), which is GDP minus depreciation expenditures, as the core national output concept (indirect business taxes are again set at zero). Using NNP as the output concept is more realistic than using GDP, because depreciation expenditures need not be assumed away as in the discussion in the main text of the chapter.

Returning to the main argument, in our Keynesian cross framework, every dollars worth of production generates exactly a dollar's worth of income to those owning the factors of production. In the aggregate, then, national output (GDP) equals national income by definition. We will take this equivalency seriously, so much so that we will even use the same symbol *Y* to simultaneously represent both national output and national income. That is, in what follows, we will call Y either national output or national income, depending on which better fits the context.

Returning now to our main line of discussion, Figure 31.1 depicts the Keynesian cross diagram, which is interpreted as follows. Assume a simplified economy where all spending is done by either consumers, investors (the latter, recall, buy capital goods, not stocks and bonds), or governments. (There is assumed to be no trade with other nations, so that net exports are zero, a common simplifying assumption known as the *closed economy* assumption. We briefly discuss the effects of net exports on planned expenditures later in this chapter.) Consumers spend according to the Keynesian (linear) consumption function

$$C = a + bY_D,$$

where C is expenditures by consumers. C depends predominately on income after taxes ($Y_D$) (or disposable income); "b," a parameter known as the *marginal propensity to consume,* gives the rate at which consumption increases in response to a change in disposable income ($0 < b < 1$); "a," a second parameter known as the *autonomous level of consumption,* captures the impact of all forces other than disposable income (such as expectations of the future, household real wealth, etc.) that affect consumption behavior ($a > 0$). It is traditional to convert the consumption function into a function of income before taxes (Y), and taxes, by introducing a simple tax equation into the

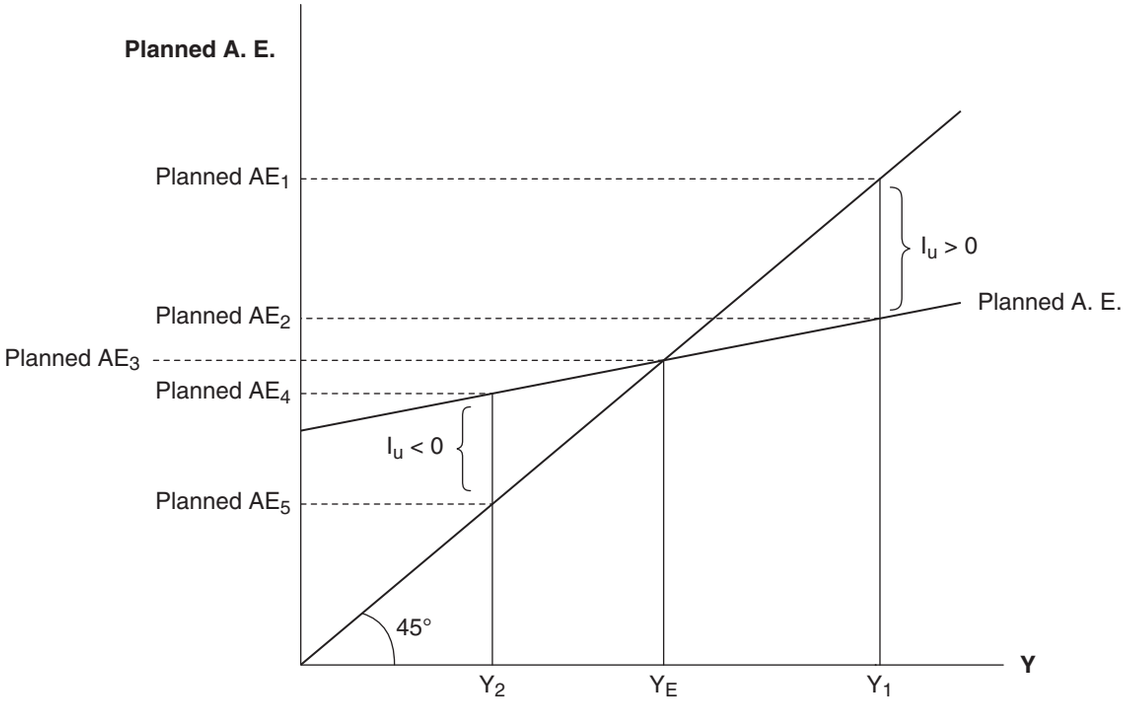

**Figure 31.1** The Keynesian Cross Diagram

discussion. Here we assume a proportional income tax system, so that T equals tY, where T is tax revenues, t is the income tax rate ($0 < t < 1$) and Y is income before taxes.

It is now traditional to assume a linear (or straight-line) consumption function, meaning that, whether income is high or low, the rate at which consumption increases with income remains the same. Keynes himself (1936/1965, pp. 31–32) and some of his followers emphasize the claim that the consumption function is nonlinear, flattening as income rises, so that consumption rises less and less per dollar of increased income as incomes rise. This notion is consistent with the claim that a society with higher income is inclined to spend proportionately less per dollar of new income, making the economy more dependent on investment and government spending if it is to reach full employment. However, many economists do not regard the nonlinearity issue as empirically significant. They prefer to use the linear consumption function, defending it as a reasonable approximation of reality that has the additional advantage of exploiting the flexibility of the linear functional form (vs. the more mathematically complex nonlinear functional form). The use of the linear form has important advantages. For example, strictly speaking, the marginal propensity to consume is defined only for very small changes in disposable income. However, if the consumption function is linear (as is assumed here), the same proportionate relationship holds for small or large changes in disposable income. We assume a linear consumption function throughout this chapter.

Substituting the tax equation into the consumption function and manipulating terms yields the revised consumption function,

$$C = a + b(1 - t)Y.$$

The advantage of this expression for present purposes is that it is expressed in terms that are easily portrayed on the Keynesian cross diagram (which measures real dollars of before-tax expenditure on its vertical axis, and dollars of real income, or output, on its horizontal axis).

The Keynesian cross diagram is designed to highlight, not the determinants of investment spending, but rather the consequences of changes in investment spending and government spending.

Accordingly, to describe the investment sector, let us take the simplest possible description of planned investment spending—one that assumes a given, exogenous level of such spending. Thus, the investment equation is

$$I = I_0,$$

where $I_0$ denotes a given level of planned investment expenditures. The interpretation here of investment spending as planned, not actual, spending is crucial. As described previously, planned investment expenditures are the level of investment expenditures such that businesses expect at the month's close to end up with their planned (or equilibrium) levels of inventory stocks. The interpretation of $I_0$ in this way means that our expenditures expression is

one of planned AE, not actual AE, which, as discussed previously, equals national output by definition. Here it is also useful to recall that planned consumption expenditures equal actual consumption expenditures by definition, and planned government expenditures equal actual government expenditures by definition (the same is true for net exports in versions of the model where they are included).

Our third source of expenditures is government. Again, we make the simplest possible assumption about government spending, which is assumed to be exogenously given as

$$G = G_0.$$

The equation for planned AE in this model is, accordingly,

$$\text{planned AE} = a + b(1 - t)Y + I_0 + G_0 = [a + I_0 + G_0] + b(1 - t)Y.$$

The rightmost side of this expression is what is called in basic algebra the *point-slope form.* Therefore, the intercept term is $[a + I_0 + G_0]$, while the slope of the line equals $b(1 - t)$. When we graph the planned AE expression on the Keynesian cross diagram, the intercept of the planned AE line is where that line intersects the vertical axis. At this intercept point, the value of planned AE equals $[a + I_0 + G_0]$, which is the amount of planned AE that corresponds to a Y level of zero (since people are earning no income at such a point, presumably they are living off their previous savings). Further, the slope of the planned AE line is $b(1 - t)$. Planned AE increases with income due to the consumption function. For every dollar of increase in income, planned AE will increase by $b(1 - t)$. For example, suppose that b equals 0.8 and t equals 0.5. Then $b(1 - t)$ equals 0.4. Each dollar's increase in income will create an additional 40 cents of planned AE (the reverse is true for one dollar's decrease in income). The planned AE line always has a slope less than 1, due to the impact of the marginal propensity to consume and the income tax rate (because both b and t are fractions, their product will also be a fraction). So long as the vertical intercept of the planned AE line is positive (as seems reasonable), the planned AE line will intersect the 45-degree line at some point.

What notion of equilibrium is appropriate for this representation of the macroeconomy? One simple idea is that equilibrium be described as a state where total planned expenditures are just sufficient to purchase all of the economy's output. This means that, in equilibrium, total planned expenditures equal GDP. It also means that planned investment expenditures equal actual investment expenditures. That is, inventories held by firms at the end of the month equal the inventories the firms planned to have when they placed their orders at the start of the month.

Strictly speaking, we are assuming that every firm has zero unplanned inventories. (In applying the framework to the actual economy, the corresponding assumption is that firms on average have inventory levels that are consistent with their planned levels.) All of the goods produced that month are being voluntarily consumed or held by some spender in the economy.

How will this reasoning play out graphically on the Keynesian cross diagram? (Please refer to Figure 31.1.) Notice first the interpretation of the 45-degree line that shoots out from the origin, cutting the graph in two. Because the vertical and horizontal axes are measured in the same units (real dollars of national output), the slope of this line equals 1, so that any point along it is a point where planned spending and national output are equal. That is, any point that rests on the 45-degree line is a point of potential equilibrium in the model. Which particular point is *the* point of equilibrium, however, will be determined by the level of planned AE that is generated by the economy's consumers, investors, and local, state, and national governments. Equilibrium occurs precisely where planned AE intersects the 45-degree line, at the point where planned AE equals planned $AE_3$ and Y equals $Y_E$. Only at this point is the amount of planned spending generated by the economy just equal to the amount of output produced by the economy.

To see further why this intersection is interpreted as a point of equilibrium, consider a point on the planned AE line that is associated with a Y level that is greater than the equilibrium point ($Y = Y_1 > Y_E$). At output level $Y_1$, the amount of planned AE needed to buy up all of the economy's output is given by planned $AE_1$—the planned AE level given by the intersection of the (vertical) $Y_1$ line and the 45-degree line. However, the planned AE actually generated by the economy at $Y_1$ (planned $AE_2$) is given by the intersection of the $Y_1$ line and the planned AE line. The amount of planned AE generated at $Y_1$ is thus less than what is needed for equilibrium.

The deficiency of planned AE at $Y_1$ will reveal itself in the form of unplanned inventory accumulation by firms ($I_U > 0$). ($I_U$ can refer to either unplanned inventory accumulation or unplanned investment spending. This is because all unwanted investment takes the form of unwanted inventories.) Businesses, finding themselves holding more inventories than planned, will reduce their orders of goods. This in turn will reduce production at the factories, pushing the economy's output leftward, away from $Y_1$ toward the equilibrium value $Y_E$. So long as unplanned inventories are positive, this trend will continue until the economy's output reaches the equilibrium point $Y_E$.

Now consider a point on the planned AE line that is associated with output level $Y_2$, which is less than the equilibrium output $Y_E$ ($Y = Y_2 < Y_E$). At output level $Y_2$, the amount of planned spending needed to buy up all of the economy's output (planned $AE_5$) is given by the intersection of the (vertical) $Y_2$ line and the 45-degree line. However, planned AE actually generated by the economy at $Y_2$ (planned $AE_4$) is given by the intersection of the $Y_2$ line and the planned AE line. Planned AE at $Y_2$ is greater

than what is needed for equilibrium. The excess of planned AE at $Y_2$ will reveal itself in the form of unplanned inventory rundown ($I_U < 0$; i.e., negative levels of unplanned inventories) on the part of firms. Firms, finding themselves holding fewer inventories than they had planned, increase their orders of goods. This in turn increases production at the factories, pushing the economy rightward toward higher output levels, away from $Y_2$ toward the equilibrium value $Y_E$. So long as unplanned inventories are negative, this trend will continue until the economy's output reaches the equilibrium point $Y_E$. Actions by firms to move their inventories to equilibrium levels is the primary mechanism driving the economy to its equilibrium on the Keynesian cross diagram.

While the preceding is the standard explanation of how equilibrium is reached on the Keynesian cross diagram, it is not necessary to rely on inventory adjustment to explain the move to equilibrium. In the mid-1980s, Robert Hall and John Taylor (1986) came out with a version of the Keynesian cross model that did not involve inventory accumulation and depletion. Their model, in brief, imagines a world without inventories of goods. Instead, firms "inventory" productive capacity by hiring workers who perform services for firms. An overly optimistic company will find itself with too many workers on staff. Productive capacity then exceeds the actual spending that the economy's spenders are able to generate. The incomes of spenders are insufficient to support the current level of output. This puts downward pressure on the economy and tends to move output downward until the excess productive capacity is eliminated and equilibrium (which Hall and Taylor call *spending balance*) is achieved. Clearly, the model is not too different from the text's inventories-based version, but, as the authors point out, it is useful to show that the mechanisms of the model do not depend on the existence of inventory accumulation in an essential way.

## Applications, Refinements, and Policy Implications

### Comparative Statics of the Keynesian Cross Diagram

The Keynesian cross diagram also can be used to show the impact on AE and equilibrium income of various changes on the demand side of the economy. Starting from the equilibrium position on Figure 31.1, consider, for example, a large, unexpected decline in planned investment. On the Keynesian cross diagram, such a change will shift the planned AE line downward (parallel to the original line). Once planned AE falls, $Y_E$ will no longer be an equilibrium value. Unplanned inventory will accumulate on firms' shelves. They will respond by cutting their factory orders, reducing production at the factories, and eventually bringing about a new equilibrium value at a smaller value of Y (to the left of the former equilibrium value, $Y_E$).

Can anything be done by government to counter such a decline in equilibrium income? In the Keynesian cross framework, the answer is an unambiguous "Yes." The government has the two main tools of fiscal policy at its disposal: changes in government spending (G), and changes in income tax rates (t). By increasing G, the government can shift the planned AE line upward—in principle, by just enough to fully compensate for a decline in planned investment spending. The government may also cut income tax rates, increasing the slope (but not the intercept, given the assumed strictly proportional income tax system) of the planned AE line. The upward rotation by the planned AE line moves the economy's equilibrium Y value upward and rightward along the 45-degree line. Either increases in G or decreases in t, or both, will increase equilibrium income, through our now standard mechanism of inducing changes in inventory accumulation (either causes inventory rundown). Retailers then increase their orders, increasing production in the factories and raising Y. The Keynesian cross diagram neatly illustrates the potential for activist government fiscal policies to counter undesirable changes in private sector spending.

Monetary policy's impact also may be represented on the Keynesian cross diagram. A stimulative monetary policy—one that increases the money supply or its rate of growth—is commonly viewed as lowering the economy's interest rates, which in turn triggers additional borrowing by firms, who then spend the money on new investment projects. The resulting rise in planned investment expenditures can be interpreted on the Keynesian cross diagram as an upward shift in the planned AE curve, which then stimulates the economy through the same inventory-based adjustment mechanism.

### The "Open" Economy

The preceding discussion, for simplicity, assumes a *closed economy*—that is, an economy that does not trade with other nations. How do things change when trade with the rest of the world is introduced? Now, a fourth potential source of spending (which can be either positive or negative) is introduced: net exports. Net exports equal the goods and services that the economy exports to other nations of its production (exports), minus the goods and services that the economy imports from abroad (imports). When exports are greater than imports, then net exports are positive and planned AE is larger than in the case of the closed economy (the economy, in this case, is often said to be running a *trade surplus*). Citizens of other nations are adding to our economy's domestic demand, causing planned AE to rise. Accordingly, when net exports are positive, the planned AE line shifts upward on the Keynesian cross diagram. By contrast, when exports are less than imports, then net exports are negative and planned AE is smaller than in the closed-economy case (the economy, in this case, is often said to be running a *trade deficit*). In this case, our economy, on net, is buying goods from abroad

that often could be purchased domestically. Other things held constant, this means less demand for goods produced in our economy. Accordingly, when net exports are negative, the planned AE line shifts downward on the Keynesian cross diagram.

When net exports are included as a source of AE, the model is known as an *open economy model.* In the open economy, AE depends on the volume of net exports in two fundamental ways. First, an increase of income in the "home" country tends to increase the purchases of goods generally, including goods produced abroad. In the short run, this increase in home country spending increases imports into the home country without increasing exports (as incomes abroad are as yet unchanged). Thus, net exports decrease and, other things equal, planned AE in the home country declines. (In the event of a given fall in income, the effect is reversed.)

Second, a given increase in interest rates in the home country relative to abroad encourages a flow of investable funds into the home country. The process of investing these funds in the home country drives up the home country's exchange rate, making home country goods more expensive to foreign citizens, and making foreign goods cheaper for home country citizens. Thus, exports fall, imports rise, and net exports fall, reducing the level of AE in the home country (other things equal). (In the event of a given fall in interest rates, the effect is reversed.)

## Meaning of "Equilibrium" in the Keynesian Cross Diagram

The interpretation of the so-called equilibrium on the Keynesian cross diagram has been the subject of much controversy. Much of the controversy centers on the concept of *full employment* and the question of whether or not an economy could be in equilibrium without being at full employment. When economists speak of the full-employment position of the economy, they mean the economy's maximum production level that is consistent with macroeconomic well-being. Too little production (i.e., an economy below full employment) means that the economy is not getting all the output out of its scarce resources that it should. Too much production (i.e., an economy above full employment) means that the economy is overheated. That is, the economy is producing at such a hefty pace that painful side effects like inflation and spot shortages of crucial raw materials (known as *bottlenecks*) are being created to an unhealthy degree. Above full employment, it is also possible for an economy to find itself destabilized, triggering a sharp decline in economic activity (even an outright recession).

In Chapter 3 of the *General Theory,* Keynes presented an aggregate demand and aggregate supply framework that later inspired the Keynesian cross diagram. Keynes emphasized that there was no particular reason why the equilibrium reached by the economy in his framework should correspond with full employment. Equilibrium could be above, equal to, or below full employment (though Keynes was quite sure that it would usually be below it; 1936/1965, pp. 118, 254). Keynes saw this equilibrium as a true point of stability—once reached, it would be hard for the economy to move itself away from it and to the economy's full employment position. To classically oriented macroeconomists who criticized Keynes, the notion of a stable macroeconomic "equilibrium" that was not at full employment was almost a contradiction in terms. (A lengthy debate about this and related matters dominated macroeconomics through much of the late 1930s and 1940s.)

When followers of Keynes such as Alvin Hansen and Paul Samuelson substituted the Keynesian cross diagram for Keynes's framework, they kept Keynes's sharp separation of equilibrium and full employment. Over time, however, macroeconomists grew increasingly uncomfortable with a notion of macroeconomic "equilibrium" that was not also situated at full employment (see, in particular, Patinkin, 1948, esp. pp. 562–564). As it had been before Keynes, price flexibility—a slow but still steady and substantial force in the economy—became again a generally accepted mechanism through which economies that were away from full employment were returned there. Many of Keynes's successors downgraded the Keynes/Hansen/Samuelson notion of equilibrium to the lower status of a mere *short-run equilibrium. Long-run equilibrium* was then defined in the traditional, classical economics manner as something occurring only at full employment.

The idea behind this divergence of equilibrium notions probably came from the microeconomics of Alfred Marshall. Marshall taught Keynes and doubtless influenced him in his decision to propose a short-run equilibrium concept in macroeconomics. In Marshall's microeconomic theory of perfect (or pure) competition, the short-run equilibrium is defined for a case where the number of firms in the industry is fixed (there is not enough time for firms to enter or exit the industry). In the long run, when free entry and exit are allowed, a long-run equilibrium emerges that is quite distinct from the short-run equilibrium.

The macroeconomic version of the idea is that, while there are certain slow-acting forces that eventually move the economy to full employment, they are dominated in the short run by quicker acting forces. Chief among these slower acting forces is price level adjustment. In theory, it alone is sufficient to eventually move an economy to the full employment position. However, in the short run, the economy's price level moves little, so that it can safely be assumed to be constant (or "sticky"). Based on such reasoning, a macroeconomic short-run equilibrium exists that is reached not through price changes but rather through changes in quantities—such as the inventory adjustment mechanism described previously. Thus, the argument concludes, a short-run model ought to emphasize planned AE and its determinants and place little emphasis on full employment, while a long-run model of the economy ought to emphasize full employment and to de-emphasize traditional Keynesian notions in favor of more "classical" ones.

More recently, the equilibrium notion in the Keynesian cross diagram has been downgraded even further into a mere "spending balance" (see Hall & Taylor, 1986, or a more recent edition of the text, such as Hall & Papell, 2005). Hall and Taylor divorce the model from its long-standing equilibrium connotation, even to the point of denying to it the term itself. The idea is that the intersection of planned AE and the 45-degree line represents a balancing point for the economy, which the economy reaches quite quickly, but which should not really be conceived as an equilibrium per se because the balance point changes quickly whenever the level of (planned) expenditures alters. Hall and Taylor reserve the term *equilibrium* only for the full employment position, insisting that only after the price adjustment process has moved the economy to the full employment point can the notion of equilibrium be usefully invoked. The authors' approach to interpreting the intersection of the 45-degree line and the planned AE line is in the spirit of modern treatments, which insist that the healing role played by price adjustment in macroeconomics be taken seriously, not suppressed, as in the Keynesian cross model.

Here it should be pointed out that Keynes and his immediate followers were thoroughly skeptical of aggregate price adjustment as a cure for recession. Keynes felt strongly enough about the issue to present a detailed critique of it as his first major topic in the *General Theory.* In a nutshell, Keynes and his followers emphasize how lower input prices brought about by price adjustment adversely impact incomes of those already employed. This downward push to demand could more than wipe out the supply-side gains from lower costs of production. For details, see Keynes (1936/1965, chaps. 2, 3, 20). Modern macroeconomics, as portrayed in the *Principles* textbooks (e.g., McConnell, 1969), implicitly assumes that these adverse demand-side forces are dominated strongly by supply-side effects of lower input prices. Later versions of Keynesianism present arguments backing up the assumption (see, e.g., Snowdon & Vane, 2005, pp. 114–116).

## Strengths and Weaknesses of the Keynesian Cross Model

Since its origination in the 1930s and 1940s by Keynes, Hansen, and Samuelson, the Keynesian cross model has been a durable workhorse of macroeconomics. Its primary strength is its highlighting of inventory adjustment as a crucial part of the short-run aggregate adjustment process. There is little doubt that incomplete inventory adjustment and the changes in output that such incomplete adjustment calls forth makes a significant contribution to short-run aggregate fluctuations. The financial press routinely refers to an inventories-driven business cycle that has contributed to cyclical movements in the post–World War II era (see, e.g., Gramm, 2009). The Keynesian cross framework captures these important real-world forces neatly in one tight diagram. As such, it is a useful tool for teaching about one of the core short-run adjustment processes of the macroeconomy (inventory adjustment) and its aggregate consequences.

That having been said, the model is not without its weaknesses. The most glaring is that prices in the model—including inventory prices—are fixed exogenously outside of the model. Consequently, one of the most fundamental mechanisms in economics—the tendency of surpluses to be eliminated by price declines, and vice versa—is not allowed to function in the Keynesian cross framework. Moreover, there is no link between the inventory adjustment process and aggregate price determination in the model. The constant-price assumption has been a significant, and much criticized, feature of many Keynesian models (particularly those dating from the early years of Keynesianism). The Keynesian cross diagram is an excellent example of such a model. Keynesians can, and do, respond that the time period of analysis assumed in the Keynesian cross model is too short to allow meaningful price adjustment. Keynesians can also cite plausible reasons why various prices should be "sticky" over short periods of time. However, the notion that price adjustment does not play at least some role in firms' elimination of stocks of unplanned inventories is, to many economists, counterintuitive. The best that can be said on this point is that the Keynesian cross model should be conceived as an exploration of the aggregate consequences of inventory adjustment subject to the assumption that prices are fixed. (Some additional criticisms of the Keynesian cross framework are discussed in Weintraub, 1977, and Guthrie, 1997.)

This criticism applies mainly to the Keynesian cross diagram as a stand-alone model. The model works better when conceived as an "input" into what Hall and Taylor (1986) have called the *aggregate demand/price adjustment model.* In this framework, the role of the Keynesian cross diagram is mainly to help generate the so-called IS curve, which gives an equilibrium relationship between various interest rate levels and planned AE. The IS (or "investment = savings") curve gives all the equilibrium points relating the interest rate and real income for a given set of model "parameters." It is drawn on a graph with the interest rate on the vertical axis and the level of real income (or real output) on the horizontal axis. The IS curve is downward sloping, reflecting how a higher interest rate drives down planned investment spending and thus lowers the economy's equilibrium income (and vice versa). The IS curve is commonly derived graphically from the Keynesian cross diagram. On the Keynesian cross diagram, a rise in the interest rate shifts the planned AE line downward (and vice versa). The derivation is done as follows. First, make an empty graph with the interest rate on the vertical axis and real income (or real output) on the horizontal axis. Second, place that graph directly above a Keynesian cross diagram. Because real output is on both horizontal axes, the two graphs "line up" vertically. Third, vary the interest rate, observing the

resulting values in equilibrium income that are generated on the Keynesian cross diagram. Finally, derive the IS curve by plotting this relationship between the interest rate and equilibrium income onto the upper graph.

Once it is derived, the IS curve is combined with a Liquidity = Money Supply (LM) curve and a price adjustment equation to create a general model of the expenditures side of the macroeconomy. The IS/LM graph in turn can be used to generate an aggregate demand curve, which relates various values of the price level to planned AE. Then, this aggregate demand curve is combined with a supply-side model to give a general macroeconomic model of the aggregate economy. This model incorporates everything from the macroeconomic consequences of deviations in planned investment spending (including planned inventory spending) and other demand-side changes, to the macroeconomic consequences (and causes) of supply-side forces and price level changes. Numerous additional important topics can be analyzed as well within this broader framework.

## Historical Development of the AE/Keynesian Cross Framework

### Development of the Planned AE (Aggregate Demand) Concept

While the Keynesian cross framework emerged out of the Keynesian revolution, many of the ideas behind that model are far older than Keynesianism. Planned AE was called *effectual demand, effective demand,* or *purchasing power* in pre-Keynesian days. Even as early as the eighteenth century, the mercantilist school emphasized what Keynes (1936/1965) later called "the great puzzle of effective demand" (p. 32; see also his chap. 23). Most leading classical economists downplayed the notion of deficiencies in planned expenditures (or aggregate demand, as planned expenditures were usually called at the time). They believed that, except for brief and self-correcting "crises," planned AE would take care of itself so long as production was unfettered and the types of goods produced were consistent with what consumers wanted and were able to purchase. Thomas Malthus, a notable exception, insisted that an economy could have serious drawn-out problems with inadequate effective demand (his arguments were a regular bone of contention in the early nineteenth century between himself and David Ricardo, a key founder of classical economics). Keynes lauds Malthus's position and writes also of how, during the heyday of the classical school, ideas that took effective demand failure seriously "could only live on furtively, below the surface, in the underworlds of Karl Marx, Silvio Gesell or Major Douglas" (p. 32).

Like Keynes, early anticlassical thinkers were concerned mainly with the prospect of secular (long-term) demand failure—not just with occasional downward fluctuations in planned AE that contributed to a downward swing in the business cycle. Keynes saw the laissez-faire macroeconomy as routinely—not just occasionally—underperforming its potential due to problems with generating sufficient levels of planned expenditures (see, e.g., Keynes, 1936/1965, chap. 1; chap. 3, p. 33, bottom paragraph; chap. 12, p. 164, final sentence; chap. 18, p. 254). There is also the fact that Keynes chooses to develop a business cycle theory only at the end of the book (chap. 22). If the *General Theory* were primarily about combating the business cycle, purely cyclical forces surely would have been given a more prominent role in the main portion of the volume.

Keynes's (1936/1965) chief (though far from sole) culprit causing inadequate AE was unstable confidence by the business investment sector, which created secular underinvestment and thus routine unemployment problems (chap. 12). The worldwide Great Depression, which raged even as Keynes was writing his famous *General Theory,* seemed thoroughly consistent with Keynes's analysis. Never before had the hypothesis of secular effective demand failure seemed so confirmed by day-to-day events.

This certainty, however, faded with time in the post–World War II era in the face of a recovered economy and a withering fire by the inheritors of the classical tradition. Since Keynes wrote, the "market failure" interpretation of the Great Depression has been effectively challenged by the heirs of the classical tradition. The most famous example is Milton Friedman and Anna Schwartz (1963; see also Friedman & Friedman, 1980, chap. 3), which emphasizes an unprecedented contractionary monetary policy during the crucial 1929 to 1933 period. Others have focused on the extraordinary uncertainty created by government actions during the decade of the 1930s (see Anderson, 1949; Smiley, 2002; Vedder & Gallaway, 1993).

It is a common misconception that the classical economists of the late eighteenth and early nineteenth centuries, as well as the early twentieth-century heirs of the classical tradition, had no interest in, or theory of, planned AE. Indeed, this is arguably a fair assessment of some classical writers. However (though the term itself was not used), short-term declines in planned aggregate spending were seen by several classical economists as being a key part of every business cycle downturn (or *crises,* as they were called at the time). Classical economists, however, differed from Keynes in two significant ways. First, they flatly rejected any notion of secular failure in planned AE. Second, they did not see declines in planned expenditures as being the ultimate cause of recession. Instead, they saw these declines as being caused by other more fundamental factors (such as disruptive government regulatory, or monetary, policies). Even before the classical era, David Hume (1752/1955, pp. 37–40) presented a very modern tale of a recession being caused by an unexpected decline in the money supply. Nearly a century later, John Stuart Mill (1844/1948, esp. pp. 68–74) described how a crisis of confidence could cause people to hoard money and so reduce their purchases of goods. Allowing for the difference in

vocabularies between his time and ours, Mill accurately described such an episode as being caused by a short-term decline in planned AE (or aggregate demand).

Early twentieth-century macroeconomists (whom Keynes, peculiarly, also labeled *classical*) also focused on aggregate demand issues—though always in the context of trying to understand cyclical, rather than secular, fluctuations. Leland Yeager (1997) summarizes numerous early twentieth-century business cycle theories that accurately identified the demand-side forces at play in the downturn—although such a downturn in demand was seen routinely as the effect of still more basic forces (such as a decline in the money supply). J. Ronnie Davis (1971) details how economists in the 1930s at the University of Chicago and elsewhere pursued lines of thinking parallel to Keynes's, suggesting that Keynes's ideas were "in the air" at the time.

Still, despite these glimmers from earlier scholars, it is without a doubt John Maynard Keynes who is primarily responsible for the ascendancy of demand-side macroeconomics through the influence of his *General Theory* (1936/1965). Keynes confronted a profession that took little explicit interest in the study of aggregate demand and left that profession positively consumed by the topic. Short-run macroeconomics, including the study of the business cycle, has since Keynes's day placed great emphasis on questions pertaining to short-run planned AE. Through about 1976, the primary focus of macroeconomics was to examine the theory and determinants of planned AE (Friedman, 1968, is still the classic brief summary of much of the period covered in this section. It is highly recommended to the student's attention). The main determinants of planned AE—consumption, investment, government, net exports, and the demand for and supply of money—the statistical properties of these components, and ways for the monetary and fiscal authorities to alter these aggregates are topics that have all been extensively explored. The profession's comprehension of the practicality of the basic Keynesian policy agenda has improved markedly as all aspects of that agenda have been placed under the magnifying glass.

At the risk of some oversimplification, it may be said that two fundamental issues dominated the policy agenda of those who worked on developing the Keynesian framework in the 30 years following Keynes's death in 1946. The first concerned mainly the channels and mechanisms through which demand-side policy worked, while the second focused on the relative strengths and weaknesses of fiscal policy (changes in government spending, tax-rate changes) versus monetary policy (changes in the money supply or in its rate of growth). Through this entire era, understanding was enhanced considerably by the development of statistical methods in economic science. Nearly every significant concept developed by Keynes that pertained to the control of planned AE was exhaustively examined, from both theoretical and statistical perspectives. (Snowdon & Vane, 2005, chaps. 1–7, is among the most useful detailed reviews of the material summarized here.)

For example, how exactly did policy and consumption interact in generating economic stimulus? Keynes (1936/1965) confined his analysis of consumption mainly to its relationship with current disposable income (chaps. 8–10). In fact, as Milton Friedman (1957) and others soon showed, expected future wealth plays a crucial role as well, especially in policy matters. Friedman showed that one recession-fighting policy tool—income tax cuts aimed at consumers—would tend to stimulate significantly less spending than that implied by the Keynesian consumption function. Consumers, looking to the future, would observe the temporary nature of the tax cut (rates would be raised again as the economy recovered). They would therefore seek to spread out the spending of their income windfall over many future periods rather than spend the bulk of it in the period of the tax cut. The result was to limit the relevance of income tax cuts as a demand-stimulating mechanism that might fight recessions. Income tax systems seem to work better as automatic stabilizers, because as income falls, one's tax burden automatically is lowered also (and vice versa) in such tax systems. But as a means of direct assault on recession, the case for such cuts, when viewed as demand-side stimulus, appears weaker than was believed in the early Keynesian era, thanks to the work of Friedman and others (specifically, Duesenberry, 1948; Modigliani & Brumberg, 1954). (So-called supply-side economics advocates income tax cuts as a means of stimulating work effort, reducing income tax avoidance/evasion, and stimulating entrepreneurial small-business activity. Friedman's work did not refute these claims. However, these are not Keynesian arguments. The supply-side argument for income tax cuts remains controversial.)

A number of additional insights were developed in the 30 years following Keynes's death. The inverse relationship between investment spending and interest rates, which had been controversial, was established as fairly strong and reliable as better statistical methods became available. Investment spending's interaction with income (known as the *accelerator mechanism*) also was established. In addition to Keynes's basic mechanism, several significant channels through which monetary policy affected planned aggregate spending were identified, and the potential for changes in the demand for money to complicate monetary policy was thoroughly examined. The determinants of net exports became much better understood. Finally, complicating factors affecting the potency of both fiscal and monetary policy became far better understood. In particular, the existence of lags delaying the effectiveness of such policies came to be seen as a significant complicating factor, especially in the case of major stimulus initiatives that involved substantial increases in government spending in an attempt to fight recessions. Invariably, it seems, increases in government expenditures to fight recessions add little stimulus until well after the recession has passed (this has, at least, been the lesson of the post–World War II era up to the present date). Lags also afflict monetary policy, although it appears that monetary policy is more able

to retain a significant stimulative role within a time frame capable of combating cyclical forces.

As understanding of the determinants of planned AE increased, a sharp debate developed between advocates of traditional Keynesian fiscal policy measures and those who advocated the superiority of monetary policy over fiscal policy (these latter scholars, who were led by Milton Friedman, were known as *monetarists,* and their movement as *monetarism*). Keynes, in the *General Theory,* had focused attention on expansionary fiscal policies as the primary cure for demand-side problems. Keynes had not ignored monetary policy, and he endorsed it also, but he feared it would be weak precisely when it was needed most—in depressed economic times. Some of Keynes's early followers went so far as to nearly deny to monetary policy any significant impact on planned AE and real GDP. This pessimism proved overblown; in fact, one of the major themes of the 1960s and 1970s was the steady growth of a consensus among macroeconomists that monetary policy was the more potent of the two policy "levers."

Another insight painfully developed during the initial post-Keynes era was a clear-cut link between monetary policy and inflation. By the mid-1970s, inflationary forces (largely stimulated by loose monetary policy during the late 1960s and early 1970s) dominated the policy front. A common notion that there was an exploitable policy trade-off between higher inflation and lower unemployment (a trade off that became known as the *Phillips curve*) was shattered by the high inflation and high unemployment of the late 1970s and early 1980s. Out of this era, for a time, there emerged a deep cynicism about macroeconomic policy generally—both fiscal and monetary, though the focus at this time inevitably was on monetary policy, which was widely seen as the more potent of the government's two core policy choices. In particular, advocates of the so-called rational expectations hypothesis argued that monetary policy would have little impact on planned AE unless that policy was unanticipated. Otherwise, "rational" individuals would alter their personal economic affairs in such ways as to defeat the stimulative intent of the expansionary monetary policy.

By the mid-1980s, the rational expectations critique of monetary policy had been exposed as overly extreme (even as the rational expectations hypothesis itself became a standard feature of macroeconomic theorizing) due to the clear-cut potency of monetary policy during the 1980s (and beyond) to impact planned AE and real GDP. During this era, attention turned to supply-side theories of cyclical activity (so-called real business cycle theory). Real business cycle theorists aggressively challenged traditional Keynesian demand-based theory, claiming (in essence) that such theories were internally inconsistent. *New Keynesian economics* developed in response to this fundamental challenge. By the middle of the 1990s, new Keynesians had met the challenge posed by real business cycle theory, in the process developing several new mechanisms through which monetary and fiscal policies might impact planned AE and real GDP. The new Keynesian success at shoring up the theoretical foundations of their macroeconomic approach had the effect of reestablishing the influence of traditional Keynesian macroeconomic analysis, which had suffered in reputation during the 1975 to 1985 period.

At least in mainstream macroeconomics, there has been no significant new challenge to the supremacy of AE policies since the real business cycle movement in the 1980s (outside the mainstream, "Austrian" macroeconomics questions this supremacy; see, e.g., Snowdon & Vane, 2005, chap. 9). Indeed, during the 1990s and early 2000s, the potency of monetary policy to stabilize an unstable economy never looked brighter. Several severe financial crises in the late 1990s and early 2000s seemed largely blunted by expansionary monetary policy, aided to an extent by expansionary fiscal policies (mainly tax cuts). However, as the first decade of the twenty-first century nears its end, unprecedentedly severe disruptions to the world's financial sector have called again to the fore the core question of the potency of traditional stabilization policy measures to combat a truly severe economic contraction. It is to be hoped that the many insights achieved since Keynes's death will prove sufficient to meet the phenomenon of the burst of a worldwide speculative bubble—a specter deeply feared and much discussed by pre-Keynesian economists, but an issue relatively unexamined in macroeconomics since 1946.

## Development of the Keynesian Cross Diagram

As is the case for planned AE, aspects of the Keynesian cross diagram also can, in part, be attributed to classical thinkers. John Stuart Mill (1844/1948) in particular displays a thorough comprehension of the inventory adjustment mechanism at the heart of the Keynesian cross. Mill writes about how in bad economic times "dealers in almost all commodities have their warehouses full of unsold goods," and how under these circumstances "when there is a general anxiety to sell and a general disinclination to buy, commodities of all kinds remain for a long time unsold" (pp. 68, 70). Seventy years later, Ralph Hawtrey (1913/1962, p. 62) shows a particularly clear grasp of the relation between inventory accumulation/depletion and aggregate economic activity. Classical economists and heirs to the classical tradition may not have conceptualized aggregate demand in the manner of Keynesian economics, but they understood the concept and its significance well enough, particularly in relation to the business cycle.

The history of the Keynesian cross framework proper begins, of course, with Keynes. Like Mill before him, Keynes (1936/1965) saw clearly the role of inventory accumulation and depletion in contributing to cyclical forces. In his Chapter 22 in the *General Theory* on the "Trade Cycle," Keynes points to how, in the downswing, the "sudden cessation of new investment after the crisis will probably lead to an accumulation of surplus stocks of

unfinished goods." He then comments, "Now the process of absorbing the stocks represents negative investment, which is a further deterrent to employment; and, when it is over, a manifest relief will be experienced" (p. 318). This is precisely the message of the Keynesian cross diagram.

However, Keynes introduces the framework that would give birth to the Keynesian cross diagram much earlier in the *General Theory.* In Chapter 3, he verbally describes a model where effective demand is set by the intersection of aggregate supply and aggregate demand. The specifics of the model need not detain us, but the model featured an upward-sloping aggregate supply relationship between employment and the minimum proceeds businesses must receive to hire a given number of workers (aggregate demand is given by what businesses actually receive in proceeds for hiring a given number of workers). Keynes does not draw a graph, but he does assume that the two schedules intersect, and under reasonable conditions his aggregate demand curve will be flatter than the aggregate supply curve.

Samuelson (1939, p. 790) was apparently first to publish a version of Keynes's framework featuring the now-standard 45-degree line combined with a flatter C + I curve representing planned AE. Samuelson also pioneered the teaching of the Keynesian cross framework by including it in early editions of his best-selling *Principles of Economics* textbook. Some early interpretations of the 45-degree line treated it as a kind of aggregate supply line (see Guthrie, 1997, for a useful discussion), and this interpretation also found its way into the *Principles* textbooks (e.g., McConnell, 1969). However, the more standard approach has been the modern one of treating the 45-degree line simply as a line of reference that shows all points where a value on the vertical axis equals that on the horizontal axis (as in Dillard, 1948; Samuelson, 1939).

## Conclusion

The development and refinement of the planned AE (or aggregate demand) concept has been a dominant theme of macroeconomics since at least 1936. Keynes (and, to a surprising extent, earlier "classical" thinkers) forged the initial path, and by 1976, a sophisticated and intricate theory of planned AE had been developed. This development has continued into the twenty-first century under the spur of attacks by opposing schools of thought that came to the fore in the late 1970s and 1980s. While challenges have been raised from time to time, it is still safe to say, 10 years into the twenty-first century, that countercyclical macroeconomic policy is primarily defined by the emphasis on planned AE that was put into place by Keynes nearly a century ago.

Few macroeconomic models have received more attention, or been studied by more college sophomores, than the Keynesian cross diagram. The model's chief virtue always has been the neat—even elegant—manner in which the Keynesian approach to macroeconomics can be made clear. The causes and effects of sudden fluctuations in planned AE can be easily and instructively represented in the model. Demand-side policy solutions recommended by Keynesian economics also are easily highlighted in the model. The model captures well one of the chief dynamics of macroeconomic adjustment—inventory accumulation and depletion, and its consequences. It also dovetails nicely (indeed, it is an input into) the more complete IS/LM model of planned expenditures, which, when combined with a theory of aggregate price adjustment, is a creditably complete, and remarkably informative, aggregate model of the macroeconomy.

If the Keynesian cross framework has one serious weakness, it is that it encourages the student to accept far too easily that AE can be easily and conveniently manipulated by governments in such a way as to improve the aggregate performance of the economy. The model presents macroeconomic problems and their solutions in a commendably clear, but vastly oversimplified, manner. It is all too easy for students to emerge from courses built around the Keynesian cross with an overblown faith in the government's ability to move an economy briskly and with almost surgical precision to "macroeconomic nirvana." In fact, lags in the effectiveness of macroeconomic policies, political complications that "hijack" such policies for the sake of personal interests, expectations-based problems where policies work only when implausible beliefs about them are held by people, and other problems bedevil the macroeconomic policy maker. Still, when the model is taken with a grain of salt and on its own terms, it can do an admirable job of acquainting the student with the primary motivating ideas of Keynesian economic theory.

# Aggregate Demand and Aggregate Supply

Ken McCormick
*University of Northern Iowa*

The aggregate demand/aggregate supply (AD/AS) model appears in most undergraduate macroeconomics textbooks. In principles courses, it is often the primary model used to explain the short-run fluctuations in the macroeconomy known as *business cycles*. At the intermediate level, it is typically linked to an IS/LM model. The IS/LM model is a short-run model, and in intermediate macroeconomics classes, the AD/AS model serves as a bridge between the short run and the long run. Many economists find the model to be useful in thinking about the macroeconomy.

People often assume that textbooks present settled theory. It might therefore be a surprise to some that economists do not universally accept the AD/AS model. It has, in fact, been the subject of a heated debate. Critics of the model charge that it is an unsuccessful attempt to combine Keynesian and neoclassical ideas about the macroeconomy. Detractors also contend that it sacrifices accuracy for the sake of easy pedagogy.

The purpose of this chapter is to examine the model and a few of the charges leveled against it. The first part of the chapter presents the model as it usually appears in textbooks. The presentation includes applications and a discussion of policy in the context of the model. Following that is a discussion of some of the main criticisms. We discover that the critics may have a point.

## Theory

### The Aggregate Demand Curve

The aggregate demand curve is drawn as a negatively sloped curve in price level/real gross domestic product (GDP) space (see Figure 32.1). It shows how real aggregate spending is influenced by changes in the price level. Aggregate spending is the sum of consumption, desired investment, government purchases of goods and services, and net exports, symbolized as C + I + G + NX. At the principles level, there are usually three explanations given for why real aggregate spending varies inversely with the price level: the wealth effect, the interest rate effect, and the foreign trade effect.

The wealth effect is also known as the *real balance* or *Pigou effect*. All else equal, as the price level rises, people

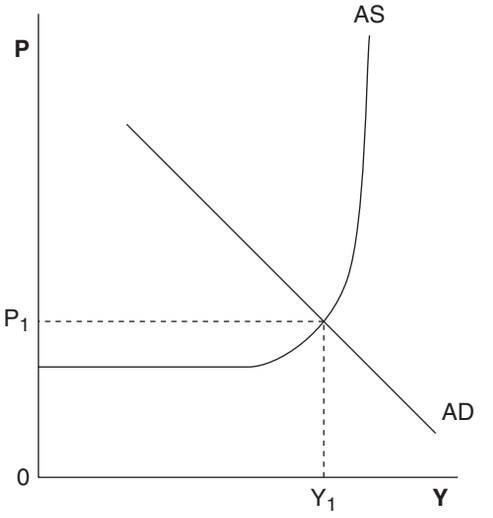

**Figure 32.1** The Basic AD/AS Model
SOURCE: Adapted from Reynolds (1988, p. 221).

who hold money discover that they can buy less with their money. In other words, they experience a decrease in the real value of their wealth held as money. As a direct result, they will buy fewer goods and services as the price level rises.

The interest rate effect is sometimes called the *Keynes effect.* To understand it, one must first understand the theory of *liquidity preference,* which is the idea that in the short run, interest rates are determined by the supply of and demand for money. In the money market, the nominal supply of money is determined by the central bank. The nominal demand for money depends on real income, the price level, and the nominal interest rate. All else equal, as real income rises, people will buy more goods and services. To do so, they will need more money. As the price level rises, people will need more money to carry out the same volume of real transactions. Money demand is negatively related to the interest rate because the rate of interest is the opportunity cost of holding money. All else equal, as the interest rate rises, people will reduce the amount of money they want to hold.

The *equilibrium short-run interest rate* is the rate that causes the quantity of money demanded to equal the quantity of money supplied. If the interest rate is too high, there will be a surplus of money in the sense that people will want to hold less money than they do. To reduce money holdings, people will buy bonds and deposit money in interest-bearing accounts. The result will be a fall in the rate of interest. If the interest rate is too low, the opposite will occur. People will want to hold more money than they have. To obtain it, they will sell bonds and withdraw money from interest-bearing accounts, and that will drive the interest rate up.

The liquidity preference theory is in contrast to how interest rates are determined in the long run. In the long run, interest rates are determined in the market for loanable funds—that is, by national saving, domestic investment, and net capital outflow (also known as *net foreign investment*). According to the doctrine of long-run money neutrality, the supply of money cannot influence the real interest rate in the long run.

So what is the interest rate effect and how does it affect the slope of the aggregate demand curve? There are two different approaches presented in textbooks that are logically equivalent. In one approach, an increase in the price level increases the nominal demand for money. For a given money supply, the increase in money demand drives up the rate of interest. A higher interest rate reduces consumption and desired investment spending. In other words, a higher price level drives up the rate of interest and thereby reduces the real quantity of output demanded.

The other approach conceives of the money market in real terms. By dividing the nominal money supply and nominal money demand by the price level, one gets real money supply and real money demand. Holding the nominal money supply constant, as the price level rises, the real money supply falls. The fall in the real money supply creates a shortage of money at the prevailing interest rate, so the interest rate rises. As with the other approach, the higher interest rate reduces consumption and desired investment and therefore reduces the real quantity of goods and services demanded.

There are two versions of the foreign trade effect. The first approach is direct: As the domestic price level rises, exports fall and imports rise as buyers substitute foreign goods for the more expensive domestic goods. The second approach, often called the *exchange rate effect,* follows from the interest rate effect. As the price level rises, the interest rate rises. A higher interest rate makes domestic bonds more attractive. As a result, domestic residents will want to buy fewer foreign bonds, and foreign residents will want to buy more domestic bonds. In the market for foreign exchange, that translates into a decrease in the supply of the domestic currency and an increase in the demand for domestic currency. That will cause the value of the currency (the exchange rate) to rise. A rise in the exchange rate means that domestic goods become more expensive relative to foreign goods. Exports will fall and imports will rise. In other words, the increase in the price level will reduce net exports, and so the real quantity of output demanded falls.

Be aware that the aggregate demand curve is not just the summation of all market demand curves, and the reasons for their negative slopes differ. For a market demand curve, a change in price is considered holding all other prices constant. It therefore represents a change in *relative* price. A market demand curve is negatively sloped because a relative price change creates income and substitution effects. A higher price causes people to substitute away from the good, and it reduces their real income. For a normal good, lower real income reduces the quantity of the good purchased. For the aggregate demand curve, a price change represents an *absolute* change in the overall price level. There can be no income effect for the macroeconomy as a whole because when the overall price level rises, both the prices people pay and the prices people receive increase. For every buyer there is a seller, so one person's higher expense is another person's higher income. To the extent that people buy more foreign goods and fewer domestic goods as the domestic price level rises, there can be a type of macroeconomic substitution effect. But as we shall see, this effect is likely to be small.

At the intermediate level, the interest rate effect is emphasized, though the other two are sometimes mentioned. In intermediate courses, the aggregate demand curve is typically derived from an IS/LM model. The interest rate effect is clearly illustrated in the IS/LM framework, as a higher price level shifts the LM curve left (upward). The result is a higher interest rate and lower real GDP in equilibrium. To the extent that the higher interest rate drives up the exchange rate, the IS curve will shift left (downward) as net exports fall. The wealth effect of a higher price level reduces consumption and so also shifts the IS curve to the left (downward). In all three cases, a higher price level is associated with lower equilibrium real GDP.

There is an alternative derivation of the aggregate demand curve based on the quantity equation, MV = PY, where M is the money supply, V is the income velocity of money, P is the price level, and Y is real GDP. MV is total spending on final goods and services. For a given value of MV, P and Y must be inversely related. In this formulation, the aggregate demand curve is a rectangular hyperbola. This version of the aggregate demand curve is less popular and is used primarily to show how changes in the money supply affect aggregate demand (Mishkin, 2007). It is less useful for showing how individual components of spending affect aggregate demand. That is because one would have to explain how a change in investment, for example, affects velocity.

## The Aggregate Supply Curve

There are two distinct textbook approaches to aggregate supply. In the simpler version, the aggregate supply curve is horizontal at the current price level for all values of output below full employment, and vertical at full employment. The idea is that as long as there is unemployment, increases in aggregate demand will increase output, not prices. Once the economy reaches full employment, further increases in demand can only drive up prices. A slightly more sophisticated version of this approach has a positively sloped region as the economy nears full employment (see Figure 32.1). The idea is that some industries will reach full employment before others, so as demand rises, some industries will respond by increasing output, while other industries will be unable to produce more and so will raise prices.

The second approach is more sophisticated and leans heavily on the research about the Phillips curve done by Nobel laureates Edmund Phelps (1967) and Milton Friedman (1968). Phelps and Friedman argued that there was a short-run trade-off between inflation and unemployment, but that the trade-off vanished in the long run. In other words, a higher inflation rate may allow the economy to move above its full-employment level of output temporarily, but not permanently.

The aggregate supply version of the Phillips curve analysis posits a long-run aggregate supply curve that is vertical at the full-employment level of output (see Figure 32.2). This corresponds to the economy's "natural" rate of unemployment that allows for only frictional and structural unemployment, but no cyclical unemployment. It is vertical because, in the long run, real GDP is determined by real forces such as the availability of resources and technology, not by the price level. Over time, the long-run aggregate supply curve will shift right as technology improves and as the economy acquires more capital and labor. Its position is also affected by tax rates and other things that affect the incentives to supply capital and labor, create businesses, and develop new technology.

Deviations from full employment can occur when the actual price level deviates from the expected price level. There is no consensus as to why this is the case, but three different explanations are commonly presented (Mankiw, 2007).

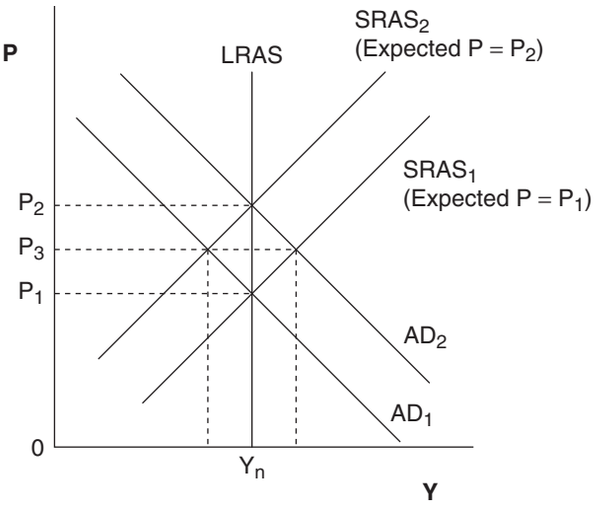

**Figure 32.2** The Enhanced AD/AS Model

SOURCE: Adapted from Mankiw (2007, p. 762).

One explanation, called the *sticky-wage model,* is based on the idea that wages are not perfectly flexible and may be fixed in the short run. Wages are set based on some expected price level, so if prices turn out to be higher than expected, real wages will be lower than expected. In response, firms will hire more workers and increase output. In other words, the aggregate supply curve will have a positive slope in the short run. The effect will not persist, however, because nominal wages will eventually adjust to reflect the higher level of prices. When price expectations are adjusted upward, workers will demand higher wages. Employment will then return to its long-run value. In terms of the model, the short-run aggregate supply curve will shift left (see Figure 32.2).

Another explanation for the short-run aggregate supply curve's positive slope begins with the observation that many prices are sticky. That means that some firms change their prices only periodically. The prices of raw commodities like grain and metal may fluctuate daily, or even hourly, but prices of finished goods behave differently. B. Bhaskara Rao (1993) found that over 85% of U.S. transactions on final goods and services take place in "sluggish price" markets. That means that sticky prices are quite common. One reason is markup pricing. Price setters often set price by adding a markup over marginal cost. Fluctuations in demand are met with changes in output, not price. A second reason is fear of competitors. Firms do not want to be the first to raise price for fear of losing customers to competitors. A third reason is menu costs: It is expensive to frequently reprint catalogs and price lists. Moreover, when firms do change their prices, they do not all do so at once. That means that as the overall price level rises, the relative price of the output produced by firms with sticky prices falls. As a result, they experience higher than normal sales. In response, the firms increase output. The result is that a rising price level is associated with rising real GDP. Once again, however, the effect is only temporary. When the firms change their prices, they will

adjust them upward in line with the overall price level. The result is that their sales will decline and output will fall. That implies that the short-run aggregate supply curve shifts to the left (see Figure 32.2).

A third explanation assumes that some firms are temporarily fooled. When the price of their output rises due to an increase in the overall price level, these firms misperceive it as an increase in the relative price of their output. In response, they increase production. As in the previous two cases, the increase in real GDP is only temporary. Firms will eventually correct their perceptions and recognize that the relative price of their output has not increased. When that happens, they will reduce production. The short-run aggregate supply curve will shift left (see Figure 32.2).

All three of these explanations can be represented in a single equation,

$$Y = Y_n + \alpha(P - P^e)$$

where Y is actual real GDP, $Y_n$ is the long-run or "natural" rate of real GDP, $\alpha$ is a positive constant, P is the actual price level, and $P^e$ is the expected price level. The equation shows that when the actual price level deviates from the price level that was expected, real GDP will deviate from its natural rate. In the long run, when expectations adjust to reality, the price level will equal the expected price level, so real GDP will equal its natural rate.

### The Adjustment to Equilibrium

As in so many other economic models, equilibrium is where the lines cross. Suppose, for example, that in Figure 32.2, $AD_2$ is the relevant aggregate demand curve and $SRAS_2$ is the relevant short-run aggregate supply curve. The economy is in both short-run and long-run equilibrium with the price level at $P_2$ and real GDP at its "natural" level, $Y_n$. Then suppose that aggregate demand falls to $AD_1$. At $P_2$, the amount of real GDP people want to buy is less than the amount firms want to sell. In the short-run, the excess supply will cause the price level to fall to $P_3$ and real GDP to fall below $Y_n$. Because the actual price level ($P_3$) is below the expected price level ($P_2$), real GDP is below its long-run value. Over time, price expectations will fall, and the short-run aggregate supply curve will shift to the right. This effect will be reinforced by the cyclical unemployment that exists when real GDP falls below $Y_n$. Unemployment puts downward pressure on wages, and that will reduce firms' costs. Eventually, the economy will return to $Y_n$ with a price level equal to $P_1$. At that point, the short-run aggregate supply curve will be at $SRAS_1$ in Figure 32.2.

## Applications and Empirical Evidence

The primary application of the model is to predict and explain short-run fluctuations in real GDP around its long-run trend. It is intended to explain how recessions and booms occur, and why the economy tends to return to its natural rate of real GDP. According to the model, deviations from the economy's long-run trend are the result of shocks to either demand or supply.

### Demand Shocks

For a given price level, a change in any of the components of aggregate demand will shift the aggregate demand curve. Recall that aggregate demand is the sum of consumption and desired investment, government purchases of goods and services, and net exports. A change in any of these can shift the aggregate demand curve. If any of them fall, aggregate demand will shift to the left. As detailed at the end of the previous section, that will cause a temporary decline in real GDP, otherwise known as a *recession*. If any of the components rise, aggregate demand will shift right. For example, in Figure 32.2, begin with $AD_1$ and $SRAS_1$. At $P_1$ and $Y_n$, the economy is in short-run and long-run equilibrium. If aggregate demand rises to $AD_2$, the short-run result is an increase in the price level to $P_3$ and an increase in real GDP above $Y_n$. The economy is in a boom period. Eventually, price expectations will be revised upward, and the short-run aggregate supply curve will shift left to $SRAS_2$. When that happens, the boom is over and the economy returns to its long-run trend.

The key point is that fluctuations in aggregate demand cause fluctuations in real GDP. The components of aggregate demand are each influenced by a large number of variables. It is therefore not surprising that aggregate demand fluctuates. The model shows how fluctuations in demand are translated into fluctuations in real GDP.

Of all of the components of aggregate demand, desired investment spending is the most volatile. As John Maynard Keynes (1936/1964) emphasized, investment is extremely sensitive to the state of expectations. That is because investors face known present costs and uncertain future returns. The decision to build a factory is an act of faith. The investor can never be certain what future demand for the factory's output will be. A recession may suppress demand and lower price. Technological change may make it obsolete. There is no way to precisely calculate the return on the factory, and Keynes argued that one typically does not even know enough to establish probabilities. It is no surprise that waves of optimism or pessimism among investors can lead to significant fluctuations in investment, aggregate demand, and real GDP.

Consumption spending is also affected by the state of expectations, though to a lesser degree. That is primarily because spending on necessities such as food, shelter, and transportation cannot be avoided. But consumption spending on some goods, such as furniture and entertainment, can be postponed. An old sofa can be made to last longer. If consumers fear a recession that might put their jobs in jeopardy, they will try to save more and consume less. If they are optimistic and believe that the economy will boom, they may expect higher income in the future. That

could lead them to save less (or borrow more) and consume more now.

Export demand depends to a significant degree on the health of our trading partners' economies. If one or more of them go into a recession, their demand for our exports will fall. That, in turn, will reduce our aggregate demand. Other things equal, the result would be to create a recession here too.

While the model correctly predicts that a decline in aggregate demand will reduce real GDP, it also predicts that the overall price level will fall. One weakness of the model becomes apparent when one realizes that the overall price level in the United States has not fallen over the course of a year since 1955. One would be hard-pressed to argue that there have not been any negative demand shocks over that period. Defenders of the model argue that there are other forces in the economy that keep the price level rising even in the face of falling aggregate demand. They contend that falling aggregate demand puts *downward pressure* on prices—that is, will slow the rate of growth of prices. That may well be true, but that is not what the model says. As some economists have argued, the model is much better at explaining output movements than price movements.

### Supply Shocks

Broadly speaking, there are two types of supply shocks: input-price shocks and technology/resource shocks. Input-price shocks lead to sudden changes in the expected price level and therefore shift the short-run aggregate supply curve. Technology/resource shocks affect the economy's production function and shift both the long-run and the short-run aggregate supply curves.

#### *Input-Price Shocks*

The aggregate demand and aggregate supply model became popular primarily because of the oil price shock that hit the West in the mid-1970s. The model was able to correctly predict the consequences of the shock. The 1973 Arab–Israeli war led Arab oil-exporting countries to embargo the West. The price of oil more than doubled in a short period of time. The price of oil is important because it contributes to the cost of producing and distributing almost everything. Inputs must be shipped to factories and output must be shipped to stores. Workers must travel to work. When the price of oil increased suddenly, people understood that costs, and therefore prices, would soon increase too. In other words, the expected price level increased, so the short-run aggregate supply curve shifted to the left.

In terms of Figure 32.2, begin with $AD_1$ and $SRAS_1$, with the economy in long-run equilibrium at $P_1$ and $Y_n$. The higher expected price level shifted the short-run aggregate supply curve to $SRAS_2$. In the short run, the price level rises to $P_3$, and real GDP falls below $Y_n$. The combination of falling output and rising prices is often called *stagflation.* The U.S. economy saw an increase in the unemployment rate from 4.9% in May of 1973 to 9.0% in May of 1975. Over the same period, the price level as measured by the Consumer Price Index increased 21.15%. A second oil-price shock hit the United States in the late 1970s, when the price of oil again more than doubled. The results were similar. The unemployment rate increased from 6.0% in May of 1978 to 7.5% in May of 1980, and the price level rose 26.69% over the same period.

In the mid-1980s, the price of oil moved sharply in the other direction. From 1982 to 1986, the price of crude oil fell more than 50%. The drop in the price of oil reduced the expected price level and shifted the short-run aggregate supply curve to the right. In terms of Figure 32.2, begin with $AD_2$ and $SRAS_2$, with the economy in long-run equilibrium at $P_2$ and $Y_n$. The fall in the expected price level shifts the short-run aggregate supply curve to $SRAS_1$. The model predicts that the price level will fall to $P_3$ and real GDP will rise above its natural rate. As the model predicts, the U.S. unemployment rate fell from 9.4% in May of 1982 to 7.2% in May of 1986. The price level rose 13.65% over the same period, contrary to the model's predictions. An explanation is that aggregate demand increased over the period, which would tend to drive up the price level.

#### *Technology/Resource Shocks*

The aggregate demand and aggregate supply model is designed to explain business cycles, but it is worth briefly mentioning a few long-run effects. Improvements in technology raise the productivity of a nation's resources and thereby increase the natural rate of GDP. As a result, both the long-run and short-run aggregate supply curves shift to the right. The acquisition of more resources through immigration, natural population growth, and capital accumulation will have the same effect on the two curves. This is another way of saying that in a growing economy, the natural rate of GDP will rise over time.

## Policy Implications

The AD/AS model as usually presented suggests that the economy will recover from adverse shocks on its own. Yet some economists argue that the process may take a long time. That is because the price level may be slow to adjust, especially in the downward direction. In other words, sticky prices and sticky wages may significantly delay the restoration of full employment. The model offers guidance to those who believe that policy can speed the process along.

### Policy Responses to Demand Shocks

If aggregate demand falls, real GDP will fall and unemployment will rise. Either fiscal policy or monetary policy (or both) can be used to increase aggregate demand. Fiscal policy uses the government's power to spend and tax. To boost aggregate demand, the government can increase its own spending or it can cut taxes so as to stimulate private

spending. The net effect on aggregate demand depends on the relative magnitude of two conflicting forces. One is the *multiplier effect.* An increase in spending raises the income of those who receive the new spending. They, in turn, will spend some of their new income, which will raise the income of somebody else. In this fashion, the initial increase in spending can induce additional spending elsewhere in the economy. The net result is that total spending in the economy can rise by a multiple of the initial increase.

The second effect is called *crowding out.* The increases in income set in motion by the multiplier effect will raise the demand for money. That will cause the interest rate to rise, which will reduce investment, consumption, and net exports. In this fashion, the initial fiscal policy action can "crowd out" other forms of spending. The crowding out will reduce the amount by which aggregate demand rises. The net effect on aggregate demand depends on the relative strength of the multiplier and crowding out effects.

Monetary policy can also be used to raise aggregate demand. If the central bank increases the money supply, the rate of interest will fall. That, in turn, will tend to raise investment, consumption, and net exports. Keynes argued in his *General Theory* (1936/1964) that monetary policy may be ineffective in a severe recession or depression because even very low interest rates may not raise spending sufficiently if investors and consumers have pessimistic expectations about the future.

### Policy Responses to Supply Shocks

Policy makers face a dilemma when confronted with an adverse supply shock. Suppose a price shock shifts the short-run aggregate supply curve to the left, which raises prices and reduces output and employment. If policy makers raise aggregate demand in order to restore full employment, the price level will rise even more. If policy makers lower aggregate demand in order to stabilize prices, output and employment will fall even farther. Any policy that changes aggregate demand will make either inflation or unemployment worse.

The only policy that *might* work to reduce both inflation and unemployment would be one that acts directly on the short-run aggregate supply curve. The options open to policy makers are limited. One possibility is to reduce business and payroll taxes in order to reduce business costs. To the extent that such a move would counteract the increase in costs caused by the price shock, the expected price level might be reduced. That would shift the short-run aggregate supply curve back to the right.

## Future Directions

The appeal of the AD/AS model is obvious. Its superficial similarity to the familiar market demand and supply model makes it easy to teach. That, together with the power of habits of thought and inertia, suggests that the model has a bright future. But as was mentioned in the introduction, the model has its critics.

### The Slope of the Aggregate Demand Curve

Consider the three reasons given for the negative slope of the aggregate demand curve. The wealth effect is much discussed, but the estimates are that it is trivially small. Nobel laureate James Tobin (1993) estimated that the wealth effect is so weak that a 10% drop in the price level would increase spending by only 0.06% of GNP. In other words, major changes in the price level would not have much of an effect on aggregate spending. As Bruce Greenwald and Nobel laureate Joseph Stiglitz (1993) argue, the excessive attention given to the wealth effect "hardly speaks well for the profession" (p. 36).

Another problem with the wealth effect is that it is selective about what types of wealth are affected by a price-level change. Specifically, it ignores the effect of a change in the price level on the real value of debt. A price-level decrease, for example, will increase the real value of debt. And while it is true that the real gains to creditors equal the real losses of debtors, the effect on spending is not neutral. This is for two reasons. The first is that, by definition, the propensity to spend is higher for debtors than for creditors. That means that the price-level decrease will reduce the economy's overall propensity to spend. The second reason is that a falling price level makes it harder to repay debt. One can reasonably expect, and history has amply demonstrated, that a decrease in the price level will increase the proportion of bad loans and the number of bankruptcies. Taken together, the implication is that a fall in the price level is likely to *reduce* the real value of spending, not increase it as the aggregate demand curve claims.

The foreign trade effect also has problems. The version of it that argues that a higher price level will make domestic goods more expensive and so reduce net exports is strictly true only if the exchange rate is fixed. If the exchange rate is flexible, then one would expect the rising domestic price level to reduce the value of the currency. The price increase and the currency depreciation should roughly cancel each other out, with minimal effect on net exports. The other version argues that the higher interest rate associated with a higher price level will drive up the exchange rate and so reduce net exports. Yet once again, the higher price level will itself reduce the value of the currency. The overall effect on net exports will be small.

According to Tobin (1993), the interest rate effect was first discussed by Keynes (1936/1964). Yet Keynes himself did not put much faith in it. The main reason is that changes in the price level that trigger the interest rate effect are likely to alter expectations. This illustrates a central problem for the model: In discussions of short-run aggregate supply, expectations have a central role. Yet in discussions of the aggregate demand curve, expectations are completely ignored. Consumers and investors are implicitly assumed to never change their price expectations.

Consider the reasonable possibility that an increase in the price level will cause people to expect even higher prices in the future. A normal reaction might be to buy *more* now to avoid paying even higher prices later. If that happened, the aggregate demand curve could have a *positive* slope. Alternatively, if the aggregate demand curve is drawn holding price expectations constant (as it is), then it would shift to the right when the price level increased.

The more general point is that it is not at all clear that a higher price level will reduce the quantity of goods and services people buy. At best, the aggregate demand curve is extremely steep, almost vertical. If that is the case, then why bother to put the price level on the vertical axis at all? As was suggested earlier, the model is much better at predicting changes in real GDP than it is at predicting changes in the price level. The prominent role of the price level in the model is no doubt an attempt to blend neoclassical economics (which views price adjustments as the primary equilibrating force) with Keynesian economics (which views output adjustments as the primary equilibrating force). The result is not always satisfactory.

### Incompatibility of the Aggregate Demand and Aggregate Supply Curves

The aggregate demand curve is in no sense a behavioral relationship like a market demand curve. The aggregate demand curve is a set of equilibrium points. This is seen clearly when the aggregate demand curve is derived from the IS/LM model, as it usually is in intermediate macroeconomics classes. The intersection of the IS and LM curves shows the equilibrium rate of real GDP where both the goods market and the money market are in equilibrium. As the price level changes, the LM curve shifts. By repeatedly changing the price level, one can generate an aggregate demand curve that shows the relationship between the price level and the rate of real GDP where the goods market and money market are both in equilibrium.

Implicit in this story is the assumption that production rises along with demand to keep the goods market in equilibrium (Barro, 1994; Nevile & Rao, 1996). As the price level falls and the LM curve shifts right (downward), the rate of interest falls and spending rises. This is the familiar interest rate effect. Output is assumed to be forthcoming to match the increase in spending. It is a manifestation of Hansen's law that demand creates its own supply. To put the matter differently, the derivation of the aggregate demand curve implies that firms can always sell everything they care to produce at whatever the price level happens to be.

The logical problem should now be apparent. The aggregate supply curve presents a much different relationship between the price level and the level of output that firms produce. Worse yet, the AD/AS model argues that if the price level is above its equilibrium value, then there will be an excess supply of goods. How can that be when the aggregate demand curve is derived with the assumption that the goods market is in equilibrium?

One cannot argue that the aggregate demand curve is a notional demand curve akin to a market demand curve, where the relationship between price and quantity demanded is hypothetical. Instead, the aggregate demand curve shows us what the *market clearing* level of output is at various price levels. And if the market is clearing, there cannot be an excess supply. This inconsistency is the primary reason that prominent macroeconomist Robert Barro (1994) said that the model is "unsatisfactory and should be abandoned as a teaching tool" (p. 1).

David Colander (1997) argues that the aggregate demand curve should be called the *aggregate equilibrium demand curve* so that its nature is apparent to students and professors alike. He goes so far as to say that the aggregate demand curve was deliberately named incorrectly in order to mislead students into thinking that macroeconomics was nothing more than "big micro."

Colander also argues that an aggregate supply curve may not exist for the same reason that a supply curve does not exist in an imperfectly competitive market. In such markets, output decisions cannot be separated from demand. A price-setting firm must choose price and output at the same time and cannot do so without reference to demand. Colander argues that most firms charge a markup over cost, and the amount they produce is based on expected demand. It is therefore impossible to create a supply function independent of the demand function.

The fundamental point is that in a Keynesian short-run world, output adjusts to clear markets. In a neoclassical long-run world, prices adjust to clear markets. The AD/AS model is an attempt to have it both ways. In it, price-level changes work to equate the quantity of real GDP demanded and supplied even in the short run. To do so, there must be separate supply and demand functions. But if Keynes and Colander are correct, one cannot separate production decisions from demand.

## Conclusion

In a famous article, Friedman (1953) argued that the real test of a model is how well it predicts. As noted previously, the AD/AS model became popular primarily because it correctly predicted the effects of the price shocks of the 1970s. It also does a pretty good job of predicting how shocks to the economy affect real GDP. But the model predicts that a decrease in aggregate demand or an increase in aggregate supply will reduce the price level, and that has not happened in the United States for over 50 years. Certainly aggregate demand has fallen and aggregate supply has increased in the last half century. Defenders of the model argue that what the model is really saying is that such events put downward pressure on the price level, so that the rate of inflation will decrease. Yet that begs the question as to why the model has the price level on the vertical axis instead of the inflation rate.

Models with the inflation rate on the vertical axis exist and occasionally appear in textbooks (Jones, 2008; Taylor &

Weerapana, 2009). These models typically derive the aggregate demand curve from a monetary policy rule (Taylor's rule) that describes how the central bank reacts to changes in the inflation rate. As the inflation rate rises, the central bank increases the nominal interest rate by more than the rise in the inflation rate. The effect is to increase the real interest rate, which reduces the real volume of spending. The approach avoids the problems with the aggregate demand curve discussed previously. John B. Taylor and Akila Weerapana's model has no aggregate supply curve. Instead, the microfoundations of price setting are discussed for the purpose of emphasizing how inflation is self-perpetuating in the short run. Charles Jones uses a variant of the Phillips curve as an aggregate supply curve. Critics of these models complain that they lean too heavily on a policy rule that may not always exist. Yet all models ultimately depend on specific institutions (such as property rights) and habits of thought. To look for a macroeconomic model devoid of an institutional foundation is to look for a chimera.

The fundamental problem is that the macroeconomy is a dynamic, complex thing. Static models cannot capture its nuances. A model simple enough to teach to undergraduates is bound to have flaws; in teaching, there is always a trade-off between accuracy and accessibility. The real question then becomes the extent to which the model convinces students of things that are not true.

Thomas Kuhn (1962/1996) famously observed that displacing well-entrenched theories is never easy. For one thing, the need for an alternative is not always clear to most scientists, and some actively suppress any heresies. It is safer to go along with the conventional wisdom. For a new approach to succeed, it must be clearly and demonstrably superior. If the AD/AS model is ever to be replaced, its critics must develop superior alternatives.

# IS-LM Model

Fadhel Kaboub
*Denison University*

The birth of modern macroeconomics is often credited to John Maynard Keynes (1881–1946) and his classic 1936 book *The General Theory of Employment, Interest and Money.* Keynes's agenda in 1936 was twofold. First, he wanted to save the discipline of economics from being completely dismissed and ridiculed by policy makers and by the general public who were fed up with the neoclassical laissez-faire policy advice that dominated the Great Depression era of the 1920s and the 1930s. Second, Keynes feared the rapid political shift to the far left in Western Europe and the growing sympathy for and admiration of the ideals promoted by communism, not just by the working class but by a certain segment of the bourgeoisie. As a matter of fact, Keynes was rushing to publish his *General Theory* in order to provide a plausible explanation for the Great Depression and lay out an effective policy response to bring capitalist societies back on the road to economic prosperity. In seeking to achieve these two goals, Keynes had to completely divorce himself from the neoclassical theoretical apparatus that had paralyzed the economics profession during the Great Depression. The ensuing Keynesian revolution has brought forward (a) the theory of effective demand, (b) the concept of quantity adjustment rather than price adjustment, and (c) an explicit treatment of the time-dependent concepts (uncertainty about the future, speculation, "animal spirits").

Keynes's work sent a shockwave through the economics profession and was met with a lot of resistance by the gatekeepers of the economics discipline. Some younger economists, however, received Keynes's work with a lot of enthusiasm and support, but many of them could not help but interpret it by using the neoclassical theoretical framework that had been engraved into their brains. Therefore, the Keynesian revolution was quickly reincorporated into the neoclassical framework that Keynes sought to destroy.

In 1937, just a little over a year after the publication of the *General Theory,* Sir John H. Hicks (1904–1989) published one of his most famous articles, titled "Mr. Keynes and the 'Classics': A Suggested Interpretation." This article was first presented in September 1936, as an attempt to explain Keynes's theory to econometricians and mathematical economists. The outcome of this article turned out to be the dominant macroeconomic model until the mid-1960s: the IS-LL model, which later became known as the IS-LM model. Hicks's interpretation of Keynes became a classic textbook section in all macroeconomics textbooks and an essential tool for policy analysis for several decades. The model, however, was far from being faithful to Keynes's economic analysis, and it soon came under harsh scrutiny by post-Keynesian economists. By 1980, just 8 years after winning the Nobel Prize in economics, Hicks admitted that there were major flaws in his model and accepted the post-Keynesian critique. The IS-LM model soon lost its premiere position in academic research but remained a classic textbook exercise in intellectual gymnastics and an easy tool to communicate policy advice to policy makers.

This chapter aims at presenting the history of the development of the IS-LM model, its theoretical formulation and policy applications, the critiques of the model, and the direction taken by the economics profession after the demise of the IS-LM model.

## The Essence of Keynes's *General Theory*

To be able to understand the development of the IS-LM theory, one has to understand the basics of the revolutionary theory that Keynes introduced to the discipline of economics in 1936. Only then can one understand the context in which

Hicks worked to develop the IS-LM model. For Keynes, economic growth is driven by effective demand, investment is driven by expectations about future profits, and money is not neutral.

Unlike neoclassical economics where economic agents operate in notional or theoretical time, in the Keynesian model, economic agents operate in real historical time (minutes, hours, days, years, etc.) under conditions of uncertainty in which the future is unknowable and the past is unchangeable. Faced with such an environment, individuals make arbitrage decisions with regard to which assets they wish to hold over time. Each asset gets a return composed of four components: $q - c + l + a$, where $q$ is the expected yield, $c$ is the carrying cost, $l$ is the liquidity premium, and $a$ is the appreciation or depreciation.

At equilibrium, all assets earn the same expected return. If an asset has a demand price higher than its supply price, then firms will produce more of it, but as its production increases, its rate of return will fall and becomes equal to the rates of return of all other assets. When consumers and firms are optimistic about the future and feel confident about their financial situation, the expected returns on capital equipment rise above the expected return on money (i.e., the interest rate), which leads to an increase in investment, thus boosting output and employment. Conversely, when the economy is overtaken by pessimistic expectations, consumers and firms prefer to remain liquid, thus abstaining from spending on consumption and investment goods, which leads to a rise in unemployment. The business cycle is therefore driven by these waves of optimistic and pessimistic expectations.

According to Keynes, unemployment is due to money's very specific nature as the most liquid asset in the economy with a near-zero elasticity of production, small elasticity of substitution, and no carrying cost. In other words, when people want to hold more money (liquidity), no significant amount of labor is directed to producing it, unlike capital equipment, which, when it is in high demand, requires additional labor input to produce it. Therefore, Keynes's conclusion was that an environment must be created that is conducive to more investment and less hoarding of money. Hence his three policy recommendations: (1) "parting with liquidity" (giving up liquid assets in exchange for employment-creating illiquid assets), (2) "euthanizing the rentiers" by lowering the interest rate so much that nobody will find it profitable to save money (because expected returns on money are less attractive than expected returns on capital), and (3) "socializing investment" through the creation of a new kind of capitalist culture of cooperation between private and public authorities (Keynes, 1936, chap. 24).

One would expect that an accurate interpretation of Keynes's theory would remain faithful to the above basic principles. Joan Robinson argued that Keynes "was himself partly to blame for the perversion of his ideas" (Robinson, 1962, p. 90) and that he "himself began the reconstruction of the orthodox scheme that he had shattered" (Robinson, 1971, p. ix). Robinson was referring to Keynes's last chapter in the *General Theory,* where he argued that "if our central controls succeed in establishing an aggregate volume of output corresponding to full employment as nearly as practicable, the classical theory comes into its own again from this point onwards" (Keynes, 1936, p. 378). This statement in the *General Theory* led many to believe that Keynes was admitting the validity of neoclassical theory and its general applicability. However, what Keynes meant was that once full employment is achieved through government spending, the neoclassical "special case" would be valid because neoclassical theory assumes that the economy operates at full employment. Hicks's interpretation of Keynes's work was capable of incorporating some of Keynes's conclusions in a very clever way but still managed to validate some of the basic neoclassical principles. That is what led to the creation of the so-called neoclassical-Keynesian synthesis school of thought.

## Development of the IS-LM Model

When Keynes wrote the *General Theory* in 1936 he was launching an attack against the "classics," by which he did not mean the classical political economy of Adam Smith, William Petty, James Mill, David Ricardo, Thomas Malthus, and Karl Marx but rather the neoclassical school of thought of John Stewart Mill, Leon Walras, Carl Menger, William Stanley Jevons, Alfred Marshall, Francis Y. Edgeworth, and Arthur C. Pigou. Keynes's contribution recognized that capitalist economies do not have any natural tendencies to stabilize at full-employment equilibrium, but instead the system is driven by destabilizing forces that push the economy into a downward spiral if the government does not intervene to alleviate unemployment.

According to Keynes, economic recessions and depressions are due to the lack of effective demand. His analysis highlighted the importance of uncertainty and expectations to the determination of the level of economic activity. In real historical time (minutes, days, and years, as opposed to notional or analytical time), the past is unchangeable and the future is unknowable; therefore, both consumption and business investment decisions are made under conditions of uncertainty. Spending decisions always depend on future expectations. A wave of positive expectations about the future will lead to an increase in business investment, which increases output, income, and employment. For Keynes, the economy moves from one equilibrium point to another through a process of quantity adjustment rather than price adjustment. The neoclassical price mechanism (prices, wages, and interest rates) plays no role in the Keynesian system. Prices are administered through relative market power relations rather than perfectly competitive market conditions. Furthermore, Keynes argued that recessions are not to be blamed on the lack of price flexibility.

If anything, price rigidity helps prevent an acceleration of the downward spiral during bad economic times.

Keynes's approval of Hicks's interpretation of his work was primarily based on the fact that the IS-LM model was able to capture the importance of effective demand, the possibility of underemployment equilibrium, and the important role of fiscal policy to achieve and maintain full employment. That was sufficient for Keynes to publicly recognize Hicks's work as a step in the right direction, even though he criticized the IS-LM model in private communications and thought that it was too simplistic to capture the complexities of economic reality.

The IS-LM model starts with Keynes's rejection of the "classical dichotomy" theory that supports the neutrality of money. Keynes argued that changes in the quantity of money will have a real impact on the quantity of output, income, and employment. There is an inevitable interaction between the monetary and the real spheres. Therefore, Hicks (1937) argued that it is necessary to solve for the money and real markets simultaneously. The IS-LM model is essentially the superposition of two curves: the LM curve, which is derived from the money market, and the IS curve, which is derived from the goods market.

The equilibrium condition in the goods market is $S = I$ (saving = investment), and the equilibrium condition in the money market is $L = M$ (money demand = money supply). The basic equations of the IS-LM model are defined as follows:

$$S = a + bY + c\,i. \tag{1}$$

$$I = d + eY + f\,i. \tag{2}$$

$$L = A + BY + C\,i. \tag{3}$$

$$M = M_0. \tag{4}$$

*a:* autonomous savings ($a < 0$)
*b:* marginal propensity to save ($b > 0$)
*c:* interest elasticity of savings ($c > 0$)
*d:* autonomous investment ($d > 0$)
*e:* marginal propensity to invest ($e > 0$)
*f:* interest elasticity of investment ($f < 0$)
*A:* autonomous demand for money ($A > 0$)
*B:* transactions demand for money ($B > 0$)
*C:* speculative demand for money ($C < 0$)
*M:* exogenous money supply determined by the central bank
*Y:* aggregate output and income
*i:* interest rate

To solve for the IS-LM equations, we set $I = S$ and $L = M$, and then we solve for the IS and LM equations. The resulting equations are the following:

$$i_{IS} = \frac{(d-a)}{(c-f)} + \frac{(e-b)}{(c-f)} \bullet Y. \tag{5}$$

$$i_{LM} = \frac{(M-A)}{C-(B/C)} \bullet Y. \tag{6}$$

Finally, to solve for the equilibrium level of interest rate ($i^*$) and the equilibrium level of output and income ($Y^*$), we have to set $i_{IS} = i_{LM}$ and solve for $Y^*$, then plug the $Y^*$ value into either Equation 5 or Equation 6 to find the $i^*$ value.

$$i^* = \frac{(M-A)(b-e) - B(d-a)}{B(f-c) + C(b-e)}. \tag{7}$$

$$Y^* = \frac{(M-A)(c-f) - C(d-a)}{B(c-f) + C(e-b)}. \tag{8}$$

Equations 5 and 6 allow us to plot a downward-sloping IS curve and an upward-sloping LM curve. However, the downward slope of the IS curve is possible only under the condition that the marginal propensity to save is greater than the marginal propensity to invest ($b > e$). Assuming that $b$ is greater than $e$, the resulting IS-LM model gives us the equilibrium level of interest rate ($i^*$) and the equilibrium level of output and income ($Y^*$). This equilibrium solution must have four characteristics:

1. it must exist (i.e., the IS and LM curves must intersect),
2. it must be unique (i.e., the IS and LM curves must intersect only once),
3. it must be positive ($i^* > 0$ and $Y^* > 0$), and
4. it must be stable (i.e., any shock to the system produces temporary disequilibrium and an eventual return to the equilibrium point).

In the goods market, the investment demand function is negatively related to the interest rate. A fall in the interest rate will result in an increase in the demand for investment, leading to an increase in the level of output (income) and employment through the multiplier effect. The IS curve is steep when the investment demand function is interest inelastic, and it is flat when the investment demand function is interest elastic. It is noteworthy here to mention that the full employment level $Y_f$ is generally higher than the equilibrium level of output $Y^*$. Contrary to the neoclassical model, there are no inherent mechanisms to ensure that the equilibrium level of output would coincide with the full employment level. Therefore, under normal conditions, the economy will be sustained at the underemployment equilibrium.

The IS curve represents the equilibrium locus that captures the relationship between the interest rate and output levels. As the interest rate rises, investment falls and so does disposable income, and thus the equilibrium level of output $Y^*$ declines. Therefore, the IS curve is downward sloping: High interest rates are associated with low-equilibrium output $Y^*$, while low interest rates are associated with high $Y^*$. This is, in fact, an equilibrium locus and not a curve, which means that at any point on the IS curve, the goods market clears (neither excess supply nor excess demand). The multiplier dynamic ensures that at any point not belonging to the IS curve ($Y > Y^*$ or $Y < Y^*$), there will be an automatic return to the equilibrium locus. Thus, points to the left of the IS curve represent situations of excess demand for goods, whereas points to the right of the IS curve represent situations of excess supply of goods.

What Keynes meant by using the term *General Theory* in the title of his book is that neoclassical economics is a "special case" in which the economy settles at a full employment equilibrium, whereas his theory explains the "general case" where the economy could be at equilibrium at any level of employment, but with a general and most likely situation of unemployment—hence the concept of "underemployment equilibrium." In trying to make this argument, Keynes had to launch a direct attack on neoclassical economics and its leading advocates, including his own professor, Arthur C. Pigou (1877–1959). According to Hicks, Keynes was wrong in claiming that the classics had no theory of money, wages, and employment. In other words, Keynes rejected the classical dichotomy between the real and monetary spheres. Hicks went even further to argue that Keynes's theory and the classical theory are both special cases. The Keynesian theory could be represented by a horizontal LM curve, in which case an increase in aggregate demand would shift the IS curve to the right, thus leading to an increase in output and employment without increasing interest rates or prices. The classical model, however, could be represented by a vertical LM curve at the full employment level, in which case any increase in aggregate demand would only lead to inflation and higher interest rates because the economy is already operating at the full employment level.

Hicks's IS-LM model generalized Keynes's *General Theory* and argued that the classical model is a special case of an economy operating at full employment, but also Keynes's theory is a special case of a Great Depression economy. The IS-LM model, however, is a more general theory as it shows the operation of the economy under normal circumstances (neither a depression nor full employment) with an upward-sloping LM curve, in which case an increase in aggregate demand would lead to a simultaneous increase in output and employment, as well as interest rates.

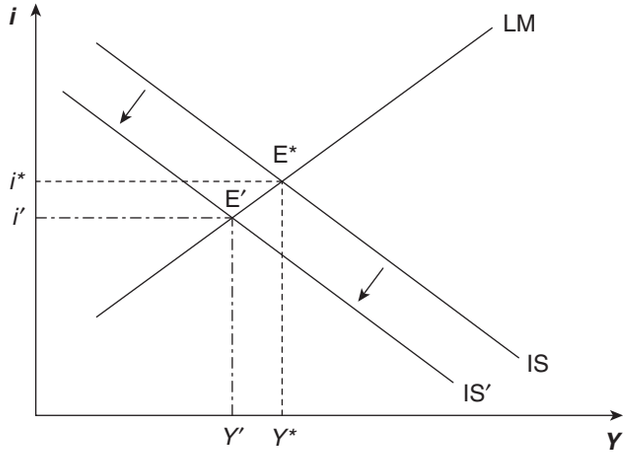

**Figure 33.1** The IS-LM Diagram

## IS-LM Policy Analysis

A major reason for the popularity of the IS-LM model from the late 1940s until the mid-1970s was its easy and convenient application in the study of alternative policy scenarios. For instance, one can easily find the impact of an increase in consumer thriftiness on the overall level of income, output, and employment. Following the IS-LM mechanism, a sudden increase in consumer thriftiness, meaning an increase in the marginal propensity to save *b*, results in a decrease in the production level *Y*, leading to a decrease in the employment level. Furthermore, as a result of the interaction of the Keynesian multiplier and the accelerator, an increase of the intended saving supposedly may result in a decrease of the actual saving. This phenomenon is known as the paradox of thrift.

Many years after the introduction of Hicks's IS-LM model, which was the first misinterpretation of Keynes's *General Theory,* Franco Modigliani (1944) revised the standard model in his PhD dissertation written under Jacob Marschak at the New School for Social Research. He proposed to add to Hicks's model the missing labor market and production function equations. As a matter of fact, Modigliani imposed the labor market-clearing assumption when he defined the labor supply function as a function of the real wage. He showed that when this assumption is added, the IS-LM model results in a price elasticity of money supply equal to 1. He concluded that money is *completely neutral,* as neither the interest rate nor the employment and output levels are affected by an increase in the money supply. In short, he established that the neoclassical results can be derived from a seemingly Keynesian-like set of equations. Modigliani's results were expected because he assumed that the labor market would reach full employment, an assumption that goes against the essence of Keynes's analysis.

In the next step of his analysis, Modigliani ran his model again without the market-clearing assumption and with the assumption of rigid money wages. His results showed that the price elasticity of the money supply is less than 1. Furthermore, an increase in the money supply results in a decrease in the interest rate and an increase in both employment and output levels to the full employment level. Therefore, he concluded that money is *not neutral* and that Keynes's conclusions are now restored. Modigliani's conclusions were adopted during the 1950s and early 1960s by the conventional wisdom of the economics discipline, which is essentially a "synthesis" of neoclassical and Keynesian theory, where the results of the model in a "perfectly working" IS-LM model (i.e., in the long run) are neoclassical (i.e., full-employment equilibrium). In an "imperfectly working" IS-LM model (i.e., in the short run, money wages are rigid), however, the Keynesian conclusions are restored.

Robert W. Clower (1965) and his student Axel Leijonhufvud (1967) launched a significant attack against

the standard IS-LM presentation of Keynes's theory and started the so-called disequilibrium[1] Keynesianism movement. Both Clower and Leijonhufvud believed that the disequilibrium situation (i.e., unemployment and effective demand failure) is the result of information and coordination deficiencies.

The IS-LM model, according to Leijonhufvud, has also a fundamental weakness, causing a terrible misinterpretation of Keynes's *General Theory*. Both Keynes's model and the IS-LM model have five goods in the system (consumer goods, capital goods, labor, money, and bonds). To solve for the three relative prices (i.e., the overall price $p$, the real wage $w$, and the real interest rate $i$), the models assimilate one good into another. The IS-LM model combines consumer goods with capital goods (commodities), whereas Keynes's model, according to Leijonhufvud, combines bonds with capital goods (nonmoney assets). This is a major difference between Keynes and the IS-LM Keynesians in the aggregative structure of their models.

In the neoclassical approach, there is only one kind of output and one price for it. However, in Keynes's model, there are two kinds of output: consumption goods and investment goods. Along with the two kinds of output come two completely different price systems: a price system for current output and a price system for capital assets, the price of which is crucial in the determination of the level of investment that will take place. The interplay between these two price systems determines the level of investment and, through the multiplier, determines the level of output and employment. Unemployment results when the two price systems fail to generate a set of prices that is consistent with the full employment level of production (i.e., either the demand price of capital assets is too low or the supply price of capital assets is too high).

The more headway the IS-LM made into economics textbooks and economic policy circles, the more scrutiny and criticism it drew from the followers of Keynes who tried to remain faithful to his theoretical analysis and to vindicate his theory from all the misuse and abuse brought by the so-called IS-LM textbook Keynesians, or "bastard Keynesians," a term used by Joan Robinson to refer to economists who do not know whether the father of their theories is Keynes or Marshall. The following is a summary of the main points of criticism made by post-Keynesians such as Joan Robinson, Richard Khan, Hyman Minsky, Paul Davidson, and Sidney Weintraub, to mention a few.

The downward slope of the IS curve is possible only under the condition that the marginal propensity to save is greater than the marginal propensity to invest ($b > e$). The most reasonable assumption, however, would suggest the exact opposite. That is to say that for most industrialized economies, the marginal propensity to invest should be greater than the marginal propensity to save, especially under a very sophisticated banking system. An upward-sloping IS curve could result in the violation of some of the equilibrium conditions. An upward-sloping IS curve may not intersect with the LM curve in the first quadrant, or it may intersect with the LM curve twice if there is a liquidity trap (i.e., in the horizontal section of the LM curve). This would violate the existence and the uniqueness conditions of the equilibrium solution in the IS-LM model.

In closing his 1937 article, Hicks recognizes some limits to his general theory—namely, the fact that most variables would remain indeterminate as long as income and distribution are unknown. He also admitted that depreciation and the timing of processes are neglected in his analysis as well. By 1976, Hicks grew more dissatisfied with the IS-LM model. In his seminal article "Some Questions of Time in Economics" (1976), he recognized the importance of the irreversibility of time. He argued that Keynes's theory was a hybrid one that is divided in two parts, one "in time" and another "out of time." Keynes's theory of the marginal efficiency of capital and his liquidity preference theory are "in time" because they are forward-looking concepts that integrate the irreversibility of time and fundamental uncertainty about the future. Keynes's multiplier theory, as well as the theory of production and prices that it implies, however, is a theory "out of time." It is a theory that runs in terms of supply-and-demand curves like the old tools of neoclassical equilibrium analysis. A state of equilibrium is by definition a state in which nothing relevant changes, and hence time is put aside. Hicks conceded that his IS-LM model has reduced Keynes's *General Theory* to equilibrium economics, even though Keynes himself did not wholly disapprove of the original IS-LM interpretation.

In another seminal article published in 1980–1981, Hicks tried to distance himself from his original 1937 theory and provided a very candid assessment of the IS-LM model. He argued that there are great similarities between his work and that of Keynes prior to the publication of the *General Theory*. They have both worked on the behavior of the economy "during a period that had a past" (i.e., in real historical time). Hicks also argued that there are some differences that he did not explicitly mention in his earlier articles. First, the IS-LM model is a flexible price model with perfect competition, while Keynes's theory is a fixed price model that is consistent with unemployment. Second, both models are in the short run, but Hicks's model is an ultra-short-run model ("one week"), while Keynes's is a "one-year" model.

More than four decades after the birth of the IS-LM model, Hicks brought two major critiques of his own work in another showcase of his intellectual honesty. Hicks admitted that the absence of the labor market and the lack of dynamics in the IS-LM model constitute two major weaknesses in his theory. He explained that in Keynes's model, there is a possibility of unemployment even when all markets are in equilibrium. He also argued that even though the labor market does not exist in the IS-LM model, a labor market that is in disequilibrium can be

added to the model without leading to inconsistencies with the Walrasian framework.

Regarding the concept of time, Hicks argued that time has not really been entirely neglected in the IS-LM model, but it is rather the flow of time within a period that has been ignored. He also recognized the problems caused by superimposing a stock (in the LM curve) and a flow (in the IS curve) where IS-LM draws an instantaneous equilibrium between a stock at time *t* and a flow at a period of time. The solution to this problem according to Hicks would be to maintain a stock equilibrium over the period that implies a flow of equilibrium over the period. That is to say that stocks rolling over time would be assimilated to a flow. As a result, Hicks found himself in a deterministic model where there is no place for uncertainty and therefore no room for a liquidity preference theory. To fix this problem, Hicks invented a pseudo-deterministic model where the variables would fall within a particular range. Thus, the equilibrium would fall within the expected range.

In the end, Hicks concluded that the IS-LM model should not be such an important policy tool but rather simply a model that will explain economic conditions in a static way, knowing that the future is unlikely to be well predicted.

Despite all the weaknesses highlighted above, and despite the fact that all economists today recognize and accept the nonvalidity of the IS-LM model, we still observe the presence of the IS-LM model as a standard section in every single intermediate macroeconomics class taught in the United States. Students are often confused as to why they are asked to study a model that has been proven to be theoretically flawed and is considered useless for policy analysis. Most economists still teach the IS-LM model because of the following three reasons.

The model serves as a good pedagogical tool to improve the students' analytical skills and graphical analysis, preparing them for the more advanced mathematical models that they will encounter in graduate school.

Most undergraduate economics instructors teach the IS-LM model, so it is considered unfair to students not to familiarize them with it in case they decide to pursue a graduate program in economics where they would be expected to be familiar with the model.

The IS-LM model has been taught as a standard model for decades, which means that nearly all policy makers in Washington, D.C., have become familiar with it over the years as a standard tool that economists use to communicate their policy advice. Economists today use mathematical models that have nothing to do with the IS-LM analysis, but they still use a simple IS-LM presentation to communicate their results and policy recommendations to policy makers who lack the sophisticated training that it takes to be able to understand the new and more advanced mathematical models.

Despite the general consensus among economists about the demise of the IS-LM model, it is still common to find no reference to any critiques of the model in undergraduate textbooks or class discussions. Students typically find out about the model's weaknesses when they take a graduate course in macroeconomics or when they take a history of economic thought course at the undergraduate or graduate level.

## Conclusion

The IS-LM model developed by Hicks (1937) and later popularized by Paul Samuelson (1948) and Alvin Hansen (1953) has provided an extremely useful diagram that explains how the economy operates and how it could be managed to reach the full-employment equilibrium through the different fiscal and monetary policy adjustments. There is no doubt that the IS-LM model is the most popular macroeconomic model used in textbooks because it was extremely efficient as a pedagogical tool.

Like most mathematical models, however, the IS-LM model should be taken with a fistful of salt. It is a simple model that superimposes equilibrium in the goods market with equilibrium in the money market to produce a general macroeconomic equilibrium for the economy as a whole, with an equilibrium interest rate and an equilibrium level of aggregate output and employment. The model was able to explain the possibility of unemployment equilibrium, which was one of Keynes's most important arguments in the *General Theory*. This was sufficient for Keynes to approve of Hicks's work and to write him a letter saying that he "found it very interesting and [that he] really [has] next to nothing to say by way of criticism" (Keynes, 1937). Keynes of course knew the weaknesses of the IS-LM model and how far it stood from his *General Theory,* but he was willing to accept it as a strategy to make the economics profession accept the fact that markets do not self-adjust and that there is a necessity for government intervention to achieve full employment.

Keynes's followers (and eventually Hicks himself) laid out the key criticisms that brought the IS-LM hegemony to an end. The model conflates short- and long-term interest rates, conflates stocks with flows, ignores the importance of uncertainty and investor's expectations in determining business cycle fluctuations, and reintegrates the price mechanism back into a seemingly Keynesian model. The economics profession has moved far beyond the limits of the IS-LM model since the 1980s, but the traditional IS-LM way of thinking about the economy has remained a habit of thought in every economist's mind to this day, not necessarily in mathematical form but at least in spirit.

## Note

1. Clower and Leijonhufvud argued that Keynes had a disequilibrium approach instead of an equilibrium approach. When Keynes used the term *equilibrium,* he did not mean the same thing as the neoclassical approach, where equilibrium means that prices adjust so that all markets clear. When Keynes used the term *equilibrium,* he meant that there are no forces to cause further movements (markets might not clear). Thus, in Keynes's

theory, unemployment is an "equilibrium" in the sense that there are no forces to cause employment to increase. Clower and Leijonhufvud thought that this is disequilibrium because they used it in the way that the neoclassicals used it.

*Author's Note:* The author thanks L. Randall Wray for comments on an earlier draft of this chapter and one anonymous referee for helpful suggestions. Rana Odeh provided invaluable editorial assistance.

# Economic Instability and Macroeconomic Policy

John Vahaly
*University of Louisville*

Macroeconomic instability and the business cycle are generally understood as changes in output or gross domestic product (GDP), unemployment, and inflation rates. The economy has a long-run growth path that is subject to short-term macroeconomic demand and supply shocks that push GDP away from its long-run potential or trend growth rate. Smith and the classical tradition that followed believed a hands-off approach was the correct policy stabilization to pursue when such short-term output disturbances arose. This reflected classical emphasis on long-run growth as a supply process that was best left to private entrepreneurial activity. Furthermore, private market economies would automatically self-correct through appropriate wage and price adjustments. Recessions, characterized by "gluts" of commodities and workers, would produce downward pressure on market prices and wages. Deflation continued until the economy had returned to full output.

Prior to the twentieth century, the classical school's reliance on self-correcting private markets, a commodity gold standard, and promotion of free trade broadly defined macroeconomics. Fiscal policy was viewed as the means by which government provided necessary public goods and services, with deficit spending occurring because of either war or weakness in the economy that lowered government tax receipts. Monetary policy for the United States, operating without a central bank until 1914, similarly was not considered a macroeconomic stabilization tool. Financial difficulties before and during the Great Depression were to change that.

## The Creation of the Federal Reserve System

Modern study of economic instability in the United States begins with the Great Depression. Prior to the 1930s, economists treated macroeconomic instability as a difficulty best resolved by private markets. Indeed, the U.S. financial system had even operated for most of the pre-Depression period without a central bank. There had been two experiments with a Bank of the United States but, for a variety of reasons, neither survived its initial 20-year charter. During the nineteenth century, the United States had experimented with a number of currency and banking regimes. With the gold standard officially adopted in 1900, the United States entered the new century without a central bank. The next financial panic in 1907 convinced Congress that the economy did need a central banking authority to ensure the soundness of the country's banking system. The Federal Reserve Act of 1913 created a system of 12 regional Federal Reserve Banks, with the New York bank assuming control of monetary policy. The U.S. banking system now had a lender of last resort.

## The Great Depression and the Origin of Macroeconomics

The causes and consequences of the Depression continue to be debated. A recession started in the summer of 1929 that was soon followed by the start of the collapse of the

U.S. stock market. In 1930, the United States decided to raise tariffs, soon matched by trading partners, in a mistaken attempt to protect import-competing jobs. More important, the United States experienced a series of financial panics and bank runs that would culminate with a bank holiday in 1933 as the newly elected President Roosevelt closed all banks to end withdrawal of money from the economy. Set up as a result of the financial panic of 1907, the Federal Reserve failed during its first major financial crisis.

This was understood by John Maynard Keynes in Great Britain. The Keynesian approach to dealing with the economic problems of the 1930s, both for Britain and the United States, was to rely on new deficit spending to make up for inadequate private sector spending by consumers and businesses. In the United States, policy emphasis on using fiscal policy was to continue for decades to come. This reflected a major concern with expansionary monetary policy: There might be inadequate demand for newly created bank reserves arising from Federal Reserve open-market bond purchases.

Keynesian theory, originally a depression-economy model, emphasized short-run demand stabilization through fiscal policy using either new government spending or deficit-financed tax cuts. The basic idea was to supplement private consumer sending (C) and business investment spending (I) with either direct government spending (G) or tax cuts (T in dollars or t in tax rates). Keynes explained how a fiscal stimulus, by increasing autonomous spending, would increase GDP by a multiple of the new deficit spending. The year following publication of Keynes's *General Theory,* economist John Hicks expanded Keynesian analysis to explicitly include a monetary sector and the interest rate. These additions made the Hicksian IS-LM model a standard part of macroeconomics. As with the Keynesian model, however, it was incomplete. It had no explicit means of analyzing either short-run supply or the price level. Because neither of these were problems in the 1930s, their omission is understandable. Subsequent macroeconomic events would remedy these shortcomings. Following the 1930s, however, the debate over countercyclical macroeconomic policy began in earnest.

## The Rise and Fall of the Keynesian Consensus, 1961 to 1973

The 1960 presidential election, at least in then–Vice President Richard Nixon's view, was determined by the 1960 recession. John F. Kennedy ran that year promising to enact a deficit-financed tax cut that would help restore full employment. Kennedy's victory brought the Keynesian "new economics" of activist demand management to the United States. The next recession was a decade away. Even the popular media in the 1960s wondered if the Keynesian macroeconomists who came to rise in 1961 with the new Kennedy administration had finally ended the business cycle. While economists debated its meaning and merits, Keynesian macroeconomics seemed to offer the option of fine-tuning the economy. Short-term demand management was explained as making a choice between relatively low unemployment but high inflation or relatively low inflation but high unemployment. This Phillips curve trade-off was the basis for the first ever governmental attempts at macroeconomic stabilization. Using the Keynesian spending (C + I + G) and the IS-LM models, Keynesians showed how monetary and fiscal policy could keep the economy on course. The 1960s was the longest economic expansion in U.S. history up to that time. However, as unemployment fell during the decade, inflation began rising and became a major domestic macroeconomic issue in the early 1970s.

## The Great Inflation, 1970 to 1981

From inflation rates of 1% to 2% in the early 1960s, an overheated U.S. economy was experiencing over 5% inflation by the end of the 1960s and into 1970. The U.S. economy had a relatively mild recession in 1970 with unemployment rising from a 1969 low of 3.4% to 6.1% by the end of 1970. As the economy slowed, it seemed reasonable to expect inflation to fall as excess demand was reduced. Somewhat surprisingly, inflation held steady. CPI inflation rose 5.5% in 1969 and was 5.7% in 1970 despite the weakening economy. Facing reelection in 1972, President Richard Nixon decided to impose a temporary 60-day wage and price freeze in August 1971.

The Nixon controls were an experiment with an incomes policy to deal with inflation. Largely voluntary, the Nixon program of two freezes and four phases of lessening degree of price and wage restraint was controversial. Predictably, shortages arose in a variety of markets, most notably in gasoline. However, President Nixon was reluctant to press for an alternative, which seemed to require monetary or fiscal restraint that might finally lower prices with the possibility of a worse recession during a presidential election. Mr. Nixon remembered the role a weak economy played in his 1960 election loss. A positive view of President Nixon's Phases I–IV controls was that they represented an attempt to help slow the wage–price spiral by signaling to U.S. business and workers that the federal government was going to reduce inflation by in essence making it illegal. Because the program was largely voluntary, it relied on a downward adjustment of inflationary expectations to ensure its success. People had to expect less inflation for a timely reduction in the wage–price spiral.

Unfortunately for U.S. efforts to lower inflation, other events interceded. In 1973, war in the Middle East resulted in an oil embargo engineered by the Organization of Petroleum Exporting Countries (OPEC) that had the

economic effect of quadrupling crude oil prices from $3 to $12 a barrel. Because oil is a primary source of energy, this meant demand increases for oil substitutes also pushed their prices upward, creating a major spike in energy prices. This adverse supply shock was a new challenge for U.S. policy makers. While even Mr. Nixon once famously declared "We are all Keynesians now," it was not clear to Keynesians what should be done about the effects of the adverse supply shock OPEC had created.

## Stagflation

In 1974, the U.S. economy did not seem to be operating according to the explanations of economists. The demand-side Keynesian model and its associated Phillips curve predicted two alternative economic states: excess demand (low unemployment and high inflation) or inadequate demand (high unemployment but low inflation)—the Phillips curve trade-off. But 1974 saw inflation rise from 6.2% to 11.0% while unemployment increased from 4.9% to 5.6% as the U.S. economy slipped into a recession. For 1975, the unemployment rate was 8.5%. A new term was coined by Paul Samuelson to describe this seemingly inexplicable situation—*stagflation.*

As these developments were unfolding in 1974, the previous decade's claims that the business cycle had been tamed were discarded. For policy makers, there were few options. Fiscal policy was effectively paralyzed in 1974 by the Watergate investigation. That shifted emphasis to the Federal Reserve (the Fed), then chaired by Arthur Burns. Chairman Burns was repeatedly asked by Congress and others to take action to rebalance the economy. Burns knew his options were limited to altering the money supply and credit conditions, which did not, and could not, reverse the impacts of the OPEC oil price shock.

Keynesian stabilization policies worked only on the demand side. Restrictive monetary policy could lower inflation, but the accompanying output decline would raise unemployment. The reverse was true for easy monetary policy that would push prices higher as unemployment fell. As stagflation pushed both unemployment and inflation higher, economists recognized the need to add short-term supply factors to macro models. These efforts created the aggregate demand and short-run aggregate supply model that illustrated the difficulties of the mid-1970s. The Phillips curve was also reinterpreted to include labor (supply-side) responses to inflation. But the new theory did not resolve the Fed's dilemma.

Bowing to the inevitable, the Fed first took action against inflation, and by 1975, it had dropped from 11% to 9.1% (5.8% in 1976). One economic cost of the Fed's action was the worst recession since the Depression. This contraction lasted from the fourth quarter 1973 (1973:4) to 1975:1, a 16-month recession that saw a 1975 monthly unemployment rate of 9.0%. Inflation had been reduced, but faith in fine-tuning the economy was one of the casualties.

## Stagflation: Part 2

In 1979, the United States had a new president, Jimmy Carter, but another supply shock. That year, OPEC again exercised its monopoly power and pushed crude oil prices over $30 a barrel. The impact in the United States was now predictable. In 1979, inflation averaged 11.3%, rising to 13.5% in 1980, a presidential election year. Unemployment also rose from 5.8% in 1979 to 7.1% in 1980 as the U.S. economy again slipped into a recession. Once again, the United States faced stagflation, but the numbers were bigger and uncertainty remained about what should be done about this situation.

The difficulty stagflation posed for the U.S. economy in the 1970s arose from its cause. Traditionally, inflation had been viewed as a problem of "too many dollars chasing too few goods." In the 1960s, the "too many dollars" or "too much spending" had raised demand-side inflation to over 5%. But the inflation problems in the 1970s arose from the supply side or the "too few goods" source of higher prices. It even appeared that causation was running in reverse as high inflation was causing the recession. As the energy price shock worked its way through the economy, nearly all prices were pushed up. U.S. consumers, no better off, could no longer afford what they previously purchased. GDP declined, causing unemployment to rise. By 1980, it appeared necessary to take some type of decisive action against the problem of double-digit inflation.

## The 1980 Presidential Election

With double-digit inflation as the major economic issue, incumbent Jimmy Carter and Republican nominee Ronald Reagan offered different policies to voters. Carter had appointed a new Federal Reserve chairman in 1979, Paul Volcker, in part to reestablish the Fed's credibility in dealing with excess inflation. Volcker knew this was his primary task. However, Mr. Carter did not want to put the economy through another long recession as had occurred during the 1973 to 1975 episode. Fed policy under a new Carter administration would be one of gradual monetary restraint to slow inflation.

Candidate Reagan offered something more appealing to voters. When running for his party's nomination, Mr. Reagan offered four economic platform promises: lower inflation, more jobs, a balanced federal budget, and an increase in defense spending (higher government spending, G). This was to be accomplished by a variety of initiatives, including market deregulation where possible and a major reduction in federal income tax rates. During the primaries, Reagan's rival but soon-to-be vice presidential nominee, George H. W. Bush, famously called the promise of a balanced budget with programs of increasing spending while cutting taxes "voodoo economics." The label that did stick to the Reagan program, however, was *supply-side economics.* This name came from the prediction

that lower federal income taxes would raise after-tax incomes for U.S. workers, thus encouraging additional work and more output. While the details were left unclear, Arthur Laffer produced a famous diagram that seemed to show that tax rate cuts, if they actually could boost work incentives, would eliminate the "too few goods" problem of inflation. The cure for U.S. inflation appeared painless.

Following the 1980 election, Congress and Mr. Reagan enacted the Kemp-Roth tax cut and began the defense buildup. The Federal Reserve, however, began ringing alarm bells. Volcker and many others viewed supply-side fiscal policy, whatever its ideological merits, as expansionary. Tax rate cuts coupled with significant government spending increases would increase the "too much spending" problem of inflation. Volcker concluded that expansionary fiscal policy would have to be offset by very restrictive monetary policy. In 1981, the Fed acted. Aggregate demand was reduced, as restrictive monetary policy more than offset the federal fiscal expansion. By 1982, inflation had dropped from 10.3% to 6.2% (3.2% in 1983). The cost of this success was another recession, this time even worse than the 1973 to 1975 slowdown, with unemployment reaching a monthly high of 10.8% in 1982. The 1981:3 to 1982:4 recession was the worst macroeconomic performance since the 1930s. A new term, *disinflation,* was coined to describe the successful lowering of inflation. Inflation had been lowered to 3% to 4% but would fall no farther in coming decades in part to avoid a repeat of the damage done by the 1981 to 1982 monetary restraint.

### The Great Bull Market and the Twin Deficits

As the U.S. economy started recovering from the 1981 to 1982 "Volcker Recession," the stock market also started to move up. The Dow Jones Industrials reached a low of 777 in August 1982. The subsequent recovery of the economy began a rise in equity values that was twice interrupted in the next 25 years. The first, "Black Monday" (October 19, 1987), occurred just as the Fed chairmanship changed from Paul Volcker to Alan Greenspan. The second and longer retrenchment was associated with the tech stock or dot-com bubble in 2000. From the 1982 low, the Dow rose to 11,722 by 2000, an increase of more than 1,500% over this 18-year period. The market subsequently dropped to 7,286 in October 2002. As the economy recovered from the 2001 recession, both the equity and housing markets moved toward historic highs. The Dow Jones reached this most recent high of 14,146 in October 2007. In the following year, the Dow Jones Industrial Average (DJIA) lost nearly half its value as the U.S. economy began a dramatic slowdown as the financial system entered a crisis period brought on by the housing market collapse.

In 1980, the U.S. national debt was $0.9 trillion, and the United States was the world's largest creditor nation. By the end of the decade, new deficit spending had raised the national debt to $3.2 trillion, and the United States had become the world's largest debtor country resulting from a decade of trade deficits. These two deficits are linked to saving rates in both the United States and abroad. Both debts would continue to expand after the 1980s.

## The 1990 to 1991 Recession and the Start of the U.S. Housing Boom

The U.S. economy did not fully recover from the 1981 to 1982 recession until the late 1980s. The monthly unemployment rate did not fall below 6% until September 1987 and did not reach 5% until March 1989. In 1990, however, the U.S. economy began to slow. One factor was a decline in the housing market following the collapse of the Savings and Loan banking sector. In the summer of 1990, unemployment started to rise, and by the end of the year, it stood at 6.3%. Officially, the recession started in July (1990:3) and lasted until March 2001, spanning 8 months. There would not be another recession for 120 months, the longest cyclical expansion in U.S. history.

The short-term policy response to the 1990 to 1991 recession was a gradual series of interest rate decreases under the guidance of Fed Chairman Greenspan, who had replaced Paul Volcker in 1987. The Federal Funds ("fed funds") interbank loan rate stood at 8% when the recession started in 1990. By the summer of 1991, it was 6%, falling to just 3% by the end of 1992. The Fed pursued gradual monetary ease to stimulate spending and help the economy recover.

This expansion also marked an increase in investment spending on the U.S. housing stock. What began as a typical housing recovery would later culminate in a speculative rise in U.S. housing prices. From 1991 through 1996, average U.S. housing prices rose at an annual rate between 2% and 4%, roughly matching inflation. From 1998 through 2006, the rate of increase doubled. At the end of the boom, housing price rises were 9% in 2004 and 2005. Once the bubble had burst, home prices rose a modest 3.3% in 2006 and fell –1.3% in 2007. The bursting of this asset price bubble was to have major macroeconomic consequences that were largely unforeseen.

## The Dot-Com Stock Market Bubble and the 2001 Recession

The DJIA reached its 2000 peak of 11,722 on January 14, 2000, falling to a low of 7,286 by October 9, 2002. This loss of financial wealth contributed to weakness in consumer spending. More important was the collapse of business investment spending, especially for computers and software, during 2001.

The 8-month 2001 recession ran from March until November of that year. In January 2001, the unemployment rate was a low 4.2%. Following the end of the recession, it peaked at 6.3% in June 2003. In response to this relatively slow recovery, the Fed once again adopted a policy of monetary

ease. 2001 started with the fed funds rate at 6%. It was progressively lowered to 1% by the summer of 2003 as the Greenspan Fed tried to move the economy back to full employment. By the summer of 2005, the unemployment rate had reached 5% as the Fed ended its policy of easy monetary policy. As 2005 began, the fed funds rate was 2.25% and would reach 5.25% in late 2006.

## The Collapse of the Housing Bubble

The National Bureau of Economic Research (NBER), established in 1920, dated a recession as starting in December 2007. The recognition of this downturn came in December 2008. This somewhat unusual delay was caused by the mixed signals being generated by macroeconomic aggregates. While real GDP grew for the first two quarters of 2008, total employment had peaked in December 2007 and fell thereafter. The employment data, and other economic indicators, convinced the NBER's Business Cycle Dating Committee that the actual recession had started December 2007.

As noted, the U.S. housing market began expanding following the 1990 to 1991 recession. The housing boom continued even during the 2001 recession with residential investment declining only in 2001:4, after the trough of the recession was reached. Home prices kept rising and even accelerated through 2005. Such asset price trends cannot be maintained, and the inevitable slowdown began in 2006. Home prices began falling as that sector was now characterized by both excess supply and falling demand. This had a variety of negative impacts on the economy, including a major decrease in financial wealth as the stock market plunged. The Dow Jones peaked at 14,164 on October 9, 2007. During 2008, the market lost one third of its value by this measure. Not only was financial wealth cut as equities dropped, but many now saw the value of their home falling as well. With this twin wealth shock, consumer confidence in the economy dropped to historic lows.

The business and financial sectors were also adversely affected. The construction industry was among the first casualties as new residential construction stalled. Worse, the financial system seemed unable to cope with the magnitude of the financial distress the collapsing housing bubble had produced.

The list of factors associated with the rise and fall of the U.S. housing market is remarkably long. Alan Greenspan acknowledged he had placed too much confidence in the self-regulatory character of complex financial markets and financial derivatives. While the boom unfolded, money was drawn to the United States from around the world. To finance the levitating housing market, first investment banks then government-sponsored enterprises (GSEs) Fannie Mae and Freddie Mac developed new sources of funding. First, this process relied on the selling of bundles of mortgages, or securitized mortgage debt, to investors eager to benefit from the housing boom. Given the demand for these mortgage-backed securities (MBS), it was not surprising loan standards were loosened as "subprime" or risky lenders were given mortgages that were quickly resold into an ever-growing mountain of paper wealth.

This expansion of housing credit occurred against a backdrop of financial deregulation, questionable rating of the risks associated with MBS and related financial contracts, complex financial investments that were usually marketed through in a lightly regulated "shadow banking system," charges of predatory lending and borrowing, and an apparent belief that the housing price rise was too good an opportunity to miss. There was also a government commitment to promote home ownership. Thus both Fannie Mae and Freddie Mac were encouraged to help provide the financing necessary to help people buy a home while the boom was in progress. Perhaps one positive, if transitory, benefit of the bubble was a 69.2% home ownership rate in 2004, the highest in U.S. history.

As the housing collapse started to have macroeconomic effects in late 2007, the economic impacts were historic. In 2008, the economy experienced the largest corporate bankruptcy in history (insurance company AIG), the largest bank failure in U.S. history (Lehman Brothers), and the largest Savings and Loan failure in U.S. history (Washington Mutual). All major investment banks failed, merged, or converted themselves into traditional deposit banks. Major U.S. commercial banks asked for Treasury funding support through new fiscal programs.

## Monetary Policy and the 2007 Recession

The macroeconomic policy response to this recession was unprecedented in its size and scope. Monetary policy in 2008, under Chairman Bernanke, was the most expansionary since World War II (WWII). The Fed's emphasis remained on the stability of the banking sector and to a lesser extent on inflationary concerns as total spending in the economy declined. As with Japan during the 1990s, concern was expressed over the appearance of deflation further reducing Fed worries over inflation.

Traditionally, monetary policy is first seen as the Federal Reserve Board, acting through the Federal Open Market Committee (FOMC), altering credit conditions in the economy using open-market operations. Predictably, following 9/11 and the 2001 recession, the Fed lowered the fed funds rate to 1% by mid-2003. Alan Greenspan, Fed chairman, made clear his policy goal was overall stimulus of the economy. However, 30-year fixed rate mortgage rates, which had been 8% in 2000, fell below 6% during the same period. Therefore, further stimulus was given to the U.S. housing market, whose growth appeared to be feeding on itself. By mid-2006, monetary restraint had pushed the fed funds rate back to 5.25%. Against this background, Greenspan was criticized for following traditional easy monetary policy in a weak economy that nonetheless was experiencing a residential and commercial real estate boom.

When the housing price bubble began to lose air in 2005 and 2006, the Fed began to take new and dramatic action. In December 2007, new Fed Chairman Ben Bernanke created the Term Auction Facility (TAF), the first of seven completely new lending operations that would provide liquidity (money) to a variety of financial institutions and markets that had stopped working efficiently. Lenders had decided to significantly reduce traditional lending as the "credit crunch" spread. There was no longer any market for MBS or other high-risk alternatives. The Fed even allowed short-term borrowing by financial institutions that were able to use some higher grade MBS as collateral and finally agreed to purchase some MBS itself. All through 2008, the Fed kept creating new auctions and programs of providing credit to the economy. The Fed also pursued traditional easy monetary programs. At the end of 2007, the Fed funds rate was 4.25%. By the end of 2008, it was 0% (officially a range of 0% to 0.25%).

The immediate question this zero-interest rate policy posed was, had the United States run out of monetary policy options just as the NBER announced a recession had started in December 2007? Certainly fiscal policy could be used to stimulate spending, but had monetary policy run aground?

While the Fed was lowering the nominal fed funds rate to zero, it simultaneously pursued a program of "quantitative" monetary ease. The Fed accomplished this in two ways. The first was continuation of traditional monetary expansion. The monetary base doubled in 2008, increasing from $855 billion in December 2007 to over $1,728 billion by December 2008. This expansion was not needed to lower the fed funds rate to zero; rather, its aim was to help recapitalize the U.S. banking system. Inflationary concerns were put on hold as the Fed kept adding to bank reserves. For the banking sector, this dramatically increased the bank holdings of excess reserves as the Fed kept adding liquidity to the economy.

The second policy still available to the Fed was to alter its holdings of U.S. Treasury securities. The Fed could provide additional monetary stimulus to borrowers by also lowering long-term interest rates. Buying long maturity Treasury bonds pushed up their prices, which pulled their yields or rates down, putting downward pressure on related long-term rates, mortgage rates in particular.

The issue of policy credibility was also important for the Fed's commitment to recovery. All through 2008, the Fed signaled that low interest rates and market support programs would be used as long as required by the economy. With support from fiscal policy actions, the Fed had embarked on the most expansionary policy in its history.

## Fiscal Policy and the 2007 Recession

Fiscal ease was viewed as an inevitable policy response to the same problems that preoccupied the Fed. Fiscal policy was used to help both the overall economy and financial markets and institutions. In early 2008, the Economic Stimulus Act of 2008 sent $150 billion into the private economy as temporary tax rebates. The worsening economy and the fact the tax change was temporary meant that much of this additional income was not spent by consumers. By the fall of 2008, fiscal action moved into new country as the Treasury Department asked for a total of $700 billion to assist the economy.

Fiscal policy embarked on programs that would produce $1 trillion deficits. Both stabilization policies tried to slow the economy's retrenchment following the collapse of the housing market. As in the 1930s, the major problem facing the U.S. economy was the potential collapse of its banking and financial sectors. The evolution of financial intermediation in the United States was thought to have been one of increasing sophistication that reduced risk while generating income. As noted previously, this view, widely expressed prior to the collapse of the housing market, was incorrect. Rather than reducing risk, debt securitization, related financial derivatives, and inadequate market supervision magnified the temptation to assume ever-growing risk. After all, the economy had grown for 25 years with no major economic difficulties. As with previous asset bubbles, the U.S. housing market boom did finally come to an end. The macroeconomic costs of repairing the damage done by this largest ever bubble will take years to complete.

## The U.S. National Debt and Foreign Trade Debt

While both monetary and fiscal policy were being used to offset spending declines arising from the 2007 recession, the twin deficits that emerged in the 1980s remain unresolved. Deficit spending, except for 3 years at the end of the 1990s, has continued. Given the combination of a weak economy and expansionary fiscal policy, deficit growth will accelerate. Thus, the short-term projection for the national debt is significant growth until full employment is restored.

The cause of the persistent trade deficits over the past quarter century arise from another domestic macroeconomic imbalance, here between saving and investment. U.S. national saving is so low that the United States must finance domestic investment spending with the help of foreign savings. Given expanding federal budget deficits, there is additional pressure on the trade deficit despite reductions in private investment spending for buildings and equipment. Most observers therefore conclude that U.S. trade deficits, and their financial liabilities, will continue until the U.S. saving rate can be increased. This adjustment can be done in an orderly fashion by promoting both private and public sector saving. It could also happen as a matter of economic necessity should the United States no longer be in a position to finance substantial federal

debt and private investment spending. That undesirable outcome is being considered if only to promote thinking about more desirable resolutions. Debt does not have to be zero, but it must be manageable.

## The Future of Macroeconomic Policy

The debate over stabilization policy displays its own cyclical features. The classical tradition of laissez-faire was displaced by the Great Depression and the demand management policies of *The General Theory*. Such countercyclical policies were applied in the 1960s when it almost seemed that the business cycle had been managed away. Theory lapses and supply shocks demonstrated the weaknesses of the Keynesian consensus in the 1970s. At best, "coarse tuning" was the new standard. A variety of new conservative macroeconomic schools emerged that encouraged reconsideration of the wisdom of laissez-faire policies for the business cycle. Despite academic debates about such issues, stabilization efforts continued after the 1970s. Volcker's Fed acted to slow inflation in the early 1980s, and Alan Greenspan's first challenge, the October 1987 stock market crash, saw the Fed act to prevent additional damage from this event. Greenspan continued to purse countercyclical policies in the two recessions that occurred during his tenure. Greenspan was even criticized for pursuing overly expansionary policies in 2003 to 2004 as the housing market boom continued. However, Greenspan said the error he made was in misjudging the stability and risk-management capabilities of financial markets. Furthermore, it was not clear that it was the Fed's responsibility to prevent the occurrence of asset price bubbles.

If anything, Bernanke's Fed has been the most active ever in dealing with the difficulties the U.S. economy was facing. Along with the recession, the Fed had to operate in an economy that was hit by a major equity-price shock as stock markets around the world dropped dramatically. For 2008, U.S. stock prices, as measured by the level of the Dow Jones Industrials, fell by one third. Across all equity markets, trillions of dollars of financial wealth were erased. This negative wealth effect affected private-sector consumer and business spending. Further eroding consumer confidence was the apparent fear of the federal government as it pushed for new emergency deficit spending to keep collapsing financial markets operating. The fiscal policy response was initially one of additional spending and tax cuts, and in relatively large amounts, before taking on regulatory reform. The combination of remarkably expansionary fiscal and monetary policy with structural reform of financial markets is being counted on to repair the damage from the greatest financial bubble in history. Macroeconomic events of the 1930s were somewhat similar, with financial turmoil, falling equity prices, and rising unemployment. It took the expansionary macro policies of WWII to finally pull the economy back to full employment. In 2009, such spending policies are in place because of the lessons of that era.

# Fiscal Policy

Rosemary Thomas Cunningham
*Agnes Scott College*

*Fiscal policy* refers to the government's use of spending and tax policies to influence the economy. When the government increases its spending for defense purposes or raises personal income tax rates, it affects the total level of spending in the economy and, hence, will affect the overall macroeconomic activity of a nation measured by such factors as gross domestic product (GDP), employment, and inflation. This is true for almost any change in spending or taxes. Any change in government spending or taxes will also affect the government's budget deficit. An increase (decrease) in spending or a decrease (increase) in taxes will increase (decrease) the government's budget deficit for a given state of the rest of the economy. Because the government must borrow by selling U.S. Treasury securities to finance its deficits, any increase or decrease in the government's deficit will affect the market for loanable funds and interest rates, which then feeds back on GDP, employment, and inflation.

This chapter looks at the impact of government's spending and tax policies, discussing the ways in which it can affect, and has affected, the economy. It also presents various arguments for greater reliance on fiscal policy to increase employment, as well as discusses the problems that increased government deficits may impose on future generations.

## Federal Government Spending

Economists categorize government spending in two types. First, there is government purchases of goods and services. Government purchases of food, military goods, and other goods needed for consumption purchases, as well as purchases of investment goods, such as buildings and the building of bridges, are included. On the other hand, the government also spends on social insurance programs, such as Food Stamps and Medicare, which are primarily transfers of income from taxpayers to needy citizens. These are referred to as *transfer payments.*

Federal, state, and local governments all purchase goods and services and have the potential to affect economic activity. According to the 2008 *Economic Report of the President,* over the past 46 years, total government spending on goods and services, as well as federal spending by itself, has fallen as a percentage of GDP while state and local spending has increased as a percentage of GDP. Total government spending was approximately 19.1% of GDP in 2007: Federal spending was 7.1% of GDP while state and local spending was 12.2%. This compares with total government spending of 21.2% of GDP in 1960, when federal spending was 12.2% of GDP and state and local spending was 9.0%.

According to Alan Auerbach (2007), since 1962 there have been substantial changes in the components of government spending. He highlights the decrease in defense spending over this time with the notable exceptions of the first half of the Reagan administration and in the post-9/11 era. However, as Auerbach explains, "entitlement spending has more than doubled as a share of GDP since the early 1960s, absorbing the 'peace dividends' provided by the conclusions of the Vietnam and Cold Wars" (p. 215).

The Congressional Budget Office (2009) provides more insight into total government spending by dividing federal government spending into discretionary spending, mandatory spending net of any offsetting receipts, and net interest. Figure 35.1 below shows how federal spending as

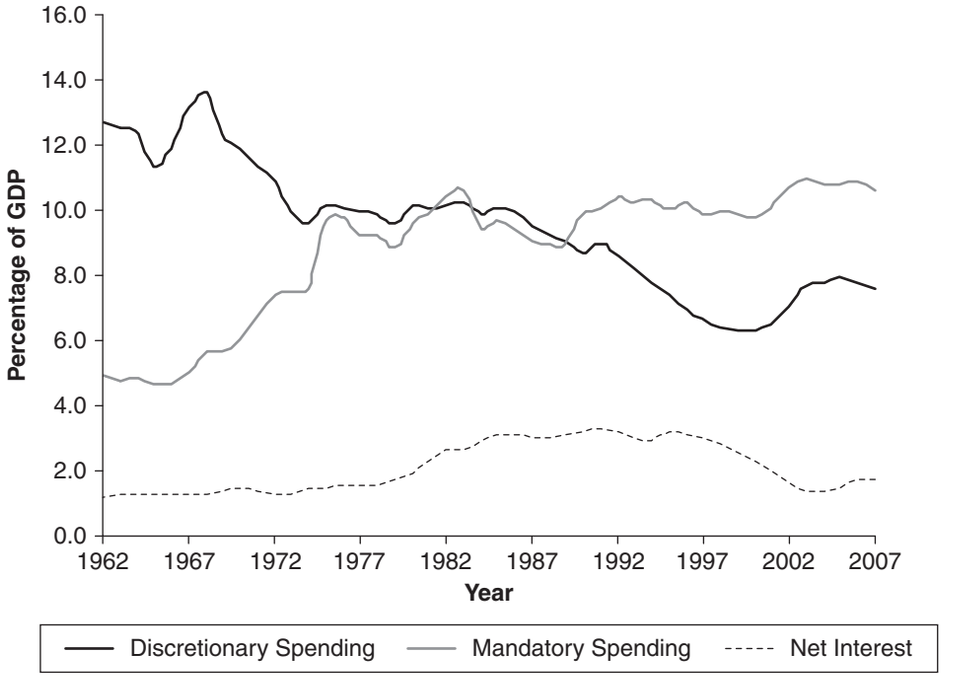

**Figure 35.1** Components of Federal Spending

SOURCE: Congressional Budget Office (2009).

a percentage of GDP has changed over time from 1962 to 2007. Discretionary spending has fallen over time, mandatory spending has risen, and net interest has varied.

*Discretionary spending* consists of items on which Congress chooses to spend, such as defense and non-defense spending, while *mandatory spending* consists of programs where spending levels are already determined as a matter of law, such as spending on Social Security, Medicare and Medicaid, and other income, retirement, and disability programs, including unemployment compensation, Supplemental Security Income, and Food Stamps, among others. Figure 35.2 shows the changing

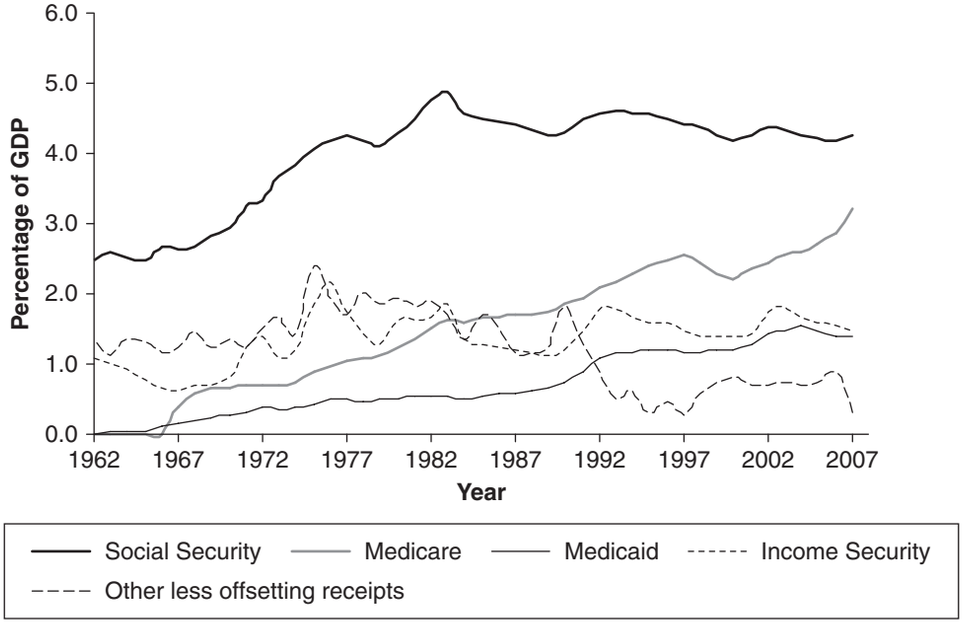

**Figure 35.2** Components of Mandatory Spending

SOURCE: Congressional Budget Office (2009).

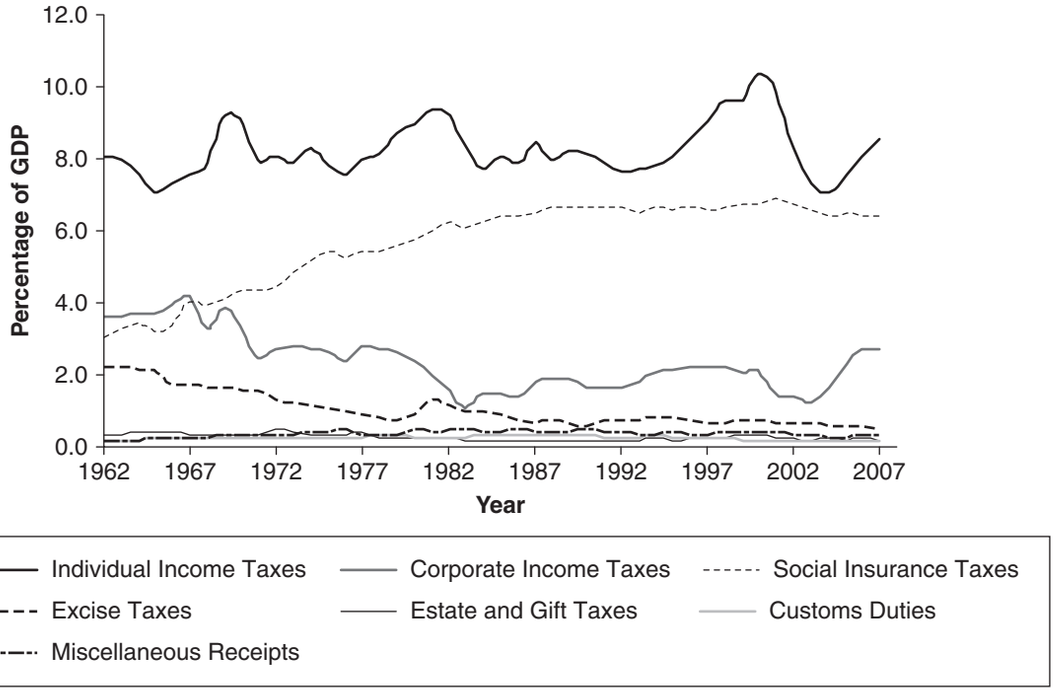

**Figure 35.3** Components of Tax Revenue

SOURCE: Congressional Budget Office (2009).

composition of mandatory spending over time. The major changes in the percentage of the components of mandatory spending as a percentage of GDP occur in both Social Security and Medicare. As the baby boomers age, these components promise to become even larger components of mandatory spending.

## Federal Tax Revenue

The federal government has several tax revenue streams, including individual income taxes, corporate income taxes, social insurance taxes (to fund programs intended to protect households from economic hardship), excise taxes (taxes on specific goods such as cigarettes), estate and gift taxes, custom duties, and other income streams. Figure 35.3 shows that individual income taxes are the most important source of tax revenue, followed by the recently more important social insurance taxes. The third most important source is excise taxes, with corporate income taxes, estate and gift taxes, and custom duties representing a small percentage of GDP. From another perspective, Figure 35.4 shows the sources of federal tax revenue in 2007. This figure again illustrates that

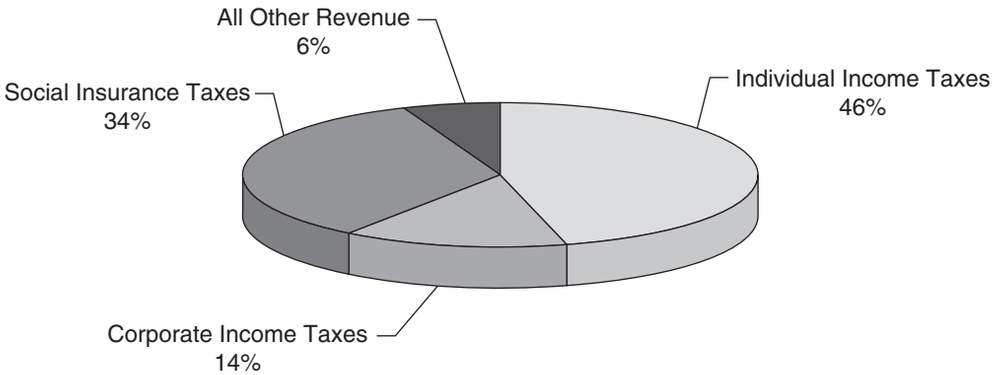

**Figure 35.4** Components of Federal Tax Revenue

SOURCE: Congressional Budget Office (2009).

individual income taxes plus social insurance taxes represent almost 80% of all federal tax revenue.

Personal income taxes in the United States are progressive, meaning that individuals with higher incomes pay a higher percentage of their income in taxes. In 2008, there were six different tax brackets with individuals paying a higher percentage of their income in taxes as their income rose. Although the income brackets change depending on whether the taxpayer is single, head of household, or married, the rates were 10%, 15%, 25%, 28%, 33%, and 35%. A report by the Congressional Budget Office to the Chair of the Finance Committee of the U.S. Senate in 2008 found that the tax system is indeed progressive in practice. The Congressional Budget Office reported that with regard to all federal taxes (not just income taxes), those individuals in the first income quintile (those whose income are among the lowest 20% in the country) pay an effective tax rate of 4.3% of income, those in the second quintile pay 14.2%, in the third pay 14.2%, and in the fourth pay 17.4%, while those whose incomes are among the 81% to 90% pay 20.3%, 91% to 95% pay 22.4%, 96% to 99% pay 25.7%, and those in the top 1% pay 31.5%.

Although it is difficult to compare tax burdens internationally, *Forbes* (Anderson, 2006) attempted to measure a Tax Misery & Reform Index that presents an international comparison of top marginal rates of taxation. The Misery scores are the sum of personal income taxes, corporate income taxes, wealth taxes, employer social security taxes, employee social security taxes, and VAT/sales taxes. From this analysis, it does not appear that Americans are particularly heavily tax burdened. Allowing for some differences within countries due to property and sales taxes, China and the original European Union-15 nations have the highest levels of tax misery, with index values ranging from 121.0 to 166.8, while the United States has an index value between 115.7 in New York and 94.6 in Texas.

## Automatic Stabilizers

Fiscal policy also provides some automatic stabilization for the economy during the business cycle. For example, government spending on unemployment compensation, Supplemental Security Income, and Food Stamps will decrease (increase) during an expansion (recession), while personal income taxes will decrease (increase) during a recession (expansion). The decrease in taxes is also more than a proportional decrease. Because the personal income tax system is progressive (i.e., individuals pay a higher proportion of their income as the income rises), it may be that the decrease in income lowers not only the total amount of taxes paid but also the proportion of income paid in taxes. So as personal income falls (rises) during a recession (expansion), fiscal policy acts as an automatic stabilizer for income by increasing (decreasing) social insurance spending and lowering (raising) taxes, thereby helping to maintain a household's income when the economy is in recession (expansion).

## Social Security and Medicare

There is a great concern that government spending on Social Security and Medicare may soon overwhelm the budget and lead to larger and larger government deficits. According to Rudolph Penner and C. Eugene Steuerle (2007), "Discretionary programs now constitute less than 40 percent of spending, whereas they were almost 70 percent of spending in 1982" (p. 1). They also explain that although today about half of federal spending goes to benefit people aged 65 and over through the Social Security, Medicare, and Medicaid programs, they warn that by the year 2030, these "programs are expected to absorb between 5 and 9 percent more of gross domestic product than they did in 2006." This is due to the increase in life expectancy and the improvement in health care. Adding to the problem is the fact that birthrates fell rapidly in the 1960s and remain low. As Penner and Steuerle explain, today's labor force, and with it the number of taxpayers, is now growing slowly, but that growth is expected to decelerate in the future.

## State and Local Government Spending and Tax Revenue

Although state and local governments may have individual income taxes, the primary ways in which they raise tax revenue is through property and sales taxes. According to the U.S. Census Bureau, in 2005 and 2006, almost 65% of all state and local tax revenue in the United States was in the form of property and sales taxes. Education, the largest single source of expenditure for state and local governments, is approximately 30% of total expenditure. It is followed by programs for social insurance and income maintenance at 22% of total expenditure and utility expenditure at 13.5%.

## Theory

Macroeconomics is a relatively new branch of economics. Although classical economists had a framework for looking at the macroeconomy, they believed that any unemployment problem would be quickly resolved and that the economy would usually function at full-employment. They argued that production was a part of the consumption process. In other words, we produce goods and services because we want to sell them for money to buy what we want to consume. If we produced too many of some types of goods and services, the prices of those goods and services would fall, and we would no longer be able to buy the goods we wanted to consume. As a consequence, we would change what we were producing, and employment would rise in the production of the higher value goods. In the view of the classical economists, the economy would tend toward full employment, and there could not be any sustained unemployment.

It was with the Great Depression and the publication of John Maynard Keynes's *General Theory of Employment, Interest and Money* that economists began to understand that there may be a role for government to play in influencing the level of output, employment, and prices. Keynes asserted that rather than supply creating demand, it was demand that creates supply, and therefore there could be a persistent oversupply of goods. There was no reason that the economy would tend toward full employment, and unemployment could be severe and persistent. Keynes argued that this was what was happening during the Depression. He also argued that the government could alleviate the unemployment by increasing demand through either increases in government spending or decreases in taxes.

## Equilibrium Output and Equilibrium Income

National output (GDP) is determined by identifying the spending in the economy by the major players: households, firms, and government. Goods bought by households are defined as consumption (C), goods bought by firms as private investment (I), and goods bought by the government as government spending (G). If the economy does not engage in international trade, total demand equals consumption plus private investment plus government spending (i.e., C + I + G). The economy will be in equilibrium when what is produced is exactly equal to what is demanded, or

$$Y = C + I + G,$$

where Y is total output produced. In this case, equilibrium output also represents equilibrium expenditure in the economy. Further, if mechanically expenditure must equal income, then Y also represents equilibrium national income.

If the economy is allowed to trade, some of the consumption, private investment, and government spending may be on goods that are not produced in the country; they may be on imports (IM). If this is the case, then these imports do not represent demand for goods produced in this country. However, it may be that foreigners will demand some goods that will be produced in this country; these are our exports (X). In an open economy, equilibrium will be achieved when domestic production equals the demand for domestic goods and services, or

$$Y = C + I + G + (X - IM).$$

There is no reason why domestic production should equal the domestic demand for goods and services at full employment. Full employment exists when workers who are willing and able to work at the going wage rate can find employment. It may be that the domestic production equals the demand for goods and services at a level of output that is less than full employment; if this is the case, the economy is in recession. Changes in government spending and taxes can help bring the economy to full employment. If an economy is in recession, the government can either increase government spending or decrease taxes (if personal taxes decrease, consumption will increase), increasing domestic demand for goods and services. Production and employment will increase. If there is inflation in the economy, the government can either reduce its spending or raise taxes, reducing domestic demand for goods and services, thereby reducing inflationary pressure. When the government uses changes in government spending or taxes to affect economic activity, it is said that the government is using discretionary fiscal policy.

## The Multiplier

According to Keynesian theory, the effect of a change in government spending or a change in consumption spending due to the change in taxes on equilibrium income will be larger than the initial change in spending. There will be a multiplied effect on output due to the initial change in spending because consumption spending itself is a function of disposable income (i.e., national income less taxes). The Keynesian view of consumption is that it is a function of disposable income. As disposable income increases, there will be a propensity to spend part of that increase and to save part of it. Given an additional dollar in disposable income, households will be likely to spend a certain percentage and to save a certain percentage. The percentage that it is likely to be spent is known as the *marginal propensity to consume* (mpc), while the percentage that it is likely to be saved is known as the *marginal propensity to save* (mps). The mpc plus the mps must equal 1.

### Government Spending Multiplier

An example can illustrate how a change in government spending can have a multiplied effect on national income. Table 35.1 shows the changes in spending and income in this example. Suppose an economy were in equilibrium at a level of output less than full employment and the government increased its spending by $100 billion. Assuming that taxes are not a function of income but are a fixed amount per person, any increase in income will also increase disposable income by that amount. However, if the marginal propensity to consume in this economy is 80%, then the initial increase in income of $100 billion will also induce an increase in consumption spending of $80 billion. This induced increase in consumption spending also raises disposable income by $80 billion, leading to a further increase in consumption spending of $64 billion, and so on. The initial increase in spending (whether government spending or consumption spending due to a change in taxes) induces various rounds of consumption spending with each round spending (and income increasing) less and less. As Table 35.1 illustrates, if the mpc equals 80% and there is an initial increase in spending of $100 billion, this will induce a total increase in consumption spending of $400 billion and will ultimately increase equilibrium income by $500 billion. In this example, the

**Table 35.1** The Government Spending Multiplier

| *Round* | *Initial Change in Spending* | *Change in Income* | *Induced Change in Consumption* |
|---|---|---|---|
| 1 | $100 | $100 | $80 |
| 2 | | $80 | $64 |
| 3 | | $64 | $51 |
| 4 | | $51 | $41 |
| 5 | | $41 | $33 |
| … | | | |
| 20 | | $1 | $1 |
| … | | | |
| All Rounds | | $500 | $400 |

multiplier is 5; with a mpc of 80%, any initial change in spending will increase equilibrium income by 5 times the initial change in spending. The value of the multiplier is

$$\text{Multiplier} = 1/(1 - \text{mpc}).$$

*The Tax Multiplier*

The government could also have a positive effect on equilibrium national income by lowering taxes by $100 billion, but the effect on the increase in national income will be smaller. The value of the tax multiplier is smaller than the value of the spending multiplier. Table 35.2 illustrates this example. If the government lowers taxes by $100 billion, disposable income will rise by $100 billion. Given the mpc of 80%, this will result in an initial increase consumption spending of $80 billion and an increase in saving of $20 billion. In contrast to the preceding example, when government spending increased by $100 billion, it is the $80 billion increase in consumption spending that starts the multiplier effect. Ultimately, the $100 billion tax cut raises equilibrium national income by $400 billion. The tax multiplier is only 4; any decrease in taxes will increase equilibrium national income by 4 times the decrease in taxes. The value of the tax multiplier is

$$\text{Multiplier} = -\text{mpc}/(1 - \text{mpc}).$$

It is negative because a decrease in taxes will increase equilibrium national income and vice versa.

*Proportional Taxes*

Relaxing the assumption that taxes are a fixed amount per person and introducing a proportional tax system (i.e., taxes are a function of income), the size of the multiplier decreases, but a change in government spending will still have a multiplied effect on equilibrium output. Continuing with the preceding example, one can determine the change in equilibrium income if the government increases its spending by $100 billion when the mpc is 80% and taxes are 10% of income. Because taxes are a function of income, disposable income equals national income minus taxes. In this case, as the government increases its spending by $100 billion, income rises by $100 billion, but now households will have to pay 10% of the increase in income in taxes leaving an increase in disposable income of only $90 billion. With an mpc of 80%, this will induce an increase in consumption spending of $72 billion. Table 35.3 shows the rounds of spending and income when a 10% proportional tax is imposed. The total change in equilibrium income is $357 billion (or approximately $36 billion in taxes and

**Table 35.2** The Tax Multiplier

| *Round* | *Initial Change in Taxes* | *Initial Change in Disposable Income* | *Initial Change in Consumption* | *Change in Income* | *Induced Change in Consumption* |
|---|---|---|---|---|---|
| 1 | –$100.00 | $100.00 | $80.00 | $80 | $64 |
| 2 | | | | $64 | $51 |
| 3 | | | | $51 | $41 |
| 4 | | | | $41 | $33 |
| 5 | | | | $33 | $26 |
| … | | | | | |
| 20 | | | | $1 | $1 |
| … | | | | | |
| All Rounds | | | | $400 | $320 |

$321 billion in disposable income) with an induced change in consumption of $257 billion. With the introduction of a 10% tax rate, the value of the multiplier fell to 3.57 from 5. With a proportional tax, the value of the multiplier can be calculated as

$$\text{Multiplier} = 1/(1 - \text{mpc} + t^*\text{mpc}),$$

where $t$ is the tax rate.

This also explains why a proportional tax system is an automatic stabilizer for the economy. The introduction of the proportional tax system lowered the value of the multiplier. Anytime there is an exogenous change in any type of spending (i.e., consumption, private investment, or government spending), the change in equilibrium income will be smaller with proportional taxes than without, helping stabilize the economy.

### "Fine-Tuning" the Economy

If the preceding example correctly represents how the economy actually works, then it appears rather easy for the government to use changes in government spending and changes in taxes to bring the economy to full employment. However, this is not the case. If the government could immediately (a) recognize that the economy is in recession, (b) agree to do something about the problem, (c) implement the program, and (d) get households and firms to respond to the plan, it might work. Unfortunately, each of these four steps takes time. The recognition, decision, implementation, and response lags take away valuable time during which the economy does not remain stagnant. It may be that by the time households respond to the plan, the economy will move from being in a recession. The policy taken to combat the recession will now be pointless or will create new problems for the economy. For this reason, fiscal policy is not used to "fine-tune" the economy—that is, keep the economy at full employment—but to combat persistent and significant macroeconomic imbalances.

## Temporary Versus Permanent Fiscal Policy Measures

Another problem when using fiscal policy to combat either a recession or inflationary pressure is that the government may want to make the policies temporary so that when the economy recovers, the discretionary policy measures do not create any unintended problems. Unfortunately, if a fiscal policy action is known to be temporary, it may not be effective. According to the permanent income hypothesis, first asserted by Milton Friedman (1957), consumers base their consumption spending on what they view as their permanent income. Because changes in income that households do not see as permanent will not lead to changes in consumption spending, temporary fiscal policy measures may have very small multipliers. A classic example of this problem is the Revenue and Expenditure Control Act of 1968, which created a temporary tax surcharge to help alleviate inflationary pressures in the economy. However, households did not see the increased tax as permanent, and it did little to lower expenditures or inflationary pressure. As Alan Blinder and Robert Solow (1974) explain, "Prices rose faster after its passage than before" (p. 10).

## Bias Toward Expansionary Fiscal Policy

The government can use expansionary fiscal policy, an increase in government spending or a reduction in taxes, to increase equilibrium income and contractionary fiscal

policy, a decrease in government spending and increase in taxes, to reduce equilibrium income and inflationary pressures. With the exception of worrying about any government deficits that may result, expansionary fiscal policy is a much more attractive policy in popular political terms than contractionary fiscal policy. Although it is unlikely that everyone will agree about which spending should be increased or which taxes should be cut, voters will be more likely to vote for an elected official who does either. On the other hand, few elected officials would look forward to a reelection after either decreasing government spending or increasing taxes. William Nordhaus (1975) explained the possibility of the existence of a political business cycle in which an elected official would choose more contractionary fiscal policies at the beginning of one's term but endorse more expansionary policies as the time for election draws new: "Moreover, with an incumbent's term in office there is a predictable pattern of policy, starting with relative austerity in early years and ending with the potlatch right before elections" (p. 187).

## Balanced Budget Rule

One of the dangers of expansionary fiscal policy is that it may increase the national debt. To finance a government budget deficit, the U.S. Treasury must borrow from either the public or the Federal Reserve by selling securities. A bias toward expansionary fiscal policy may lead to an ever-increasing national debt. To avoid this, there have been many calls for some type of balanced budget rule. However, whether the balanced budget rule is imposed through a constitutional amendment or some other mechanism, it would take away the ability of the government to use fiscal policy to counteract a recession and would also lead to greater instability in the economy (i.e., it will increase the value of the multiplier).

A balanced budget rule increases the value of the multiplier because it requires that when an exogenous decrease in spending lowers equilibrium income and threatens to bring the economy into recession, the government must reduce its own spending as tax revenues fall with income. Table 35.4 illustrates the particular example of a decrease of $100 billion in private investment spending, perhaps due to increased pessimism about the state of the economy among the business community. If the government is required to maintain a balanced budget, as private investment spending and income decreases, not only does this induce decreases in consumption spending, but tax revenues fall, which induce cuts in government spending to keep the government's budget balanced. At each round, income decreases because of decreases in both consumption expenditures and government expenditures. On net, the decrease in private investment spending will decrease equilibrium income by $556 billion; the multiplier is 5.56. With proportional taxes and a balanced budget rule, the multiplier is

$$\text{Multiplier} = 1/[(1 - \text{mpc})*(1 - t)].$$

Without a balance budget rule, this same $100 billion decrease in private investment would have decreased equilibrium income by only $357.

A major disadvantage of a balanced budget rule is the increase in the value of the multiplier. Anytime there is a major decrease (increase) in spending, not only can the government not use expansionary (contractionary) fiscal policy, but the resulting decrease in

**Table 35.4** The Balanced Budget Multiplier

| *Round* | *Initial Change in Spending* | *Change in Income* | *Change in Taxes* | *Change in Government Spending* | *Change in Disposable Income* | *Induced Change in Consumption* |
|---|---|---|---|---|---|---|
| 1 | $100.00 | $100.00 | $10.00 | $10.00 | $90.00 | $72.00 |
| 2 | | $82.00 | $8.20 | $8.20 | $73.80 | $59.04 |
| 3 | | $67.24 | $6.72 | $6.72 | $60.52 | $48.41 |
| 4 | | $55.14 | $5.51 | $5.51 | $49.62 | $39.70 |
| 5 | | $45.21 | $4.52 | $4.52 | $40.69 | $32.55 |
| … | | | | | | |
| 20 | | $2.30 | $0.23 | $0.23 | $2.07 | $1.66 |
| … | | | | | | |
| All Rounds | | $556 | $56 | $56 | $500 | $400 |

national income or inflationary pressure will be worse than if the government was not forced to respond to the change in spending.

## Full-Employment Budget Balance

Although the budget deficit worsens when the government uses expansionary fiscal policy and improves when it uses contractionary fiscal policy, the budget balance by itself may not be a good measure of whether the government is using expansionary fiscal policy. The budget deficit also changes with the business cycle. As an economy expands, tax revenues rise and government spending on social insurance programs falls; the government's deficit gets smaller. This is true whether or not the government is concerned that the economy's expansion may be excessive. So if the government's deficit is getting smaller while the economy expands, it is impossible to determine whether the decrease is due to automatic stabilizers or to discretionary fiscal policy just by looking at the net change in the budget balance. The same is true if the economy is heading into a recession. In that case, there would be a worsening of the budget deficit whether or not the government engages in expansionary fiscal policy. However, it is possible to calculate what the government's budget balance would be if the economy were at full employment. Also known as the *cyclically adjusted budget balance,* it adjusts the actual budget balance for any extra tax revenue the government would collect or social insurance payments it would save if the economy were not in a recession. With this control, if there is an increase in the full-employment budget balance, it must be because the government is engaging in contractionary fiscal policy while any decrease would indicate expansionary fiscal policy.

## The Problem of Crowding Out

Using expansionary fiscal policy may have some unintended consequences that can decrease the value of the multiplier. When the government increases its spending or decreases taxes, its budget balance declines. The only way the government can finance a deficit is to sell U.S. Treasury securities and, depending on who buys the securities, the increased deficit may lead either to increased inflationary pressure or higher interest rates.

If the government finances the deficit by selling U.S. Treasury securities to the Federal Reserve, this will increase the money supply and potentially increase inflationary pressure. Increases in the money supply will lower interest rates, encourage interest-sensitive consumption and private investment spending, and, if the economy is close to full employment, lead to increases in the price level.

On the other hand, if the government finances the deficit by selling U.S. Treasury securities to the public, this will put upward pressure on interest rates. This can be seen in the loanble funds market in Figure 35.5. The demand for loanable funds comes from the borrowing needs of businesses and government, and is inversely related to the interest rate. Because each possible private investment project available has an expected rate of return, businesses will take on those projects for which the expected rate of return exceeds the interest rate. As the interest rate falls, more projects are profitable, leading to an increase in the quantity of loanable funds demanded. This assumes that the government deficit, that is, demand for loanable funds on the part of the government, is not related to the interest rate but is determined by the size of the deficit. The supply of loanable funds reflects the relationship between saving and the interest rate in the economy. As the interest rate increases, the reward for saving increases, and there is an increase in the quantity supplied of loanable funds. In the figure, D shows the demand for loanable funds before the expansionary fiscal policy, and D' is the demand for loanable funds with the increased borrowing needs of $100 billion from the government. Prior to the government engaging in expansionary fiscal policy and increasing its demand for loanable funds, the equilibrium interest rate is 5% and the equilibrium level of loanable funds is $500 billion. After the government borrows $100 billion to cover its deficit, the equilibrium interest rate rises to 5.5% and the equilibrium level of loanable funds rises to $550 billion. Because the government's share of loanable funds rose by $100 billion, but the total amount of loanable funds rose by only $50 billion, the increase in the interest rate must have decreased the quantity demanded of loanable funds by $50 billion. In other words, the increased borrowing needs of the government crowded out private investment.

Additionally, the increase in interest rates may affect the exchange rate leading to changes in the trade balance

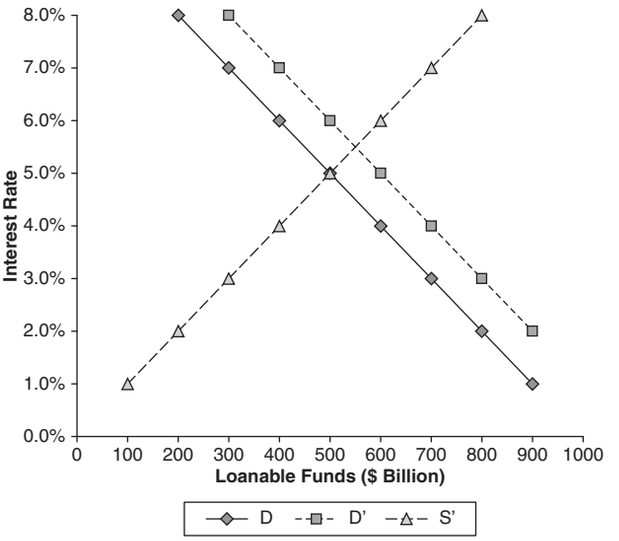

**Figure 35.5** The Market for Loanable Funds

that further reduce the effectiveness of expansionary fiscal policy. As interest rates in the United States increase, both domestic residents and foreigners will want to buy U.S. assets. In the market for the U.S. dollar, this will increase the demand for dollars (foreigners wanting to buy U.S. assets first need to buy U.S. dollars) while decreasing the supply (Americans who may have bought foreign assets and consequently foreign currencies will not do so). Both factors will lead to an appreciation of the dollar and encourage an increase in U.S. imports of foreign goods and services while discouraging foreign purchases of U.S. exports. This decrease in expenditure on domestic goods and services will further limit the increase in equilibrium income in response to the expansionary fiscal policy.

It is even possible that there may be complete crowding out of private investments. Given the effects on the interest rate and the exchange rate, the increase in government spending might just provoke a decrease in spending on domestic goods and services that completely offsets any increase in national income.

## Ricardian Equivalence

An alternative view of why expansionary fiscal policy may not increase national income is the Ricardian equivalence theorem. As Robert Barro (1992) explains it, the demand for goods by households is a function of the expected present value of taxes. Households determine how much to consume based on their net wealth position or the expected present value of income less the expected present value of taxes. Any increase in government spending or decrease in taxes financed through an increase in the deficit will only lead to an increase in expected future taxes equal to the same present value as the fiscal policy stimulus and will not lead to an increase in consumption spending. In Barro's (1989) words, "Fiscal policy would affect aggregate consumer demand only if it altered the expected present value of taxes" (p. 39).

### Empirical Evidence

Although the advocacy of fiscal policy to affect the economy began with John Maynard Keynes's publication of *The General Theory of Employment, Interest and Money,* it was only when the government increased military spending for World War II that his theory was truly implemented. During the Great Depression, Franklin Roosevelt experimented with Keynesian theory when he implemented the New Deal. Although the programs of the New Deal were implemented prior to the publication of *General Theory,* its emphasis on increased government spending to stimulate the economy is exactly what Keynes was advocating.

After World War II, Keynesian economics and the beneficial effects of fiscal policy were definitely in vogue. Through the 1950s and 1960s, the economy behaved in a manner similar to the Keynesian model. The economy varied between times of low unemployment and high inflation and of high unemployment and low inflation. The Keynesian policy prescription was clear: Use expansionary fiscal policy to cure an unemployment problem and a contractionary one to cure inflation.

## Emphasis on Monetary Policy

Unfortunately, in the 1970s, the rapid increase in the price of oil appeared to change the relationship between unemployment and inflation. During this time, the economy experienced *stagflation,* that is, the combination of both unemployment and inflation. The Keynesian model seemed to be failing to explain the economy, and fiscal policy did not seem to hold much potential to mitigate the problems. At the same time, increases in the size of the U.S. government deficit and national debt caused many to worry about the effects of further expansionary fiscal policy on future generations. According to John Taylor (2000), by the end of the 1970s, discretionary countercyclical fiscal policy was no longer considered a serious policy option in the United States. As Laurence Seidman (2001) explains, "Whereas Congress enacted a major fiscal stimulus package to counter the 1975 recession, it did not even consider a serious package in the 1991 recession" (p. 18). The focus had shifted to the use of monetary policy. As Taylor (2000) writes, "Over the [1980s and 1990s], the Federal Reserve's interest rate decisions have become more explicit, more systematic, and more reactive to change in both inflation and output" (p. 21). The economy performed well under this regime with only two relatively mild recessions, one in 1980 to 1982 and one in 1990 to 1991.

However, signs of the weakness of monetary policy became apparent when looking at the slump in the Japanese economy. After amazing postwar growth that propelled war-torn Japan to a major industrial nation, a real estate and stock market boom in the 1980s was followed by a crash in both markets and a period of relatively slow growth or recession since 1991. This period has also been characterized by very low interest rates as the Bank of Japan tried to stimulate the economy with expansionary monetary policy. Similar to our experience during the Great Depression, the Japanese economy had fallen into a liquidity trap. First described by Keynes, a *liquidity trap* is when interest rates are at or close to zero but the low interest rates do not spur interest-sensitive spending. Because an expansionary monetary policy affects the economy when an increase in the money supply lowers interest rates and encourages interest-sensitive spending, when interest

rates are at or close to zero, there is little impact on the economy. As in the Great Depression with the impotence of traditional monetary policy, Japan turned to fiscal policy to help promote growth in the economy.

### Economic and Financial Crisis of 2008

After a relatively long expansion and large increases in stock price during the late 1990s, the economy began to show signs of weakness in early 2000. What has been called the *dot-com bubble,* the large increase in the stock prices of technology stocks, burst in early 2000, and for most of 2001, the economy was in recession. The recession, along with the terrorist attacks of September 11, 2001, led the Federal Reserve to lower interest rates significantly. The Fed lowered the target federal funds rate 11 times in 2001 from a rate of 6.00% to 1.75%. The decrease in interest rates helped lead the economy out of recession in part by increasing the demand for new homes. Housing prices soared along with consumer spending in response to higher wealth and to lower interest rates. From the beginning of 2001 until housing prices peaked in mid-2006, according to the S&P/Case-Shiller Price Index, housing prices essentially doubled in 10 major metropolitan cities. However, once housing prices began to fall and the subprime mortgage crisis ensued, the economy began to slow and went into recession in December 2007. Although the Federal Reserve attempted to encourage consumption and private investment spending through further decreases in interest rates, by the end of 2008, the target rate for the federal funds rate was essentially zero, and the U.S. economy faced its own liquidity trap. Although the Federal Reserve continued to provide liquidity into the markets through various lending facilities and quantitative easing, policy makers began looking once again to fiscal policy to help the economy out of recession.

### Size of the Multipliers

A major controversy about using fiscal policy concerns the size of the government spending and tax multipliers. As previously discussed, the multipliers depend on the magnitude of the marginal propensity to consume and the tax rate. However, it is not so simple to calculate the size of the multipliers in the real world. E. Cary Brown (1956) was one of the first to attempt to estimate the sizes of the multipliers by looking at the effectiveness of fiscal stimulus during the Great Depression. Using Brown's work, Gauti Eggertsson (2006) measured the real spending (holding the budget deficit constant) multiplier to be 0.5 and the deficit spending (cutting taxes and accumulating debt while holding real government spending constant) multiplier as 2 during the 1930s.

More recent estimates on the values of the multiplier vary widely and are the topic of great debate within the economics profession. Olivier Blanchard and Roberto Perotti (2002) estimate that the value of the multipliers are close to 1. They explain, "While private consumption increases following spending shocks, private investment is crowded out to a considerable extent. Both exports and imports also fall." On the other hand, Eggertsson (2006) finds that "each dollar of real government spending increases output by 3.37 dollars and each dollar of deficit spending increases output by 3.76 dollars. These multipliers are much bigger than have been found in the traditional Keynesian literature." Christina Romer, President Obama's Chair of the Council of Economic Advisors, and Jared Bernstein, chief economic advisor to Vice President Biden, arguing in support of the American Recovery and Reinvestment Plan, estimate the output effects of a permanent increase of government purchases of 1% of GDP to be 1.57% after 10 quarters, and of a permanent tax cut of 1% of GDP to be 0.99%.

## Future Directions

A big challenge facing fiscal policy in the future is meeting the increasing costs of Social Security, Medicare, and Medicaid programs. Penner and Steurele (2007) estimated that between 2006 and 2010, the cost of these three programs would grow by $326 billion, while the growth in tax revenues is expected to be only $494 billion. As they explain, "The three programs will absorb two-thirds of all revenue growth, even though they still only constitute[d] about 40 percent of total spending in 2006" (p. 3). Barring a broad reform of these programs, Penner and Steurele argue that some type of "trigger" system for these benefits be constructed. For example, a trigger system would set a particular growth rate for these benefits when the economy is close to full employment and another during a recessionary period.

Seidman (2001) argues for improving existing automatic stabilizers. As he asks, "Why not automatically trigger a tax cut in a recession?" (p. 39). By this, Seidman means a tax cut in addition to the automatic fall in revenue due to our progressive tax structure. Such a trigger would not require any legislative action but therefore would occur much more quickly than under the current system.

Another important discussion concerns the highly political atmosphere in which fiscal policy is set. Having served on both the Council of Economic Advisors and the Board of Governors of the Federal Reserve System, Blinder (1997) describes his different experiences with the setting of fiscal and monetary policies. Whereas monetary policy is in the hands of the Federal Reserve, an agency relatively independent of politics, fiscal policy is the result of a highly political process. As Blinder explains, although a policy discussion begins with social welfare as its main goal, it often "turns to such cosmic questions as whether the chair of the

relevant congressional subcommittee would support the policy, which interest groups would be for and against it, what that 'message' would be, and how that message would play in Peoria." *The Economist* ("Fiscal Flexibility," 1999) has called for serious consideration of an independent fiscal authority. Seidman (2001) proposed that members of such a group would be appointed in a similar manner as the members of the Federal Reserve. The budget would continue to be set by the president and Congress, and "the board would implement periodic adjustments in taxes and government spending relative to the budget enacted by Congress."

## Conclusion

Fiscal policy has been and continues to be an important stabilization policy of the government. This chapter reviews the theory of fiscal policy and how it has been used in the United States. It gives insight into some of the major debates surrounding fiscal policy and future directions for research. Although the efficacy of discretionary policy measures continues to be debated and there is concern about the growing expenditures for Social Security, Medicare, and Medicaid, government spending and taxes will continue to be an important component of the policy toolbox available to influence the economy.

# Government Budgets, Debt, and Deficits

Benjamin Russo

*University of North Carolina at Charlotte*

This chapter describes the economics of government budgets, with particular attention to government borrowing in the United States at the federal, state, and local levels. The next section provides definitions and describes some principles of federal, state, and local budgeting. The third section focuses on major issues pertaining to federal government borrowing. The final section is a summary.

## Definitions and Principles of Government Budgeting

### Preliminaries

Equity and efficiency are crucial concepts in economics, so it is useful to begin by defining these terms. Two principles guide evaluations of the effect economic policies have on equity. The *benefit principle* is the viewpoint that it is equitable for citizens who benefit from government services to pay for them. The *ability-to-pay principle* is the viewpoint that it is equitable for a citizen's tax liabilities to be correlated with the citizen's economic resources. It follows that taxpayers with equal abilities to pay should be taxed equally (horizontal equity) and that tax liability should increase as ability to pay increases (vertical equity). Resources are allocated efficiently if and only if they are used where they have the highest social value.

### Operating and Capital Budgets

State and local governments report operating budgets and capital budgets. In general terms, an *operating budget* is an enumeration of (a) expenditures on current operations and (b) the revenue inflows required to finance those operations (current operations take place each period). Typical expenditures on current operations include purchases of services and of tangible items. *Services* are commodities that cannot be stored, for example, state employee salaries and interest payments on government debt. *Tangibles* are items that are used up each period, for example, stationery and gasoline. Revenue inflows collected in 2009 include tax and fee collections that are used to pay for 2009 operating expenditures.

*Capital budgets* enumerate (a) planned spending on purchases and repairs of capital assets and (b) the means of financing capital assets. In contrast to current operations, capital assets are used for many periods (examples are roads, school buildings, and water treatment plants). Because capital purchased in the current period produces services in the future, capital, like houses, often is financed with borrowed funds. Governments borrow by selling bonds, which are repaid over many periods, when the services produced by capital are enjoyed. A legal obligation requiring future expenditures is a financial liability. Thus, a capital budget is an enumeration of expenditures on capital assets and newly incurred liabilities in a given period. In contrast to most state and local

governments, the federal government does not report a capital budget.

A fiscal year is a 12-month period covered by an operating budget. The U.S. federal government's fiscal year begins on October 1 of each calendar year and ends on September 30 of the following calendar year. Before the beginning of a fiscal year, governments formulate *planned* operating budgets, which show planned expenditures and expected tax and fee revenues. However, some operating expenditures are difficult to plan for (e.g., disaster assistance), and tax and fee revenues are difficult to predict (e.g., sales tax revenue). Thus, within any fiscal year, actual expenditures may differ from plans, and actual tax and fee revenue may fall short of predictions. In all cases except Vermont, U.S. state governments are constitutionally required to adjust their operating budgets so that by the end of each fiscal year, actual expenditures do not exceed tax and fee revenue. Economists call this restriction the government's *current budget constraint.* Note that if expenditures equal tax and fee revenue, the state budget is said to be balanced.

Although the national government also must satisfy a current budget constraint, the restriction is much less severe than that faced by subnational governments. This is true because national governments, generally, are not required to balance their operating budgets. Thus, national governments can borrow to finance operating expenditures. The national current budget constraint states simply that in a fiscal year, government expenditures cannot exceed the sum of borrowed funds plus tax and fee revenue. Additionally, many national governments can issue money, which can be used to finance expenditures. Of course, there is a limit to money finance because money creation tends to cause inflation. U.S. law precludes the federal government from directly issuing money to finance expenditures. However, if the U.S. Federal Reserve Bank (the Fed) buys U.S. Treasury bonds, the money stock increases. This is a form of indirect money finance. However, U.S. law precludes the federal government from compelling the Fed to buy Treasury bonds. For most of its history the Fed appears not to have engaged in indirect money finance.

Governments' current budget constraints restrict expenditure and revenue choices within a fiscal year. Governments, like individual consumers and businesses, also face a constraint that extends into future periods, namely, the intertemporal budget constraint (IBC). IBC dictates that the sum of current and all future expenditures plus currently outstanding debt cannot exceed current plus all future tax and fee revenue (*outstanding debt* is debt that has not yet been paid off). Here, future expenditures/revenues are measured in "present value terms." (Note that the present value of a dollar to be received in a future period is the dollar adjusted downward by the opportunity cost incurred by not having the dollar for a period. The opportunity cost is the rate of return that could have been earned if the dollar were invested during the period.)

There seems to be a great deal of public confusion about IBC, so it is important to be clear about what restrictions it does and does not impose. In general, the IBC imposes the condition that any increase in expenditure implies an increase in current taxes or future tax liabilities equal in present value to the expenditure. By way of a false analogy, IBC sometimes is taken to mean that governments must repay principal on their debts. This is incorrect. To see why, first note the economic incentives that motivate creditors to lend. Creditors are willing to forgo consuming their wealth for some period of time if they are *compensated with a market rate of return* on the loans. Second, because individual consumers, sadly, live only finite periods of time, they must repay debt principal before they or their estates expire. Creditors will demand that the principal is repaid. For if creditors were not repaid the principal, they would suffer a large opportunity cost, namely, the opportunity to continue to earn the market rate of return.

However, the same cannot be said for governments and successful business firms because their "lifespans" effectively extend into the indefinite future: They are not finite. As a result, if a government reliably pays the market rate of return on its outstanding debt, and creditors believe the government will continue to do so, the government can satisfy its creditors by servicing its debts forever; it is not required to repay the principal on the debt.

IBC may seem to be a weak restriction on government choices. Nonetheless, IBC does place an important restriction on government debt policy: The government cannot sustain a policy that would cause debt to grow faster than the economy in the long run. If the debt did grow faster, it would outrun the economy's ability to generate the revenue that must be collected to pay the market rate of interest on the debt. In this case, creditors eventually would stop making loans to the government, and the policy must terminate. Is recent U.S. debt policy sustainable?

## Why Report Budgets?

The U.S. government reports a budget each fiscal year in accord with Section 9, Article 1, of the U.S. Constitution, which states that "a regular statement of accounting of receipts and expenditures of all public money shall be published from time to time." The states have stringent constitutional provisions, requiring construction of budgets, and states impose similar requirements on their local governments.

But what is the value added of a government budget? Government budgets have two major purposes. First, budgets provide information the public needs to evaluate the costs and benefits of public goods and services. This information is fundamental in democracies. Underlying the relations between a democratic government and its citizens is an assumption that government activities are sanctioned by a social contract in which citizens relinquish some freedom in return for public goods and services. Without a budget, this evaluation would be more difficult than it is.

Second, budgets indicate whether governments' expenditure and revenue decisions are financially responsible. Without a budget, it is harder to know if fiscal policy satisfies the government's budget constraints, and it would be difficult, if not impossible, for the public and the government itself to know whether spending, revenue, and borrowing policies are financially sound.

## Why Report Capital Budgets?

State and local governments separate operating from capital expenditures, and report a separate capital budget. For example, spending on public capital infrastructure (government buildings, highways and bridges, etc.) is included in state capital budgets, whereas spending on teacher and administrative salaries is included in operating budgets. Many foreign national governments publish capital, as well as operating, budgets. Capital budgeting requires time and resources.

Do capital budgets have economic benefits that offset these costs? Public capital goods generate returns and impose risks, just as private capital does. Governments issue bonds, so there is risk of government bond default. Governments also maintain portfolios in trust for the public (largely in the form of pensions). There is a risk to taxpayers that pension assets will lose value. Government capital budgets allow taxpayers and investors to more easily evaluate the risk and returns of funds held in trust by the government.

State and local governments are required to balance their budgets. If there were no separation of capital expenditures from current expenditures, the balanced budget requirements would prevent state and local governments from borrowing to finance capital assets. In this case, states would need to finance capital expenditures by collecting taxes in the period the purchases were made: In no period could capital purchases exceed tax revenue collected in that period. This would be inefficient and inequitable.

To see why it would be inefficient, note that financing capital purchases from current tax collections would require outsized tax increases in periods when purchases are made, because capital, by nature, is very costly relative to a single period's income. Tax finance of capital would lead to large variations in tax revenue requirements because purchases of capital tend to be "lumpy." For example, once a new school or courthouse is built, government does not need to build another for a while. As explained next, tax variability is economically inefficient (Barro, 1979). As well, the expenditure could require a single-period increase in tax revenue too large to be politically tenable, which could lead to a less than efficient level of investment in public capital.

Financing capital purchases from current tax collections would also be inequitable. First, it would violate the benefit principle because future generations could consume government capital services they have not paid for. Borrowing today and repaying part of the debt with future tax dollars allows the cost to be shared with the future beneficiaries of capital services. Second, it would violate horizontal equity because households with equal abilities to pay, and who receive equal government services but are born to different generations, would face different tax burdens.

## Should the U.S. Government Report a Capital Budget?

The U.S. federal government does not publish a capital budget. Some economists argue that publication of a federal capital budget would be beneficial. Others argue that a federal capital budget would be difficult to implement.

A federal capital budget would make it easier for taxpayers and investors to evaluate the risk and returns of federal government investments. Marco Bassetto and Thomas Sargent (2006) argue that the absence of a federal capital budget may tempt some policy makers to make choices inconsistent with Generally Accepted Accounting Principles. For example, it is sometimes argued that the government should sell some of its physical assets to reduce the federal government's debt. In general, this is not an economically meaningful way of satisfying the government's budget constraint; instead, it merely replaces a physical asset for cash, and has no effect on social net wealth. The exchange would be economically meaningful only if the private sector pays more for the asset than its true social value. This seems unlikely in most cases. If the federal government published a capital budget, the economic futility of such an exchange would be easier to understand and avoid.

It has been argued that it would be hard to implement a federal capital budget because it is difficult to categorize some public expenditures. Examples are highway spending, public education, and spending on public safety. State governments address this issue by including the cost of school building in capital budgets and teacher salaries in operating budgets. It is unclear why the federal government could not or should not take the same approach.

## Weaknesses in Government Budgeting

Budgets should be designed to aid policymaking and provide the public with information about fiscal policy. In this way, budgets provide rough guides to the social costs and benefits of government. However, these goals can be subverted in a number of ways.

First, the government can impose costs and provide benefits in ways that are not captured in budgets. For example, the U.S. federal government has imposed unfunded mandates on subnational governments (e.g., requirements for school achievement), but the costs of such programs do not appear in the federal budget.

Second, many government-imposed costs and benefits are intangible and hard to measure. For example, it may be impossible to measure the social benefits of public

education. Even if possible, the cost of conducting the measurements could be prohibitive. In the case of government guarantees of private loans, an implicit social cost is created because taxes may have to be increased if the loans go into default; however, the social cost is not reported in budgets. As well, governments can rule some expenditures "off budget." In this case, although measurements are available, the government does not report them in its operating budget. At the federal level, Social Security is an example of an off-budget program.

Third, government budgets may be constructed using substandard accounting. For example, most governments use *cash flow accounting.* Under cash flow accounting, revenues are included in the budget in the period when received: Expenditures are included in the period when they are paid. In contrast, Generally Accepted Accounting Principles, which are established by the Financial Accounting Standards Board and must be followed by all publicly traded corporations, require private firms to use *accrual accounting.* In accrual accounting, revenues are included in the budget in the period earned, and costs are included when incurred. Cash accounting is easier (than accrual accounting) to manipulate in ways that produce a misleading representation of the government's true fiscal position. For example, if a state's operating budget is out of balance, the state may postpone payment for goods and services until the following fiscal year, or may order tax liabilities due in the following year be prepaid, making the budget to appear to be in balance. Cash flow accounting manipulation may delay the appearance of budget problems but does not solve them. In the interim the government's fiscal position can worsen.

In the United States, delay and erosion in the federal government's fiscal position appear to be most severe in the Social Security and Medicare programs. Social Security uses "pay-as-you-go" finance—that is, currently employed workers pay Social Security (payroll) taxes, and the government uses the tax collections to make benefit payments to current beneficiaries (mostly retirees). However, pay-as-you-go Social Security satisfies the government's intertemporal budget constraint only if there are sufficient young taxpaying workers to finance benefits. Assuming the system initially is in balance, if the number of young workers subsequently declines relative to the number of beneficiaries, the system will no longer be sustainable: To satisfy the constraint, benefits must be reduced, taxes must be increased, or both. In the past 35 years, the average U.S. fertility rate has declined, diminishing the number of young workers per retiree, and the mortality rate of retirees has decreased, increasing the number of retirees per young worker. As currently structured, the U.S. Social Security system appears unsustainable, but this is not reflected in the budget.

In any year, the lion's share of U.S. federal and state budgets consist of previously established programs. The majority of budgeted programs are not subjected to systematic review of their costs and benefits. Programs that outlive their original motivation and usefulness can become a net burden on society, subverting a basic reason for budgeting. Some observers advocate *zero-based budgeting.* In this case, the government would reevaluate each program at the beginning of each budget year. Such close monitoring of government programs has a potential to reduce unproductive government spending. However, close monitoring imposes administrative costs. Zero-based budgeting would be an improvement if the cost of unproductive programs exceeds the administrative costs of monitoring programs.

## State and Local Government Budget Shortfalls: Rainy Day Funds

From time to time, actual expenditures expand faster than tax and fee revenue, or revenue may actually decline, causing a budget shortfall. Budget shortfalls often occur during economic contractions. Shortfalls are created as the decline of household and business income reduces income tax revenue, consumer spending, and sales tax revenue. Occasionally, property values also decline, reducing property tax revenue. Making matters worse, during contractions, demand for government expenditures on social programs tend to increase (e.g., unemployment insurance and social welfare spending increase in recessions).

Can budget shortfalls be avoided by eliminating the instigating factor, economic contraction? The National Bureau of Economic Research defines the *business cycle* as the recurring and persistent contractions and expansions in economic activity. The term *recurring* is emphasized because past experience offers convincing evidence that economic contractions are indicative of developed economies and will recur from time to time. The correlated budget shortfalls create enormous fiscal stress, because states must balance their operating budgets. The question here is, how can state and local governments respond to periodically recurring budget shortfalls?

One response is to increase taxes and reduce expenditures. This approach can be counterproductive and tends to be politically difficult. It can be counterproductive because reducing demand for goods and services can worsen the shortfall. It is difficult to increase taxes in contractions because income declines as workers lose jobs and firms go out of business. However, there is a sound alternative to tax increases and expenditure cuts during contractions. Because recurring contractions are almost a certainty, sound fiscal planning would have state and local governments act before economic disaster strikes by establishing budget stabilization funds, also known as *rainy day funds* (RDFs). In the ideal case, during economic expansions, RDFs would accumulate tax revenue in trust funds. During subsequent contractions, the trust funds would be used to support expenditures, reducing the need to raise taxes and cut expenditures.

The Advisory Council on Intergovernmental Relations, a group of tax administrators and state government officials,

recommends that RDFs be established at a target level of 5% of a state's annual expenditures. However, the 5% target has proven to be very inadequate. For example, in recessions in 1981 and 1982, 1990 and 1991, and 2001, North Carolina budget shortfalls averaged 19% of a typical year's expenditure. There is evidence that absent or insufficient RDFs contribute to fiscal stress, imposing substantial yet avoidable costs on society (Russo, 2002). How?

First, without a sufficient RDF, policy makers and administrators spend substantial time and energy reworking policies in response to budget shortfalls, rather than on the formulation of social policy and the ordinary business of running the government. Ignoring the ordinary business of government causes government services to deteriorate.

Second, without a sufficient RDF, state and local governments risk lower credit ratings from bond rating agencies. Lower credit ratings cause interest rates on state and local borrowing to increase, which leads to avoidable increases in future tax liabilities.

Third, without a sufficient RDF, there is a risk to private investment and planning because taxes would otherwise need to be increased, or expenditures cut, or both, during economic contractions. Stop-and-go fiscal policy increases uncertainty, which discourages private investment and tends to retard economic growth.

Fourth, without a sufficient RDF, taxes tend to be more variable than otherwise. More tax variability implies a larger excess burden of taxation. The *excess burden* of a tax is the social burden of the tax in excess of the amount of tax revenue collected. Excess burden occurs because people substitute lower valued untaxed commodities for higher valued taxed commodities, reducing economic welfare by more than the tax payment remitted to the government. Without RDFs, policy makers tend to respond to budget shortfalls by increasing tax rates. An appropriately sized RDF can reduce excess burden by reducing the need to increase tax revenue during budget shortfalls.

## National Debt and Deficits

### What Is the "National Debt"?

National government financial debt is created when the expenditures in a fiscal year exceed tax and fee revenue. The national government finances the excess of expenditure over revenue by borrowing. For example, the U.S. government auctions off U.S. Treasury bills, notes, and bonds (U.S. bonds, hereafter). The U.S. Treasury defines the *Gross Debt* to be the value of all national government bonds outstanding. However, the media and the public often refer to this same concept as the *National Debt.* Gross Debt and National Debt are synonyms. The remainder of this chapter uses the former term.

A government's ability to sell bonds depends on creditors' faith that the bonds will be repaid and on the creditors' financial capacity to buy the bonds. Creditors' faith depends on the economy's ability to generate future tax revenue, which depends on the economic growth rate. Creditors' financial capacity depends on their incomes and saving. Because saving cannot grow faster than the economy in the long run, creditors' financial capacity to buy bonds is limited by the economy's long-run growth rate. Therefore, if Gross Debt grows faster than the economy in the long run, the economy's ability to generate tax revenue to service debt, and creditor's capacity to buy new debt, falls short of the government's liabilities. If the public understands that the Gross Debt continually grows faster than the economy, creditors will demand abnormally high interest rates to compensate for the risk of not being repaid. Or creditors may simply refuse to purchase additional government debt. In this case, the government faces a "debt crisis," and the government's choices become severely constrained: (a) taxes must increase or expenditure must be cut, or both, or (b) government must default on its liabilities and convince creditors to reschedule debt payments. If these options are not available, the only recourse is for the government to repudiate the debt. In this case, government simply declares its intention to not repay the debt.

Interest rates tend to increase greatly in debt crises, and living standards tend to decline. If the government responds to a debt crisis by raising taxes and reducing spending, this exacerbates the decline. Fortunately for the United States, its national government has never experienced a debt crisis. Nevertheless, some public finance economists (Blocker, Kotlikoff, & Ross, 2008; Gokhale, Page, Potter, & Sturrock, 2000; Kotlikoff, 1992) worry that in the decades ahead U.S. Medicare and Social Security obligations could generate fiscal imbalances that could approximate a debt crisis. They argue that U.S. tax rates must increase substantially or benefits must be cut by painful amounts.

Countries that default on debt often have attempted to maintain financial viability by rescheduling debt payments. In this case, the government usually ends up paying much higher interest rates to compensate for the increase in risk perceived by creditors. Even though interest rates increase, the exchange value of the country's currency tends to decline greatly, as creditors shift funds to safer environments. A large decline in the currency reduces the standard of living because imports become more expensive.

### Debt Repudiation

Debt repudiation is the most drastic response to a fiscal crisis. One form of debt repudiation occurs when a government renounces its debt obligations. In 1917, Russia announced that it would not repay debt incurred by the Czars. In the 1930s, the Peronists renounced Argentina's government debt. A second form of debt repudiation occurs when a government prints money to repay outstanding debt. This form of repudiation often leads to inflation that reduces the real value of debt. After World War I, the Allies imposed war reparation payments on Germany. The

German government created a hyperinflation that effectively made the reparation payments worthless.

An advantage of debt repudiation is that it eliminates the burden on taxpayers of repaying previously issued debt. A disadvantage is that repudiation usually decimates the value of a country's currency, its ability to trade, and the standard of living. For a long time after repudiation, a country may not be able to borrow at all, making it difficult to maintain government services.

## How Large Is the U.S. Gross Debt?

The U.S. Gross Debt was about $10 trillion at the end of the federal government's 2008 fiscal year. As of early 2009, the U.S. Congressional Budget Office estimated that fiscal 2009 borrowing would increase the Gross Debt by about $1.2 trillion.

However, this figure could provide a misleading measure of the effects the debt has on the U.S. standard of living. There are a number of reasons for this.

First, the government's ability to service its debt, as well as the extent of the debt's effect on interest rates and the standard of living, depend on the size of the economy. For example, a debt of $10 trillion would overwhelm a small country such as Costa Rica, whose 2007 gross domestic product (GDP) is estimated to be about $48 billion (CIA World Factbook, 2008). If Costa Rica's debt were this large, interest rates would rise to extreme levels, and the value of its currency probably would decline precipitously along with its standard of living. The $10 trillion U.S. Gross Debt does not cause these dire results because U.S. GDP, at a little less than $14 trillion in 2008, is 287 times larger than Costa Rica's. Thus, the U.S. debt is a much smaller fraction of its credit markets, so the debt is much easier to service and sustain. As a result, the absolute amount of debt in countries cannot usefully be compared unless each country's debt is adjusted for the scale of the economy. In fact, a single country's debt in different periods cannot be usefully compared because the scale of the economy increases over time.

Because economic scale differs across countries and over time, a more accurate assessment of the economic impact of debt is made by adjusting the absolute amount of debt for scale. A common way to do this is to divide the absolute amount of a country's national debt by its GDP. When the U.S. Gross Debt was $10 trillion, the debt/GDP ratio was about 71% ($10 trillion/$14 trillion). In historical comparison, the U.S. debt/GDP ratio was 120% at the end of World War II (WWII) and did not decline to 73% until the mid 1950s. During the Clinton administration, the ratio declined to about 60% (see Figure 36.1). The 2007, debt/GDP ratios in seven large capitalist-oriented economies were 64.2% in Canada, 104% in Italy, 170% in Japan, 63.9% in France, 64.9% in Germany, and 43.6 % in the United Kingdom. The arithmetic average is 85.1%.

Second, the U.S. Federal Reserve holds a substantial fraction of the Gross Debt. Federal Reserve holdings of the debt do not impose the same tax burden as other publically held debt because the Fed remits interest income it earns on U.S. bonds back to the Treasury. Prior to the 2008 financial crisis, the Federal Reserve held about $800 billion of the Gross Debt. Subtracting this amount from the Gross Debt reduces the debt/GDP ratio to about 65.7% ($9.2 trillion/$14 trillion).

Third, federal agencies, such as the Social Security Administration, have large holdings of federal government bonds. At the end of fiscal 2008, intra-agency debt was more than $4 trillion. Some public finance economists argue that this debt is not a true burden on taxpayers: Although it is a liability of one government agency, it is an asset to another agency. However, this point is controversial, because Social Security and Medicare suffer from

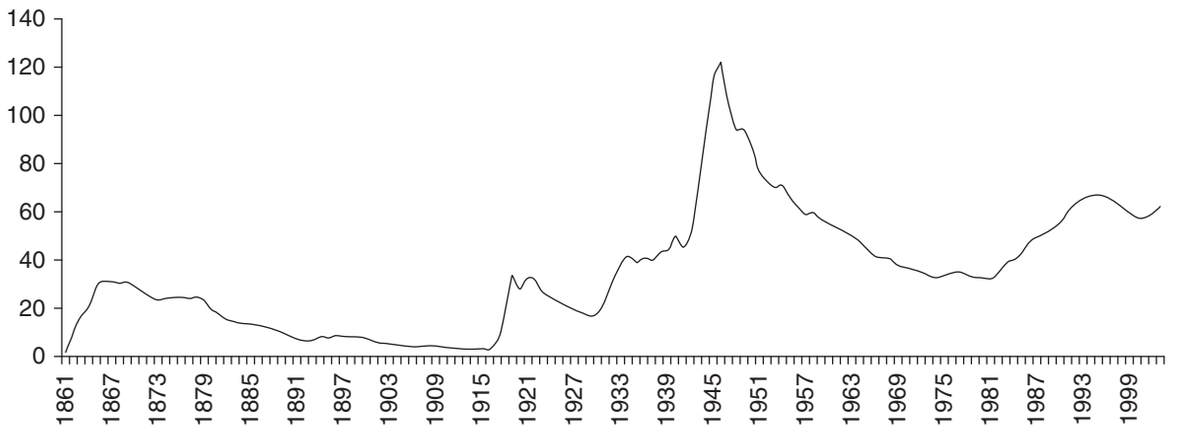

**Figure 36.1** Ratio of U.S. Federal Gross Debt to U.S. GDP, 1861–2003

SOURCE: Noll (2008). Derived from figures provided by Robert Sahr, Oregon State University.

NOTES: The figure shows what the U.S. Treasury and this chapter refer to as Gross Debt. The U.S. Treasury defines the *publicly held debt* to be the Gross Debt minus U.S. trust funds.

large fiscal imbalances that imply large future tax liabilities (more on this point subsequently).

Fourth, state and local governments include bond finance of capital infrastructure expenditures in capital budgets. In contrast, the U.S. government does not report a capital budget. Instead, it includes debt finance of capital expenditure in the Gross Debt. However, to the extent that public capital is productive, it provides taxpayer benefits that tend to offset the liabilities. Productive public capital can increase national income, generating tax revenue that reduces future borrowing needs. The 2008 *Economic Report of the President* reports that federal government net investment was $38 billion in 2007.

Fifth, most outstanding U.S. debt held by the public has a fixed dollar value. However, inflation reduces the real value of this debt. This means that inflation reduces the real value of tax revenue that will be needed in the future to finance debt service. Thus, the current dollar value of the debt overstates its real economic effect. This should not be taken to imply that the national government has license to reduce its real debt by expansionary money policy that would create inflation. For, taxpayers learn to expect persistent inflation. Expected inflation causes nominal interest rates to increase, which causes the dollar value of the debt to rise. Everything else constant, over time, inflation loses its ability to decrease the real value of debt.

Sixth, Laurence Kotlikoff (1992) argues that proper accounting reveals that the true value of the U.S. government's liabilities far exceeds the Gross Debt. In addition to the government's explicit liabilities counted in the Gross Debt, there are large implicit liabilities created by the Medicare system and Social Security. Future revenues expected to be generated by these programs fall far short of the implicit liabilities. Estimates of the shortfalls vary between $25 trillion (Rosen & Gayer, 2008) and $40 trillion (Kotlikoff & Burns, 2004). However, in the future, the U.S. government could legislate lower benefits, whereas it almost certainly will not default on its bonds. Thus, the true size of the U.S. Gross Debt remains a matter of debate.

## What Is a Budget "Deficit" and What Is Its Relation to the Debt?

A national government budget deficit occurs when expenditure exceeds tax and fee revenue in a single fiscal year. In this case, the government must borrow to make up the difference. Therefore, a deficit causes the Gross Debt to increase. For example, U.S. federal government expenditures exceeded its revenues by $363 billion in 2007. Thus, the Gross Debt increased from about $8.5 trillion at the end of 2006 to about $8.9 trillion at the end of 2007.

The official deficit reported by the U.S. Treasury in 2007 was $162 billion. Note that this is less than the $363 billion figure just cited. The smaller figure results from the fact that the official deficit includes the "surplus" in the Social Security program. The government spends Social Security surpluses each year. Because the surpluses are spent, when Social Security receipts eventually fall short of benefits paid (around 2017), the difference must be made up by public bond sales, or by increased taxes, or by decreased spending. Public finance economists argue, therefore, that a more accurate accounting of growth in the debt would exclude Social Security surpluses from the deficit. In this case, the $363 billion figure is a more precise measure of the increase in the debt than the official deficit reported by the Treasury.

Recall that the absolute dollar amount of the national debt does not convey its impact on the economy because the size of the economy grows over time. Economic scale also affects the economic impact of a country's deficit. The preceding figure indicates that the Gross Debt/GDP ratio reached its highest recorded value at the end of WWII. At that time, the deficit/GDP ratio also reached its highest value, about 13%. In 1983, the ratio reached a postwar record of 4.9% (see Figure 36.1). In 2008 the deficit/GDP had fallen to about 2.8%. However, at this writing, the Congressional Budget Office has predicted that the recession that began at the end of 2007 could drive the ratio above 8% in fiscal 2009.

## Do Budget Deficits Improve Economic Welfare?

Almost without exception, U.S. federal government deficits have been a fact of life since the early 1960s. Partly as a result of this record, a vigorous debate over the costs and benefits of deficits has arisen. Deficits have potential to both improve equity and diminish it. They can create efficiencies as well as inefficiencies. This section reviews the arguments pro and con.

It is useful to begin with what the debate is *not* about. Deficit expenditures on productive public capital investment can be efficient in cases where private markets underproduce such investment. For the most part, the deficit debate is not about debt finance of public capital infrastructure. Instead, the discussion in this section focuses on deficit finance of the national government's operating expenditures.

The economics of budget deficits are somewhat different in wartime and peacetime. Consider wartime. Wars tend to absorb outsized amounts of an economy's resources. Rather than relying solely on taxes to acquire resources, national governments often resort to borrowing (see Figure 36.1). The alternative is to increase taxes. Because the wartime generation sacrifices the use of resources, while future generations presumably benefit from the wartime effort, it has been argued that borrowing to finance wars is equitable. By the same token, it has been argued that debt finance of a war is an efficient investment if it makes citizens in current and future generations better off than they otherwise would be.

The economics of peacetime deficits are more complicated. First, the effects of deficits appear to depend on the specific types of expenditures the deficits support. Second, the effects of deficits appear to depend on the

way household saving responds to deficits. Third, the impact deficits have depends on where the economy is located in the business cycle when the deficit is incurred.

Before discussing these issues, it is useful to address a general problem that may arise in the case of debt finance of most types of public expenditures. If current taxpayers believe that others, not they, must repay funds borrowed by the government, debt finance tends to be more politically palatable than taxes. In this case, the ability to finance debt may lead to larger government expenditures than taxpayers would choose if they believed, instead, that they themselves would be required to repay the debt. Therefore, the government's ability to use deficit finance can lead to inefficiently large amounts of expenditure.

This inefficiency may be offset, to some degree, by the fact that debt finance can be used to reduce the variability of tax liabilities. Reduced tax variability is more efficient (Barro, 1979). To see how, note that variation in tax liabilities from period to period reduces taxpayer welfare, even if the overall tax liability is unchanged. This is true because variability in tax liability causes variability in disposable income, which, in turn, causes variability in household consumption. By the well-known economic law of diminishing returns, an increase in consumption adds less to welfare than a decline in consumption reduces welfare. Consider two ways a household can allocate a given level of income: In the first case, consumption is high at first, followed by low consumption; in the second case, the same level of income is consumed evenly over time. The second case provides more utility. It follows that a given level of tax liabilities reduces utility by less, if tax liabilities are constant over time. In the short run, government revenue requirements vary greatly because of short-run variation in demand for government services. Altering tax liabilities each period to equal the changing revenue requirements reduces welfare more than smooth tax liabilities. Debt finance can be efficient if it is used to smooth tax liabilities: The government can maintain constant tax liabilities by borrowing when revenue requirements are relatively high (e.g., in wartime or in economic crisis) and by repaying loans when requirements are relatively low.

Kotlikoff (1992) argues that the U.S. pay-as-you-go Social Security system incurs large *implicit* deficits. If the Social Security program is not reformed, current generations are receiving Social Security benefits that must be paid for by future generations, transferring wealth from future generations to current generations. In this case, implicit deficit finance is inefficient: Resources are not allocated where they have the highest social value in the sense that if all citizens, future and current, were fully informed about the system's costs and benefits, they would chose a different allocation. The Social Security system also is inequitable because citizens who are born into different generations, but have equal abilities to pay, face different levels of taxation.

Further, deficit finance, implicit as well as explicit, has a potential to inefficiently reduce future production and a nation's standard of living (Altig, Auerbach, Kotlikoff, Smetters, & Walliser, 2001; Auerbach & Kotlikoff, 1987; Feldstein, 1974). This point requires some explanation.

Deficits can reduce the future standard of living if they increase consumption and reduce national saving. To see this, note that national saving is the sum of private, business, and government saving. Also note that the economic effect of borrowing is equivalent to a decline in saving. For example, a household can finance a car by reducing its bank account by $25,000, reducing savings, or by retaining the bank account and borrowing $25,000: The economic effects are the same. Therefore, a deficit is a decline in government saving. If a deficit-induced decline in government saving is not accompanied by an equal increase in private saving, national saving will be lower than otherwise. Lower national saving tends to increase the interest rate: In this case, investment declines because the interest rate is a principal part of the cost of capital. The process by which increased deficits cause investment to decline is called *crowding out.*

If deficits crowd out private investment, and the government does not use the borrowed funds to purchase productive capital, national capital investment will be lower than it otherwise would be. In this way, crowding out can reduce the amount of capital inherited by future generations, thereby lowering future standards of living. Douglas Elmendorf and N. Gregory Mankiw (1999) estimate that deficits have reduced U.S. incomes by 3% to 6% annually. In this case, unless there is an offsetting economic rationale to run deficits, they are inefficient.

However, deficits may not have such dire effects and, Robert Barro (1974) argues, may not matter at all. Barro argues that deficits (implicit or explicit) do not affect national saving, capital investment, or the future standard of living. This will be true if private savers respond to the deficits by saving more, thereby offsetting the deficit's negative effect on national saving. Private savers might increase saving if they foresee the negative effect the deficit otherwise could have on future living standards, and if they are determined to prevent deficits from undermining their children's futures. In opposition to this idea, B. Douglas Bernheim (1987) argues that deficits reduce national saving if the amount that households can borrow is restricted by financial markets. In this case, deficit-financed tax cuts provide these households with funds they would like to borrow from markets, but cannot. These households treat deficit-financed tax cuts as they would borrowed funds, and spend them, reducing private saving and national saving.

Whether debt finance does or does not reduce national saving is an empirical issue and can be decided only on the basis of careful statistical analysis of savers' behavior (Bernheim, 1987). Currently, there appears to be fairly widespread agreement among economists that deficit finance tends to reduce national saving. In particular, there appears to be a consensus that deficits increase aggregate demand. Economists who take this view argue that if

deficit finance is used to increase government expenditures, aggregate demand increases directly. If deficit finance is used to reduce taxes, taxpayers spend at least part of the tax cut, increasing aggregate demand indirectly. The remainder of the discussion studies the effects of deficits in these cases.

Tax collections based on personal income, corporate income, and sales decline during contractions. At the same time, social spending by government tends to rise during contractions. Thus, if the federal government were prohibited from running deficits in contractions, it would be required to increase taxes or cut spending, or both. The federal government's budget is a very large share of the U.S. economy (about 20% of GDP), so such tax increases or spending decreases would tend to exacerbate contractions, which would inefficiently increase the extent of unemployed resources. Thus, contraction-induced deficits are favored by many macroeconomists and policy makers.

Are contraction-induced deficits consistent with the government's IBC? As explained before, the important economic implication of IBC is that government must reliably pay the market rate of return on its debt; thus, the debt cannot grow faster than the economy in the long run. If the government ran persistent deficits, the debt would outrun the economy's ability to produce tax revenue required to service the debt, so persistent deficits are not sustainable. Thus, contractionary deficits satisfy IBC only if the government eventually runs surpluses. An efficient deficit policy would have the government repay recessionary deficits with expansionary surpluses. In this case, the government budget would be balanced *across the business cycle:* Resources absorbed by the government during recessionary deficits would be freed up during subsequent expansions.

Because resources are underutilized during recessions, many macroeconomists argue that the government can and should be more proactive than simply permitting recessionary deficits. They argue that the government should purposely increase deficits during economic contractions, and that doing so would increase aggregate demand, thereby reducing the severity of contractions. In this case, policy makers would resist cyclical contractions by legislating larger expenditures and lower taxes. This is called *activist counter-cyclical* fiscal policy. Such policy has a potential to be efficient, if it does not short-circuit the economy's self-correcting mechanisms and if the government balances its budget over the business cycle.

## How Are Government Debt and Foreign Debt Related?

The *foreign debt* is the accumulated amount that foreigners have lent to both private and government borrowers in the United States, minus the accumulated amount foreigners have borrowed from (primarily private) U.S. lenders. A substantial fraction of loans to U.S. governments are provided by foreigners. For example, before the 2008 financial crisis set in, about 32% of U.S. Gross Debt was owned by foreigners.

As explained earlier, budget deficits tend to increase interest rates, particularly if the economy is expanding. The increase in interest rates encourages foreign lending to the United States, which increases the U.S. foreign debt. Thus, U.S. government debt tends to be positively correlated with the U.S. foreign debt.

## Does Foreign Ownership of U.S. Debt Affect the Standard of Living?

By themselves, deficits tend to increase interest rates. Foreign lending increases the supply of loanable funds, which tends to offset the positive pressure deficits exert on interest rates. More generally, foreign lending tends to reduce the cost of U.S. borrowing, which can support economic growth. However, foreign lending also tends to increase the foreign exchange value of the U.S. dollar because lenders must buy dollars in order to buy the U.S. debt. An increase in the exchange value of the dollar tends to reduce U.S. exports and increase U.S. imports, which tends to reduce economic growth. Therefore, the net effect that foreign lending has on the U.S. standard of living is an empirical question and cannot be determined by theory alone.

Many economists assume that foreign lending increases growth and the standard of living, at least in the short run. If so, the effect may be temporary: After all, interest on foreign debt must be paid, and foreigner lenders may someday choose not to refinance loans to the U.S. Does government borrowing from foreign investors increase the U.S. standard of living in the long run? There are a number of possibilities.

First, if U.S. governments use the borrowed funds for productive capital investment, the capital stock will be larger and future U.S. production will be larger. If the productivity of the public capital investments exceeds the interest on the loans, future U.S. living standards will tend to be higher than otherwise. However, if interest payments exceed the productivity of public capital, future U.S. living standards would tend to be lower than otherwise, even if U.S. production is larger. In this last case, even though the borrowed funds increase U.S. output, the income generated contributes to foreign living standards, not U.S. living standards.

Second, if U.S. governments use the borrowed funds for consumption, the foreign debt does not contribute to future production, and debt service would reduce future U.S. living standards because part of the unchanged level of production must be delivered to foreign lenders.

Third, a large and rapid shift away from foreign lending to the U.S. could cause the foreign exchange value of the dollar to decline precipitously. In this case, U.S. interest rates would rise, and the U.S. standard of living could decline sharply. Fortunately, events such as these have never occurred in the U.S. However, they are a real risk

whose possibility should be taken seriously in fiscal policy makers' deliberations.

### A Balanced Budget Amendment?

The federal government is not required to balance its budget. Because deficits can be used to increase government expenditure above the amount fully informed taxpayers would choose, some public policy analysts advocate a strict Balanced Budget Amendment (BBA) to rule out federal deficits.

A disadvantage of a strict BBA is that it would prohibit deficit spending in recessions. This would require the government to increase taxes or cut spending during economic contractions, which would tend to exacerbate downturns and make taxes more variable, both of which are inefficient. Further, a strict BBA would prohibit countercyclical fiscal policies of the sort that observers of many political persuasions support during recessions.

### Are U.S. Deficit (Debt) Policies Sustainable?

The crucial economic implication of the IBC is that government debt cannot persistently grow faster than the economy. If the debt growth persistently exceeds GDP growth, investors would eventually demand prohibitively high interest rates, or simply refuse to purchase additional government debt. The relative growth rates of debt and GDP are reflected in the debt/GDP ratio, which increases if the debt grows faster than the economy. In 1980, 1990, 2000, and 2008, the debt/GDP ratio was, respectively, 32.0%, 55.2%, 57.3%, and 73.0%. For 3 decades now, U.S. debt policy has been on an unsustainable path. The longer the U.S. continues on this trend, the more serious the economic repercussions will be.

## Conclusion

Government budgets provide information the public needs to evaluate costs and benefits of government services and indicate whether the government is operating in a financially responsible manner. Capital budgets allow taxpayers and investors to evaluate the risk and returns of government investment more easily. State and local governments report capital budgets. The U.S. federal government does not. A federal capital budget would make it easier for taxpayers and investors to evaluate the risk and net returns of federal government programs.

State and local governments can reduce the adverse budget effects of economic contractions by properly structured and appropriately sized RDFs. RDFs can help reduce the need for ad hoc reductions in expenditures and increases in taxes that often accompany budget shortfalls. Thus, RDFs can reduce the risk of credit downgrades, uncertainty, and the excess burden of state and local taxes.

The National or Gross Debt is the value of all outstanding national government bonds. If government debt persistently grows faster than the economy, creditors will demand abnormally high interest rates or may refuse to purchase government debt. The economy can suffer severe damage. In a debt crisis, the government must raise taxes or cut government expenditure, default on its liabilities, or repudiate the debt.

There is a long list of reasons why the reported value of national debt must be interpreted cautiously, if one is to understand its economic effects. First, the debt/GDP ratio adjusts the raw value of the debt for economic scale and provides a reasonable tool that can be used to compare debt policies in different countries, as well as the debt of a single country in different years. Second, central banks hold substantial fractions of national debt: This tends to diminish some of the adverse effects of government debt and should be taken into account in attempts to evaluate debt's economic impact. Third, some fraction of debt finances public capital, which can contribute to economic growth and tax revenue needed to service the debt. Thus, government infrastructure investment also should be accounted for when evaluating the effects of debt. For this reason, many economists favor a federal government capital budget separate from the operating budget. Fourth, a substantial part of the debt has a fixed dollar value, which declines in real terms when inflation is positive. Thus, many economists agree that the real value of the debt influences interest rates, investment, and the standard of living. Fifth, the U.S. government has incurred large implicit liabilities that are not counted in the Gross Debt. Thus, the reported national debt understates the government's true financial liabilities and provides a misleading estimate of future tax revenues necessary to sustain U.S. fiscal policy.

Debt issue can be used to reduce the variability of taxes, increasing efficiency. It can be used to spread out the costs of government to future generations, who benefit from current government expenditures, which most observers judge to be equitable. However, the ability to issue debt can lead to inefficiently large government expenditure if voters believe they will benefit from spending they will not pay for. Implicit government borrowing can also be used to transfer wealth from future to current generations, which can be inefficient and inequitable (Kotlikoff, 1992). Debt finance can reduce future production and a nation's standard of living, if deficits crowd out private investment and government does not use the borrowed funds to purchase public capital.

Many macroeconomists argue that the government can and should use countercyclical deficit policy to reduce the severity of economic contractions. Countercyclical fiscal policy has a potential to be efficient, if it does not short-circuit the economy's self-correcting mechanisms, and assuming the government balances the budget over the business cycle.

Deficit-induced increases in interest rates encourage foreign lending to the United States, which increases the foreign debt. Foreign lending tends to reduce borrowing costs and can contribute to economic growth. However, foreign lending also tends to increase the foreign exchange value of the U.S. dollar, which can reduce U.S. net exports, reducing growth somewhat. The net effect cannot be determined by theory. Funds borrowed from foreign investors and used for public investments can increase the standard of living in the long run, if the return on investment exceeds the interest cost. If the funds are used for consumption, foreign lending will tend to reduce future U.S. standards of living. Foreign debt runs a risk that foreigners may suddenly shift investments away from the United States, which can damage the U.S. economy severely.

Finally, government debt cannot grow faster than the economy in the long run. U.S. Gross Debt has grown faster than the economy for decades. U.S. fiscal policy surely is not sustainable.

# Monetary Policy and Inflation Targeting

Pavel S. Kapinos
*Carleton College*

David Wiczer
*University of Minnesota*

Inflation targeting (IT) is a framework for the conduct of monetary policy, under which the monetary authority announces a medium- or long-run inflation target and then uses all available information to set its policy instrument, the short-term nominal interest rate, so that this target is met. Short-lived deviations from the inflationary target may be acceptable, especially when there may be a short-run trade-off between meeting the target and another welfare consideration, for example, the output gap—the difference between actual and potential output. Hence, although the central bank commits to meeting a certain inflationary target, in practice, IT takes a less rigid form, with the central bank exercising some discretion over the path of actual inflation toward its target. Recently, dozens of central banks around the world have introduced IT as their operational paradigm. Numerous studies indicate that this policy has been successful in achieving macroeconomic stability at no long-run cost in terms of lower real activity. Many central banks that have not explicitly subscribed to IT have been shown to follow it implicitly.

IT provides a way for the central bank to communicate its intentions to the public in a clear, unequivocal manner, making the conduct of monetary policy more transparent and predictable. Transparency allows the public to hold the central bank accountable for its policy actions. In fact, in some countries, inflation-targeting central banks are subject to intense public scrutiny from the legislative bodies. Predictability of monetary policy allows the central bank to manage public inflationary expectations and better anchor them around the inflationary target; this allows the central bank to achieve macroeconomic stability more effectively.

Alan Greenspan (2004) has famously posited that "the success of monetary policy depends importantly on the quality of forecasts" (p. 39). In practice, monetary policy affects macroeconomic activity with a lag, hence forming accurate forecasts of the future macroeconomic activity is of paramount importance. Several IT central banks are reforming their communications procedures to make their macroeconomic forecasts, as well as projections of the nominal interest rate path to meet their stated objectives, publicly available.

Although, historically, central banks have paid close attention to a large number of macroeconomic variables, there are several reasons for the central bank to focus on only one variable as its target and to make inflation that variable. The central bank generally has only one independent instrument: the short-term nominal interest rate. With this single instrument, the Tinbergen principle states that they can achieve their target for only a single variable. Even though they may rightly care about many macroeconomic variables, they would need new tools to move each one independently. Furthermore, theoretical literature

focusing on the role of forward-looking (rational) inflationary expectations formed by the public has shown that central banks that take a particularly tough stance against inflation may generate better macroeconomic performance in the long run (Rogoff, 1985). Inflationary conservatism on behalf of the central bank moderates inflationary expectations and brings about full employment at a lower rate of inflation.

Beyond its theoretical advantages, IT succeeds in practice with lower, more stable inflation and more stable real activity. As more countries adopt the IT framework, the evidence in its support grows. After New Zealand in 1990, a cascade of developed and developing countries followed, including relatively large economies, such as Canada and Brazil, and relatively small ones, such as the Czech Republic and Israel. Although the largest central banks, the European Central Bank (ECB) and the U.S. Federal Reserve, have yet to adopt IT explicitly, in practice, their monetary policy conduct seems to match the IT framework quite closely, with Ben Bernanke, the Chairman of the Federal Reserve, known as an early vocal proponent of explicit IT. Its growing popularity clearly signals the merits of adopting IT as the paradigm for the conduct of monetary policy.

This chapter's assessment of modern IT first traces its historical roots, exploring both the antecedent monetary frameworks and the developments in economic theory that motivated its present-day form. We then discuss how IT is implemented in practice and the preliminary empirical evidence from the countries that have adopted it. To conclude, we offer suggestions on how the IT consensus might grow and its prospects as a unifying framework for monetary policy.

## Historical Background

In 1931, faced with the global depression and speculative attacks on its currency's gold peg, the Swedish Riksbank began a 6-year experiment with price level targeting (PLT), the first and only of its kind. Just as the gold standard was renounced, the bank promised price stabilization "using all means available." Like modern IT, PLT sought to commit monetary policy to a single nominal goal. The Riksbank was a likely pioneer, given the country's economics tradition. As early as 1898, Knut Wicksell, a Swedish economist, discussing the role of the monetary instrument, recommended that the discount rate should move with the price level to dampen its volatility. When its PLT policy was first formulated, the Riksbank was given instrument independence—that is, it could use interest rates any way it saw fit to meet the price level target set by the government.

The price-targeting regime was, however, conceived in a very different context than that faced by the modern IT adopters. In the depressed economic conditions of the 1930s, deflation was a serious risk, and even though many feared inflation after Sweden eschewed the gold standard, adhering to the price level target was also meant to fight deflation that crippled the rest of the world. Indeed, from 1928 to 1932, Swedish prices declined steadily in line with the rest of the world but then rose slowly for the rest of the decade, and though unemployment peaked in 1933, output stayed comparatively strong through the 1930s.

As a proto-targeting regime, the Swedish experiment differed in several ways from modern IT. By committing to hold a specific price level, excess inflation has to be compensated with periods of deflation. In contrast, modern IT does not compensate for inflationary buildup in prices, as long as the rate of inflation returns to the target. The Swedish experiment was initially meant to be only a temporary break from the gold standard. They announced the policy with the caveat that it was a temporary measure, but without a strict ending date. Modern inflationary targeting, on the other hand, can be successful only in the long term, because much of its performance depends on how well the central bank can build credibility and manage the public's inflationary expectations. To further muddle policy design, the parliament gave the Riksbank its targeting mandate but did not communicate a quantitative target, nor even a price measure (i.e., CPI, wholesale prices, etc.). And while an IT central bank today uses forecasts to communicate its intentions, the Riksbank never published these. The Riksbank's PLT experiment ended in 1937 when monetary and fiscal policies were reorganized along Keynesian lines to pursue aggregate demand stabilization.

Keynesian thinking dominated policy right through the 1960s, and policy prioritized full employment above price stability. Fitting its diminished importance globally, monetary policy was squeezed into a tight framework after World War II. World prices were anchored to the dollar, which hypothetically was convertible to gold. Central banks still worried about inflation but believed that it could be easily traded off against unemployment in a fashion that did not change over time. A coordinated action of taxing, spending, and discount rate manipulation would pinpoint a position on the so-called Phillips curve, an empirical regularity characterizing the trade-off between inflation and unemployment that policy makers felt could be exploited to match social preferences with respect to these two variables.

The major question became gauging what combination of evils, unemployment versus inflation, would be most socially tolerable. Not surprisingly, the generation that still remembered the Great Depression was more sensitive to unemployment. The popular press was sure of the economists' prowess, proclaiming in a 1965 *Time* cover story that successful policy could coax an economy to full employment. The story was titled "We Are All Keynesians Now," a quote from Milton Friedman[1], but it never mentioned policy's role in guiding inflationary expectations. In the 1950s and 1960s, macroeconomists rarely objected to linking unemployment and inflation with some linear

relation and estimating the equation's coefficients. This led to a natural policy prescription that anytime lower unemployment is desired, inflation should be allowed to increase. The working assumption was that inflation would move along a static Phillips curve, given the rate of unemployment.

An undercurrent of economists in the 1960s and a deluge in the 1970s called to question the status quo that had developed up until then. Accelerating inflation in the United States spread across the world, and the economics profession began to question whether these reduced-form equations really were as time invariant as Keynesians claimed. They tried to ground macroeconomic relationships in models of rational individuals and found Keynesian economics critically incomplete and misleading. The result was a Phillips curve incorporating inflationary expectations that became central in explaining the dynamic macroeconomic evolution.

In his celebrated presidential address to the American Economic Association, Friedman (1968) suggested that a monetary policy that actively tries to promote macroeconomic stability may actually disrupt it because of the poor quality of information available to policy makers. He suggested targeting monetary aggregates (by keeping money supply growth constant) to promote long-term stability. Friedman's speech almost perfectly coincided with the breakdown of the Bretton-Woods system in the early 1970s, in whose wake central banks were forced to design new operational paradigms for the conduct of monetary policy. This sort of policy is an "intermediate target" because money supply is not a welfare criterion in itself but is a major determinant of inflation.

Money targeting had to be abandoned relatively quickly due to the unstable relationship between monetary and other macroeconomic aggregates. There is widespread consensus that the Federal Reserve pursued monetary targets only between 1979 and 1982. Instead, central banks have started searching for alternative frameworks for the conduct of monetary policy, and toward the 1990s, a number of central banks were poised to start IT.[2] Before we document the adoption of IT by central banks around the world, we will lay out a simplified version of the theoretical framework that is frequently used for analyzing the design of an IT regime.

## Implementing IT: Theory

A large body of recent theoretical literature has been dedicated to the study of monetary policy. Richard Clarida, Jordi Gali, and Mark Gertler (1999) and Michael Woodford (2003) provide a comprehensive overview of the issues and methods involved in studying monetary policy conduct from the New Keynesian perspective. The baseline version of the model has three sectors: households, firms, and the monetary authority. The first-order conditions from the household utility maximization problem give rise to the IS schedule that describes the equilibrium evolution of a measure of real activity or *output gap,* defined as the percentage deviation of actual output from potential, as a negative function of the real interest rate. By adjusting the nominal interest rate, therefore, the central bank can influence the level of real activity in the economy.

Monopolistically competitive firms set optimal prices for their output, with different firms resetting prices at different points in time, which gives rise to changes in relative prices of different outputs and hence welfare-loss-generating distortions that the policy maker is called to moderate.[3] The first-order condition to this problem yields the New Keynesian Phillips curve (or the aggregate supply relation); a key feature of this structural equation is the presence of forward-looking, rational inflationary expectations. The baseline version of this Phillips curve takes the form

$$\pi_t = \beta \pi_{t+1|t} + \kappa (y_t - y_t^n) + \varepsilon_t,$$

where $\pi_t$ is inflation, $\pi_{t+1|t}$ is the expectation of next period's inflation based on information available at the present time period, $(y_t - y_t^n)$ is the (log) difference between actual and natural (or potential) output—or output gap—and $\varepsilon_t$ is the cost-push shock. The *output gap* term can be motivated by changes in the firm's labor costs, whereas the cost-push shock is by changes in the markup that firms charge in excess of their labor costs. The presence of the *expected inflation* term is due to price stickiness modeled by the firm's potential inability to change prices optimally in the future. Anticipating future inflationary pressures then enters the firms' current pricing decisions and makes it important for the central bank to engage in managing inflationary expectations, as moderating those will result in lower inflation in the present.

Finally, the central bank needs to determine how the nominal interest rate is set in order to close this three-sector model. There are two ways of thinking about the conduct of monetary policy that have been widely used in the recent literature. One is due to the insight of John Taylor (1993), who pointed out that the Federal Reserve seemed to set the nominal interest in response to inflation and output gap. A number of empirical studies have confirmed that following this so-called Taylor rule has characterized the conduct of monetary policy in the United States in the recent past quite well. A large body of theoretical literature has shown that Taylor rules deliver macroeconomic stability in a variety of models.

Another way that monetary policy has been modeled is by assuming that the central bank minimizes a discounted stream of weighted averages of squared deviations of inflation from its target level and output from its target level (set at the potential level of output). Lars Svensson (2002, 2003) has been a particularly strong advocate of thinking about monetary policy in terms of minimizing volatility of inflation and output around their target levels rather than

the mechanistic approach exemplified by Taylor rules. (Svensson calls the former *targeting rules,* because they are built around inflation and output targets, and the latter *instrument rules,* because they explicitly define the value of the nominal interest rate in terms of the other variables.) This setup places the conduct of monetary policy into a dynamic setting and offers a richer variety of insights.

One such key insight is the problem of the time inconsistency of optimal policy, originally pioneered by Finn Kydland and Edward Prescott (1977) and Guillermo Calvo (1978). Suppose that the economy experiences a positive transitory cost-push shock. The central bank can moderate its instant inflationary effect by promising to keep output below potential in the future time period. This reduces inflationary expectations and (partially) offsets the effect of the cost-push shock. Hence in the present, this shock will generate lower inflation and a smaller decrease in output below potential. In a way, the central bank commits to spread the real-economic pain from the cost-push shock over several time periods, even when the immediate impact of the shock is long gone. Although this policy generates optimal outcomes over the long haul, it does run into short-run difficulties. In particular, in the time period following the transitory shock, the central bank has no incentive to make good on its promise to generate a recessionary environment, which helped moderate inflationary expectations—that is, it has an immediate incentive to renege on its contractionary promise because the effects of the shock have already dissipated. But if it discretionarily reneges on its promise, once another cost-push shock materializes, it will not be able to pursue a dynamically optimal stabilization policy with any measure of credibility, hence generating worse macroeconomic outcomes from there onward.

Another implication that emerges out of the dynamic targeting setup is that, especially given the long and variable lags in the transmission of monetary policy through the economy, it makes little sense for a central bank to set the nominal interest rate in response to a small number of contemporaneous variables in a predetermined, mechanical fashion. Furthermore, given the forward-looking nature of macroeconomic agents, what may matter more for the successful conduct of monetary policy is not the current level of the nominal interest rate but its projected path over some future time horizon. Identifying such a path is impossible without first postulating a dynamic objective over which the central bank wants to optimize.

In practice, these challenges make it virtually impossible for a central bank to achieve its target with current inflation, and instead, it will target expected inflation some periods into the future. Targeting future inflation also gives the central bank greater flexibility in considering output volatility as well. Woodford (2003) explains,

> The argument that is typically made for the desirability of a target criterion . . . with a horizon $k$ some years in the future is that it would be undesirable not to allow temporary fluctuations in inflation in response to real disturbances, while the central bank should nonetheless provide clear assurances that inflation will eventually be returned to its long-run target level. (p. 292)

IT central banks seem to exhibit their most meaningful differences by the length of this lag. More "flexible" IT regimes accommodate some real shocks and often will not return inflation to its target for much longer than their "stricter" counterparts who target the earliest feasible date. Svensson (1998) estimates that this time range for meeting the target is anywhere from 1.5 to 2.5 years. (As discussed below this "flexibility" opens these central banks to the criticism that their policy making is actually arbitrary.) More flexible IT regimes may allow the monetary authority to give some attention to unemployment or a real objective while still promising a certain level of inflation in the long run. Additionally, they may also allow greater instrument stability, as wide swings in interest rates may be painful in themselves. To show how the central bank balances these additional criteria, the terms that characterize their stabilization can be added into the central bank's objective function with weights to show their relative importance. In a more strict IT regime, other concerns have relatively low weights, so that it may worry about large swings in these variables, but it still chiefly focuses on inflation stabilization.

Some critics of IT insist that insofar as the duration of actual inflation being off its target is uncertain, IT affords the monetary authority too much flexibility and is therefore destabilizing. For instance, in his criticism, Benjamin Friedman (2004) invokes the Tinbergen principle, which holds that with only one independent instrument, the variables relevant to monetary policy can be expressed in relation to one particular variable. This means that when a shock hits, and output and inflation are both off their desired level, the transition path of output is dependent on the path of inflation, so by choosing how long inflation may be out of the target range, the central bank implicitly chooses how output will respond. Since IT states the target for only one variable—inflation—and fails to communicate the central bank's preferences with respect to other variables of interest, it may be viewed as too opaque. This critique, however, does not breach the consensus view that IT is successful in augmenting the central banks' transparency, accountability, and success in mitigating business cycle volatility.

Although a tremendous amount of progress has been made in identifying the chief challenges of monetary policy making and demonstrating the benefits of IT, there does not exist a universal consensus on the exact methods for the implementation of IT. The next section reviews the recent experience of different countries whose central banks have adopted IT. Despite considerable differences in implementing this policy, the picture that emerges

from our description points to its success in achieving macroeconomic stability.

## Implementing IT: Practice

New Zealand was first to set an explicit inflation target for the medium run. The Reserve Bank of New Zealand (RBNZ) had a wide-ranging mandate from a 1964 law that charged it with "promoting the highest degree of production, trade and employment and of maintaining a stable internal price level." Inflation stayed in double digits for most of the 1970s and 1980s, a cumulative 480% between 1974 and 1988. But by the time IT was introduced in 1990, a period of very high interest rates had inflation mostly under control. Ben Bernanke, Thomas Laubach, Frederic Mishkin, and Adam Posen (1999) believe that this timing was important to build confidence in the IT framework, as the public did not blame the new policy regime for the induced tight monetary conditions.

The inflation target was in fact a range set by the government that gradually fell from 2.5% to 4.5%, to 1.5% to 3.5%, and finally to 0% to 2% after December 1993. Though the government held the central bank accountable to keep inflation in the middle of a range it set, the RBNZ enjoyed instrument independence—that is, the central bank could independently choose its policy for interest rate and exchange rates. The IT framework in New Zealand also evolved to become less strict, in that deviations are now allowed to persist longer than the initial yearly horizon.

IT in New Zealand was also pioneering in the degree of transparency and the central bank's communication of its decision making to the public. The RBNZ is legally required to produce a *Monetary Policy Statement* twice a year that outlines policy decisions. It also publishes forecasts in an *Annual Report,* other research in an annual *Bulletin* and a bi-annual *Financial Stability Report.* Starting in 1996, it has released a *Monetary Conditions Index* to summarize its forecasts.

Despite the eventual success of IT, the RBNZ did initially encounter some difficulties in its implementation. It first tried using "headline" or all-goods consumer price index (CPI) but found this too volatile. The RBNZ developed a concept of *underlying inflation* similar to a core measure to avoid including prices that were themselves sensitive to the first-round effects of a cost-push shock. Unfortunately, the core's components changed occasionally, making it somewhat ad hoc, and its time series was marked by definitional breaks. The relatively tight, certainly by the standards of a small open economy, inflation target range of 0% to 2% imposed additional challenges, as the RBNZ was occasionally forced to produce large swings in the interest rate in order to meet its objective. Several times, inflation breached its ceiling, which was lifted to 3% in 1997. Still, the experiment with IT at the RBNZ has undeniably been a success, as chronic and volatile inflation seems safely in the past.

In 1991, Canada was next in the steady succession of IT adopters, following an announcement by the head of its central bank and the Minister of Finance but without a legislative mandate, unlike in New Zealand. Prior to adopting IT, Canada's experience with inflation was less extreme than New Zealand's, but the 1989 inflation rate of 5.5% was deemed unacceptably high. As the policy was adopted, the disinflation was accomplished by high interest rates and a sharper than expected cyclical downturn; on the upside, however, IT accomplished low inflationary expectations. According to Gordon Thiessen (1999), the Governor of the Bank of Canada from 1994 to 2001, inflationary expectations did not fall because the bank promised it but because low rates of inflation were "realized"; however, the promise helped to entrench these gains:

> It is unlikely that the 1991 announcement of the path for inflation reduction had a significant immediate impact on the expectations of individuals, businesses, or financial market participants. On balance, I think that it is the low realized trend rate of inflation in Canada since 1992 that has been the major factor in shifting expectations of inflation downwards. But the targets have probably played a role in convincing the public and the markets that the Bank would persevere in its commitment to maintain inflation at the low rates that had been achieved.

Canada's IT regime focuses on the medium-term inflationary expectations because they are particularly susceptible to short-run shocks as a small, commodity-exporting economy like New Zealand. Following the RBNZ, the Bank of Canada excludes volatile components from their "core" price index that, in its judgment, are transitory. If these excluded shocks are mean-zero, then headline and core will move together in the medium term. This flexibility allows a central bank to avoid the adverse output implications of contractionary policy and is common among other IT regimes.

Canadian policy makers also emphasized a dialogue with the public, which has become important for the transparency of IT regimes. To help formulate policy response to inflationary expectations, they follow the *Consensus Forecasts* of market economists compiled by the private Conference Board of Canada. They have also geared their own publications to be easily digestible. The Bank of Canada produces the *Monetary Conditions Index,* a summary statistic for price-level determinants, and uses more charts in their *Annual Report* to encourage public confidence in the Bank's ability to meet its IT responsibilities.

Following New Zealand and Canada, the ranks of inflation targeters swelled during the 1990s. The United Kingdom and Sweden experienced sharp downturns and high inflation in the early 1990s and adopted IT regimes shortly thereafter. On the other hand, Australia's situation was similar to New Zealand's—a 1991 recession reduced

inflation before their IT regime was enacted. Thereafter, a slew of developing countries created explicit inflation targets, ranging from traditional inflationary basket cases, such as Israel and Brazil, to postsocialist economies, such as the Czech Republic and Poland. Each has its own idiosyncrasies: Some target *all-items inflation* (e.g., Israel and Spain), while others target an underlying or core measure (e.g., Australia and the Czech Republic). Table 37.1 summarizes the list of inflation targeters and the time of adoption of this policy.

The U.K. experience exemplifies the rationale for IT adoption in many industrialized countries. Following an inflationary bout in the 1980s, the British had stabilized their currency by tying it to the Deutsche Mark. But when large-scale speculation forced the authority to break their peg, the Bank of England experienced a great deal of exchange rate volatility and abruptly lost their intermediate target. To stabilize exchange rates and regain an anchor for price stability, they implemented a band for their medium-term inflation target and long-term goal of 2%. After Britain's success, other developed countries, such as Finland, Spain, and Sweden, also adopted inflation targets in response to foreign-exchange pressure.

Transitional and middle-income countries often have more volatile macroeconomic conditions and so may have even more to gain from the stability that IT imparts. Brazil's inflation has fluctuated wildly through its diverse monetary regimes. When its fixed exchange rate regime failed in 1999, it began IT as part of an International Monetary Fund program. In the market turmoil of 1997 to 1998, the Czech Republic's exchange rate target became untenable, and it adopted IT. To fit the regime to postcommunist transition, the Czechs have introduced a net inflation index, which excludes administered, or controlled, prices. Poland and Hungary followed, trying to stabilize their inflation to better integrate with Europe. South Korea began its policy under considerable duress after its financial crisis in the late 1990s, whereas Israel was trying to lock in its already completed disinflation.

Though the list of IT countries is 26-strong, the so-called G3—the U.S. Federal Reserve, the ECB, and the Bank of Japan—are notably absent. This is especially ironic given the Fed's long, (mostly) successful history of pursuing price stability and the enthusiasm for IT of its chairman, Ben Bernanke, during his distinguished stint as an academic economist. Despite the lack of a formal commitment to a clear inflation target, there has arguably been a progression toward the IT framework and greater transparency. In February 1981, the Supreme Court defended the Fed's right to secrecy, saying, "At bottom, the FOMC [has] concluded that uncertainty in the monetary markets best serves its needs" (*Merrill v. Federal Open Market Committee*). By 2004, Bernanke described an "ideal world" in which "the Federal Reserve would release to the public a complete specification of its policy rule, relating the FOMC's target for the federal funds rate to current and expected economic conditions, as well as its economic models, data, and forecasts." Presently, this ideal has not been reached.

Along with increasing its transparency, the Federal Reserve has been edging toward a de facto target range. In 2002, the term *comfort zone* appeared in a *New York Times* headline (Stevenson, 2002) and has subsequently been used by the Fed governors themselves to describe their desired inflation level. Still, they seem to lack credibility in this target, as admitted by Bernanke (2004): "Today

**Table 37.1** Inflation Targeting—Time of Adoption and Target Range

| *Country* | *Adoption* | *Target* | *Country* | *Adoption* | *Target* | *Country* | *Adoption* | *Target* |
|---|---|---|---|---|---|---|---|---|
| New Zealand | 1990 | 1%–3% | Chile | 1999 | 2%–4% | Hungary | 2001 | 3%(±1%) |
| Canada | 1991 | 1%–3% | Columbia | 1999 | 2%–4% | Peru | 2002 | 2%(±1%) |
| United Kingdom | 1992 | 2% | Switzerland | 2000 | <2% | Philippines | 2002 | 4%–5% |
| Sweden | 1993 | 2%(±1%) | South Africa | 2000 | 3%–6% | Indonesia | 2005 | 6%(±1%) |
| Australia | 1993 | 2%–3% | Thailand | 2000 | <3.5% | Romania | 2005 | 4%(±1%) |

long-term inflation expectations in the United States remain in the vicinity of 2-1/2 to 3 percent, above the range of inflation that many observers believe to represent the FOMC's implicit target."

Although much of the Fed's attention during the later part of 2008 was dedicated to the ongoing financial crisis, the minutes of the December 16, 2008, Federal Open Market Committee meeting reveal the participants' deliberation whether "a more explicit indication of their views on what longer-run rate of inflation would best promote their goals of maximum employment and price stability." The financial market turmoil drove the nominal interest rate toward its lower limit of zero. An explicit positive target rate of inflation may be needed to keep the nominal interest rate positive in the wake of large negative demand disturbances, such as a financial crisis. Matt Klaeffling and Victor Lopez Perez (2003), for instance, find that the presence of the zero bound implies that the optimal rate of inflation should be somewhat higher than in its absence, even if higher long-term inflation generates stronger macroeconomic volatility.

The ECB also does not consider its policy to be an explicit inflation target but has announced that an inflation rate below 2% is desirable. It promises to direct its policy to protect this bound. The legal basis of the ECB is also similar to an inflation target, as Article 105(1) of the treaty establishing the European Community mandates price stability as "the single monetary policy for which [the ECB] is responsible." But, in keeping with the flexibility under IT, its Web site notes that the ECB "typically should avoid excessive fluctuations in output and employment" (ECB, n.d.). The de facto similarity to a flexible IT regime leads some commentators to discuss the ECB as if it were one, although its own leadership rejects the label.

Arguing from the position of an ECB board member, Jürgen Stark (2007) suggested that part of the reason why the ECB does not explicitly join the ranks of inflation targeters is in order to preserve institutional continuity with its predecessors. The new authority wishes to be seen as inheriting the German Bundesbank's tenacity in controlling inflation. With its current strategy, Stark argues, the ECB has more flexibility in medium-term and long-term objectives and in communication strategy, as it can put less emphasis on forecasts. With a firm record of keeping its informal target, perhaps the ECB has already attained the credibility that an IT regime hopes to create.

Many early adopters of IT have been quite successful under the new monetary regime, but it has proven difficult to take a definitive stance on its overall effect. Table 37.2 compares the summary statistics for measures of inflation and output growth for IT and non-IT countries. In the 10 years prior to IT, New Zealand averaged 10.8% inflation with a standard deviation of greater than 5%, 1.8% output growth with a standard deviation of 1.85%. From 1990 to 2006, inflation was below 2% with a standard deviation of about 1%, and growth was higher and less volatile, about 3% with a standard deviation of 2%. Similarly, since Canada stabilized its inflation target

in 1995, inflation has been in its target 1% to 3% range almost continually, and its business cycles have been relatively mild.

Even countries that have missed their inflation targets, as have many of the adopters in developing countries, have had relatively strong performances and have reformed their policy practices in the aftermath of IT adoption. The Czech Republic is a good example of this, as it severely undershot its target in 1998 and 1999. It later began targeting headline CPI, rather than a restricted core, and made the target more strict, by promising to hold it continuously rather than just at year's end. In its first decade of IT, Czech output has been stable, averaging 4.1% with a standard deviation of 1.9%, and its inflation has been low and stable, averaging 2.1% with standard deviation 1.8%. Even when countries overshot their inflation targets, as Israel in 2002, the IT policy makers have been able to regain control. Despite very large exogenous shocks, the inflation spike was brief and has been within the target since, while real output growth has averaged over 5%.

Several attempts have been made to systematically study countries before and after implementing IT and to compare them to non-IT countries. This is complicated because in the 1980s, just before most targets were adopted, inflation and output performance was generally poor and volatile, while the 1990s were relatively prosperous and stable. It is difficult to isolate the IT effect from generally favorable world economic conditions in the experimenting countries. Laurence Ball and Niamh Sheridan (2005) use a panel regression approach with 20 Organisation for Economic Co-operation and Development countries, but find that an IT regime does not significantly improve the level or variance of output growth or inflation when they control for pre-IT conditions, which were generally worse in the adopting countries. However, Marco Vega and Diego Winkelried (2005), using a similar methodology but including developing countries into the sample, show that the policy regime choice *does* have a statistically significant effect. David Johnson (2002) finds that IT significantly reduced inflation expectations as measured by the average among professional forecasters. Frederic Mishkin and Klaus Schmidt-Hebbel (2007) find that IT reduces inflation levels and volatility and lowers interest rates, and this effect is stronger in industrial countries. More conclusive evidence about IT may only come with more practical experience and further academic effort.

## Conclusion

The adoption of IT may very well be the most significant development in monetary economics over the last couple of decades. The number of central banks around the world that have officially adopted IT as the framework for their conduct of monetary policy has been steadily increasing. Although the time frame for evaluating the success of IT may be relatively short, the preliminary results that have emerged are encouraging. None of the IT adopters have abandoned this policy, and several central banks that have not formally announced IT as their policymaking framework have acted in a way that is fully consistent with it.

Although little theoretical literature on IT existed prior to New Zealand's adoption of IT in 1990, the policy has been studied extensively in academia and in the central banks' research departments. There may not be overwhelming consensus on the exact operational details of implementing IT in practice, but the general opposition to IT is rather slim. Given the international monetary trends in the past few decades, it seems reasonable to suggest that IT will continue to be the predominant paradigm for the conduct of monetary policy in the near future.

## Notes

1. In a letter to the editor, Friedman said the full quote was, "In one sense, we are all Keynesians now; in another, nobody is any longer a Keynesian."
2. Svensson (2008) suggests that the Bundesbank, although declaratively a monetary aggregate targeter, in fact followed IT through the 1980s, which may explain its success in achieving inflationary stability earlier that other central banks.
3. A pricing mechanism due to Calvo (1983) or price adjustment costs are popular theoretical devices that motivate these pricing decisions.

# Debates in Macroeconomic Policy

John Vahaly
*University of Louisville*

Modern economics began with Adam Smith's *The Wealth of Nations* (1776), which established the promotion of rising living standards as the major economic goal. Smith labeled economic thought of his time as Mercantilism, which seemed to place emphasis on the acquisition of money, gold and silver primarily, as the key to prosperity.

*The Wealth of Nations* integrated eighteenth-century political and economic thinking to present a new framework for economic organization to promote economic well-being. Smith demonstrated that the then prevailing emphasis of government accumulation of specie—gold and silver—was misplaced. For Smith and the following classical school, the correct view of economic progress had nothing to do with money.

Just as in modern views of economic growth, rising living standards depended on increasing the productivity of resources, primarily labor and physical capital. Many factors contribute to rising levels of productivity with the classical tradition favoring reliance on private entrepreneurial activity with essential but limited roles for government.

Smith understood that market or capitalist economies require government oversight and productive contributions. Private markets can fail to operate in society's interests in a variety of ways, requiring government intervention to reallocate resources as with public goods and externalities and to promote competition where impediments exist. Smith also understood the income distribution or fairness issue and was an early supporter of progressive taxation. However, with respect to the business cycle with contractions and expansions of national production, Smith and the classical economists supported a laissez-faire approach. Thus, if a recession arose, excess output could always be sold through price reductions. Similarly, workers could always find work through wage declines. A general deflation would then gradually move the economy back to its full-employment resting place. Flexible wages and prices would move in the opposite direction, should an economy become overextended in an inflationary boom

This leads to the second tenet of classical macroeconomics—the relevant time frame of interest is the long run. Whatever short-term instability existed was best remedied by the economy's self-correcting mechanism. The more quickly wages and prices adjusted to economic shocks, the faster the economy would return to its full-employment level of income and output.

Finally, only the supply or production side of the economy mattered for economic growth. Say's law of markets, namely, that "supply creates its own demand," meant the demand side was not a concern. Employment of resources automatically generated incomes sufficient to purchase what was produced. Any income not spent was automatically placed back into the economy through business investment spending on the physical capital through the loanable-funds market.

The nineteenth century is also associated with establishment of a global trading system that relied on both free trade and the "classical" gold standard. The case for trade was inherent in Smith's discussion of specialization and exchange. However, the formal logic for trade was provided by David Ricardo's principle of comparative advantage. The idea that competition or trade between nations raises living standards remains a principle in modern economics.

The international gold standard served two functions. The first was to create an international payments system

to finance trade. The second was to regulate the amount of money in circulation. In a true gold standard, gold circulates both as money and as a commodity and is freely exchangeable between such uses. Because the amount of money was determined by a commodity, the price level was highly correlated with changes in the amount of gold in circulation. Prices rose and fell with new gold discoveries, bullion ship sinkings, and new technologies in gold mining. Such situations produced alternate inflations and deflations as nations allowed their domestic money supplies to be determined by the international gold standard. This system provided two major benefits: it was self-regulating and did not require direct monetary intervention, and it produced long-run price stability. The short-term record, however, was one of instability and unpredictable swings in prices.

David Hume is credited with formalizing this link between the money supply and the price level in the quantity theory of money, MV = PY. The money supply, M, multiplied by its annual turnover rate or velocity, V, equaled nominal gross domestic product (GDP), PY. Nominal GDP has two components: the level of prices, P, and real GDP, Y, calculated using prices from a base year. The quantity theory was famously used to explain how a mercantilist country that attempted to block imports, forcing trading partners to pay for exports with gold, must fail. A simple interpretation of the quantity theory shows that an increase in gold, thought to be the source of wealth, puts upward pressure on P, the domestic price level, thereby reducing exports while promoting imports. In the long run, rigging trade to acquire gold must fail. Better policies were free trade, private-market resource allocation, and laissez-faire.

During the nineteenth century, the U.S. economy operated according to classical rules. In the 1890s, the United States experienced several major recessions. Real output actually fell 3 years with the price level declining in 6 years. Real output was higher at the end of the decade by nearly half, but the short-run economic record saw recession and deflation. For macroeconomic thinking, this was how the business cycle should operate.

## The Panic of 1907 and Creation of the Federal Reserve

The classical hands-off approach also applied to commercial banking and financial markets. Twice, the United States had established a central bank prior to the twentieth century, but neither survived original chartering. In 1907, as had previously happened, a major New York bank failed. This triggered a financial panic that had the impact of producing a sharp drop in the U.S. money supply and subsequent reduction in real output. The panic would have been worse had not John Pierpont Morgan opened his personal fortune to deposit money in banks in a vote of financial support. A century later, a similar but larger crisis would confront the U.S. economy.

The lesson drawn from this episode was to make clear the need for a central source of reserves for the U.S. banking system. What emerged was the Federal Reserve Act (1913) and the Federal Reserve System that opened in 1914. The System, composed of 12 regional banks, was dominated by the New York Federal Reserve until events in the Great Depression resulted in an overhaul of the U.S. monetary structure.

## John Maynard Keynes and the Great Depression

No event in U.S. economic history has had more impact than the Great Depression. Debate continues today as to the causes and consequences of this economic disaster. The collapse that lasted from August 1929 to March 1933 saw real output fall more than 26%. Unemployment rose from 3.5% to over 25% while the price level dropped 26%. The breakdown appeared to mirror past macroeconomic declines in that falling output and rising unemployment were accompanied by deflation. However, this decline seemed to have no end. And at Cambridge University, a new approach to the business cycle was being created to help deal with a global depression.

In *The General Theory of Employment, Interest and Money* (1936), John Maynard Keynes revolutionized macroeconomics. Classical thinking was discarded as emphasis was changed from the long to the short run and from supply to demand. For Keynes, events in the 1930s required immediate policy response. Furthermore, economies had excess supplies of labor, capital, and other productive resources. Therefore, the key problem was a lack of short-term demand or spending on output. The key question became how to best stimulate total expenditure on GDP. The private sector was in disarray as spending by consumers (C) and businesses (I) fell between 1929 and 1933. Consumer expenditure dropped from $752 to $558 billion (using prices from the year 2000) with private investment spending collapsing from $91 to just $17 billion over this period.

The Keynesian alternative outlined in *The General Theory* called for the use of deficit spending as a short-term policy to restore full employment. The federal government could either directly raise spending (G) or reduce taxes (T), which through a multiplier process would ultimately raise output and income. Alternatively, the Federal Reserve could pursue expansionary policies that would help lower interest rates to promote new spending. Following publication of *The General Theory,* however, fiscal policy became the preferred stabilization policy tool. The alternative to this was to wait an indeterminate time period while the economy's self-correcting forces operated. While U.S. monetary and

fiscal authorities took action, unemployment stayed in double digits until the outbreak of World War II. The modern debate over the government's role in stabilizing the economy had started.

Keynes offered an alternative for ending the Depression. But what had caused the collapse? A recession had started in the summer of 1929, which was soon followed by the Great Crash during the fall of 1929. The negative impact of the 1930 Hawley-Smoot tariff increase contributed. Perhaps the two greatest economists of the twentieth century, John Maynard Keynes and Milton Friedman, both agreed the greatest problem for the United States was a series of policy mistakes made by the Federal Reserve. The Fed failed to contain a series of financial panics between 1930 and 1933. The financial system was so unsound that the newly elected Franklin Roosevelt had to close all banks to help restore financial soundness. This overhaul was accompanied by new laws guaranteeing depositor money (Federal Deposit Insurance Corporation) and a new structure for the Federal Reserve itself in which the Board of Governors and the Federal Open Market Committee (FOMC) were placed in charge of monetary policy and the determination of credit conditions and interest rates. These actions were taken after 1933, after both the nominal money supply and the number of U.S. banks had dropped by one third.

## The Postwar Study of Economic Growth

With the Depression behind them, macroeconomists again took up the study of economic growth. Logically, these efforts took Keynesian ideas and developed their implications for growth theory. Evsey Domar and Roy Harrod independently created similar models of economic growth that were familiar to Keynesian economists. The Harrod-Domar growth model emphasized the importance of saving, a major problem for low-income countries, as well as the productivity of the capital stock.

Robert Solow added a fundamental contribution to growth theory that remains the starting point for such analysis. Solow's model, referred to as the *neoclassical growth model,* was a supply-side approach to thinking about raising living standards. For the next decade, economic growth theory built on Solow's model, which gave new life to the classical interest in long-run growth.

Solow's theory contained two insights. Starting with the simplest model of supply, Solow showed that *rising* living standards, the goal of economic growth, do not arise from having a relatively high *level* of national saving. Nations can divert current income to saving and then to investment or real capital formation. This will raise living standards, but only once. Additional saving that can provide workers more capital (machines) with which to work can raise productivity levels. However, additional saving must occur if workers are to become even more productive. In Solow's model, technological change is the reason why nations can experience continuous improvements in real living standards. When technological advance occurs, workers in affected sectors can become more productive. Modern economic growth is thus a record of technological change.

Solow's model makes no attempt to model or to explain a theory of technological change. The neoclassical model assumes that technology changes for reasons that cannot be predicted, or that technological change is exogenous and independent of the model. Somewhat surprisingly, the key to growth is not explained. The Solow model nonetheless remains the starting point for the economic growth studies.

## The Arrival of Keynesian Macropolicy in the United States

Keynesian macroeconomics came to the United States in the 1960 presidential election. A recession was under way in 1960, and John F. Kennedy proposed a deficit-financed tax cut to stimulate the economy and end the recession. The Kennedy tax plan was not enacted until 1964 and was accompanied by two contemporaneous fiscal shocks. The first came from the new President Lyndon Johnson's Great Society program and its War on Poverty. The second was the Vietnam War. These three demand shocks produced an overheated economy that by the end of the decade had produced a very low unemployment rate of 3.5% but an accelerating inflation rate that topped 5%. Two points stood out to economists in 1969. First, there had been no recessions during the 1960s, and Keynesian-style demand management was given credit for the longest period of economic expansion in U.S. history up to that time. Second, the economy was behaving precisely as had been expected. Excess demand had resulted in higher prices, or the increase in inflation, while driving down unemployment. In macroeconomic books, the Phillips curve inflation–unemployment trade-off emerged as the tool economists used to explain how the U.S. economy operated.

The ascendancy of the original Keynesian model was challenged by macroeconomic events of the 1970s. The decade began with a recession that produced higher unemployment but without any decline in inflation. This surprised Keynesian economists, who had come to rely on the Phillips curve to portray an inverse relationship between inflation and unemployment. In the early 1970s, however, the trade-off seemed to be weakening. Then President Nixon resorted to wage and price freezes and controls in 1971 to slow the 5% inflation, then viewed as a major macroeconomic problem. President Nixon, remembering his loss to Kennedy in 1960, did not want to risk another recession in 1972, a presidential election year. While the U.S. experiment with wage and price controls seemed to initially produce positive results with

inflation starting to fall, international events would overtake the attempt to slow inflation.

## Stagflation and the Reemergence of Conservative Macroeconomics

War in the Middle East in 1973 lead the Organization of Petroleum Exporting Countries (OPEC) oil cartel to quadruple crude oil prices that year. As this energy price shock spread through the global economy in 1974, it produced a phenomenon that required a new word—stagflation—to describe the simultaneous occurrence of both higher inflation and unemployment. The Phillips curve seemingly could not account for this event. For U.S. policy makers attempting to deal with what was a new macroeconomic crisis, the choices were few. Fiscal policy was effectively paralyzed by the Watergate investigation, and Fed chairman Arthur Burns was asked repeatedly by Congress and a growing number of U.S. citizens to do something about double-digit inflation and rising unemployment.

The Fed's dilemma, which also directly applies to fiscal policy action, had to do with the basics of the Keynesian model. Developed for a country suffering from very high unemployment, the Keynesian model was concerned only with short-run demand or spending issues and what government might do to make up a spending gap should private (C + I) spending be too low to produce full employment. Supply was not part of this framework. This omission was correct for the 1930s, as there were abundant quantities of labor, capital, and other scarce resources. But this omission was to undermine the Keynesian consensus in the early 1970s.

Edmund Phelps and Milton Friedman explained why the original Phillips curve—spending approach to understanding countercyclical stabilization policy—was wrong. The fatal omission was on the supply side. How would the economy respond to changes in the unemployment (output)–inflation (price level) mix as these two variables changed? The Friedman-Phelps idea was that the rising demand-side inflation in the late 1960s caused a supply-side reaction. U.S. workers saw prices rising for commodities they purchased, but without an increase in nominal wages, their real purchasing power or living standards fell. To prevent this, workers would demand a nominal wage increase at least equal to what they *expected* inflation to be. The increase in wages would prompt another round of price increases. Once set into motion, this wage–price spiral seemingly took on a life of its own. Wage increases boosted the cost of doing business, as workers received higher wages to offset inflation, thereby helping to perpetuate the upward rise in prices. All this was missing from the original interpretation of the Phillips relation.

The new Friedman-Phelps interpretation, termed the *expectations-augmented* Phillips curve, was revolutionary. It correctly predicted that the short-run trade-off between inflation and unemployment lasted only as long as the actual and expected or perceived inflation rates differed. In 1969, actual inflation was above 5%, but expected inflation, reflecting inflationary expectations, lagged. Once inflationary expectations rose to match reality, the economy had restored balance to price, or inflation, and wage growth. This is the logic that underlies the modern natural rate hypothesis that identifies *full-employment real GDP* as that rate of output where inflation tends to remain constant. Inflation tends to remain fixed at the natural rate because actual and expected inflation are the same. Workers are not expecting prices to grow faster than their wages, and managers are not expecting labor costs to grow faster than prices. Corresponding to the natural rate of real GDP is the natural rate of unemploy ment at which the economy has reached this inflation and output balance point. Milton Friedman famously said that there is no way to quantify this natural rate of unemployment, but other economists have tried to do this for the United States and other economies, and current views allow for the natural rate of unemployment to vary over time.

If the Phillips curve trade-off lasted only as long as there was a difference between actual and expected inflation, it appeared to make little sense to attempt stabilization policy that required the presence of "fooling," using Friedman's term, on the supply side. For Friedman, the short-run Phillips trade-off required workers to not correctly understand what was happening to prices. In other words, there had to be unanticipated inflation for policy makers to exploit the trade-off. In rebuttal, Keynesians identified a wide variety of both nominal and real rigidities in the economy that prevent relatively quick matching of actual and expected inflation. This debate is an ongoing area of interest and research.

Also during the early 1970s, Robert Lucas and Thomas Sergeant extended the conservative rebirth by broadening the role of "rational expectations" and going well beyond the Friedman-Phelps contribution. Friedman and Lucas provided the cornerstone for a macroeconomic counterrevolution. For both, the task of stabilizing the U.S. economy was a goal not worth pursuing.

Friedman explained that macroeconomic stabilization policy was doomed to fail because it was too difficult to achieve. Four beliefs were offered as proof. First is the challenge posed by time lags with obtaining economic information, forming policy, policy implementation, and policy effects, all of which are "long and variable." For example, the 1964 Kennedy-Johnson tax cut was enacted to help end the 1960 recession. Next is the frank admission that we do not understand the U.S. economy well enough to effectively stabilize it. Contemporary difficulties with stagflation seemed to clearly make this point. The rational expectations revolution seemed to emphatically make this point. In the Lucas critique, Lucas also pointed to the naïve

approach to understanding and modeling expectations in the original Keynesian model.

Third is the miserable past performance of stabilization efforts, particularly with monetary policy. The three major economic contractions of the twentieth century were caused or made far worse by restrictive monetary policies. Finally, there is the issue that leads to Friedman's policy recommendation—policy rules are inherently superior to discretionary policy. While the Congress and the president are elected and answer to voters, the Fed and monetary policy are effectively shielded from the ballot box.

Friedman's macroeconomic school was monetarism. To deal with the rules-discretion problem, Friedman proposed a simple monetary rule of matching monetary growth to real GDP growth. Thus, as the economy grew, the Fed would simply add enough money to the economy to finance the additional transactions. During the 1970s, faced with rising inflation, this type of approach made sense to a growing number of people. Friedman (1992) famously stated that "inflation is everywhere and always a monetary phenomenon" (p. 193), and his monetary rule was based on this view. In essence, Friedman proposed lowering inflation, or the growth of prices, by matching money growth to no more than an expanding economy needed to finance additional transactions. Inflation arose when "too many dollars, or too much spending, chased too few goods." Monetarism dealt directly with the too many dollars issue, leaving the supply-side, or "too few goods," to the private economy where it belonged. For Friedman, all the Fed had to do was add sufficient reserves to the U.S. banking system to allow the money supply to expand as fast as real output. People had known for centuries that excess creation of money by resorting to the printing press could produce hyperinflation, and modern examples of this can still be found. On the other hand, the Depression clearly demonstrated the consequences of large monetary reductions.

Friedman's constant growth rate rules (CGRR) offered a secure return to the laissez-faire macroeconomics of the past. Its popularity was ended, however, in the early 1980s with the deregulation of U.S. commercial banking and financial markets. The high inflation of the 1970s and the new opportunities for managing cash holdings created in the early 1980s had a major impact on the demand for money.

In the GDP version of the quantity theory, MV = PY. Expressed as rates of growth, the quantity theory is written as follows: money growth + velocity growth = inflation + real GDP growth. Friedman had linked money growth to real GDP growth, assuming the growth of both V and P would be modest at best. If V is interpreted as the amount of money people choose to hold as a fraction of nominal income, PY, then instability in the growth of velocity ruins the CGRR. If velocity grows or declines in an unpredictable fashion, a fixed monetary growth policy would be destabilizing.

Robert Lucas and Thomas Sergeant had prepared the way for another attempt to restore laissez-faire macroeconomics while attempting to increase understanding of the U.S. economy. It was first common to refer to their approach as the *rational expectations school.* The label soon changed to the *new classical school,* both to reflect the ties back to pre-Keynesian economics that placed emphasis on long-run supply issues and to indicate that there was something new being studied.

The Lucas approach was pioneering in that it appeared to restore the primacy of microeconomics in the effort to comprehend macroeconomic aggregates. In microeconomics, economic agents—consumers and producers—are modeled as being rational decision makers. Consumers maximize utility; producers maximize economic profit. Macroeconomics should reflect this microfoundation. The theory of the business cycle that first emerged from this approach was initially quite similar to other macroeconomic schools. In Friedman's natural rate hypothesis, demand disturbances had caused workers to be "fooled" when demand-side inflation pushed prices above wages. In the new classical school, the presumption was the divergence that occurred between what economic agents expected prices, or inflation, and actual values arose because of "expectational errors." More formally, explanations of the business cycle presumed that there would be "price surprises," as happened in the late 1960s, for the economy to move away from its natural rate of output.

The logical conclusion to draw from this approach was that attempts to stabilize the economy could not be productive. Successful stabilization policy would have to generate a price surprise for it to matter for the real economy, but rational economic agents will always be able to divine macropolicy direction. The national economy would operate more effectively if stabilization policies were eliminated. Monetary policy would also be directed to operate more or less along Friedman's lines so that there would be no surprises that would contribute to macroeconomic instability.

The new classical school added microeconomic rigor to the debate about macroeconomic stabilization policy. As with monetarism, it ran into difficulties. Few economists had difficulty accepting the idea that expectations about macroeconomic variables, especially inflation and nominal interest rates, were formed rationally using available information. However, the claim that monetary and fiscal policy could not affect output and employment in the short run seemed incorrect. As mentioned earlier, Keynesians pointed to a variety of potential impediments to price and wage adjustments that delay movement from one equilibrium to the next. There may indeed be no surprise in the Fed's actions with the money supply, but those actions will have real impacts in the macroeconomy. In macroeconomic jargon, money mattered and was not "neutral" in the short run. In the long run, the quantity of money does not matter for living standards, excluding small gains from

avoiding barter. The quantity of money does affect nominal magnitudes, prices, nominal wages, nominal interest rates, and nominal GDP. It does not affect real macroeconomic values. The new classical school seemed to be saying that it was also neutral in the short run unless some type of surprise occurred.

The idea that there must be uncertainty about future actions had unexpectedly widespread impacts in macroeconomics. This introduced the idea that game theory could be applied to the decision made concerning monetary policy. One of the difficulties of the 1960s and 1970s was that there was little coherence in actions taken by the Federal Reserve when economic conditions deteriorated. Improved policy response required actions to be credible and consistent with no attempts to pursue conflicting goals. This was clearly a step beyond the original promises of fine-tuning made by economists in the 1960s. This issue became especially important in the debate over the U.S. macroeconomic policy in response to the collapse of the U.S. housing and financial markets in 2009.

## The Great Inflation and the Volcker Recession: Disinflation in the 1980s

In 1979, OPEC pushed crude oil prices over $30 per barrel, producing the second energy price shock of the decade. The economy slowed as prices rose even faster with a minor recession in 1980. That was also a presidential election year, and voters wanted to know what was to be done to fix the economy. President Carter had just appointed a new Fed Chair, Paul Volcker, in 1979, with a clear order to bring double-digit inflation under control. In 1980, some measures of inflation were approaching 15% with interest rates moving over 20%. Ronald Reagan's approach to the inflation problem presented a new approach to the stagflation problem. If supply problems had created the difficulties, supply-side policies had to be the remedy.

The supply-side school that emerged in the early 1980s shared the laissez-faire philosophy of the more academic monetarists and new classical schools. This was interpreted to lend support to federal income tax rate reductions as a means to lower inflation. The logic was that lower income tax rates would increase work incentives and therefore supply. Because part of the inflation problem is "too few goods," the tax cut was an anti-inflationary program. The Reagan platform also included expansion of government spending as part of a defense buildup. Added with the income tax reductions, this led many economists to conclude that fiscal expansion was being adopted that would only add to current inflationary pressures.

President Reagan followed through on his electoral program: Defense spending rose while federal taxes were lowered by the Kemp-Roth tax cut. Paul Volcker and others at the Fed tried to make clear that fiscal policy was too expansionary. In 1981, the Fed acted to slow total spending in the economy, thereby creating the worst recession since the Depression. Unemployment was pushed over 10% in some months in 1982, but the Fed's commitment to lower inflation seemed to take hold. By 1983, the inflation rate fell from 12% to 4%, adding the term *disinflation* to the U.S. economic vocabulary. Faced with no alternative, the Fed had to slow the economy sufficiently to reduce both actual and expected inflation. In the spirit of the rational expectations movement, this meant that the Fed had to make clear its commitment to restrictive policies until its inflation target was achieved.

## Real Business Cycle Models

The new classical school had based its price surprise model on concepts imported from microeconomics, including near-perfect flexibility of wages and prices. While this is a standard assumption in microeconomics, it appeared to many economists that it is demonstrably not the case in macroeconomics. The new classical assumption of wage and price flexibility was necessary for its business cycle model to operate as its supporters explained it. When this assumption was challenged, along with its prediction of short-run monetary neutrality, the new classical school changed.

Edward Prescott moved past the new classical school in the early 1980s when he combined the Lucas rational expectations approach with evidence from the economy's growth record. In Solow's neoclassical model, higher real GDP per capita arose from capital accumulation and technological change. Any growth in living standards that could not be accounted for by increases in the capital and labor must be due to exogenous or autonomous change in technology. This approach of measuring technological change as a residual from a basic growth equation produced a surprising result. Solow's technology residual seemed to be highly correlated with detrended changes in real GDP. Could technological change, a supply-side phenomenon, be the source of the business cycle? If this were true, and if strict microfoundations applied, then all government stabilization effort should be focused on promoting creation and application of technological change, understood to be a relatively broad concept.

This new real business cycle (RBC) model completely changed the interpretation of the business cycle. If short-run microconsumer and producer markets are continuously in equilibrium, their aggregates should also display this result. The macroeconomy is subject to external shocks, but growth evidence pointed to technology or supply-side factors as the cause. The business cycle arose from real shocks to the growth process, and the resulting cyclical disturbances must be optimal responses to these changes. Because micro–decision making is optimal, in the absence of market failure, macrodisturbances could be interpreted as movements from one equilibrium state to another.

The case for laissez-faire had seemingly been reestablished. Macroeconomics returned to its starting point. The task of raising living standards was confirmed as being a supply-side, long run (or short run, as they could be interpreted as being equivalent), with little discretionary role for government.

While the RBC model was being developed, new Keynesian macroeconomists also built on rational expectations and microfoundations, but with the goal of making stabilization policy's foundations even stronger. Distinctions are still made between the long and short run (and a medium term) in which stabilization policy efforts can be useful. For a variety of market imperfections and rigidities, both monetary and fiscal actions have short-term real impacts.

## The Savings and Loan Crisis

Macroeconomic policy debates in the 1980s covered a variety of issues, from the growth of the "twin deficits" to interest-rate targeting by the Federal Reserve. Major macroeconomic events of the 1980s included the 1981 to 1982 recession, the stock market crash on October 19, 1987, and the collapse of Savings and Loan (S&Ls) banks. S&Ls originally provided fixed, 30-year mortgage financing for the U.S. housing market. This traditional role was discarded during the economic turmoil of the late 1970s and 1980s. With the hope of fostering more competition, regulations were relaxed as S&Ls moved financial activities into new higher return but much riskier markets. The S&Ls, in a scenario to be repeated 15 years later, ignored risk in the pursuit of short-term profit opportunities. Speculative investments in commercial and residential real estate, lax and ineffective regulation, and outright fraud finally bankrupted the industry. The federal government took over the failed S&Ls in 1989 at significant taxpayer cost. A regulatory commission was established to reform and restructure both S&Ls and their regulation. S&L assets were sold off over time, but a precedent had been set. Overextension in the banking sector appeared to have a new lender of last resort: the U.S. taxpayer. In addition, federal policies now gave additional responsibility to private corporations, or government-sponsored enterprises (GESs), to support the goal of promoting homeownership. These agencies, in particular Fannie Mae and Freddie Mac, would play a major part of the next major wave of banking failures.

## The Rebirth of the Economic Growth Theory

As the liberal–conservative debate over the usefulness or even wisdom of stabilization policy was under way, macroeconomics returned to the study of economic growth and Solow's neoclassical growth model. While the new classical model's explanation of the business cycle had run into difficulties, interest in the creation of macromodels derived directly from the rational world of microeconomics expanded into the study of economic growth.

The new growth theory sought to explain changes in Solow's residual or exogenous technological change. Using the microfoundations approach, technological change was analyzed as the result of profit-maximizing business activity. Firms engage in developing new technologies, which can include development of labor skills or human capital, when economically profitable. In private markets, patent protection and government subsidies were ways in which individual firms could gain from developing new products and markets. The importance of competition—even if imperfect—trade, property rights, and other necessary factors for growth were emphasized as key underpinnings for promoting change and higher living standards. However, the goal of modern growth theory to help narrow the gap between average living standards between nations is still being pursued.

## Activist Macroeconomic Policy: The Great Depression and the Great Recession of 2007

The 1990s saw two macroeconomic milestones. The first was the "Long Boom," the longest cyclical expansion in U.S. history. This period lasted 120 months from March 1991 (trough) to March 2001 (peak). Following the 1990 to 1991 recession, the Fed followed countercyclical expansionary monetary policy, pushing the fed funds rate from a prerecession high of 8% to a 1992 low of 3%. Fed policy was even more expansionary during the 2001 recession. The fed funds rate was 6% at the beginning of 2001, but by late 2003, it was 1%. By 2009, the Fed moved even farther by lowering the target fed rate to essentially 0% following the start of the 2007 recession. In an old macroeconomic phrase, the Fed was actively "leaning against the wind."

The second was the emergence of another boom in the U.S. housing market. This boom and rising home prices encouraged financial markets to create bundles of real estate assets or mortgage-backed securities (MBSs) that allowed buyers to participate in the ongoing housing boom. Supporters of these new financial instruments thought that they diversified risks associated with investing in real estate markets. However, the opposite happened when the bubble began to collapse in 2006. Home prices began falling and home foreclosures rose markedly. MBSs and other widely marketed financial instruments became unmarketable, crippling U.S. credit markets. The economy began slowing with a recession starting in 2007 that also triggered a major retreat in stock prices. Many U.S. households saw significant reductions in personal wealth as the

value of both real estate and equity holdings were significantly lowered.

The 2007 recession posed a new set of challenges for the conduct of monetary and fiscal policies. Both the U.S. Treasury and the Fed were called on to deal with a banking crisis that was much larger than the S&L crisis but not as severe as during the Depression.

In the 1930s, fiscal policy was characterized by deficit spending arising from both the weak economy and New Deal spending programs. The federal deficit in 1934 was 5.9% of GDP, but it fell to just 0.1% in 1938. In 2009, projected deficits were on the order of 10% of GDP.

Monetary policy differences between the 1930s and 2009 were even more dramatic. Between 1929 and 1933, the nominal money supply fell by one third. This drop arose from Fed inaction, as successive waves of financial panics crippled the banking system. In 2009, the Fed was actively pursuing the opposite course through conventional monetary expansion supplemented with an array of new lending and asset-purchasing programs unprecedented in Fed history. Interest rates have been pushed to historic lows, and Fed Chair Ben Bernanke has made it clear that expansionary policy will continue until financial market health is restored.

## The Current Debate: Activism Versus Laissez-Faire

As this central debate about stabilization policy continues, the Great Depression of the 1930s continues to affect this macroeconomic debate. In the Keynesian view, problems in private spending coupled with the near collapse of the banking and financial sector produced the worst economic crisis in U.S. history. Through Keynes, a new approach was developed to mitigate the worst consequences of cyclical instability. Ironically, it had been the failure of the Federal Reserve to help the banking sector that contributed to the depth of the Depression. The possibility of such failures remains.

In the twenty-first century, these events are being studied again as economies struggle with financial, banking, and credit crises. The new consensus requires that action be taken to reduce adverse impacts arising from either demand or supply shocks. There will always be debate about how much and how far these actions should be taken. Macroevents and theoretical developments have clearly shown, however, that neither simple laissez-faire nor fine-tuning are sensible approaches to follow.

During the past 70 years, macroeconomic analysis has made enormous progress via the sustained accumulation of knowledge and is now firmly established as an essential component of effective public policymaking in every modern economy. In retrospect, it is uncontroversial that the "Keynesian revolution" transformed the approach of governments to economic management. Although the Keynesian consensus prevailed during the 1950s and 1960s, and was labeled the *neoclassical synthesis* by Paul Samuelson, the intellectual journey from Keynes's *General Theory of Employment, Interest and Money* (1936) to the contemporary consensus (the *new neoclassical synthesis*) has been marked by periods of considerable controversy (Blanchard, 2000; Woodford, 1999). In particular, during the early 1970s, there emerged a powerful intellectual counterrevolution directed against the central tenets of mainstream Keynesian macroeconomics. The ideas of this emerging school of thought, initially referred to as *rational expectations macroeconomics,* were soon labeled by Thomas Sargent the *new classical macroeconomics* (see Snowdon & Vane, 2005).

In many intellectual revolutions, there is often one person who stands out in terms of leadership. This is certainly the case in economics, where John Maynard Keynes and Milton Friedman are clear examples with respect to Keynesianism and monetarism. In the development of new classical macroeconomics, the economist who undoubtedly provided the intellectual stimulus to the new wave of ideas in macroeconomics was Robert Lucas, Jr., who in 1995 was awarded the Nobel Memorial Prize in Economics "for having developed and applied the hypothesis of rational expectations, and thereby having transformed macroeconomic analysis and deepened our understanding of economic policy" (Fischer, 1996, p. 11). In a series of highly technical papers, published during the period 1972 to 1976, Lucas established the analytical base of the rational expectations equilibrium approach to macroeconomic theorizing (Lucas, 1981). These seminal contributions, combined with the work of other prominent new classicists, such as Robert Barro, Finn Kydland, Edward Prescott, Thomas Sargent, and Neil Wallace, transformed the whole course of macroeconomic debate and led to a new classical revolution in macroeconomic analysis (Hoover, 1988).

In terms of theory, it is appropriate to divide the new classical contributions into two distinct time periods. New classical macroeconomics mark I (NCMI) evolved during the 1970s and was dominated by the development of the monetary equilibrium approach to business cycle theory (MEBCT). During the 1980s, the monetary equilibrium approach was replaced by new classical macroeconomics mark II (NCMII), more commonly known as *real equilibrium business cycle theory* (REBCT).

## Theoretical Foundations of NCMI: From Friedman to Lucas

In the late 1960s, at the height of the Keynesian consensus, Milton Friedman (1968) and Edmund Phelps (1968) provided a devastating critique of one of the most famous relationships in macroeconomics, namely, the hypothesis that there is a stable, long-run trade-off between inflation (a nominal variable) and unemployment (a real variable). The Friedman-Phelps expectations-augmented Phillips curve analysis is rightly celebrated as one of, if not *the,*

most important theoretical contributions to macroeconomic analysis in the postwar era, not least because of its influence on Robert Lucas, who extended and refined Friedman's monetarist analysis within a Walrasian general equilibrium framework (Hoover, 1988). Lucas became convinced that any modern theory of the business cycle must be consistent with the Friedman-Phelps natural rate hypothesis.

To both Friedman and Lucas the original Phillips curve is inconsistent with the so-called classical dichotomy—that is, the principles of rationality and optimizing behavior dictate that nominal variables cannot influence real variables because supply decisions should be based on relative prices. By adopting a neoclassical approach to the labor market, Friedman demonstrated that the microfoundations of the Phillips curve need to be framed in terms of real rather than nominal wages. Because the supply of labor depends on the anticipated real wage, the expected rate of inflation ($P^{e*}$) must play a key role in the determination of money wage inflation. However, once expectations are allowed to play a role alongside excess demand (proxied by unemployment as an empirical counterpart) as a determinant of money wage (or price) inflation, the idea of a unique and stable long-run trade-off is no longer theoretically plausible. Instead, there is a whole series of short-run Phillips curves, each associated with a specific expected rate of inflation, but no long-run trade-off between inflation and unemployment ($U$). In long-run equilibrium, at a natural (equilibrium) rate of unemployment—that is, a level of unemployment consistent with zero excess demand—the actual rate of inflation ($P^*$) equals the expected rate of inflation. It should be noted that the natural rate of unemployment is determined by supply-side factors and will therefore vary as supply-side conditions (such as labor market incentives) change in the economy (Friedman, 1968).

While there are subtle differences between the analyses of Friedman and Phelps, their basic idea, the expectations augmented Phillips curve, can be represented by Equation 1:

$$P^* = f(U) + \lambda P^{e*}. \quad (1)$$

Because inflation results when there is excess demand (aggregate demand exceeds aggregate supply), Equation 1 states that actual inflation depends on the level of unemployment, which captures the influence of the degree of excess demand in the economy, but is also influenced by agents' expectations of inflation. In this model, the actual rate of unemployment can be only temporarily reduced below the natural rate of unemployment by expansionary demand management policies that create *unexpected* inflation. This raises a crucial question: How are inflation expectations formed by economic agents?

Prior to the 1960s, the treatment of expectations in mainstream macroeconomics had been neglected. This changed dramatically following the incorporation, by both Friedman and Phelps, of the error-learning, or adaptive expectations, hypothesis into their analysis. According to this hypothesis, agents gradually adjust their current expectations of inflation ($P_t^{e*}$) on the basis of past rates of expected ($P_{t-1}^{e*}$) and actual inflation ($P_{t-1}^{*}$), as shown in Equation 2:

$$P_t^{e*} = P_{t-1}^{e*} + \psi (P_{t-1}^{*} - P_{t-1}^{e*}). \quad (2)$$

The acceleration of inflation during the 1970s, even though unemployment was not falling, appeared to verify the Friedman-Phelps analysis. However, to neoclassical purists, the Friedman-Phelps analysis was less than satisfactory, particularly in terms of the use of a backward-looking expectations hypothesis. Enter Robert Lucas.

## Foundations of NCMI

The new classical approach to macroeconomics, as it evolved in the early 1970s, exhibited several important features: (a) a strong emphasis on underpinning macroeconomic theorizing with neoclassical choice-theoretic microfoundations (methodological individualism); (b) a preference for embedding macroeconomic models within a Walrasian intertemporal general equilibrium framework; (c) the adoption of the key neoclassical assumption that all economic agents are *rational,* that is, continuous optimizers subject to the constraints that they face; (d) agents may have incomplete information but never suffer from money illusion; (e) only *real* magnitudes (relative prices) matter for optimizing decisions; and (f) complete and continuous wage and price flexibility ensure that markets continuously clear as agents exhaust all mutually beneficial gains from trade, leaving no unexploited profitable opportunities. Given this overall framework, the main building blocks of new classical mark I analysis comprise three key ideas, namely, (1) the rational expectations hypothesis, (2) continuous market clearing, and (3) the Lucas "surprise" aggregate supply hypothesis.

### The Rational Expectations Hypothesis

During the 1970s, the rational expectations hypothesis (REH) gradually replaced the adaptive expectations hypothesis as the dominant way of modeling endogenous expectations. A major weakness of the adaptive expectations hypotheses is the implication that economic agents make *systematic errors,* an outcome inconsistent with optimizing behavior.

In the macroeconomics literature, the REH came in two main forms. A *weak* version of the hypothesis states that, in forming expectations about the future value of a variable, rational economic agents will make the *best* (most efficient) use of *all* publicly available information about the factors that they believe determine that variable, subject to the constraint of the costs of collecting that

information. A *stronger,* and much more controversial, form of the REH is the Muthian hypothesis "that expectations since they are informed predictions of future events are essentially the same as the predictions of the relevant economic theory" (Muth, 1961, p. 316). This strong version was adopted by leading exponents of the new classical school and incorporated into their macroeconomic models. In the Muthian REH, economic agents' *subjective* expectations of economic variables will coincide with the true or objective mathematical conditional expectations of those variables. With respect to the formation of expectations of inflation ($P_t^{e*}$), the REH can be expressed as follows in Equation 3:

$$P_t^{e*} = E(P_t^* \mid \Omega_{t-1}), \tag{3}$$

where $P_t^*$ is the actual rate of inflation; $E(P_t^* / \Omega_{t-1})$ is the rational expectation of the rate of inflation subject to the information available up to the previous period ($\Omega_{t-1}$). It is important to emphasize that agents with rational expectations do not have perfect foresight. To form a rational expectation of inflation, agents will need to take into account what they believe to be the "correct" macroeconomic model of the economy. Agents will also make errors in their forecasts due to incomplete information. However, with rational expectations, agents' expectations of economic variables on average will be correct. Furthermore, unlike the adaptive expectations hypothesis, where agents make repeated errors, rational agents will not form expectations that are systematically wrong (biased) over time. If expectations turn out to be systematically wrong, agents will learn from their mistakes and change the way they form expectations, thereby eliminating systematic errors. More formally, the strong version of the REH implies that the forecasting errors from rationally formed expectations will be random with a mean of zero, will be unrelated to those made in previous periods (serially uncorrelated over time), and will have the lowest variance compared to any other forecasting method. Notwithstanding the many criticisms launched against the REH, during the 1970s, there was undoubtedly a "rational expectations revolution" in macroeconomics to such an extent that by the late 1970s, the REH was being incorporated into "new" Keynesian models with sticky wages and prices (Gordon, 1990).

## Continuous Market Clearing

A second key feature of new classical models is the adoption of the assumption that all markets in the economy continuously clear so that the economy is viewed as being in a permanent state of (short- and long-run) equilibrium. In new classical theories, equilibrium is interpreted to mean that all economic agents within a market economy have made choices that optimize their objectives subject to the constraints that they face, *including imperfections of information.* Because even rationally formed expectations can turn out to be incorrect due to incomplete information, this means that, at least until agents acquire more accurate information, a currently observed market clearing equilibrium may differ from a full information equilibrium.

The assumption of continuous market clearing is probably the most critical and controversial assumption underlying new classical analysis. The assumption of perfectly flexible prices and wages is in stark contrast to Keynesian economics, where it is assumed that, in the short run, markets fail to clear because of the slow adjustment of prices or wages, or both (Gordon, 1990; Keynes, 1936; Tobin, 1980).

## The Lucas Aggregate Supply Hypothesis

The new classical approach to aggregate supply derives mainly from Lucas (1972, 1973). In these two papers, Lucas assumes that economic agents know the current price of their own good or service, but acquire information about prices in all other markets only after a time lag. Therefore, all agents are faced with a *signal extraction* problem, in that they have to distinguish between variations in relative and absolute prices. Rational agents, seeking to maximize their utility or profits, should supply more goods, services, or labor only in response to a real (relative) rise in their supply price. A purely nominal price change—that is, an increase in price that is common in all markets—does not require any positive supply response. According to Lucas, the greater the variability of the general price level, the more difficult it will be for any economic agent to extract a correct signal from a change in prices, and hence the smaller the supply response is likely to be to any given change in prices (Lucas, 1977).

The analysis of the behavior of individual agents in terms of the supply of both labor and goods has led to what is referred to as the *Lucas surprise* aggregate supply function, in the following form:

$$Y_t = Y_{Nt} + \alpha\,[P_t - E(P_t / \Omega_{t-1})]. \tag{4}$$

Equation 4 states that output ($Y_t$) deviates from its natural level ($Y_{Nt}$) only in response to deviations of the actual price level ($P_t$) from its (rational) expected value [$E(P_t / \Omega_{t-1})$]—that is, in response to an unexpected (surprise) increase in the price level. For example, when the actual price level turns out to be greater (less) than expected, individual agents are "surprised" and mistake the increase (decrease) as a change in the relative price of their own output, resulting in an increase (decrease) in the supply of output and employment in the economy. In the absence of such price surprises, output will remain at its natural level ($Y_{Nt}$).

Note that in Equation 4, a real variable ($Y$) is linked to a nominal variable ($P$). But, as Lucas demonstrates, the so-called classical dichotomy breaks down only when a change in the nominal variable is *unanticipated.*

Furthermore, Lucas (1996) notes that this distinction between anticipated and unanticipated monetary changes is a feature of all rational expectations-style models developed during the 1970s to explain the monetary nonneutrality exhibited in short-run trade-offs and, in his view, is one of the most important ideas in postwar macroeconomics.

## Theory, Policy Implications, and Empirical Evidence

During the 1970s, a burgeoning new classical research program led to a number of important and controversial contributions to macroeconomic analysis, in particular with respect to the Phillips curve, business cycles, the effectiveness and conduct of monetary and fiscal policy, and macroeconometric modeling and methodology.

### The New Classical Phillips Curve and Equilibrium Business Cycle Theory

In his seminal 1972 *Journal of Economic Theory* paper, Lucas demonstrated that within a Walrasian general equilibrium framework, monetary changes have real consequences, but "only because agents cannot discriminate perfectly between monetary and real demand shifts" so "there is no usable trade-off between inflation and real output" (p. 119). In Lucas's model, "the Phillips curve emerges not as an unexplained empirical fact, but as a central feature of the solution to a general equilibrium system" (p. 122). How can this be?

The answer provided by Lucas relates to agents (workers, households, firms) having imperfect information about their relative prices. As noted earlier, if agents are used to a world of price stability, they will tend to interpret an increase in the price of the good (or service) they produce as a relative price increase and supply more in response. Therefore, an unexpected increase in the price level will surprise agents, and they will misinterpret the information they observe. Agents have what Lucas (1977) refers to as a "signal extraction problem," and if all agents make the same error, the aggregate data will display a strong positive correlation between output and the general level of prices. Because Lucas's model is "monetarist," the increase in the general price level is caused by a prior increase in the money supply, and we therefore observe a positive money to output correlation (the nonneutrality of money).

Building on these key insights, the intellectual challenge facing Lucas was to provide a coherent and plausible monetary theory of aggregate instability in real variables (business cycles and the nonneutrality on money) in a world inhabited by rational profit-maximizing agents and where all markets continuously clear. His main innovation was to extend the classical model so as to allow agents to have *imperfect information.* As a result, Lucas's (1975) MEBCT has come to be popularly known as the *misperceptions theory.*

In the MEBCT, the supply of output at any given time ($Y_t$) has both a permanent (secular) component ($Y_{Nt}$) and a cyclical component ($Yc_t$), as shown in Equation 5:

$$Y_t = Y_{Nt} + Yc_t. \tag{5}$$

The permanent component of gross domestic product (GDP) reflects the underlying growth of the economy and follows the trend line given by Equation 6:

$$Y_{Nt} = \lambda + \Phi_t. \tag{6}$$

The cyclical component is dependent on the price surprise together with the previous period's deviation of output from its natural rate as shown in Equation 7:

$$Yc_t = \alpha\ [P_t - E(P_t \mid \Omega_{t-1})] + \beta\ (Y_{t-1} - Y_{Nt-1}). \tag{7}$$

The lagged output term in Equation 7 implies that deviations in output from the trend will be more than transitory due to the influence of a variety of propagation mechanisms, and the coefficient $\beta > 0$ determines the speed with which output returns to its natural rate after a shock. The observed serially correlated movements in output and employment (persistence) have been explained via a number of mechanisms that include reference to lagged output, investment accelerator effects, information lags and the durability of capital goods, and the existence of contracts inhibiting immediate adjustment and adjustment costs.

By combining Equations 5 to 7, we get the modified Lucas aggregate supply relationship given by Equation 8:

$$\begin{aligned} Y_t = {} & \lambda + \Phi_t + \theta\alpha\,[P_t - E(P_t / \Omega_{t-1})] \\ & + \beta(Y_{t-1} - Y_{Nt-1}) + \varepsilon_t, \end{aligned} \tag{8}$$

where $\varepsilon_t$ is a random error process, and $\theta$ represents the fraction of total individual price variance due to relative price variation. Thus, the larger is $\theta$, the more any observed variability in prices is attributed by economic agents to a real shock (i.e., a change in relative price) and the less it is attributed to purely inflationary (nominal) movements of the general price level. As Lucas's (1973) empirical paper demonstrates, this implies that monetary disturbances (random shocks) are likely to have a significant impact on real variables in countries where price stability has been the norm. In countries where agents are used to high inflation, monetary disturbances are unlikely to have any large impact on real variables. A major policy implication of the MEBCT is that a benign monetary policy would eliminate a large source of aggregate instability. Thus, new classical economists come down firmly on the side of rules in the "rules versus discretion" debate over the conduct of monetary policy.

## Policy Ineffectiveness Proposition

Although implicit in the early new classical papers by Lucas, the new classical policy ineffectiveness proposition was first formally presented in a highly controversial paper by Thomas Sargent and Neil Wallace (1975). The proposition can best be illustrated using the conventional aggregate demand/supply (AD/AS) model shown in Figure 39.1. Assume that an economy is initially operating at point A, where the price level ($P_A$) is fully anticipated and output and employment (and by implication, unemployment) are at their long-run (full information) equilibrium (natural) levels. Suppose the monetary authorities announce that they plan to increase the money supply from $M_1$ to $M_2$. Rational economic agents will take this information into account in forming their expectations and fully anticipate the effects of the increase in the money supply on the general price level, so that output and employment will remain unchanged at their natural levels. The rightward shift of the aggregate demand curve from $AD_1(M_1)$ to $AD_2(M_2)$, induced by an *announced* monetary expansion, will be completely offset by an upward shift of the short-run aggregate supply curve from $SRAS_1$ to $SRAS_2$, as money wages increase in response to an upward revision of price expectations. In the case of an anticipated monetary expansion, the economy will move immediately from point A to C, with no change in output and employment even in the short run (monetary neutrality). In contrast, if the monetary authorities surprise economic agents by engineering an unanticipated increase in the money supply (a monetary shock), rational economic agents with incomplete information will misperceive the resultant increase in the general price level as an increase in relative prices and react by increasing the supply of output and labor.

In terms of Figure 39.1, the aggregate demand curve would shift to the right from $AD_1(M_1)$ to $AD_2(M_2)$, to intersect $SRAS_1$ at point B. Output ($Y$) will deviate from its natural level ($Y_{Nt}$) as a consequence of deviations of the price level ($P_B$) from its expected level ($P_A$). Any increase or decrease in output or unemployment will only be temporary because once agents realize that there has been no change in relative prices, output and employment will return to their long-run equilibrium (natural) levels. In terms of Figure 39.1, as agents fully adjusted their price expectations the aggregate supply curve shifts upward, from $SRAS_1$ to $SRAS_2$ to intersect $AD_2$ at point C. The analysis is symmetrical with respect to a fall in aggregate demand to $AD_3(M_3)$. Here an *unexpected* negative monetary demand shock leads the economy to follow a path illustrated by points D and E, whereas an *expected* negative monetary demand shock will move the economy from A to E.

The policy ineffectiveness proposition has major implications for the controversy over the role and conduct of macroeconomic stabilization policy. If the money supply is determined by the authorities according to some "known" rule, then they will be unable to influence output and employment even in the short run. The use of a *systematic* monetary policy will be anticipated by agents. Hence, only departures from a known monetary rule will

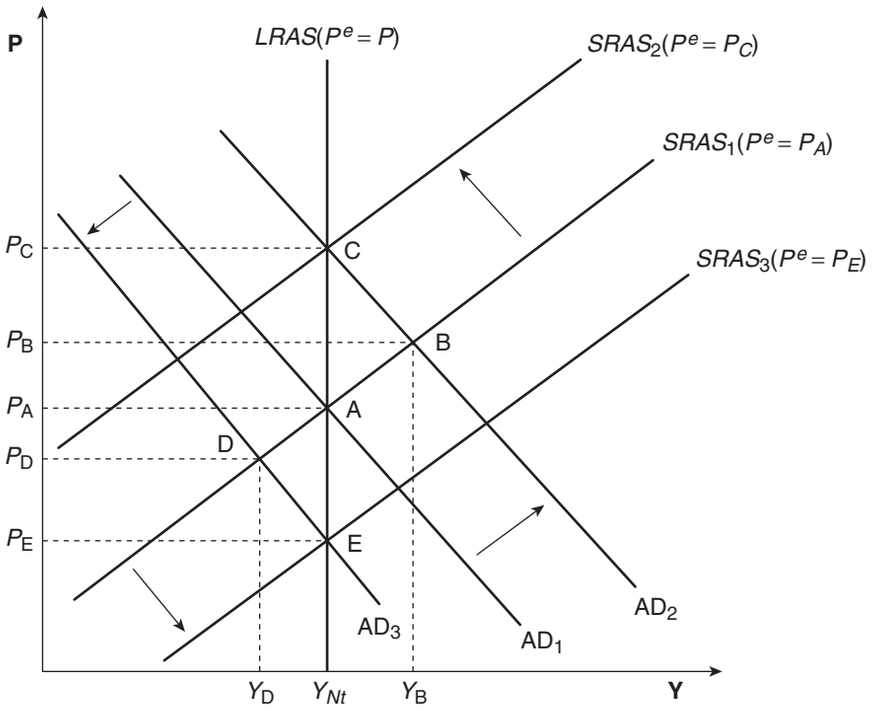

**Figure 39.1** Monetary Policy Effectiveness and Expectations
